32 Medical evaluation and management of pregnant patients undergoing non-obstetrical surgery

John G. Gianopoulos

The approach to the pregnant patient undergoing nonobstetric surgery requires thorough knowledge of the normal maternal physiologic and anatomic adaptation to pregnancy, potential fetal effects of diagnostic tests or ancillary pharmaceutical therapies, and the potential for any obstetric complications.

MATERNAL ADAPTATION OF PREGNANCY

There is a significant alteration in both the physiology and the anatomy of many maternal organ systems in response to the hormonal changes of pregnancy. A thorough understanding of these alterations is needed in establishing the diagnosis, monitoring during a procedure, and conducting the operative procedure for a safe maternal and fetal outcome (Table 1).

Cardiovascular System

The cardiovascular system undergoes significant alteration under the influence of the altered hormonal milieu of pregnancy. Progesterone inhibits distal tubular sodium reabsorption leading to natriuresis. The *juxtaglomerular cells* of the kidney in response to this secrete renin to stimulate aldosterone release from the adrenals, maintaining sodium homeostasis (1–3). Renin is converted into angiotensin and catecholamines are released from the adrenal gland. Pregnancy is a state of maternal hyper-catecholaminism from its early stages. These catecholamines stimulate both inotropic and chronotropic effects on the heart, leading to an increase in cardiac output. Cardiac output begins to rise in the first trimester and continues on a steady increase to peak at 30% to 50% of the preexisting levels by approximately 32 weeks of gestation (3–7). Both heart rate and stroke volume increase. Peripheral systemic vascular resistance is reduced secondary to progesterone, exerting a direct effect to relax the intimal smooth muscle in the precapillary resistance vessels (2,3). The resulting vasodilatation leads to a decreased vascular resistance. There is a slight decrease in mean arterial pressure in the second trimester of a normal pregnancy due to the reduction in peripheral resistance. Blood volume increases with pregnancy, peaking at approximately 50% of prepregnancy levels at around 32 weeks of gestation. As the pregnant woman approaches term, mean arterial pressure normalizes as the increase in blood volume compensates for the decreased resistance and fills the capacitance of the vasculature (8,9).

The pulmonic and systemic circulations undergo similar alterations. There is vasodilatation with an increased volume of capacitance. However, in the pulmonic circulation, the volume and the capacitance change almost equal each other. Therefore, there are no changes in pulmonic pressures. When the pulmonic circulation is evaluated by central catheterization, no changes in pulmonary artery pressures or wedge

pressures are seen due to pregnancy (6,7). The change with increased pulmonic blood volume and increased capacitance fills the pulmonic circulation. This renders the pregnant women susceptible to fluid overload and pulmonary edema (10). Pulmonary edema will occur much more readily in pregnancy, secondary to this maternal adaptation.

In the third trimester, the enlarged uterus may compress the vena cava (especially in the supine position). This may lead to a decrease in cardiac venous return and a drop in cardiac output with a drop in systemic blood pressure. While positioning for operative procedures, the pregnant patient is best positioned with the uterus displaced to the left, allowing adequate vena cava flow and cardiac return to avoid hypotension. Increased cardiac output leads to an increased flow across the aortic valve, thus producing a soft aortic flow murmur. This murmur is auscultated from approximately the mid-second trimester through term in many pregnant patients. Diastolic murmurs or harsh crescendo–decrescendo murmurs in the systolic range are always considered pathologic. However, a soft continuous flow murmur heard in the aortic valve region may be physiologic due to the increased flow in pregnancy.

Respiratory Adaptations

Progesterone has a direct effect on the hypothalamic apneustic center, altering its CO₂ sensitivity. The hypothalamic response to a lower level of CO₂ drives an increased tidal volume and respiratory rate. This reduces CO₂, and pH begins to rise. The kidney secretes bicarbonate equalizing the system and acid–base balance. The pregnant woman is in a chronic state of compensated respiratory alkalosis. The normal blood gases of pregnancy are compensated respiratory alkalosis (11). The normal pH is 7.44 and bicarbonate levels decrease by 4 meq/L. This loss of bicarbonate buffer renders the pregnant women more susceptible to metabolic acidosis. Arterial PO₂ rises by approximately 5 to 10 mm of mercury. However, in the supine position, arterial PO₂ decreases by at least 6 to 10 mm of mercury. Positioning the pregnant women with the uterus displaced to the left reduces this positional effect on oxygenation in the blood. Vital capacity and maximum voluntary ventilation are not altered. Functional residual capacity is reduced as the diaphragm is elevated by the rising uterus (11,12).

Hematologic Adaptations

The hematologic system undergoes marked change secondary to pregnancy. Plasma volume increases by 50% over prepregnancy levels. There is a stimulation of the bone marrow by renal erythropoietin, which increases the red cell mass by approximately 30%, over prepregnancy levels (9,13). As the plasma volume increases more than the red cell mass, a

Table 1 Physiologic Maternal Adaptation to Pregnancy

System	Alterations
Cardiovascular system	Cardiac output $HR \times SV = CO$ Increased 20–30% Both heart rate and stroke volume increased
Peripheral vascular resistance	Decreased as resistance vessels with vasodilatation
Blood flow	Increased to Uterus Skin Kidneys Breasts
Pulmonic circulation	Blood volume increases equal capacitance increase No change in pulmonary artery pressures
Pulmonary system	Tidal volume increased Respiratory rate increased Functional residual capacity reduced Compensated respiratory alkalosis
Renal system	Renal artery perfusion increased Glomerular filtration rate increased Creatinine clearance increased BUN, serum creatinine, serum uric acid decreased Renal clearance of drugs increased Bladder muscularis relaxation Urinary stasis infection risk Dilated renal pelvises and ureters
Gastrointestinal system	Decreased gastric motility Aspiration risk with anesthesia Decreased colonic motility Constipation complaints
Hematologic system	Plasma volume increases 40–50% Red cell mass increases 20–30% “Physiologic anemia” Leukocytosis Increased liver-produced clotting factors Increased fibrinogen Hypercoagulable state

Source: From Ref. 112. Abbreviations: HR, heart rate; SV, stroke volume; CO, cardiac output; BUN, blood urea nitrogen.

delusional effect occurs decreasing hemoglobin concentration (lower normal 10.5–11 g/dL), and hematocrit levels decrease to 30% to 35% (13). This phenomenon has been termed the “physiologic anemia” of pregnancy.

White blood cell (WBC) count increases by 5000 to 10,000 cells/mL in the pregnant women. This is due to the stimulation of demargination of white cells from the endothelial wall by catecholamines and steroids. These cells are all mature polymorphonuclear leukocytes. Care must be taken in interpreting the increased WBC counts in pregnancy (9,13). The differential count is very helpful since if marrow elements are observed (bands or blasts), pregnancy adaptation is not the etiology of the leukocytosis and infection or inflammatory etiologies should be pursued.

Estrogen has a direct effect on the hepatocyte endoplasmic reticulum, leading to increased protein production. All liver-produced clotting factors (II, VII, IX, and X) are increased in

pregnancy. Fibrinogen also increases by 20% to 30% with an average level of fibrinogen of approximately 400 mg in normal pregnancy (14). The pregnant woman is in a hypercoagulable state from the first trimester of pregnancy. Pregnant woman undergoing prolonged procedures or placed immobile at bed rest requires venous thromboembolism prophylaxis to prevent thromboembolic events. Sequential pneumatic compression devices or heparin are used as prophylaxis. Unfractionated heparin due to its reversibility with protamine and ease of monitoring with a partial thromboplastin time is preferred over fractionated heparins in acute surgical situations. Subcutaneous heparin 5000 to 10,000 units BID are recommended as a prophylaxis.

Renal Adaptations

There is a significant increase in renal blood flow in pregnancy both to the glomeruli and to the renal parenchyma. Renal plasma blood flow and glomerular filtration rate increase by approximately 30% to 50% over prepregnant levels (15). This results in an increased creatinine, urea, and uric acid clearance, with a resultant decrease in serum creatinine (normal 0.5–0.9 mg/dL), blood urea nitrogen (normal 10–15 mg/dL), and uric acid (normal 2.5–3.5 mg/L) (13–15). Drugs with renal clearance will have an increased clearance resulting in lower plasma and blood levels. Therefore, these doses need to be adjusted to account for this to maintain therapeutic blood and plasma levels during pregnancy (14). The muscularis of the bladder is relaxed by progesterone, and urinary stasis occurs. Urinary tract infections are common in pregnancy as the urethral vaginal angle is altered and vaginal bacteria may enter the bladder. If bladder catheterization is needed for more than 12 hours following a surgical procedure, antibiotic prophylaxis should be considered to prevent urinary tract infection.

Gastrointestinal Adaptations

Progesterone produces smooth muscle relaxation throughout the body. Gastric motility, gastric emptying, and small bowel transit time are all reduced in pregnancy. Pregnant women undergoing emergency surgery are at significant risk for the aspiration of gastric contents (8,10,16). Whenever possible, regional anesthetic techniques are preferred over general inhalational anesthesia to reduce the risk of aspiration of gastric contents. It is recommended to premedicate gravida patients undergoing surgery with antacid preparations to reduce gastric pH (16–18). Agents to stimulate gastric emptying, such as metoclopramide, are also useful to reduce aspiration risk. Patients who require emergency general inhalational anesthesia may benefit from nasogastric aspiration of stomach contents prior to extubation. Premedication with antacids is also a recommended technique to reduce gastric pH and prevent possible pulmonary injury from aspiration of gastric contents.

FETAL CONSIDERATIONS

Diagnostic Radiation Exposure

Diagnostic radiologic procedures are often necessary as a preoperative assessment in patients needing nonobstetric surgery during their pregnancy. These procedures may be undertaken with care. Adverse fetal effects from ionizing radiation have been reported with fetal exposure of greater than 10 cGy.

Microcephaly, intrauterine growth restriction, poor fetal development, and death have all been reported (19–21). Direct fetal exposure of 5cGy or less has not been shown to increase fetal malformation rates. There is a very small risk of increased childhood malignancies, particularly leukemias, with the level of radiation of 5cGy or less. Direct fetal exposure of 1cGy or less has not been shown to produce any significant fetal effect (19–21). Single-shot direct images such as chest X-rays, abdominal images, or images of long bones expose the fetus to little or no risk. Fluoroscopic examinations expose the fetus to significant radiation risk and should be avoided if possible in pregnancy. Computed tomography (CT) exams of the cranium and thorax expose the pelvis to very little direct radiation (0.05–0.1 cGy). These exams, if clinically indicated, may be undertaken with relative safety (22).

Abdominal and pelvic CT exams expose the fetus from 3 to 10cGy and should be avoided if possible during the first trimester. In the second and third trimesters, these exams may be performed, but care must be taken in making the decision to do these as the fetus will be exposed to a significant radiation dose (22,23). If a significant alteration in the management will result from the information gained from abdominal and pelvic CT examinations performed during pregnancy, then the potential fetal risk is warranted (22,23).

Magnetic resonance imaging (MRI) has not been extensively studied in pregnancy. This technology has been considered safe, to date, with no untoward fetal effects reported. MRI scanning may be considered a safe alternative to CT scan in the first trimester (24,25). MRI exams have been shown to be helpful in the second and third trimesters to clarify diagnosis in fetal cranial anomalies and in determining aberrant placental implantations (accreta, increta, percreta). Gadolinium contrast agents should be avoided throughout the course of pregnancy, if possible.

Radionuclide procedures may be done in pregnancy; generally, the radiation dose to the fetus is low. Most radionuclide contrast agents are renal cleared. Indwelling bladder catheterization will reduce total fetal exposure by avoiding retained urine in the maternal bladder containing radioactive agents from increasing the total radiation dose to the fetus.

If the fetus is inadvertently exposed to significant amounts of ionizing radiation, it is important to calculate a fetal isodose radiation curve. Exposure of 10cGy or greater may produce significant fetal effect. Table 2 outlines the potential fetal effect from in utero radiation exposure (26) Tables 2,3.

Anesthetic Effects

Inhalation anesthetic agents (nitrous oxide, cyclopropane, diethyl ether, and halothane) are lipid soluble and readily cross the placenta. Animal models have raised some concern, as these agents have had teratogenicity in some animal models. The human data regarding these agents are not robust. However, anecdotal data, risk assessments, and epidemiologic assessments point to the relative safety of these agents (14,16,17,27,28). Exposure to inhalation anesthetic agents in the first trimester of pregnancy (especially during the period of organogenesis 3–8 weeks) is estimated to produce a relative risk of malformation of approximately 0.2% to 0.5%. Neural tube, limb, cardiac, and gastrointestinal abnormalities

Table 2 Estimated Radiation Dose to Pelvis at Ovarian Level from Common Radiologic Procedures

Procedure	Pelvic dose (cGy)
Chest radiography	8

Table 3 Radiation Dose and Fetal Effect

Radiation dose to fetus	Theoretical or actual fetal effect
0–5cGy	No reported malformation. Potential for oncogenesis and increased cancer risk
5–10cGy	Potential for oncogenesis, Potential for IUGR*
10–20cGy	Microcephaly, IUGR, 2.4% mental retardation
20–50cGy	Microcephaly, IUGR, fetal death, mental retardation
50–100cGy	Microcephaly, IUGR, 18% mental retardation, fetal death

Source: From Ref. 112. *Abbreviation: IUGR, intrauterine growth restriction.

have all been reported. Regional block anesthetic techniques are recommended in the first trimester. If surgery is semi-elective and can be safely delayed until at least 12 weeks, the fetus will not suffer exposure to these agents during a critical organ-forming period. If, however, the clinical situation requires a general anesthetic technique in the first trimester, the physician and the patient can be reassured that overall fetal risks are small, then these agents should not be withheld if clinically indicated (29). A few studies have critically assessed anesthetic drugs in pregnancy and no consistent pattern of human malformation has been observed (28–30).

Analgesic Agents

Pain control in both the pre- and postoperative period may be obtained with the use of opiate narcotic agents. Morphine, meperidine, hydromorphone, and fentanyl administered orally intramuscular or intravenously in patient-controlled pumps or by delivery patch have demonstrated no adverse fetal effects in the short term (29,31,32). Chronic opiate use in pregnancy has been associated with deleterious fetal effects. Intrauterine growth restriction and intrauterine and postnatal fetal/neonatal withdrawal have all been reported (29). In utero fetal withdrawal has been linked to intrauterine fetal demise (29). Chronic oral opiate use for pain control in pregnancy should be used with extreme caution. Codeine-containing compounds have been shown to have a small teratogenic effect and should be avoided if possible in the first trimester (29). In the second and third trimesters, these compounds may be used for short

Table 4 Antibiotics in Pregnancy

Penicillin/cephalosporin No adverse effect in nonallergic patient	Sulfa drugs Avoid first trimester
Aminoglycosides	Third-trimester use with bilirubin displacement
Renal toxicity and ototoxicity Use in life-threatening infections	Kernicterus Chloramphenicol
Tetracycline	Gray baby syndrome
Contraindicated	Fluoroquinolones
Staining of teeth Bone demineralization	Fetal effect—avoid use
<i>Source:</i> From Ref. 112.	

intervals with little fetal effect. Nonsteroidal inflammatory agents should be avoided, if possible. They have been shown to decrease fetal renal blood flow, which has resulted in significant oligohydramnios. After 32 weeks of gestation, these agents may cause permanent closure of the ductus arteriosus in utero with resultant fetal pulmonary hypertension (29). Prior to 32 weeks of gestation, intermittent ductal constriction occurs and may also lead to fetal pulmonary hypertension. As a tocolytic agent, short courses of indomethacin have been shown to be effective without profound significant fetal effect. Benzodiazepam compounds may be used and have not been shown to be associated with adverse fetal outcomes. At or near the time of delivery, these agents have been associated with significant neonatal depression and should be avoided during the parturient period (18,30,33).

Antibiotics

Adjunctive antibiotic therapy is often indicated in nonobstetric surgery during pregnancy. Penicillin, penicillin derivatives, and first- and second-generation cephalosporins have no reported fetal adverse effects (29). Erythromycin base, clindamycin, and azithromycin are considered safe in pregnancy. Vancomycin, although considered relatively safe, has had some case reports of fetal renal toxicity. *Aminoglycosides*, although used when needed, have been associated with fetal ototoxicity and renal toxicity (18,29,34). Streptomycin and kanamycin have been reported to have both ototoxicity and renal toxicity. Gentamicin has not shown significant fetal ototoxicity and may be used with careful monitoring of maternal blood levels in life-threatening maternal infections (34).

Sulfonamides displace bilirubin from protein binding and if given near delivery (especially in the late third trimester) may lead to neonatal hyperbilirubinemia and kernicterus. These agents may be used for infections remote from delivery especially in the second trimester (18,29,34). Tetracyclines need to be avoided throughout pregnancy as they lead to permanent staining of the teeth and abnormal long bone development (18,29,34). Fluoroquinolones have been shown to disrupt fetal cartilage production leading to skeletal abnormalities and they are best avoided throughout pregnancy (Table 4).

Preoperative, Inoperative, and Postoperative Evaluation and Management

The preoperative evaluation of the pregnant patient should include all the elements one would perform if the patient were

not pregnant plus an antenatal assessment of the fetus and pregnancy to assess for the effect of the condition needing the surgery on the outcome of the pregnancy. Determination of gestational age, fetal well-being by nonstress test or biophysical profile assessment, assessment of the maternal cervical status, and an assessment for contractions should be carried out. Laboratory assessment, imaging studies, and preoperative assessments must take into account the maternal adaptations of pregnancy and gestational age. Ionizing radiation studies should be limited and fetal status should be considered before any imaging studies are performed.

If elective or semi-elective procedures are needed, it is best to wait until the second trimester of pregnancy if possible. If emergency surgery is needed, it can be done in any trimester. In the first trimester, if regional anesthesia is a choice, it is preferable over general anesthesia due to the small teratogenic risk of general anesthesia during the first trimester of pregnancy. Before proceeding to the operating room, the patient should be given 30 mL of 0.3 M sodium citrate (bicitra) to help neutralize gastric pH and decrease the risk of chemical pneumonitis if aspiration of gastric contents were to occur (35).

Intraoperative Management

In the second and third trimesters, if non-abdominal surgery is being performed, the patient should be positioned with the uterus displaced to the maternal left side, to improve the vena cava return to the heart. This is best accomplished with a wedge placed under the maternal right hip. It is important to maintain maximal oxygenation status keeping maternal O₂ saturation above 90% to 95% to meet fetal oxygen needs (36,37). Maternal blood pressure should be kept in the normal range to continue normal uterine blood flow, and if pressors are needed during a procedure, dopamine or isoproterenol at lower doses do not disrupt uterine artery flow. Hypotension secondary to regional anesthesia may be corrected with phenylephrine with little adverse effect to the fetus. After viability, 23 to 24 weeks of gestation, in non-abdominal surgery, continuous fetal monitoring is indicated. If excessive blood loss occurs, transfusion of packed RBCs is needed to maintain maternal hemoglobin above 8 g/dL to insure adequate uteroplacental perfusion.

If intra-abdominal procedures are being performed either laparoscopically or via open technique, care must be taken to avoid excessive manipulation of the pregnant uterus to prevent the stimulation of uterine contractions.

Postoperative Management

The patient should be recovered in an obstetric unit with continuous fetal monitoring. Contraction monitoring with external tocodynamometer should be done. If preterm contractions are observed, hydration with IV fluids often will alleviate them, as most often maternal dehydration is the etiology of these contractions. If tocolytic medications are needed, terbutaline 0.25 mg subcutaneously or nifedipine 10 mg PO every 20 minutes for three doses often will stop these contractions (38). Precipitation of frank labor and subsequent fetal delivery is a rare event following nonobstetric surgery in pregnancy. If ovarian cysts are removed prior to 15 weeks of gestation, particularly if the corpus luteum is felt to have been removed, progesterone supplementation may be considered to

reduce fetal loss (38). Analgesia for pain can be accomplished with the use of opiate narcotics. Codeine or opiate narcotics combined with acetaminophen as discussed earlier are often safe in pregnancy. Nonsteroidal anti-inflammatory agents should be avoided due to their risk of oligohydramnios and disruption of ductus arteriosus flow. All ancillary pharmacologic agents needed, such as antiemetics, antibiotics, antihypertensive medications, should be reviewed for their fetal safety profile before administration. If labor ensues, a recent abdominal incision does not contraindicate valsalva in the second stage of labor and vaginal birth should be performed. *Cesarean* section should be reserved for routine obstetric indications (39).

Laparoscopic Surgery in Pregnancy

Laparoscopic surgical procedures may be performed in the first and second trimesters of pregnancy with relative fetal and maternal safety. These procedures offer the advantage of shorter recovery time, less blood loss, and shorter hospital length of stay. A theoretic risk to the fetus exists with insufflations of the abdominal cavity (40–44). As intra-abdominal pressure rises, uterine blood flow may be compromised. This could potentially lead to fetal hypoxemia, acidosis, and injury. To prevent this, it is best to keep the intra-abdominal pressure as low as possible (43). A maximum intra-abdominal pressure of 15 mmHg has been advocated (43). There is also the potential risk of perforating the uterus with the veres needle or trochar, which could directly injure the fetus or lead to ruptured membranes and preterm delivery (45). Veres needle insertion under ultrasonic guidance can reduce this risk. The trochar should be positioned at least 6 cm above the uterine fundus (45). This may require a supra-umbilical right or left upper quadrant insertion site. Tenting of the abdominal wall away from the uterus has also proven effective. In the mid-to-late second-trimester open laparoscopic techniques have proven safer than traditional veres needle and trochar insertions (41,43). Maternal respiratory functions need to be closely monitored. Arterial or transcutaneous carbon dioxide monitoring has been recommended. Maternal end-tidal volume carbon dioxide determination may not be as informative a measure due to the carbon dioxide absorption that is changed because of pregnancy. As with all proposed surgical procedures if the laparoscopic procedure can be safely delayed until after the pregnancy is completed, it should be done at that time (41,43).

SPECIFIC SURGICAL PROCEDURES

Any surgical procedure performed during pregnancy can pose some risk for the mother and the fetus. As pointed out in the previous sections of this chapter, maternal adaptation to pregnancy may increase the risk of *thromboembolism*, organ injury, hemorrhage, and the onset of labor. Fetal risks due to pharmacologic agents, anesthesia, diagnostic radiographic procedures, and the risk of preterm birth are low but remain significant. Therefore, any surgical procedure performed during pregnancy needs to be carefully considered. Purely elective procedures for nonthreatening conditions are best delayed until pregnancy is completed. However, there are some conditions that require intervention during pregnancy. Some urgent but not emergent procedures are best delayed

until after the first trimester; however, emergency conditions that require surgical intervention should not be delayed despite the maternal pregnancy.

Breast Disease in Pregnancy

Breast malignancies are not an uncommon occurrence in pregnancy; approximately 10,000 pregnancies per year are associated with breast cancer (46). The prognosis of pregnant patients with breast carcinoma is poorer than those without pregnancy, not due to blood flow changes or hormonal milieu but due to a delay in diagnosis. Physiologic and anatomic alterations of the breast function and anatomy may mask parenchymal breast lesions and self-discovery of a mass or discovery by physical exam may be delayed until a mass has grown to a larger size (47,48). Breast engorgement, proliferation of glands and ducts, lactation, and increased vascularity all contribute to this phenomenon (48,49).

The incidence of breast carcinoma in pregnancy is 1 in 3300 to 5000 pregnant women (47–49). The prognosis is poorer in pregnant women due to delay in diagnosis with approximately 75% of pregnant patients with breast carcinoma having positive axillary lymph nodes at the time of diagnosis. Five-year survival rates have been reported as low as 17% in this group of patients (49,50). The key to improved outcome is early diagnosis. There should be no reluctance to biopsy of any suspicious mass due to the patient's pregnant state. Needle aspiration, fine needle biopsy, or open biopsy all may be performed. Milk abscess, galactorrhoea at the biopsy site, and infection are more common with biopsies performed in pregnancy (50). Imaging lesions with mammography is less sensitive in pregnancy due to increased radio density of the breast in pregnancy and suspicious lesions may be missed (48–50). Ultrasound and MRI are less affected by the anatomic alterations of pregnancy and are recommended as imaging techniques in pregnancy.

The management of a breast carcinoma in pregnancy is similar to the nonpregnant state. Mastectomy is more often performed, as radio therapy is relatively contraindicated in pregnancy as there is significant spread of radiation to the pelvis even with shielding (50,51). Chemotherapy may be used in pregnancy in the second and third trimesters with little fetal effect. Agents such as methotrexate or taxol may cause fetal death and are best avoided (50–53). Alkylating agents such as cytoxan, 5-fluorouracil, and adriamycin also may be used. Chemotherapy should be avoided in the first trimester if possible. Breast carcinoma may metastasize to the placenta, but there have been no reported case of fetal metastases to date. Pregnancy termination has not been shown to effect maternal outcome. The decision to terminate a pregnancy, if first trimester chemotherapy is needed, for fetal indication, should be discussed with the patient. A full explanation of fetal and maternal risks should be undertaken (50–53).

Appendicitis in Pregnancy

The most common general surgical condition complicating pregnancy is appendicitis. Acute appendicitis occurs in approximately 1 in 1500 gestations (54). The clinical symptoms of appendicitis are similar in pregnancy to the nonpregnant state: right lower quadrant pain, nausea, vomiting, pyrexia, anorexia, and malaise. In the past, the

location of the pain in acute appendicitis was felt to change with the changing gestational age and the enlarging uterus moving the cecum higher into the abdomen with the third-trimester acute appendicitis pain found in the right upper quadrant. However, it has now been shown that most patients with appendicitis in pregnancy will have right lower quadrant pain regardless of their gestational age (55,56). Some patients, however, will have the anatomic location of the appendix change and appendicitis needs to be considered when patients present with right upper quadrant pain or even flank pain in the case of retrocecal appendix.

Clinical symptoms of nausea, vomiting, and anorexia are common in early pregnancy and sometimes delay in the diagnosis of appendicitis occurs (55,56). Leukocytosis is often associated with appendicitis. However, there is a physiologic leukocytosis of pregnancy as outlined earlier. The leukocytosis of pregnancy may be as high as 20,000 to 30,000 cell/cm³ (57). All of these cells are mature polymorphonuclear leukocytes. If bands or marrow elements are observed, infection and inflammation should be suspected. The differential count, therefore, is very helpful in establishing this diagnosis.

Physical findings of acute peritonitis such as guarding and rebound may not be found in the pregnant women with acute appendicitis. The gravid uterus may tent the parietal peritoneum and omentum away from the inflamed appendix, thus producing less peritoneal inflammation and less abdominal wall symptoms (58–60). Imaging may be performed. Ultrasound of the appendix with graded compression has been shown to be very sensitive (86%) and specific (81%) (61,62). Ultrasound due to its fetal safety should be the image modality of choice. MRI has also been shown to be very sensitive and specific for the diagnosis of appendicitis in pregnancy (96% and 93.6% respectively) and should be used in cases where ultrasound is inconclusive (63–66). CT exams are also very sensitive (94%) and specific (95%) in the diagnosis of acute appendicitis in pregnancy. Although the risk is low, there is concern for fetal exposure to ionizing radiation and these exams should be used if ultrasound is inconclusive and MRI is not available (67,68).

Once a diagnosis is made or strongly considered, laparoscopy or laparotomy and appendectomy should be performed. Delay of more than 24 hours increases the risk of perforation, which will occur in 14% to 43% of patients. Preterm labor and delivery are much higher if appendiceal perforation occurs (36% vs. 15%) (69,70). In the third trimester, cesarean section at the time of appendectomy is not indicated unless there is an obstetric indication. After the appendectomy procedure, in the third trimester, if the patient goes into labor, vaginal delivery may occur and the risk of rupture of the abdominal wall repair is low. In the late second and throughout the third trimesters, laparotomy is performed with relative maternal and fetal safety. In the first and early second trimesters, laparoscopic approach may be entertained with care in technique as described earlier.

Biliary Disease in Pregnancy

The maternal adaptations to pregnancy predispose to the formation of cholesterol, *cholelithiasis* in pregnancy (71). Biliary disease requiring surgery occurs in 0.2 to 0.5 per 1000 pregnant women (72). Biliary sludge or small gallstones have

been found on ultrasound in 5% to 8% of pregnant women in the late second and early third trimesters (71–73). Symptoms of acute cholecystitis in pregnancy are similar to the nonpregnant state: nausea, vomiting, right upper quadrant pain, and anorexia. Imaging with ultrasound will show stones, sludge, and wall thickening (73–75). Management is usually conservative. Most patients will improve with supportive care, nothing-by-mouth, IV hydration, analgesics, and low-fat diet. If cholecystitis or cholangitis is suspected, antibiotics may be added (76). If there are progressive symptoms unresponsive to supportive therapy, surgery is indicated. The best time period to perform these surgeries, with the least pregnancy effect, is the second trimester. However, cases that require immediate intervention such as perforation, gangrene, progressive fever, or intractable pain should have surgery regardless of the gestational age. In the first and early second trimesters, laparoscopic techniques can be performed (75–77). There have been case reports pointing to the safety of these techniques in early pregnancy. In the late second and third trimesters, laparotomy is needed. Occasionally, with cholecystectomy, uterine contractions have been produced and tocolytic agents are needed. Most patients who require cholecystectomy in pregnancy do well.

Ovarian Masses

Pathologic adnexal masses have been estimated to complicate 0.2% to 2% of all pregnancies (78). As many as 10% of pregnant women will have a cyst of at least 5 cm in the first trimester of pregnancy. By 10 to 11 weeks of gestation, only 1.3% of pregnant patients have a persistent significant ovarian cyst (79,80). The appearance of the mass on ultrasound is very important in differentiating between benign and malignant lesions. Solid components, excrescences into the cyst, abnormal blood flow patterns, and Doppler assessments are suggestive of malignancy (79,80). Fortunately, most ovarian masses diagnosed during pregnancy are not malignant. Leiserowitz and colleagues reported on 9000 pregnant women with ovarian masses in 2006. Only 0.93% of these masses were malignant, and more than half (57%) of these malignant masses were of low malignant potential (78).

Most ovarian lesions are found inadvertently on an ultrasound. Occasionally, symptoms of pain may prompt on ultrasonic investigation. The most common neoplasm found in pregnancy is cystadenoma (33%), followed by mature teratoma (dermoid; 27%). Biochemical tumor markers such as CA125 and alpha-fetoprotein are elevated in normal pregnancy and are not very useful in the management of these lesions in pregnant women (79).

Most ovarian lesions found in pregnancy may be treated conservatively. Even if they are found to be malignant at a later time, most are slow growing and no further spread would have occurred due to the delay (81,82). There are however some ovarian masses that must be surgically removed in pregnancy. These are ruptured hemorrhagic cysts, acute ovarian torsions, and those masses that are highly suspicious for malignancy. It is reported that approximately 1 in 1300 pregnancies will require surgery for an ovarian mass during pregnancy (81,82).

The mass that is growing during pregnancy or presents at a size greater than 6 cm into the second trimester will require surgical evaluation. Patients who present with acute pain or an

acute abdomen due to torsion or ovarian cyst rupture also require acute surgical intervention (81–83). Highly suspicious findings on ultrasound, for malignancy in an ovarian mass such as size >10cm, nodularity, cystic and solid components, internal septation, abdominal ascites, or pelvic fixation also require surgical exploration. If the patient is near term, exploration for these masses may be delayed until the postpartum period. If found in the second and early third trimesters, surgical exploration should not be delayed (83,84). First-trimester masses that do not present with acute symptoms could have surgical exploration delayed until at least 11 to 12 weeks of gestation (84–88).

If a functional ovarian cyst (corpus luteum) is removed before 12 weeks of pregnancy, the patient should be given progesterone supplementation. This may be administered as an IM injection of 50mg of progesterone in oil daily or via vaginal suppository 100mg twice daily. This supplementation may be discontinued after 12 to 14 weeks of gestation (86).

An adnexal mass incidentally encountered during a c-section should be removed at the time of the c-section by cystectomy. Simple aspiration is not recommended as seeding of malignancy to the peritoneal cavity may occur if the mass is malignant.

Cardiac Thoracic Surgery During Pregnancy

Cardiac disease complicates approximately 1% to 1.5% of pregnancies. In the past, rheumatic heart disease once was considered the most common cardiac condition complicating pregnancy. However, as more patients with congenital heart disease are now surviving to reach childbearing age, congenital heart disease, either surgically corrected or uncorrected, has become the most common condition complicating pregnancy (86). Most cardiac conditions do not require corrective surgery during pregnancy. Congenital cardiac lesions are best corrected prior to attempting pregnancy or postponed until pregnancy has been completed. If patients however decompensate during pregnancy with pulmonary edema, hemoptysis, or heart failure unresponsive to medical interventions, then either discontinuation of the pregnancy or cardiac surgery should be entertained (7,89).

The approach to any planned cardiothoracic surgical intervention during pregnancy must account for the significant physiologic and anatomic alterations produced in pregnancy. These were reviewed earlier in this chapter. The diagnostic assessment of a pregnant patient with cardiac disease does not differ from the nonpregnant patient. These include a careful history and physical assessment and ancillary diagnostic studies. The ancillary diagnostic studies include electrocardiogram, echocardiogram, hemoglobin/hematocrit, chest X-ray, and rarely cardiac catheterization or stress electrocardiogram or echocardiograms. The optimal gestational age to perform cardiac surgery during pregnancy is 14 to 20 weeks of gestation (89,90). After 28 to 32 weeks of gestation, the peak cardiovascular effects at pregnancy occur increasing the potential operative morbidity. However, regardless of the gestational age, if the maternal condition warrants intervention, it should be undertaken. After 30 to 32 weeks of gestation, consideration for preterm delivery of the fetus should be entertained prior to maternal cardiac surgery.

If necessary, cardiopulmonary bypass procedure can be performed in pregnant patients, but care must be taken to prevent hypotension and decreased placental perfusion (89,90). Alteration in bypass technique to adjust flow ratios to avoid these systemic volume shifts is needed to prevent disruption of adequate placental perfusion and fetal oxygenation (89,90). Continuous fetal monitoring is helpful in monitoring the adequacy of fetal placental perfusion while the patient is on cardiopulmonary bypass. It is also vital to maintain maternal temperature to prevent maternal hypothermic response, which can also disrupt placental blood flow (91,92).

Valvuloplasty with catheterization balloon technique has been shown to be safe during pregnancy and may be an alternative to open valvuloplasty during pregnancy (93,94). There have been reports of fetal decelerations and bradycardia during balloon inflation. There have been rare reports of placental abruption due to maternal hypotension. Therefore, these procedures should be undertaken only if there is immediate availability of cesarean operation with personal resources available (93,94).

Rarely, coronary bypass surgery is necessary during pregnancy. There have been case series reports of successful outcomes for pregnancy in these patients (92). However, due to the length of time needed on bypass, these procedures are best delayed until after pregnancy, if possible. Robotic bypass surgery with beating heart technique, with no cardiopulmonary bypass, may offer a safer alternative to coronary artery bypass perfusion if coronary artery bypass is needed during pregnancy. These procedures are relatively new and little data of these during pregnancy exist.

Neurosurgery During Pregnancy

Brain neoplasms requiring neurosurgical intervention in pregnancy is an uncommon event. There are approximately 90 to 100 cases reported annually in pregnant patients in the United States (95). Most benign lesions will not require surgical interventions during pregnancy and definitive treatment may sometimes be delayed until pregnancy has been completed (95,96). If malignant neoplasm is suspected and is potentially operable, surgery should not be delayed and intervention is warranted. Benign lesions that cause significant symptoms such as increased intracranial pressure, intractable headaches, or disk disease may require surgical intervention during pregnancy.

Agents to treat cerebral edema such as mannitol and dexamethasone may be used during pregnancy. There are little data regarding the use of stereotactic radiosurgery to treat deep inoperable lesions during pregnancy and fetal safety has not been established. However, if the risk–benefit ratio for the mother warrants these procedures, they can be entertained with full explanation of the small but potential fetal risks discussed (19,97,98).

Patients with intracranial lesions or increased intracranial pressure do not require cesarean section. Vaginal delivery with avoidance of maternal valsalva maneuvers is the preferred route of delivery. The second stage of labor is shortened by employing vacuum or forceps delivery techniques (99).

Traumatic Injury in Pregnancy

Traumatic injury in pregnancy is the most common cause of maternal mortality not related to obstetric factors.

Approximately 6% to 7% of all pregnant patients will suffer a traumatic injury during pregnancy, but only about 1% of these patients are seriously injured enough to require hospitalization (100). The pregnant patient is much less likely to demonstrate signs of hypovolemia and shock after acute blood loss due to the increased maternal blood volume that manifests during gestation. However, intravascular volume shifts decreasing uterine blood flow occur early in hypovolemia maternal states, leading to fetal compromise. The abdominal position at the uterus in the third trimester makes this organ much more susceptible to traumatic injury especially in cases of penetrating traumatic injury.

The most common traumatic injury seen in pregnancy are motor vehicle accidents accounting for 60% of traumatic injuries in pregnant women. Pregnancy outcome is directly related to the severity of the maternal injuries. The most common cause of fetal loss is maternal death (100,101). The most common obstetric complication following blunt or deceleration injury is placental abruption occurring in approximately 2% to 4% of patients suffering these injuries (101–103). Most abruptions will occur within the first 4 to 8 hours following the injury. Ultrasound has shown poor positive predictive value for the diagnosis of abruption (103).

Uterine contraction monitoring has a high negative but low positive predictive value for the diagnosis of posttraumatic abruption. The absence of uterine contractions following blunt trauma or deceleration is highly predictive of no abruption having occurred (104,105). All Rh-negative patients should receive Rhogam, 300mg/IM. Delayed abruption, up to 48 hours post-injury, has been observed although there is no test to accurately predict delayed abruption (104). Patients with significant fetal-maternal hemorrhage are at greater risk. A positive Kleihauer-Betkier test for fetal-maternal hemorrhage should warrant a longer period of post-injury observation (104).

Penetrating injuries to pregnant women are most commonly knife or firearm wounds. As the large muscular uterus protects the maternal intra-abdominal organs, pregnant patients have a better prognosis from penetrating abdominal trauma. However, the fetus is at significant risk due to the anterior and central location of the uterus in the maternal abdomen. The fetus sustains injury in over 60% of those cases with a 40% to 70% fetal mortality rate (106–108). Both conservative and surgical management in these cases have been advocated. The best approach is to individualize with surgical exploration performed when fetal or maternal conditions warrant (107,108).

Burn Injuries in the Pregnant Patient

Patients who suffer burn injuries in pregnancy should not have their management altered due to the pregnancy (109). Antibiotics, fluid replacement, and oxygen administration remain the recommended therapeutic approach. The severity of the maternal injury and any secondary maternal complications will dictate the fetal outcome. When the pregnant patient suffers a greater than 50% body surface burn injury, fetal mortality rate approaches 100%. Where there is a 50% or greater burn injury to the pregnant patient in the third trimester, delivery of the fetus is indicated (110). With lesser degrees of surface area involvement (30% or less), fetal

survival approaches 80% (110). Steroids to enhance fetal pulmonary maturity are indicated in these pregnant patients with significant burn injury who are remote from term. Maternal septic complications may lead to labor or the development of chorioamnionitis. Mainstays of burn therapy such as antibiotics, *immunoglobulin* therapy, and *tetanus toxoid* are not contraindicated in pregnancy and should be given to these patients as needed (111). The optimal pregnancy outcome will occur when therapy is early and aggressive and not delayed due to the patient's pregnant state.

SUMMARY

Nonobstetric surgical procedures may be undertaken during pregnancy, when indicated, with relative fetal and maternal safety. A thorough understanding of the maternal adaptations of pregnancy and potential fetal risks of diagnostic studies or pharmacologic agents, as well as any potential effect to the pregnancy, is necessary before proceeding with any procedure. In most cases, this will result in a good outcome for both the mother and the fetus.

33 Anesthesia and analgesia in pregnancy

Steven T. Fogel

INTRODUCTION

The first public demonstration of the use of ether for anesthesia in 1846 was quickly followed by its application to obstetrics in January 1847 by James Young Simpson of Scotland. Almost immediately, controversy surrounded its use. In the United States, Charles D Meigs, Professor of Obstetrics at Jefferson Medical College, denounced attempts to ameliorate the pain of labor, claiming that it was inseparable from the effectiveness of uterine contractions. Simpson, on the other hand, claimed that the pain of labor was of no physiologic value (1). Eventually, then, as today, public demand for effective relief of labor pain settled the argument. By the latter half of the 20th century, there was nearly full agreement within the medical profession that relief of labor pain should not be withheld from a woman in active labor. This position was formally recognized in 1992 when the American College of Obstetricians and Gynecologists and the American Society of Anesthesiologists published a joint statement underscoring the importance of the availability of pain relief for the parturient:

“Labor results in severe pain for many women. There is no circumstance where it is considered acceptable for a person to experience untreated severe pain, amenable to safe intervention, while under a physician’s care. In the absence of a medical contraindication, maternal request is a sufficient medical indication for pain relief during labor. Pain management should be provided whenever medically indicated” (Joint ASA–ACOG Statement, American Society of Anesthesiologists, Park Ridge, IL: October 21, 1992; amended October 1997) (2). While many women may choose to labor without any pharmacologic intervention, the provision of pain relief during childbirth has become an integral part of obstetric practice.

NOCICEPTIVE PATHWAYS OF PARTURITION

During the first stage of labor, pain signals from nociceptors in the myometrium and cervix are transmitted via the paracervical and hypogastric plexi, and, traveling with sympathetic fibers of the lumbar sympathetic chain, enter the spinal cord at segments T10 to L1. These fibers synapse with secondary neurons in the Rexed laminae of the dorsal horns and are modulated by mu receptors in the substantia gelatinosa, also located in the dorsal horns of the spinal cord. The pain is perceived primarily as visceral pain. Pain signals in the second stage of labor are transmitted via the pudendal nerves, which enter the spinal cord via nerve roots S2–S4. From there, pain signals are transmitted via secondary neurons to the contralateral spinothalamic tract and on to the thalamus. Signals from the thalamus are then projected to cognitive cortical centers, where they are perceived primarily as somatic pain. Pain can be modulated or interrupted with blockade at several levels during its transmission. Paracervical block provides pain

relief during the first stage of labor as does epidural and/or spinal blockade with local anesthetics or with spinal opiates either alone or in combination with local anesthetics. Pain during the second stage of labor can be managed with pudendal block, spinal (saddle) blockade, or extension of epidural blockade. Since the pain of the second stage of labor is somatic, it is not as responsive to spinal opiates as is the pain of the first stage of labor.

NONPHARMACOLOGIC METHODS OF PAIN RELIEF

Psychoprophylaxis is probably the most common method of nonpharmacologic management of labor pain. Its premise is that knowledge, education, and preparation reduce the severity of the fear–tension–pain cycle. The process usually begins with childbirth education classes that inform the pregnant patient and her partner of the normal progress of pregnancy, labor, and delivery as well as the expectations. In addition, relaxation and distraction techniques are taught as an adjunct to the management of labor pain. These include breathing exercises, focal points, and massage. The patient’s partner plays an important role in the process. Emotional support decreases the level of isolation the patient may feel. Nonfamily individuals trained to provide support (doulas) have been shown to have a beneficial effect on the patient’s perception of pain and the progress of labor (3). Touch and massage are frequent components used to alleviate the pain of labor. These techniques may include effleurage, light touch, and/or counterpressure applied to the low back. The ultimate goals are for the parturient to take an active role in the management of her labor and labor pain. Indeed, studies have shown that patients who have successfully completed a program of childbirth education and utilized the above techniques have a lesser need for pharmacologic treatment as well as a lower incidence of obstetric interventions (4,5). Other non-pharmacologic techniques that have been used include transcutaneous electrical nerve stimulation (TENS), acupuncture, and hypnosis.

TENS has had no discernible adverse fetal effects. Its efficacy has been reported to be essentially of minimal benefit to possibly shorter labors (6–9). Acupuncture requires knowledgeable and skilled practitioners, which probably explains the varied results that have been reported (10–13). Because of the need for additional training as well as for cultural reasons, this technique is not likely to be widely practiced in the foreseeable future. Like acupuncture, hypnosis requires a trained practitioner. It is time consuming and at least partially depends on the susceptibility of the patient to this technique. Patients who are susceptible to hypnosis have been shown to require less systemic analgesia than patients in a control group as well as experience shorter labors. Patients who are not susceptible to hypnosis do not experience much benefit (14).

SYSTEMIC ANALGESIA

Systemic analgesics have been widely used throughout the latter half of the 20th century. The mainstay of this technique is the use of opioids, both naturally occurring and synthetic. Morphine is derived from opium and has a very long history of use. As with all opioids, it binds to mu receptors in the CNS and, in addition to providing analgesia, may also cause respiratory depression, nausea, vomiting, and sedation. Systemically administered morphine can induce histamine release and cause pruritus (15). An associated skin rash may also develop. When given intravenously (IV), its onset of action is within 3 to 5 minutes with peak effect in 20 minutes. The pharmacologic effect of morphine does not correlate well with plasma concentrations following intravenous administration. This is believed to be secondary to a delay in transfer across the blood-brain barrier since a large percentage of morphine is ionized at physiologic pH (16–18). An intramuscular (IM) injection will have an onset of 15 to 30 minutes with a peak effect of 45 to 90 minutes. Morphine undergoes hepatic metabolism. With the availability of more potent synthetic opioids such as fentanyl, remifentanyl, and the agonists/antagonists nalbuphine and butorphanol, morphine is more commonly used during prelabor or the very early stages of labor and less so during active labor.

Meperidine is a widely used opioid that has the benefit of low cost and a long history of successful administration. Usual doses are 25 to 50mg IV/IM. Like most opioids, it has the potential of causing respiratory depression in both the mother and the neonate. Onset is within 5 minutes of intravenous administration. The neonatal half-life of maternally administered meperidine is considerably longer than maternal half life, approximately 18 versus 3 hours (19,20). A limiting factor in the administration of meperidine is the accumulation of the metabolically active metabolite normeperidine, which can cause seizures when levels are sufficiently high (17). Normeperidine can remain in the neonate for as long as 60 hours (21). The pharmacokinetics of meperidine is such that the optimal time for delivery is either within 1 hour after maternal administration or more than 2 to 4 hours following administration, depending on the dose (22,23).

Fentanyl is a potent synthetic opioid. The potency relative to morphine is 100 to 1. It is most often administered IV and has a rapid onset of less than 1 minute. It has a relatively short duration of action and requires frequent dosing (18). Because of its short duration of action, it is titratable and hence it is attractive when administered as patient-controlled analgesia (PCA). Because its potency is much greater than morphine and meperidine, it has a greater potential for causing severe respiratory depression. Patients receiving fentanyl should be closely monitored. Nevertheless, studies have demonstrated a lesser degree of neonatal effects with the use of fentanyl than with the use of meperidine or morphine (24,25).

The agonists/antagonists nalbuphine and butorphanol have also been widely used in many institutions for labor analgesia. These drugs act primarily at the kappa receptor and more weakly at the mu receptor (18). Their advantage over pure opiates is a ceiling effect on respiratory depression. When compared with meperidine, nalbuphine causes less maternal nausea and vomiting, but lower neonatal

neurobehavioral scores at 2 to 4 hours of age (26). Butorphanol, when compared with meperidine, affords similar degrees of pain relief (27). Like nalbuphine, there is less maternal nausea and vomiting compared with meperidine. Fetal and neonatal effects are similar when comparing butorphanol and meperidine (28).

In the general patient population, PCA has been found to provide better pain relief than intermittent, nurse-administered analgesia (29). Nalbuphine has been shown to provide better labor analgesia when administered in a PCA mode, while PCA administration of meperidine does not demonstrate any significant improvement (30,31). Opioids that are shorter acting may lend themselves well to PCA administration. Fentanyl has been used in a PCA mode, but neonatal depression has been reported. In one retrospective study, the total dose of fentanyl received by mothers of infants who required naloxone was significantly higher than the group of mothers whose infants did not require naloxone (32). Remifentanyl is a synthetic opioid with a very short duration of action. It is rapidly metabolized by blood esterases with a half-life of 3.5 minutes. There are no active metabolites, no drug accumulation, and metabolism is not organ dependent (33). Remifentanyl has been administered in a PCA mode successfully for labor analgesia. Problems have been reported with respect to maternal respiratory depression and decreasing oxygen saturation, but adverse neonatal effects are few (34–38). Remifentanyl administered via PCA may be the best opioid analgesic alternative when epidural analgesia is contraindicated.

Ketorolac is a nonsteroidal anti-inflammatory agent that has good analgesic efficacy for various types of painful conditions. It is attractive in that it causes no sedation and no respiratory depression (39). There are concerns about its use in obstetrics in that it may decrease uterine contractions and/or close the fetal ductus arteriosus. In one study comparing the analgesic effect of ketorolac with meperidine, ketorolac was not found to be superior (40). Another study demonstrated potential adverse effects on neonatal platelet function (41). At present, there appears to be no benefit from the use of ketorolac for labor analgesia.

Placental Transfer

Virtually, all drugs administered maternally have the potential to transfer to the fetus. Several mechanisms are involved in the placental transfer of drugs from the maternal to fetal circulation, the more common of which being simple diffusion, facilitated diffusion, and active transport. Simple diffusion is governed by the Fick equation:

$$Q/T = [kA(C_m - C_f)]/D$$

Where Q/T is the rate of diffusion of a given drug and k is a diffusion constant determined by the lipid solubility, molecular configuration, and molecular weight. A is the area available for diffusion, C_m is the maternal blood concentration, and C_f is the fetal blood concentration. D is the thickness of the diffusion membrane. Thus the size and thickness of the placental membrane along with variations in the distribution of vascular flow determine the rate of placental drug transfer. Other determinants include drug ionization, protein binding, and maternal and

fetal metabolism. Protein binding can be an important factor in drug transfer. Differences in protein binding in the maternal and fetal circulations may either inhibit or facilitate the degree of transfer. Variations in maternal blood concentrations of protein as may occur in various disease states may also influence drug transfer. Substances of smaller molecular size (less than 500 daltons) are more likely to transfer than larger molecules. Large polar compounds such as muscle relaxants that are used in general anesthesia transfer only in small amounts.

The rate and degree of drug transfer are measured by comparing umbilical vein (UV) and maternal vein (MV) concentrations. UV drug concentration reflects the amount of drug transferred to the fetal circulation via the placenta. A UV/MV ratio close to 1 indicates a high degree of placental transfer. The degree of fetal drug distribution and metabolism is reflected by comparing the umbilical artery (UA) and UV concentrations of a drug. Thus a UA/UV ratio of 1 will indicate equilibrium between fetal drug delivery and fetal distribution. A UA/UV ratio of less than 1 will indicate continued fetal drug uptake and a UA/UV ratio greater than 1 will indicate fetal elimination of drug via distribution into the maternal circulation.

The placental transfer of morphine is rapid. UV to MV ratio is close to 1 at 5 minutes. Fetal heart rate (FHR) variability is often decreased following maternal administration of morphine; however, fetal metabolism of morphine is high. Studies of morphine metabolism in the fetal baboon show that it is limited primarily by hepatic blood flow (42–44). Because the fetal exposure to morphine is short, it may actually be more beneficial than meperidine when used for systemic labor analgesia.

Maternally administered intravenous meperidine appears in the fetal plasma within 2 minutes and reaches equilibrium in 6 minutes. The UV/MV ratio increases with greater time following IM administration (21,22,45,46). Like morphine and other opioids, a decrease in FHR variability can be expected (47). However, variability is not effected during fetal movements or uterine contractions (48).

Fentanyl rapidly crosses the placenta and is detectable in fetal blood within 1 minute (49). Depending on total dose, UV/MV ratios of 0.05 to 0.76 have been reported. A decrease in FHR variability has been noted with a duration of approximately 30 minutes (50).

The UV/MV ratio for nalbuphine is reported to be 0.61 to 0.74 (26,51,52). Fetal effects include decreases in frequency of accelerations, decreased FHR variability, and the appearance of sinusoidal patterns (53,54). In spite of these changes, the fetus will still respond to fetal acoustic stimulation (55).

Butorphanol rapidly crosses the placenta. In fetal sheep, butorphanol can be detected within 1 minute of maternal administration (56). The UV to MV concentration ratio is 0.84. When compared with meperidine, there were no differences in effect on FHR (27).

PARACERVICAL AND PUDENDAL BLOCKS

Up until the mid-1970s, paracervical and pudendal blocks were frequently used in many centers for analgesia for labor and vaginal delivery. Paracervical block interrupts nerve transmission at the paracervical plexus. It provides several

hours or more of pain relief during the first stage of labor, depending on the local anesthetic used. During long labors, it may need to be repeated. Paracervical block is useful only during the first stage of labor. It is of no value during the second stage of labor. In the 1970s, multiple reports of fetal bradycardia began to appear. The mechanism was believed to be a transfer of large amounts of local anesthetic to the fetal circulation via the uterine artery. Other mechanisms that have been proposed are uterine artery vasospasm, UA vasospasm, and uterine hypertonus (57–60). Currently, paracervical block for labor analgesia is rarely used because of the concerns regarding adverse fetal effects. It may have some utility in special circumstances such as in patients with intrauterine fetal death who, in addition, have contraindications to epidural analgesia.

Pudendal anesthesia is achieved by blocking the pudendal nerve as it exits the pelvis at the ischial spine. It provides anesthesia to the perineum and lower one-third of the vagina. It is useful for late second-stage labor and vaginal delivery. It is of no value during the first stage of labor or for intrauterine manipulation. Because of the flexibility and reliability of epidural analgesia for both the first and second stages of labor, the use of pudendal block has been declining. It is rarely used at the University of Missouri, and the Mayo Clinic recently reported declining usage as well (61). Nevertheless, it is a valuable option when neuraxial analgesia is contraindicated or unavailable.

NEURAXIAL ANALGESIA

Epidural analgesia has become a very successful and widely used technique for managing the pain of labor in the United States. In 1992, epidural analgesia was used in slightly greater than 50% of laboring women delivering in hospitals with greater than 1500 deliveries per year (62). Today, rates of 75% or greater are not uncommon. Continuous lumbar epidural analgesia provides pain relief that is superior to any other method of labor analgesia. Compared with parenteral opioids, epidural analgesia provides superior pain relief, greater maternal satisfaction, and less neonatal depression (63). Epidural analgesia has been shown to significantly decrease the stress response to labor. Stress indicators such as epinephrine, cortisol, and beta-endorphins decrease following epidural analgesia (64–68). This can be important when dealing with patients with cardiac disease (see below).

Epidural analgesia involves the placement of local anesthetics often combined with low-dose opioids in the epidural space via a small-gauge catheter. The posterior epidural space is bound by the ligamentum flavum posteriorly and the dura anteriorly. Typically, the patient is placed in a sitting or lateral decubitus position. The lumbar approach is commonly used, most often L2 to L5. Following an aseptic technique with local anesthetic injected at the chosen interspace, an epidural needle is inserted into the epidural space utilizing a “loss of resistance” technique with a syringe filled with saline or air. An epidural catheter is then threaded into the epidural space and the needle is removed. The catheter is then secured and local anesthetic infused until an appropriate level of analgesia is achieved. Since the epidural catheter can be placed intravascularly or in the subarachnoid space, a test dose is

performed to rule out placement at these sites. A small dose of local anesthetic with epinephrine is injected via the catheter following careful aspiration. Typical test doses include 45 mg of lidocaine and 15 mcg of epinephrine. If injected IV the small dose of epinephrine will cause a transient maternal tachycardia. If injected into the subarachnoid space, the parturient will develop a limited motor block. Neither of these responses will occur if the catheter is in the epidural space.

Utilizing an epinephrine containing test dose as a marker of intravascular catheter, placement is not always accurate, however. Colonna-Romano and colleagues showed that the epinephrine test dose has a 100% negative predictive value, but a 55% to 73% positive predictive value. They calculated that as many as 27% to 45% of epidural catheters with a positive epinephrine test dose would be unnecessarily removed (69). Other authors have questioned the value of an epinephrine containing test dose as a method of detecting an intravascularly placed epidural catheter (70,71). The catheter design may also affect the positive and negative predictive value of test doses. Closed-tip multiport catheters, which are popular among many anesthesiologists because of improved local anesthetic spread, may present problems with multi-compartment placement (72). Because of these limitations, anesthesiologists have taken the position that every dose of a local anesthetic administered via an epidural catheter should be considered a test dose. Local anesthetics are therefore administered in small aliquots and the patient is observed for signs of toxicity (intravascular placement) or unexpected levels of motor block (subarachnoid placement).

Once the epidural catheter is placed, secured, and tested, it is dosed with a low concentration of local anesthetic alone or in combination with an opioid to achieve a T10 level. This usually requires a bolus loading dose of volumes ranging from 8 to 16 mL given in 5-mL aliquots. While intermittent single “top up” doses were given in the past for maintenance, continuous infusions are now almost universal. Patient-controlled epidural analgesia (PCEA) has gained popularity in a number of centers. Usually a background infusion of dilute local anesthetic with or without opioid is maintained and the patient is allowed to self-administer a “top up” dose with a predetermined lockout and hourly maximum volume programmed into a pump device. PCEA has been shown to improve patient satisfaction and decrease the number of anesthetic interventions with lower total volumes of local anesthetic than conventional continuous infusion techniques (73–75). A number of regimens for both continuous and PCEA techniques have been proposed, each with varying results. At the University of Missouri, PCEA is used almost exclusively.

A modification of conventional epidural analgesia, the combined spinal–epidural (CSE) technique, has also been gaining usage at major centers over the past decade. Following placement of the epidural needle in the epidural space, a small-gauge pencil-point spinal needle is passed through the epidural needle and the dura is punctured. A small dose of preservative-free opioid or opioid local anesthetic combination is injected intrathecally. The epidural catheter is then passed through the epidural needle and tested. Analgesia is achieved rapidly and there is no need for a bolus loading dose of local anesthetic via the epidural catheter (76,77). Following placement and testing

of the epidural catheter, a maintenance infusion is begun. By the time the intrathecal dose has dissipated, the epidural infusion has reached a sufficient level to maintain satisfactory analgesia.

The CSE technique has several distinct advantages. If an opiate alone is administered intrathecally, then there is no motor block and the patient is able to ambulate for a period of time, usually 90 to 120 minutes (the so-called walking epidural). Some institutions will follow the intrathecal dose with an ultralow concentration of local anesthetic with opioid and epinephrine adjuvants to allow continued ambulation (78,79). The CSE technique allows confirmation of epidural placement of the epidural needle, which may decrease the need for replacement of failed epidural catheters (80,81). A recent retrospective study suggested that the quality of analgesia obtained with a CSE technique is better than that obtained with a traditional epidural technique (82). Because of the rapid onset of analgesia when the CSE technique is used, patients with advanced labor may still be able to benefit from neuraxial analgesia. At the University of Missouri, patients rarely fail to receive neuraxial labor analgesia because it is “too late.” Comparisons of outcome of labor and complications between CSE and conventional epidural techniques have shown the two to be similar (83–85). A more recent study showed that when an epidural catheter is dosed for cesarean delivery, those catheters placed via a CSE technique are more likely to be successful than those placed via a traditional epidural technique (86). CSE is therefore used almost routinely at the University of Missouri.

While epidural and CSE analgesia for labor have distinct advantages over other methods of labor pain management, absolute and relative contraindications exist. Patient refusal, untreated sepsis, frank coagulopathy, uncorrected hypovolemia/hypotension, and infection at the injection site are the generally accepted absolute contraindications. Relative contraindications may include uncooperative patient, neurologic disease, severe obstructive cardiac lesions, thrombocytopenia, and prior spine surgery. Fortunately, absolute contraindications are rare and the greatest majority of parturients can benefit from neuraxial analgesia.

Complications of Neuraxial Analgesia and Anesthesia

Serious complications from epidural analgesia are rare, but include local anesthetic toxicity, high or total spinal anesthesia, epidural hematoma or abscess, and permanent neurologic injury. Less serious but more troublesome complications are hypotension and post-dural puncture headache.

Local Anesthetics and Local Anesthetic Toxicity

The local anesthetics most commonly used in obstetric anesthesia are bupivacaine, lidocaine, 2-chloroprocaine, ropivacaine, and levobupivacaine. Local anesthetics are composed of a lipophilic aromatic moiety and a hydrophilic amine moiety linked by either an amide or an ester intermediate chain. They are therefore classified as either amides or esters. Except for 2-chloroprocaine, all of the local anesthetics commonly used in obstetrics are in the class of amide local anesthetics. 2-Chloroprocaine is an ester local anesthetic. Of the above local anesthetics, bupivacaine is the most potent, most lipophilic, longest lasting and slowest in onset. Lidocaine

is intermediate in these characteristics and 2-chloroprocaine is the fastest in onset, least potent, least toxic, and shortest in duration. Bupivacaine has been popular as a local anesthetic for epidural labor analgesia because of its capacity to develop a "differential block," meaning that it can provide greater sensory block with less associated motor block at low doses. Bupivacaine, however, has greater cardiotoxic potential than does lidocaine and has been the limiting factor in its use. Generally, seizures will occur during a local anesthetic toxic reaction prior to the onset of cardiac arrhythmias or arrest. However, the cardiotoxic to central neurotoxic plasma ratio for bupivacaine is higher than that for lidocaine, and with a rapid intravascular injection of bupivacaine, cardiac toxicity may be the first event. In addition, bupivacaine has a very slow washout from cardiac tissue and makes resuscitation difficult (87). Indeed, cardio-pulmonary bypass may be needed as a last ditch heroic measure (88). More recently, lipid emulsions have been used successfully to treat toxicity from local anesthetics, specifically bupivacaine (89). Some anesthesia units are now keeping intralipid on their resuscitation carts. It has been thought that pregnancy confers a greater sensitivity to the cardiotoxic effects of bupivacaine (90). This, however, has not been borne out in more recent studies (91). Ropivacaine and levobupivacaine are newer local anesthetics that are related to bupivacaine. While potencies may vary from bupivacaine, they are less cardiotoxic (91). As a result, ropivacaine has become popular in obstetric anesthesia. Concentration of 0.1% or 0.2% ropivacaine with additional opiate is used almost exclusively for labor epidural analgesia at the University of Missouri.

In the event of a toxic reaction, seizures should be controlled with either propofol, midazolam, or thiopental; the airway should be controlled with endotracheal intubation; ventilation should be supported if necessary; and the parturient should be placed in left lateral uterine displacement position. Supplemental oxygen should be administered and fluids be begun. Blood pressure should be supported with additional fluids and vasopressors. Further therapy depends on the results of initial treatment. The administration of intralipid in the face of bupivacaine toxicity is worthy of serious consideration. Cardio-pulmonary resuscitation should be performed in the left lateral position to facilitate venous return and maintain uteroplacental blood flow.

Hypotension

Epidural analgesia has the potential of creating a sympathetic block and subsequent hypotension. This is primarily dependent on the level of block and the rate of administration. It is therefore common practice that patients are prehydrated with 500 to 1000 mL of crystalloid immediately prior to initiation of epidural analgesia. In some cases, a colloid such as hetastarch may be used. The need for routine prehydration with currently used epidural and CSE techniques, however, has been questioned (92). This may be important when caring for patients with conditions mandating limited fluid administration. Clinically significant hypotension that is otherwise asymptomatic to the mother may manifest itself as late decelerations of the FHR or fetal bradycardia. Treatment includes left uterine displacement to

increase venous return, cardiac output and uterine blood flow, intravenous fluids, and judicious administration of vasopressors and oxygen. Ephedrine is the vasopressor of choice. It is both an alpha and a beta receptor agonist and has the potential of causing maternal tachycardia. When maternal tachycardia preexists or is undesirable, then phenylephrine, a pure alpha agonist, can be used.

FHR Changes

Not long following the introduction of CSE analgesia for labor, reports of sudden fetal bradycardia appeared. This was believed secondary to the rapid onset of analgesia with a subsequent drop in circulating catecholamines, resulting in uterine disinhibition and markedly increased uterine activity (93). Subsequent studies comparing the fetal effect of CSE analgesia versus conventional epidural analgesia had varying results. A systematic review in 2002, however, demonstrated that there was indeed an increased risk of fetal bradycardia following CSE analgesia compared with conventional epidural analgesia. Surprisingly, there was no increased risk of cesarean section with CSE, nor was there an increased risk of cesarean delivery in yet another large study of the use of CSE (94,95). Another study in 2004, however, compared the incidence of fetal bradycardia among three groups of patients. Group 1 received a conventional epidural, group 2 received a CSE regimen consisting of low-dose intrathecal bupivacaine and low-dose opioid, and Group 3 received a CSE regimen of only high-dose intrathecal opioid. There was no difference in the incidence of fetal bradycardia between groups 1 and 2, but there was a higher incidence of fetal bradycardia in group 3. The authors recommended limiting the amount of opioid administered intrathecally (96). At the University of Missouri, we therefore use a combination of 3 mL of isobaric ropivacaine 0.1% and 6 µg of fentanyl intrathecally in our CSE regimen. When fetal bradycardia does occur following CSE secondary to uterine hyperactivity, we treat with either terbutaline or sublingual nitroglycerin, both of which have been reported to be effective (93,97,98).

Accidental Dural Puncture

Accidental dural puncture (ADP) is not an uncommon complication of epidural analgesia. The rate may vary from 0.6% to 4.2% in training institutions (83,99). ADP would not necessarily present a problem were it not for the 70% post-dural puncture headache rate associated with the use of 18-gauge epidural needles (100,101). Post-dural puncture headache (spinal headache) typically presents approximately 24 to 48 hours following dural puncture. It is rare for symptoms to appear before 24 hours. Patients typically present with a fronto-occipital headache that may be described as throbbing and severe with associated posterior cervical pain or stiffness. The headache will be totally or nearly totally gone with the supine position and reappear within minutes of obtaining an erect position. It cannot be overly stressed that the hallmark of a post-dural puncture headache is its positional nature. Almost universally, the relief of headache is very noticeable when taking the supine position. The headache is believed to be secondary to low cerebrospinal fluid (CSF) pressure when erect causing traction on meninges and/or reactive cerebral vasodilation (102,103).

Post-dural puncture headache can mimic other more serious conditions, which may include intracranial hemorrhagic disorders, mass lesions and cortical venous thrombosis (104–106). Not all postpartum headache is a post-dural puncture headache. Patients who do not present with classic features of a post-dural puncture headache should be evaluated with further studies such as MRI or CT scanning of the central nervous system.

Post-dural puncture headache can be very debilitating. While the nonpregnant patient recovering from surgery or illness may tolerate long periods of bed rest, the parturient must be able to care for an infant. Inability to maintain an erect posture may interfere with breast-feeding. Treatment of post-dural puncture headache in the obstetric patient population may therefore carry greater importance than that in the rest of the population.

Typical conservative measures of treatment include bed rest, hydration, caffeine, opioids, and nonsteroidal anti-inflammatory analgesics. Caffeine has vasoconstrictive properties that counteract the presumed vasodilation that occurs reactively to low CSF pressures. Sumatriptan, another medication with vasoconstrictor properties used to treat migraine headache, has been shown to be effective in one study but ineffective in another (107,108). Generally, it has not been used as a first-line drug for post-dural puncture headache in the obstetric population.

Epidural blood patch is considered the definitive treatment for post-dural puncture headache. The technique involves the injection of 10 to 20mL of autologous blood in the epidural space near the original epidural puncture site. Its effectiveness has been reported to be as high as 97% (109). A long-term follow-up study of nonobstetric patients, however, showed that only 61% of patients had a permanent resolution of headache despite an initial success rate of 88% to 96% (110). More recently, a study in an obstetric population showed that only 15% required a repeat blood patch (111). Epidural blood patch has a long history of effectiveness and safety. Nevertheless, if a patient should require more than two blood patches, a search for another cause of headache should be made.

Other Complications

High spinal anesthesia is a potentially lethal complication. Large volumes of local anesthetics are required to establish adequate labor analgesia for both the first and second stages of labor. An accidental intrathecal injection of a large volume of local anesthetic has the potential of causing respiratory arrest, hypotension, and even cardiac arrest. Treatment is supportive and requires respiratory assistance including tracheal intubation, fluids, and vasopressors until the block recedes. Careful use of an appropriate test dose prior to dosing the epidural catheter will markedly decrease the likelihood of this complication.

Epidural abscess and epidural hematoma are very rare complications that can be devastating if not diagnosed in a timely manner. Both present as mass spinal lesions with pain, sensory and/or motor loss, and, in the event of abscess, fever. Both almost always require surgical drainage. The risk of abscess can be decreased by paying close attention to sterile technique and by avoiding neuraxial analgesia/anesthesia in

the face of untreated bacteremia or septicemia. Epidural hematoma can be minimized by avoiding neuraxial regional analgesia/anesthesia in the patient at risk for coagulopathy.

Peripheral neuropathies are not rare in the obstetric patient population. When these problems occur in a patient who has had epidural analgesia, the anesthesiologist is often consulted. Lower extremity peripheral neuropraxia can result from stretch or compression lesions that occur during labor and delivery. Foot drop, quadriceps weakness, weak hip adduction, and meralgia paresthetica can result from lumbosacral trunk or peroneal nerve, femoral nerve, obturator nerve, and lateral femoral cutaneous nerve injury, respectively. Peroneal nerve injury can result from nerve compression at the knee due to positioning equipment. Femoral and lateral femoral nerve injury can result from prolonged hip flexion during the second stage of labor. If the patient has a dense epidural block at that time, she may not complain of pain or numbness with overzealous hip flexion. Detailed and conscientious evaluation will help differentiate peripheral obstetric neuropathies from direct nerve root or spinal cord injuries (112). Early neurology consultation and spine imaging may elucidate the etiology and direct appropriate treatment in a timely manner.

Epidural Analgesia and the Progress of Labor

The effect of epidural analgesia on the progress and outcome of labor has, in the past, been controversial. Retrospective studies have demonstrated an increased risk of cesarean delivery when epidural analgesia was utilized (113). Subsequent prospective randomized studies, however, did not show any significant difference in the cesarean delivery rate when patients were randomized to receive either epidural or parenteral analgesia (114,115). While prospective randomized studies provide good data, problems still exist. Patients do not always stay in their assigned group, leading to “intent to treat” analyses. Retrospective “sentinel” event studies overcome this confounding factor. These studies examine the cesarean delivery rate before and after the institution of an “on demand” epidural analgesia service (116). While retrospective in nature, there are no selection biases and no opportunity for patients to drop out of a study group. Results of these studies show that there is no increase in cesarean delivery rate when there is a sudden increase in the utilization of epidural analgesia. One study in particular did offer an interesting insight. While there was no change in cesarean delivery rate with a marked increase in epidural analgesia overall, it was noted that following the institution of epidural analgesia on demand, those women who went on to cesarean delivery for dystocia were approximately eight times more likely to have had an epidural. The authors concluded that dystocia is more painful and women who request epidural analgesia are already at risk for cesarean delivery for dystocia (117). This result may explain why retrospective studies that examined cesarean delivery rates in institutions where epidural analgesia services were well established showed higher rates of cesarean delivery in association with epidural analgesia. Patients who request epidural analgesia are different from those who do not. Epidural analgesia is therefore a risk marker, not a risk factor.

While epidural analgesia does not increase the risk of cesarean delivery for dystocia, it does slow labor. A meta-analysis of randomized trials published in 1998 concluded

that, overall, the first stage of labor increased by 42 minutes and the second stage of labor by 14 minutes (114,118). A more recent study concluded that while the first stage of labor is not prolonged, the second stage is (119). Not only does epidural analgesia not increase the incidence of cesarean delivery for dystocia but neither does the timing of epidural placement. A study published in 2005 examined the cesarean delivery rate of early (less than 4cm dilatation) versus late epidural placement and found no difference in the cesarean delivery rate for dystocia. Indeed, patients who had early CSE analgesia had shorter labors (120). At the University of Missouri, women are not required to reach a preset cervical dilatation before epidural analgesia is administered. This position is supported by the American College of Obstetricians and Gynecologists, which has recently stated:

... the decision of when to place epidural analgesia should be made individually with each patient, with other factors, such as parity, taken into consideration. Women in labor should not be required to reach 4–5cm of cervical dilatation before receiving epidural analgesia (121).

Epidural Analgesia and Maternal Fever

A rise in maternal temperature has been associated with the use of epidural analgesia (122). Studies that are retrospective and/or nonrandomized are likely to be biased because factors that lead to increased requests for epidural analgesia such as long labors complicated by dystocia are also likely to lead to maternal fever. Nevertheless, prospective randomized trials have shown that a rise in maternal temperature can occur in association with epidural use in the absence of infection (123). The reasons are unclear and have been attributed to alterations in vascular responsiveness and thermoregulatory control. Parturients who shiver immediately following induction of epidural analgesia are more likely to develop an earlier and greater rise in temperature than those who do not (124). While mild to modest increases in maternal temperature may not have significant physiologic significance, it has led to increases in neonatal sepsis evaluations (125). When criteria for neonatal sepsis evaluations are better refined, however, there are no increases in sepsis evaluations of neonates born to women with epidural-associated fevers (126). Currently, the wide use of epidural analgesia does not seem to be negatively effected by concerns regarding the association of epidural use and maternal fever (119).

ANESTHESIA FOR CESAREAN DELIVERY

The cesarean delivery rate in the United States has steadily increased during the past several decades. In high-risk tertiary care institutions, rates have climbed higher than 30% (127).

In 1981, general anesthesia was used more often than either epidural or spinal anesthesia in larger institutions (>1500 deliveries per year). By 2001, only 3% of elective cesarean deliveries were performed under general anesthesia, the remainder utilizing either spinal or epidural anesthesia (128). These data underscore the preference for regional anesthesia for cesarean deliveries. Significant advantages exist over general anesthesia: an awake mother with spontaneous respirations and ability to control the airway with a lower

risk of aspiration, contracted gut, more complete muscular relaxation, and an opportunity to provide excellent post-operative analgesia with the use of spinal opiates.

From 1979 to 1990, the maternal mortality rate from anesthesia-related causes for patients undergoing cesarean delivery in the United States steadily decreased for regional anesthesia but remained approximately the same for general anesthesia. By 1990, the relative risk of death from anesthesia-related causes in cesarean delivery patients was 16.7 for general versus regional anesthesia (129). By 1996, the relative risk decreased to 6.7 (130). The major risks from general anesthesia are primarily inability to intubate, inability to ventilate and aspiration. Pregnant patients at term and in labor are considered to be individuals with “full stomachs” due to increased gastric emptying time. In addition, pregnant patients at term are more likely to present with “difficult airways” that cannot be intubated by conventional means or ventilated (131). Because term pregnant patients are considered to have “full stomachs,” general anesthesia must be administered via a “rapid sequence” induction technique. With patients who are not at risk for aspiration, anesthesia is generally induced with an intravenous agent that usually renders the patient apneic. An attempt at mask ventilation is made and, if successful, a muscle relaxant is administered and mask ventilation is continued until the patient is ready for intubation. During this time, aspiration is possible since airway reflexes are obtunded and the airway is unprotected. This event is extraordinarily rare, however, in patients who have no risk factors for aspiration such as morbid obesity, full stomachs or trauma. In patients who are at risk of aspiration, such as pregnant women, an induction agent is administered and immediately followed with a rapidly acting muscle relaxant and intubation without first testing the airway with mask ventilation. Cricoid pressure is applied to reduce the chance of regurgitation. This technique, known as the rapid sequence induction, diminishes the time that the airway is unprotected and is therefore the standard technique used for patients who are at risk of aspiration. Patients who are unexpectedly found to have an airway that cannot be intubated or ventilated at this time, however, become susceptible to hypoxic injury or death. For this reason, all pregnant patients at risk for cesarean delivery should have their airways evaluated. At the University of Missouri, all patients admitted in labor are examined regardless of the anticipated need for analgesia/anesthesia. This allows the anesthesiologist to identify in advance patients who may have a “difficult airway.” Plans to avoid or limit the likelihood of general anesthesia for a “stat” cesarean delivery can then be made in advance for these at risk patients.

General Anesthesia

Despite the increased risks of general anesthesia over regional anesthesia, it still has indications and some advantages under specific circumstances. It can be administered quickly and reliably. Uterine relaxation responds to potent inhalation anesthetics (e.g., sevoflurane, isoflurane, and desflurane) in a dose-dependent manner. When marked uterine relaxation is required such as with in utero fetal surgery, intrauterine manipulations, and placental extractions, general anesthesia with potent inhalational anesthetics is reliable and effective. General anesthesia is most often chosen either because of

coexisting contraindications to regional anesthesia or because circumstances do not allow time to establish a sufficient level of regional anesthesia.

The usual technique for general anesthesia for cesarean delivery is to administer a non-particulate clear antacid shortly prior to induction. The patient is then placed in supine position with left uterine displacement, standard monitors are applied, and the patient is pre-oxygenated with four or five vital capacity breaths of 100% oxygen. Cricoid pressure is then applied just prior to induction with an intravenous agent such as propofol or thiopental and followed immediately with the administration of the rapid-onset, short-acting muscle relaxant succinylcholine. Following approximately 60 seconds, the trachea is orally intubated. Once intubation is confirmed via breath sounds and end-tidal CO₂, the cricoid pressure can be released and incision made. Potent inhalational agents are usually continued at low concentrations with or without the addition of nitrous oxide. Pregnancy confers a greater sensitivity to anesthetics, which is fortuitous because inhalational agents cause uterine relaxation in a dose-dependent manner. At low concentrations of inhalational agents, oxytocin can still be effective in providing uterine contractility and hemostasis. When necessary, the potent inhalational agent can be discontinued. Nitrous oxide does not cause uterine relaxation and can be initiated or continued with the addition of narcotics, benzodiazepines, and muscle relaxants. In order to decrease the risk of aspiration upon emergence, the patient should be extubated when sufficiently awake such that airway protective reflexes are intact and the risk of laryngospasm is low.

A misconception that many obstetricians have is that time is of the essence in performing a cesarean delivery under general anesthesia. Uterine incision to delivery time is more important in neonatal outcome than induction to delivery time. With regional anesthesia, neonates do not become acidotic until greater than 3 minutes have elapsed following uterine incision (132). Induction agents used for general anesthesia do not anesthetize the neonate when usual doses are given. The reasons for this are multifactorial and include dilution of the induction agent with blood from the fetal vena cava, first-pass fetal hepatic metabolism, and fetal shunting. Furthermore, in sheep models, a period of 15 to 20 minutes is required for isoflurane administered to the ewe to reach full anesthetizing levels in the fetal circulation (133). Even if a prolonged induction to delivery time is required, as long as maternal blood pressure and oxygenation are maintained, an anesthetized but not severely acidotic neonate is likely to be delivered as long as fetal distress was not present at the time of induction and uterine incision to delivery time was less than 3 minutes. It is probably better for the obstetrician to take sufficient time to perform a careful operation than risk maternal injury for fear of delivering an anesthetized infant.

Spinal Anesthesia

Spinal anesthesia is more correctly termed intrathecal or subarachnoid anesthesia as the local anesthetic drug is injected through the dura–arachnoid into the CSF below the terminal end of the spinal cord. The most common interspaces chosen are the L3–4 or L4–5 levels. Hyperbaric bupivacaine is most commonly used in the United States. A dosage of 12 mg

reliably offers a sufficient level of anesthesia to keep the patient comfortable, although some practitioners may use slightly more or less than 12 mg (134,135). This dosage may be less than what is commonly used in the nonobstetric patient population as pregnancy confers greater sensitivity to local anesthetics. In addition, engorged epidural vasculature may lead to lower spinal CSF volumes. While a lower abdominal incision is utilized in cesarean deliveries, a T4 anesthetic level is required for lower abdominal intraperitoneal operations. Pain from peritoneal traction may be referred to mid or upper thoracic levels. Testing the level of anesthesia at the lower abdomen prior to incision will therefore not guarantee a sufficient level of anesthesia once the peritoneal cavity is entered. A single injection spinal anesthetic utilizing 12 mg of hyperbaric bupivacaine will provide 90 to 120 minutes of anesthesia.

Hypotension is the most common side effect of spinal anesthesia and can be limited but not completely prevented by prehydration with 1000 to 1500 mL of crystalloid administered immediately prior to induction. The use of colloid may be more effective (136). When fluid administration is insufficient to prevent or treat hypotension, vasopressors are often required. In the past, ephedrine had been the drug of choice. Ephedrine has both alpha and beta agonist properties. Phenylephrine, however, is a pure alpha vasoconstrictor and was once considered to be potentially harmful as it was shown in sheep models that potent vasoconstrictors decrease uterine blood flow (137). More recently, it has been determined that, clinically, phenylephrine does not have deleterious fetal/neonatal effects when administered judiciously. Indeed, infants born to mothers receiving phenylephrine have higher umbilical cord arterial blood pH levels than those treated with ephedrine (138). Another troublesome side effect from spinal anesthesia is post-dural puncture headache. The use of small-gauge pencil-point needles, however, has reduced the incidence of post-dural puncture headache to an acceptable rate of 0.5% to 1% (139). In a 2001 survey, spinal anesthesia was the most commonly used anesthetic technique for elective cesarean delivery. Even for emergent cesarean deliveries, spinal anesthesia was used 45% to 59% of the time (128).

Epidural Anesthesia

Epidural anesthesia for cesarean deliveries is most often used for women who have been in labor with an active epidural analgesic already in place. The level of the block can be intensified and extended by dosing the catheter with 2% lidocaine with epinephrine, 3% 2-chloroprocaine, 0.5% bupivacaine, or 0.5% ropivacaine. Epidural anesthesia has the advantage of titration of the level of block, slower onset with greater ability to manage hypotension, and flexibility. The epidural catheter can be re-dosed as needed for procedures that end up being longer than anticipated. Lidocaine 2% with epinephrine 1:400,000 or 1:200,000 is probably the drug most often used. It is relatively rapid in onset and of intermediate duration lasting 90 to 120 minutes. 2-Chloroprocaine 3% has an onset time within 8 minutes or less in laboring patients with preexisting epidural catheters and can be used for urgent cesarean deliveries (140). It is rapidly metabolized in maternal serum with little transfer and accumulation in an acidotic fetus (141). 2-Chloroprocaine has a shorter duration of action,

however, lasting 40 to 50 minutes. When used, it must be followed up with additional local anesthetic, most often 2% lidocaine. 2-Chloroprocaine may interfere with the effectiveness of subsequently administered bupivacaine or epidurally administered opioids (142,143).

Epidural anesthesia for cesarean delivery may not be as reliable as spinal anesthesia. Incomplete or "patchy" block may limit its usefulness. This may require extra time to allow further distribution of the local anesthetic. The addition of epidural adjuvants such as fentanyl may be helpful. Intravenous additives such as opioid, small judicious doses of propofol, or ketamine may also be required. The anesthesiologist must be careful not to obtund the patient's airway reflexes. Ketamine in small doses is often useful under these circumstances as it provides profound amnesia and analgesia. It can cause dysphoria and therefore requires the addition of midazolam to limit this unpleasant side effect. When epidural anesthesia is ineffective, general anesthesia may be necessary. From the standpoint of airway protection, general endotracheal anesthesia is the most conservative approach to take. Ineffective or incomplete epidural anesthesia during cesarean delivery can be avoided if the effectiveness of the labor epidural is carefully evaluated prior to cesarean delivery. If there is any question, then proceeding to spinal anesthesia or repeat placement of the epidural catheter is in order (144).

If spinal anesthesia is chosen immediately following failed or unsuccessful epidural anesthesia, then caution must be taken to avoid a high spinal block, which may render the patient hypotensive and/or apneic. The reasons for this may be related to an already existing partial block or compression of the intrathecal sac from epidurally administered fluid. A downward adjustment of local anesthetic dose may therefore be necessary (145). If the anesthesiologist chooses to replace the epidural catheter, the potential for local anesthetic toxicity must be kept in mind as large doses of local anesthetic are typically used.

CSE Anesthesia

CSE anesthesia offers the advantages of both the techniques for cesarean delivery. Spinal anesthesia provides a more rapid onset and more reliable block than does epidural anesthesia (146). Because of its rapid onset, however, maternal hypotension may be problematic. In addition, spinal anesthesia provides a fixed time period of anesthesia. Should the operative time run beyond the length of the spinal anesthetic, then general anesthesia may be required for the remainder of the procedure. CSE anesthesia allows for the use of lower doses of spinal anesthetic, minimizing maternal hypotension, and has the flexibility to extend and prolong the duration of the block via epidural "top-ups" during the procedure (147,148). At the University of Missouri, we often use CSE anesthesia when a longer than usual procedure is anticipated such as multiple prior cesarean deliveries, morbid obesity, or anticipated cesarean hysterectomy. The more favorable hemodynamics and reliability of CSE anesthesia have allowed regional anesthesia to be utilized in patients with severe pre-eclampsia and obstructive cardiac lesions (149–151).

Post-cesarean Pain Management

The increasing use of regional anesthesia for cesarean delivery has been paralleled with an increasing use of spinal opioids for

the management of postoperative pain. Postoperative pain following cesarean delivery is unique in that the parturient must care for a newborn infant as well as for herself. Parenteral opioids have a long history of effectiveness, but can be associated with troublesome side effects, particularly somnolence. Spinal opioids administered epidurally or intrathecally can provide effective pain relief with a minimum degree of somnolence. Preservative free morphine is probably the most commonly used drug in the United States. It can be administered intrathecally at the time of spinal anesthesia or via the epidural catheter during or immediately following cesarean delivery. A single dose of morphine, 2 to 5mg, administered via an epidural catheter will provide pain relief for up to 24 hours (152). While a portion of the morphine administered into the epidural space will be absorbed into the vasculature and redistributed to the CNS, the remainder will transfer directly to the CSF and bind to mu receptors at the spinal cord level. Stimulation of mu receptors in turn blocks the transmission of nociceptive signals to higher levels (153). Administered intrathecally at the time of spinal anesthesia, small doses of morphine, ranging from 0.1 to 0.25mg, will provide analgesia for 18 to 24 hours (154,155). Unlike local anesthetics, spinal opiates do not cause motor block and allow for early ambulation.

Other opiates have been used in place of or in addition to morphine. Meperidine and hydromorphone have also been used successfully (156,157). Fentanyl is more lipid soluble than morphine. It quickly binds to mu receptors at the spinal cord level and is of much shorter duration lasting only a few hours. It is usually used as an adjunct to local anesthetics during cesarean delivery. If it is to be used at all for postoperative pain relief, it is usually added to a continuous epidural infusion of low-concentration local anesthetic.

While effective in providing pain relief, spinal opiates are not without troubling side effects. Nausea and vomiting, pruritus, and respiratory depression can complicate an otherwise excellent method of postoperative analgesia. These side effects are primarily mediated by mu receptors. Mu antagonists can therefore be used for treatment when side effects become particularly bothersome. It is important to note that pruritus from spinal opiates is not primarily histamine mediated. Antihistamines are therefore less likely to be effective in treating pruritus than mu antagonists. Low-dose naloxone either as a bolus or continuous intravenous infusion can effectively treat side effects without diminishing analgesia (158). Agonists-antagonists such as nalbuphine have also been used successfully (159).

Of the side effects that can occur with the use of spinal opiates, respiratory depression is the most concerning. Fortunately, most obstetric patients are young and healthy with a very low incidence of significant respiratory depression following the use of spinal opiates (152). Nevertheless, it is prudent to follow these patients closely with hourly nursing checks and/or continuous pulse oximetry. It is important to note that with spinal morphine, respiratory depression may be delayed by up to 12 hours following administration. Most anesthesiologists therefore wish to be consulted before any sedative drugs are administered to patients who have received spinal morphine during the first 24 postoperative hours. While side effects and the fear of respiratory depression may be

disconcerting, spinal opiates have become the mainstay of postoperative pain management following cesarean delivery in the United States.

ANESTHESIA FOR THE HIGH-RISK PATIENT

Of the myriad complications of pregnancy that have anesthetic implications, pre-eclampsia and deteriorating fetal status (fetal distress) are among the more common. In prior decades, patients with congenital heart disease did not often survive to reproductive age. Currently, however, more and more patients are living to childbearing age and it is becoming more common to encounter patients with corrected or partially corrected congenital heart lesions. With the obesity epidemic making its way into an ageing obstetric population, we can expect to see an increase in the frequency of cardiovascular diseases complicating pregnancy.

Pre-eclampsia/Eclampsia

Hypertensive disorders complicate 5% to 10% of pregnancies. While pre-eclampsia affects multiple systems, the cardio-pulmonary, hepatic, coagulation, and airway systems are of particular interest to the anesthesiologist. Patients with severe pre-eclampsia are intravascularly volume depleted even though there may be a positive water and sodium balance. Intravascular volume depletion may present a challenge to the anesthesiologist providing regional analgesia for labor or anesthesia for cesarean delivery. In addition, most patients with severe pre-eclampsia have some degree of increased systemic vascular resistance with varying degrees of cardiac function ranging from hyperdynamic to normal to impaired (160). In the past, epidural analgesia for labor was controversial in patients with severe pre-eclampsia because of the concern for marked reductions in blood pressure and utero-placental blood flow. Epidural analgesia, however, has been shown to provide superior pain relief, decrease blood pressure, decrease catecholamine levels, and improve utero-placental blood flow (161,162). Marked drops in blood pressure can be prevented with judicious use of crystalloids and or colloids for prehydration and treated with small doses of ephedrine. Indeed, in a 2001 study, the incidence of hypotension requiring treatment was only 11% (163). In patients whose severe pre-eclampsia is complicated by pulmonary edema and/or oliguria, further studies including invasive central monitoring and/or echocardiography may be indicated before initiating epidural analgesia.

General anesthesia for cesarean delivery in patients with severe pre-eclampsia can be particularly hazardous. An edematous airway can make intubation difficult or impossible, posing a serious threat to maternal safety. Tracheal intubation during general anesthesia is very stimulating and can be associated with dangerously high blood pressures placing the patient at risk for intracranial hemorrhage. For these reasons, regional anesthesia is the preferred method of anesthesia in patients with severe pre-eclampsia. When general anesthesia is necessary, blood pressure should be controlled with additional doses of antihypertensives. The response to intubation can be blunted with opioids and/or intravenous lidocaine just prior to induction. Awake intubation may be necessary to avoid the very dangerous cannot-intubate/cannot-ventilate scenario.

In the past, spinal anesthesia was not recommended in patients with severe pre-eclampsia undergoing a cesarean delivery. Many anesthesiologists believed that spinal anesthesia would lead to difficult-to-treat hypotension. More recent studies however have shown that the incidence or severity of hypotension is no greater in severe pre-eclamptic patients having spinal anesthesia than epidural anesthesia (164). It is interesting to note that a study as far back as 1950 demonstrated that severe pre-eclamptic patients were more resistant to hypotension following spinal anesthesia than were normal patients (165). At the University of Missouri, spinal anesthesia is frequently administered to patients with severe pre-eclampsia undergoing cesarean delivery.

The coagulopathy that may accompany severe pre-eclampsia is another major concern to the anesthesiologist. Uncorrected severe coagulopathy is an absolute contraindication to regional analgesia/anesthesia for fear of traumatizing the epidural vasculature, which in turn may lead to the formation of an epidural hematoma. Most anesthesiologists will place an epidural catheter or perform a spinal anesthetic with platelet counts above 100,000/mm³ in the absence of any clinical evidence of abnormal bleeding. There is no absolute cutoff for platelet counts below which regional anesthesia is contraindicated. Regional analgesia/anesthesia has been safely performed in parturients with platelet counts as low as 50,000/mm³ to 69,000/mm³ when other coagulation indices are normal and there is no clinical evidence of abnormal bleeding (166,167). The decision to perform regional analgesia/anesthesia in a patient with thrombocytopenia, however, must always be made on an individual basis keeping the risk/benefit ratio in mind. It is also worthwhile to keep in mind that epidural hematomas are very rare in the pregnant patient population. Difficult airways, unfortunately, are not.

Early anesthesia consultation is recommended when the obstetrics service admits a patient with severe pre-eclampsia. This is particularly true in patients who are at risk for an emerging coagulopathy. Many obstetric anesthesiologists are now advising early epidural placement when the patient is committed to delivery. As the disease progresses, regional anesthesia may not be possible further in labor if a coagulopathy is already well established. An epidural catheter placed early in labor can be continued even if the platelet count drops to very low levels. Not only would this allow the patient to receive the benefit of epidural analgesia for labor, but in the event of cesarean delivery, the epidural catheter can also be dosed to a surgical level of anesthesia and avoid the much greater hazards of general anesthesia.

Deteriorating Fetal Status

The term “fetal distress” is imprecise and nonspecific. Its use can often lead to unnecessary haste, placing both the mother and the fetus at risk for complications and medical errors. The American College of Obstetricians and Gynecologists has recommended that the term “fetal distress” be replaced with “non-reassuring fetal status” with further descriptors clarifying the abnormality or presumed etiology (168). Either regional anesthesia or general anesthesia can be used for cesarean deliveries performed for non-reassuring fetal status with comparable outcomes (169). In instances of non-reassuring fetal status, the degree of urgency and time limitations often

determine the choice of anesthesia. Some practitioners have the perception that general anesthesia can be administered more rapidly than regional anesthesia and have encouraged its use when "fetal distress" is diagnosed. It must be kept in mind, however, that the risk of maternal mortality from anesthetic causes is significantly greater for general anesthesia than regional anesthesia (130). Recognizing the increased maternal risks of general anesthesia versus regional anesthesia, the American College of Obstetricians and Gynecologists has recently stated:

The significant added morbidity of general anesthesia over regional anesthesia for cesarean delivery suggests that regional anesthesia is the preferred method of pain control and should be used unless a contraindication to regional anesthesia is present. Although general anesthesia may be indicated in some cases of fetal heart rate abnormality, the severity of the abnormality should be considered before incurring the excess risk of maternal mortality associated with general anesthesia (170).

Inability to intubate and aspiration of gastric contents present the greatest risk of general anesthesia to the parturient. The incidence of failed intubation has been estimated to be as high as 1 in 250 patients (171). When patients at risk for failed intubation are identified, close communication among obstetric and anesthesia team members is critical. These patients may benefit from early epidural catheter placement. When anesthesia team members are notified early in the process of initiating a "stat" cesarean delivery, dosing a well-established labor epidural catheter for cesarean delivery can be performed nearly as rapidly as general anesthesia (172). When an unexpected difficult airway is encountered, a decision must be made to proceed without the benefit of endotracheal intubation, incurring the risk of aspiration, or allowing the patient to awaken and proceeding with an awake intubation technique, which will usually require much more time to accomplish than the standard rapid sequence induction. Newer ventilation and intubation methods such as the laryngeal mask airway (LMA), intubating LMA, and Pro-Seal LMATM have been recognized as valuable techniques for managing these very stressful situations (173,174). If ventilation cannot be established, then either the patient must be awakened or a surgical airway be established (175).

The importance of close communication between obstetrician and anesthesiologist cannot be stressed more. The highest risk to the patient occurs when an anesthesiologist first encounters a patient already in the operating room prepped and draped for "stat" cesarean delivery. The anesthesiologist is given very little time to evaluate the patient and prepare for anticipated difficulties. Conversely, the obstetrician must be apprised as early as possible when the anesthesiologist anticipates difficulty. At the University of Missouri, when patients are brought to the operating room for "stat" cesarean delivery for rapidly deteriorating fetal status, FHR monitoring is continued. This allows the establishment of regional anesthesia to continue if the FHR returns to normal or to stable levels. If an internal electrode is in place, it is

not removed until just prior to incision or may be kept in place if general anesthesia is required. The real-time information gained with this approach may help guide the management of a failed intubation. In the event of a failed intubation, if fetal status has improved and remains stable, the patient can be awakened and a different course of action can be taken. If there is continued fetal deterioration, the anesthetic can then be continued by mask or LMA as noted above, with continuous cricoid pressure (176).

Cardiac Disease

The cardiac adaptations to pregnancy are well known. Blood volume and cardiac output increase significantly during gestation and are tolerated very well in healthy individuals. Women with cardiac disease who otherwise may be sufficiently compensated in the nonpregnant state, however, may deteriorate significantly when faced with the cardiac demands of pregnancy.

Congenital Heart Disease

In 2001, the majority of pregnant women presenting with cardiac disease were those with congenital heart disorders (177). This is not surprising since a greater number of women with congenital heart disease are living to childbearing age than that in earlier decades. Patients with fully corrected lesions with no residual dysfunction do well during pregnancy and do not require special attention other than prophylactic antibiotics. Those with partially corrected lesions or residual dysfunction, however, may require special considerations.

Individuals with shunts must maintain a balance between right- and left-sided pressures. Increasing left-sided pressures such as systemic hypertension may worsen preexisting left-to-right shunting. A right-to-left shunt will worsen if peripheral vascular resistance drops as it may with regional anesthesia. Patients with obstructive lesions who are preload dependent may decompensate if there is a significant drop in venous return. In the past, regional anesthesia was considered relatively contraindicated in these individuals. More recently, however, regional anesthesia has been shown to be of benefit in many patients and is recommended when it is advisable to avoid the high catecholamine levels of pain and stress, which may lead to maternal tachycardia, systemic hypertension and pulmonary hypertension (178). Patients with obstructive lesions and pulmonary hypertension who do not tolerate drops in venous return or systemic vascular resistance may still significantly benefit from epidural analgesia, provided that it is dosed slowly while maintaining preload and systemic vascular resistance. Patients with regurgitant lesions and left-to-right shunts may benefit from the decreased systemic vascular resistance that epidural analgesia provides as it promotes forward flow. The increased demands on cardiac output, workload, and oxygen consumption present during the second stage of labor can be ameliorated with a carefully managed epidural analgesic allowing for a passive second stage of labor. Patients with these lesions may require invasive monitoring as well as continuous oxygen saturation monitoring to optimize cardiac function and avoid the hemodynamic perturbations that regional anesthesia may cause.

Valvular Lesions

Patients with stenotic valvular lesions and dynamic obstructive cardiomyopathy do not tolerate tachycardia and decreased systemic vascular resistance well, nor do they tolerate the tachycardia and stress associated with the pain of labor. Epidural analgesia is beneficial in these individuals as long as preload and systemic vascular resistance are maintained. This is particularly true during the second stage of labor. When treating hypotension in these patients, beta agonists are to be avoided.

Epidural analgesia is the preferred pain management technique in patients with regurgitant valvular lesions. The decreased systemic vascular resistance that results from regional anesthesia decreases afterload, reduces the regurgitant fraction, and improves forward flow. In addition, it prevents the increase in systemic vascular resistance that results from the pain of labor.

Ischemic Cardiac Disease

Ischemic cardiac disease in pregnancy is rare. Nevertheless, as the pregnant patient population ages, particularly in association with assisted reproductive techniques used in an aging population, we can expect to see increasing numbers of patients with coronary artery disease. Epidural analgesia is well suited to this patient population. The sympathectomy associated with epidural analgesia decreases catecholamine levels and cardiac workload. A passive second-stage labor can be achieved, which will further decrease myocardial oxygen demand. Perfusion pressures must be maintained, however, but epinephrine-containing local anesthetic and beta agonists should be avoided as they may lead to troublesome tachycardia. Intensive cardiac monitoring may be necessary in patients who have significant myocardium at risk.

The successful management of the pregnant cardiac patient requires an interdisciplinary approach. Obstetrician, cardiologist, and anesthesiologist should be involved early in the patient's pregnancy. Clinical data, particularly results of echocardiograms and stress tests, should be shared among all involved prior to the patient's arrival on labor and delivery. It does not serve the patient well when the anesthesiologist is first consulted at the time that the patient is already in active labor or presents for cesarean delivery. Early consultation will provide for a coordinated team approach leading to the best results possible (178).

CONCLUSION

Obstetric anesthesia has made great strides over the past 50 years. Maternal mortality from anesthetic causes has declined dramatically, primarily due to increasing usage of regional anesthesia. Regional analgesia for labor is effective, safe, and has little effect on the course of labor or neonatal outcome. Newer techniques have led to the expansion of regional analgesia to allow for its application to a wide range of patients with pregnancy complications. In contemporary labor and delivery units, virtually all patients are able to enjoy the benefits of regional analgesia should they choose to do so.

Currently, a national effort is underway to improve patient safety. As part of this effort, anesthesiologists are becoming more and more proactive in perioperative and obstetric care. At the University of Missouri, strategies have been developed

and are continuing to be refined, to help reduce general anesthesia-related morbidity and mortality. An attempt is made for an anesthesiologist to evaluate all patients admitted to labor and delivery regardless of the anticipated need for anesthesia services. Patients who may present with potential anesthetic complications are referred for anesthesia consultation during gestation, prior to admission. This includes patients who are morbidly obese, have had prior anesthetic difficulties or a family history of anesthesia complications. This is also true for patients with heart disease, prior spine surgery, neurologic, hematologic, or significant pulmonary disorders. Patients with an anticipated or known difficult airway are encouraged to have an epidural catheter placed early in labor. This is also true for patients at risk of developing a coagulopathy, such as with severe pre-eclampsia or hemolysis, elevated liver enzymes, and low platelet count syndrome.

It cannot be overstressed that continuous close communication with all members of the obstetric team is vital to improving patient outcome.

34 Breast cancer and pregnancy

Beth Kliethermes, Dani Stramer, and Edward R. Sauter

EPIDEMIOLOGY

Three percent of all cases of breast carcinoma occur in women aged 35 or younger. Breast cancer is the leading cause of cancer death for women 15 to 29 years of age (1) with approximately 11,000 new cases of in situ or invasive breast cancer and 1100 breast cancer deaths in women younger than age 40 (2).

Young women with breast cancer are more likely to present with more advanced disease and have worse outcomes than older women (3). This is likely due to a variety of factors, including the biology of the disease and the challenges to early detection in young women. Young women with breast cancer are more likely to have hormone-insensitive, higher grade disease, with a higher proliferative rate (4) and a higher likelihood of bone marrow metastases (5).

Studies investigating how reproductive factors influence the development of breast cancer are increasing our understanding of possible reasons why carcinoma presents at an advanced stage among this group of women. Specifically, concurrent or recent pregnancy is associated with increased aggressiveness of the tumor and poorer survival. While the occurrence of breast cancer at the time of pregnancy or lactation is 3% or less of all women who develop breast cancer (6), the prevalence increases to over 15% among women before age 40. Pregnancy-associated breast cancer (PABC) is defined as breast cancer diagnosed during pregnancy or within the first 12 months postpartum. Currently, the average age of women with PABC is between 32 and 38 years (7), and the median gestational age at the time of diagnosis is 17 to 25 weeks (8). The incidence of PABC may increase as a growing number of women are choosing to postpone childbearing until their mid-to-late 30s.

ETIOLOGY

Reproductive factors such as age at menarche, parity, and age at first birth are well-established risk factors for breast cancer incidence due to their influence on the length of hormonal exposure to estrogen and progesterone (9). Epidemiologic studies confirm that pregnancy has a dual effect on breast cancer risk (10). Childbearing reduces the lifetime risk of developing breast cancer, although risk increases during the time surrounding pregnancy (11).

Women who have their first full-term pregnancy at an early age (defined variously as before 20 up to age 26) have a decreased lifetime risk of developing breast cancer. When compared with nulliparous women, the risk of breast cancer increases in women whose first full-term pregnancy occurred after 35 years of age (12). Nonetheless, for women who develop PABC, early age at first full-term pregnancy has been associated with more aggressive breast cancers. A recent study found that a woman with a first full-term pregnancy before age 20 had a 3.2 increased odds of having an aggressive tumor (13).

Studies have also shown that a diagnosis of breast cancer shortly after pregnancy is associated with reduced chance of survival (14). The transient increase in breast cancer risk for 3 to 15 years after childbirth is followed by a decrease in long-term risk (15).

The relationship between age at first full-term pregnancy and risk of breast cancer is likely related to physiologic and hormonal changes that occur during and after pregnancy (14). An early first full-term pregnancy imprints a specific genomic signature on the breast tissue, with differences in RNA expression and protein concentration compared with those with a later age at first childbirth (16). First full-term pregnancy appears to have a lasting effect on the hormonal environment of the mother and on her metabolism of estrogen (17). One of the mechanisms suggested to account for the incidence of breast cancer in general is exposure to high endogenous estrogen levels. Estrogen levels peak during pregnancy. Endogenous estradiol can initiate the transformation of premalignant to malignant breast cells or accelerate the progression of existing tumors (18). In addition to estrogen, a full-term pregnancy alters the concentration of other hormones, providing another possible way in which pregnancy might influence breast cancer risk. As a result, specific changes in the levels of hormones during and following pregnancy may affect the breast tissue by increasing the risk of mutations, by altering the tissue's susceptibility to hormones, or by modulating its levels of gene expression (19).

Studies specifically addressing the issue of breast differentiation and involution after pregnancy and lactation may shed light on the possible mechanisms of PABC, including changes in the pattern of breast lobular development and differentiation, cell growth, and gene expression (20). The mammary gland reaches full lobular development late during a woman's first full-term pregnancy in preparation for lactation. If this occurs at a young age, the chance for mutational events to have occurred in the breast epithelium prior to pregnancy are less than if a woman's first pregnancy is at an older age. It is therefore less likely that the stimulatory effects of pregnancy on the breast will drive abnormal breast epithelial cells to progress to cancer. Moreover, during weaning, breast epithelial differentiation and involution occurs leading to a long-term breast cancer risk reduction. Differentiated cells do not divide or proliferate under normal conditions and are less susceptible to carcinogenic transformation long term (21). Breast remodeling following lactation resembles the microenvironment that occurs with inflammation. The activated cells secrete proteins, growth factors, tissue-remodeling enzymes, and provisional extracellular matrix, all of which facilitate the return of the breast to the prepregnancy state. This involution microenvironment may promote the growth and development of transformed tumor cells if present in the

tissue (22). Furthermore, metastatic spread is facilitated by the increased vascularity and lymphatic drainage from the gravid and lactating breast (23). These observations suggest that women with precancerous or cancerous epithelial cells within the breast at the time of pregnancy may be at a high risk for tumor promotion and metastasis.

PATHOPHYSIOLOGY

Overall, women with PABC have similar pathologic features to age-matched controls. The most common histologic subtype is invasive ductal carcinoma, which is usually high grade (24). Tumor size, degree of nodal involvement, and stage at diagnosis are usually more advanced among women with PABC compared with age-matched nonpregnant women with breast cancer (25,26). Controlling for disease stage, tumor size, hormone receptor status, age, race, and type of surgery, PABC is associated with approximately a 14% increase in risk of death compared with nonpregnant controls (27). The reason(s) for this is not clear, since overall rates of treatment with radiation and chemotherapy are similar. Theories proposed include the relative immune suppression of pregnancy and differences in tumor biology due to elevated estrogen and progesterone levels during pregnancy (27). Other studies do not indicate that termination of pregnancy improves the prognosis of PABC (28).

Hormone receptor status in PABC tumors is commonly negative, more often than their age-matched controls with breast cancer (29). Between 54% and 80% of PABCs are ER-negative, possibly due to the downregulation of receptors in pregnancy (30). Using a variety of antibodies, HER2 positivity has been observed in 28% to 58% of PABCs. Sample sizes in these studies are too small to conclude whether the frequency of HER2 positivity is higher than that seen in age-matched controls (31).

DIAGNOSIS

Clinical examination of the breast is more difficult during pregnancy and nursing because the breasts are hypervascular, engorged, and nodular. Pregnancy-related changes can conceal otherwise palpable tumors in the breast. PABC most commonly presents as a painless mass or thickening. A discreet mass is often difficult to palpate during lactation and involution, and malignancy may be mistaken for mastitis (32).

On average, diagnosis of PABC is delayed 5 to 15 months (7). Difficulty in evaluating mass lesions in the pregnant and lactating breast, a reluctance to perform biopsy, false diagnosis as an inflammatory mass, and inadequate follow-up by patient and physician have all been reported as possible reasons for this delay (33). Mammography with abdominal shielding poses a low risk of radiation to the fetus in the second and third trimesters, but is not recommended in pregnant or postpartum women because the high density of the breast leads to a high rate of false negatives (34). Ultrasonography is a more sensitive alternative for pregnant and lactating women and can distinguish between cystic and solid lesions (35). Magnetic resonance imaging offers high sensitivity but low specificity for the diagnosis of breast cancer. This imaging technique is not recommended during the first trimester until more information becomes available (8). Gadolinium should be avoided if possible

since it crosses the placenta and its effects on the fetus are unknown (36). Available evidence indicates that fetal exposure to less than 0.05Gy ionizing radiation is not associated with a detectable increase in deleterious effects (37). CT scans to assess disease extent, especially those of the abdomen and pelvis, are generally not recommended during pregnancy due to the relatively high mean doses to the fetus of 0.0036Gy for abdominal and 0.089Gy for pelvic irradiation (38).

Since PABC often presents as a palpable mass, core or open biopsy is an effective diagnostic procedure. Lactation should be suppressed prior to biopsy in nursing women to reduce the risk of abscess and milk fistula formation (39). Fine-needle aspiration is less reliable during pregnancy and lactation due to the hyperproliferative features in the tissue of the pregnant, lactating, or involution breast (40).

MANAGEMENT

Patients with PABC should be treated as soon as possible and according to the latest clinical guidelines, carefully weighing the risk to the fetus. The first treatment for most breast cancer patients is surgery. General anesthesia is safe if precautions are taken to compensate for physiologic changes induced by pregnancy (41). During the first and second trimesters of pregnancy, modified radical mastectomy is recommended to eliminate the need for postoperative radiation therapy and chemotherapy for patients with early-stage disease. For accurate staging, axillary evaluation is necessary to determine nodal status. Nodal metastases are relatively common in PABC, and disease extent affects the need for adjuvant chemotherapy (42). For women diagnosed with PABC late in pregnancy or after delivery, lumpectomy with axillary dissection can be performed, with radiation treatment after childbirth (43). A small series that used Tc-99m and/or blue dye in women of gestational ages ranging from 4 to 32 weeks suggests that lymphatic mapping followed by sentinel lymph node biopsy is safe (44). Therapeutic radiotherapy is unsafe for the fetus and is contraindicated throughout all stages of pregnancy.

Adjuvant or neoadjuvant chemotherapy is potentially teratogenic to the fetus in the first trimester of pregnancy (45), with an estimated risk of fetal malformations of up to 17% when administered during the first trimester (8). If it is felt unsafe to delay adjuvant therapy until after delivery, chemotherapy can be considered in the second and third trimesters. The anthracyclines doxorubicin (46) and epirubicin (47), as well as taxanes (48), appear relatively safe, with the few series available reporting a 0% to 6% death rate (intrauterine, stillbirth, or neonatal) after treatment. It is postulated that placental P-glycoprotein may limit the transplacental transfer of these agents. Chemotherapy should be administered at least 3 weeks before delivery to avoid sepsis and bleeding in a mother with low red blood cell, white blood cell, and platelet counts (28). Trastuzumab use to treat HER-2-positive PABC was associated with anhydramnios in three of six women and should be avoided during pregnancy since it appears to interfere with the normal development of the fetal kidney (48). Lactation should be suppressed during chemotherapy to prevent agent transmission to the infant (49). The long-standing recommendation to avoid pregnancy for 2 years after a diagnosis of breast cancer is being questioned, since median time to relapse is more than 5 years, even for

patients with stage II node-positive disease who receive standard-of-care regimens of surgery and adjuvant therapy (50).

There are few reports documenting the long-term effects of chemotherapy. One study that assessed physical, neurologic, and psychologic development of 84 children with a median age of 18.7 years born to mothers who received chemotherapy during pregnancy found normal development, and no reports of malignancy (51). Two large prospective studies, one initiated by the German Breast Group and another by the Breast International Group (BIG-03), should provide more information on long-term sequelae after in utero exposure to chemotherapy (8).

For hormone-sensitive tumors, tamoxifen, a selective estrogen-receptor modulator, may be used as adjuvant treatment after surgery or as treatment for advanced cancer. Due to possible teratogenic effects, tamoxifen is not recommended during pregnancy (52). Bisphosphonates are often used to manage the complications of breast cancer skeletal metastases. Reports of their use during the third trimester of pregnancy suggest that postpartum, neonates of mothers treated with the bisphosphonate pamidronate were hypocalcemic but otherwise developed normally, suggesting that calcium levels should be closely monitored in neonates of mothers treated with these agents (53).

35 Neoplasia in pregnancy

Nora T. Kizer and David G. Mutch

Cancer complicates approximately 1 in 1000 pregnancies (1). The Third National Cancer Survey found that 12.8% of all cancers in women occur during the reproductive years, and the three most common cancers in decreasing order of frequency are thyroid, cervical, and melanoma of the skin (2). The most common malignancies actually encountered during pregnancy include cervical, breast, and hematologic malignancies (3).

Malignancy in pregnancy is a rare and distressing condition, which requires consideration of mother and fetus. Specific issues that complicate medical management of malignancy in pregnancy include the possible benefits of pregnancy termination to allow aggressive treatment, the effect of therapy on the developing fetus, the timing of delivery or termination with ongoing treatment, and the role of altered immune and hormonal status during pregnancy, which may affect the prognosis of the coexistent cancer. Most malignancies in females occur outside the reproductive age group; therefore, there are few large studies that adequately examine these issues in detail. However, in reviewing the composite literature, several general guidelines have emerged. First, the anatomic and physiologic changes of pregnancy can obscure the signs and symptoms of early malignancy. Patient complaints are often dismissed as simply symptoms of pregnancy, thereby delaying the performance of timely examination and diagnostic studies. Second, although immunosurveillance may be altered in pregnancy, stage-for-stage prognosis and survival data for malignancy in pregnancy when properly treated are not significantly different than those for the nonpregnant population. Finally, the risk of an anomalous fetus resulting from treatment depends upon the gestational age of the fetus, as well as the mode and intensity of therapy. Many cancers arising during pregnancy can be treated aggressively with surgery, chemotherapy, and even radiation, without necessarily requiring therapeutic abortion.

GYNECOLOGIC MALIGNANCIES

The following section details the gynecologic malignancies by disease site. Staging for the major gynecologic malignancies is presented in Tables 1–5 (4). Overall, endometrial cancer has the highest incidence among gynecologic malignancies for all age groups, followed by cervical and ovarian cancers. The incidence of gynecologic malignancies in the reproductive age group is altered, as cervical cancer far outranks ovarian cancer while endometrial carcinoma is the rarest, unless one considers gestational trophoblastic disease (GTD) in this group. A brief outline of etiology, epidemiology, diagnosis, and treatment of each disease site is presented, with specific reference to pregnancy.

Human Papillomavirus/Warts of Lower Genital Tract

The human papillomavirus (HPV) is the causative agent of genital warts, is related to a variety of skin diseases in humans,

and plays a role in the tumorigenesis of a variety of malignant tumors of the head, neck, anus, and lower genital tract. The discovery of its predominant role in the development of cervical cancer has allowed the development of a variety of screening and prevention protocols. To date, more than 100 HPV types have been identified. The prevalence of HPV in pregnancy has been reported anywhere from 6% to 70% (5) with the highest prevalence in women under the age of 26. It has also been suggested that the pregnant state may activate HPV expression, the mechanism of which is unclear, but likely involves a change in the immune status of the mother. HPV is of concern during pregnancy for several reasons. First, although it remains unclear the frequency of perinatal transmission, consensus holds that neonates can be exposed to maternal cervical HPV during pregnancy and birth. Studies have shown HPV to be causally related to recurrent laryngeal papillomatosis in children (6,7). Maternal history of genital warts in pregnancy has been shown to be the strongest predictive factor for respiratory papillomatosis in the child (8). A second concern is that the papillary lesions can proliferate and cause soft-tissue dystocia or potential hemorrhage upon attempted vaginal delivery.

Treatment during pregnancy is problematic, but when the lesions are occluding, the introitus and/or vagina are large and friable, treatment with trichloroacetic acid, and rarely laser or cryotherapy, may be attempted. Podophyllin and interferon are contraindicated in pregnancy. Without adequate resolution of obstructive or hemorrhagic papillomas, cesarean section is indicated. When smaller lesions or subclinical infections are present, the decision as to the route of delivery can be problematic. Recent evidence suggests that perinatal transmission of HPV may not be avoided by abdominal delivery, since transplacental in utero infection may be possible with intact membranes (9,10). Additionally, there is a lack of concordance of HPV types detected in newborns compared with their mothers, suggesting other routes of transmission that may occur postnatally (11). Other theories include acquisition via semen at fertilization, hematogenously, or via an ascending maternal infection. Overall, further studies are required to elucidate the mode of transmission and the potential benefits of cesarean section delivery over vaginal delivery to avoid maternal–fetal transmission.

Recently, investigative work has focused on the development of HPV vaccines as primary prevention of HPV infections and the subsequent development of cervical cancer (12–15). At this time, a quadrivalent vaccine is approved and a bivalent vaccine is undergoing phase III clinical trials both for both primary prevention and therapeutic benefits (14,15). As both vaccines target HPV 16 and 18 strains, they could potentially prevent 70% of future cervical cancer cases. At this time, controversy still exists as to what age groups should

Table 1 International Federation of Obstetrics and Gynecology Staging of Vulvar Carcinoma (3)

Stage 0 Tis	Carcinoma in situ, intraepithelial carcinoma
Stage I T1 N0 M0	Tumor confined to the vulva and/or perineum—2cm or less in greatest dimension. No nodal metastasis
Stage II T2 N0 M0	Tumor confined to the vulva and/or perineum—more than 2cm in greatest dimension. No nodal metastasis
Stage III T3 N0 M0	Tumor of any size with
Stage T3 N1 M0	1. adjacent spread to the lower urethra and/or the vagina, or the anus; and/or
Stage T1 N1 M0	2. unilateral regional lymph node metastasis
Stage T2 N1 M0	
Stage IVA T1 N2M0	Tumor invades any of the following:
Stage T2 N2 M0	Upper urethra, bladder mucosa, rectal
Stage T3 N2 M0	mucosa, pelvic bone, and/or bilateral
Stage T4 any N M0	regional node metastasis

Table 2 International Federation of Obstetrics and Gynecology Staging for Vaginal Carcinoma (3)

Stage 0	Carcinoma in situ, intraepithelial carcinoma
Stage I	The carcinoma is limited to the vaginal wall
Stage II	The carcinoma has involved the subvaginal tissue, but has not extended to the pelvic wall
Stage III	The carcinoma has extended to the pelvic wall
Stage IB	The carcinoma has extended beyond the true pelvis or has involved the mucosa of the bladder or rectum; bullous edema as such does not permit a case to be allotted to stage IV
Stage IVA	Spread of growth to adjacent organs and/or direct extension beyond the true pelvis
Stage IVB	Spread to distant organs

receive the vaccine, what methods should be employed to implement international public health policies regarding its use, and as to what marketing strategies against a sexually transmitted infection would be acceptable. Furthermore, these vaccines are currently contraindicated during pregnancy, and long-term data are necessary to evaluate their impact on overall mortality.

Cervical Neoplasia

The most common gynecologic neoplasia encountered during pregnancy arises from the cervix, including both invasive and preinvasive diseases. Although the mean age of diagnosis for carcinoma of the cervix is 50 years, this disease process has a bimodal peak incidence with age ranges of 35 to 39 years and 60 to 64 years (16). Clearly, this early peak corresponds with the reproductive age group. The incidence of preinvasive and invasive cancer of the cervix is estimated to be 1.3 and 0.45 to 1.0 per 1000 pregnancies, respectively (17).

Preinvasive Disease

Cervical intraepithelial neoplasia (CIN) arises in the transformation zone between squamous-lined ectocervix and columnar-lined endocervix and has a peak age in the mid to late

Table 3 International Federation of Obstetrics and Gynecology Staging for Cervical Carcinoma (3)

Stage 0	Carcinoma in situ, intraepithelial carcinoma
Stage I	The carcinoma is strictly confined to the cervix (extension to the corpus should be disregarded)
Stage IA	Preclinical carcinoma of cervix; that is, those diagnosed only by microscopy
Stage IA1	Minimal microscopically evident stromal invasion
Stage IA2	Clinical lesions detected microscopically that can be measured; depth 65mm from the base of the epithelium, either surface or glandular, from which it originates and horizontally spread
Stage IB	Clinical lesions confined to the cervix of preclinical lesions greater than IA
Stage IB1	Clinical lesions no greater than 4.0cm in size
Stage IB2	Clinical lesions greater than 4.0cm in size
Stage II	Carcinoma extends beyond the cervix, but not to pelvic wall. The carcinoma involves the vagina, but not as far as the lower third
Stage IIA	No obvious parametrial involvement
Stage IIB	Obvious parametrial involvement
Stage III	Carcinoma has extended to the pelvic wall or tumor involves the lower third of the vagina. Hydronephrosis or nonfunctioning kidneys are stage III, unless due to other causes
Stage IIIA	No extension to the pelvic wall
Stage IIIB	Extension to the pelvic wall and/or hydronephrosis or nonfunctioning kidney
Stage IV	
Stage IVA	Spread of growth to adjacent organs (i.e., bladder or rectal mucosa)
Stage IVB	Spread to distant organs

Table 4 International Federation of Obstetrics and Gynecology Staging for Endometrial Carcinoma (3)

Stage IA, G123	Tumor limited to endometrium or invasion to less than one-half of the myometrium
Stage IB, G123	Tumor invasion to more than one-half of the myometrium
Stage II	Cervical stromal invasion
Stage IIIA, G123	Tumor invasion of serosa and/or adnexa
Stage IIIB, G123	Vaginal metastases
Stage IIIC1	Metastases to pelvic lymph nodes
Stage IIIC2	Metastases to para-aortic lymph nodes with or without positive pelvic lymph nodes
Stage IVA	Tumor invasion of bladder and/or bowel mucosa
Stage IVB	Distant metastases, including intra-abdominal and/or inguinal lymph nodes
Stage G1	5% or less of a non-squamous or non-morular solid growth pattern
Stage G2	6–50% of a non-squamous or non-morular solid growth pattern
Stage G3	>50% of a non-squamous or non-morular solid growth pattern

twenties. Over recent years, the integral role of that HPV plays in the genesis of CIN and subsequent transformation into malignant cells has been further elucidated. The progression of CIN to invasive disease does not appear to be accelerated by

Table 5 International Federation of Obstetrics and Gynecology Staging for Ovarian Carcinoma (3)

Stage I	Growth limited to ovaries
Stage IA	Growth limited to one ovary; no ascites present containing malignant cells; no tumor on external surfaces; capsule intact
Stage IB	Growth limited to both ovaries; no ascites present containing malignant cells; no tumor on external surfaces, capsule intact
Stage IC	Tumor involving one or both the ovaries either with tumor on external surfaces, or with capsule ruptured, or with ascites containing malignant cells, or with positive peritoneal washings
Stage II	Growth involving one or both the ovaries with pelvic extension
Stage IIA	Extension and/or metastases to uterus and/or tubes
Stage IIB	Extension to other pelvic tissues
Stage IIC	Tumor either stage IIA or IIB, but with tumor on surface of one or both the ovaries, or with capsule(s) ruptured, or with ascites present containing malignant cells, or with positive peritoneal washings
Stage III	Tumor involving one or both the ovaries with peritoneal implants outside the pelvis and/or positive retroperitoneal or inguinal nodes. (Superficial liver metastasis equals stage III. Tumor is limited to the true pelvis but with histologically proven malignant extension to small bowel or omentum.)
Stage IIIA	Tumor grossly limited to the true pelvis with negative nodes, but with histologically confirmed microscopic seeding of abdominal peritoneal surfaces
Stage IIIB	Tumor of one or both the ovaries with histologically confirmed implants of abdominal peritoneal surfaces, none exceeding 2cm in diameter; negative nodes
Stage IIIC	Abdominal implants greater than 2cm in diameter; negative and/or positive retroperitoneal or inguinal nodes
Stage IV	Growth involving one or both the ovaries, with distant metastasis. (If pleural effusion is present, there must be positive cytology to allot a case to stage IV. Parenchymal liver metastasis equals stage IV.)

pregnancy, despite the possibility that pregnancy represents an immunocompromised state and may even activate HPV infections. As in the nonpregnant state, the screening method of choice for CIN is the Papanicolaou test, which should be performed at the first prenatal visit. Although not approved by the manufacturer for use in pregnancy, studies have shown that use of the standard cytobrush is safe and effective during pregnancy and can be routinely employed when obtaining cervical cells for evaluation. Although the pregnant cervix differs from the nonpregnant cervix with the appearance of greater inflammation, larger ectropion, and the presence of decidual cells (Arias-Stella reaction) that mimic atypical cells, evidence demonstrates that the accuracy of the Pap test in pregnancy remains unchanged. LaPolla and colleagues (18) reported a cytologic and histologic concordance rate of 84% in 248 pregnant patients with abnormal Pap tests who underwent

colposcopically directed biopsies and found no false-negative results after rigorous postpartum follow-up. Furthermore, in pregnancy, the transformation zone is expanded and, as such, a Pap test obtained during pregnancy that lacks endocervical cells should be repeated.

Abnormal Papanicolaou Results

The management of an abnormal cervical Pap test is a clinical dilemma often encountered during pregnancy. The algorithm for management of an abnormal Pap test is shown in Figure 1. Key points include that HPV triage of a Pap test showing atypical squamous cells of undetermined significance is acceptable in pregnancy. However, colposcopy may be deferred until the 6-week postpartum visit. Similarly, women with a result of a low-grade squamous intraepithelial lesion (LSIL) on Pap test may also defer colposcopy until the postpartum period. Those women who do undergo colposcopy antenatally and receive a histologic diagnosis of CIN I should have follow-up postpartum without any further treatment. To do otherwise is considered unacceptable. Patients with a high-grade squamous intraepithelial lesion by Pap test have a 1 in 100 chance of an invasive lesion. Most will have persistence of the high-grade lesion on postpartum follow-up without progression. Colposcopy with directed biopsies during pregnancy is recommended and should be performed by an experienced clinician. A result of atypical glandular cells on a Pap test in pregnancy should be managed in a fashion identical to that of a nonpregnant woman except that endometrial biopsy and endocervical curettage are contraindicated, and cold-knife conization is not advisable unless invasion is otherwise suspected. Postpartum evaluation may be negative as a high-grade lesion may commonly resolve after delivery. However, a thorough postpartum evaluation is necessary to determine whether the lesion is still present. Of note, patients with normal Pap tests but who are HPV positive for high-risk strains should have repeat testing 6 weeks postpartum as HPV infections are often transient during pregnancy.

Diagnostic Procedures in Pregnancy

In determining which diagnostic and therapeutic interventions to utilize for the assessment of an abnormal Pap test in pregnancy, maternal risk in the form of underdiagnosed invasive cancer, and thus inadequate or delayed treatment, must be balanced against fetal risk, in the form of premature rupture of membranes, chorioamnionitis, and spontaneous abortion from conization. As mentioned earlier, conservative management should be exercised with low-grade cervical lesions as these patients are highly unlikely to have an invasion lesion on pathologic examination (19). Additionally, Patsner (20) used serial evaluation of the Pap test, colposcopy, and directed biopsy to rule out occult or new malignancy in a large group of pregnant patients with mild dysplasia; the conclusion of this study was that patients with mild dysplasia require at most one antepartum colposcopy prior to thorough postpartum reevaluation, without significant increased risk of developing invasive cervical cancer. Some authors now suggest that it is neither cost-effective nor necessary to perform colposcopy on every patient with LSIL on Pap test (19). Advocacy of conservative management assumes that

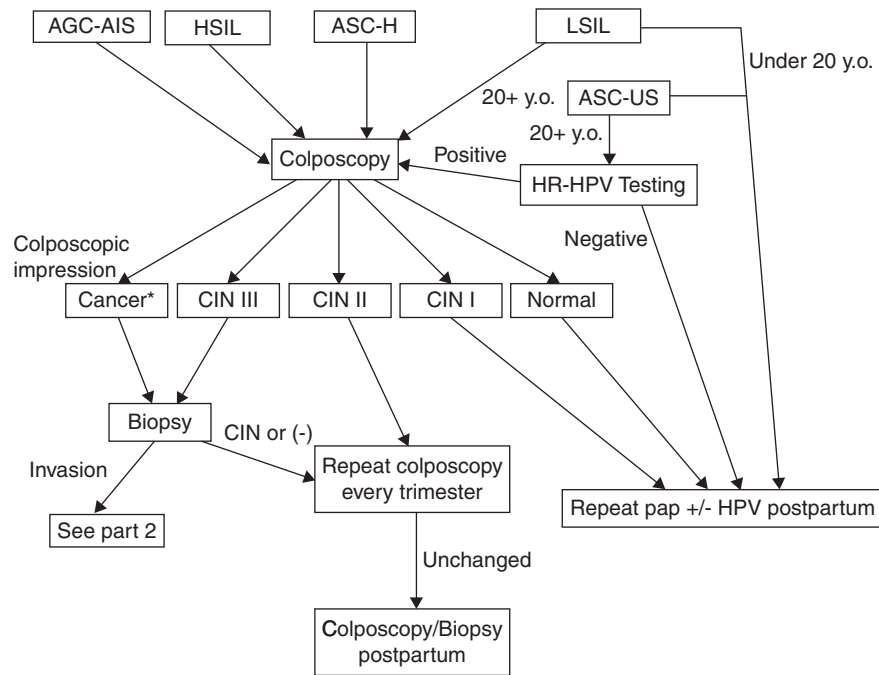

Figure 1 Algorithm for the management of the abnormal Pap smear and cervical intraepithelial neoplasia (CIN) in pregnancy. Abbreviations: AGC, atypical glandular cells; AIS, adenocarcinoma in situ; ASC-H, atypical squamous cells favoring high grade; ASC-US, atypical squamous intraepithelial lesion of undetermined significance; HR-HPV, high-risk human papillomavirus testing; HSIL, high-grade squamous intraepithelial lesion; LSIL, low-grade SIL. Source: From Ref. 42.

colposcopy is performed by an experienced operator, while cytology and histology are reviewed by a reliable laboratory. If these standards are not met, more frequent colposcopy and closer follow-up are probably necessary. Colposcopy with biopsies should always be performed for high-grade lesions and any lesion on repeat examination that appears to have progressed or is suspicious for invasive carcinoma.

Colposcopy During Pregnancy

The pregnant cervix is actually quite amenable to colposcopy, as the transformation zone tends to evert as pregnancy progresses and allows for optimal colposcopic visualization of the cervix. However, given the changes that occur within a gravid cervix compared with the nonpregnant state, it is imperative that the colposcopy be performed by a skilled physician with experience and training in advanced colposcopy. Colposcopic appearance of the pregnant cervix is highlighted by edematous and hyperemic changes secondary to increased vascularity and an underlying decidual stromal reaction. Increased friability with brisk bleeding upon cervical contact may be encountered during pregnancy and, if persistent, is an indication for evaluation. Acetic acid staining is often more intense during pregnancy, causing some minor abnormalities to be interpreted falsely as significant lesions. Nonetheless, aceto-white areas, especially those that have more opaque changes with mosaicism, punctuation, or frankly atypical vessels, deserve histologic evaluation by biopsy. Any gross lesion and the worst representative abnormal areas by colposcopic visualization should be biopsied regardless of gestational age unless delivery is imminent, whereby biopsy may be delayed up to several weeks. Cervical biopsy during pregnancy may cause increased bleeding, which is generally well controlled by silver nitrate sticks, ferric sulfate solution, or, rarely, suture placement. In a series of 100 pregnant

patients, Hacker and associates (17) reported a diagnostic accuracy of 99.5% and a complication rate of 0.6% for colposcopy with biopsies. No endocervical curettage should be performed on any patient with known or suspected pregnancy. The overall goal of a thorough colposcopic cervical examination in pregnancy is to exclude invasive disease, thus averting unnecessary conizations and allowing safe postponement of ablative therapy for CIN, including carcinoma in situ, until after delivery. Thus, the treatment of all forms of CIN in pregnancy is conservative, with required follow-up postpartum. It is imperative that all patients with histologically proven CIN 2 and 3 antenatally have repeat colposcopy with biopsies at the 6-week postpartum visit.

Large Loop Excision of the Transformation Zone

Inadequate colposcopic visualization of either the transformation zone or the entire proximal extent of a lesion is generally delayed during pregnancy and performed postpartum. In addition, endocervical curettage is not performed during pregnancy; thus, the primary indications for excisional procedures during pregnancy are histologic microinvasive disease or marked discordance between a Pap test suggestive of carcinoma and a histologic specimen with minimal abnormalities. Every effort should be made to reconcile such discordance by review of the cytologic interpretation and even repeat colposcopic biopsies to avoid unnecessary excisional procedures during pregnancy. Overall, a diagnostic excisional procedure should be considered only if the cytology, colposcopic impression, or cervical biopsies are suspicious for invasive carcinoma only. Treatment during pregnancy is otherwise unacceptable. When excision by large loop excision of the transformation zone (LLETZ) is required, it is best performed in the first or early second trimester when the risk of spontaneous abortion and bleeding from the increased

vascularity of the cervix are reduced. Current evidence demonstrates mixed results in regard to the impact of LLETZ on risk for premature rupture of membranes, preterm labor, and cesarean section (21–23). As such, it is considered acceptable to perform LLETZ with reasonable maternal safety if indicated. However, it should be performed by an experienced surgeon and ideally during the previable stage of pregnancy and when invasive cancer is highly suspected. These procedures should always be performed in the operating room with sufficient appropriately trained staff.

Cone Biopsy During Pregnancy

Averette and coworkers (24) collected the largest series of conizations during pregnancy with 180 patients and reported that 9.4% required a blood transfusion and 63% underwent a spontaneous abortion. Others have described less frequent but significant complications associated with cone biopsy in pregnancy, including cervical infection, stenosis, chorioamnionitis, preterm labor, thrombophlebitis, pulmonary embolism, and cervical laceration during labor. In an attempt to minimize bleeding and violation of the endocervical canal, DiSaia and colleagues (16) and others (25) have advocated excising a shallow “coin”-shaped biopsy rather than a “cone”-shaped specimen. Multiple hemostatic sutures can be placed at the vaginal reflection of the cervix and a vasoconstrictive agent can be used to infiltrate the cervical stroma in an attempt to decrease blood loss. Overall, the standard cone biopsy is not recommended during pregnancy due to the high complication rate associated with its use.

The so-called coin biopsy has been described as a safe method for performing diagnostic conization during pregnancy (26). The biopsy shape is usually smaller and shallower, resulting in an increased risk of residual disease with positive margins. The compilation of seven studies by Hacker and colleagues (17) showed 43.4% of cones for carcinoma in situ have residual disease upon repeat conization or hysterectomy. As such, this technique is considered diagnostic rather than therapeutic.

Invasive Cervical Carcinoma

More than 40% of cervical cancer cases occur in women of childbearing age, and up to 3% of all cases of cervical cancer are diagnosed during pregnancy (27–29). The incidence of invasive disease varies from 1 to 13 cases per 10,000 pregnancies (16,17). Pregnancy is not thought to play an etiologic role in the development of cervical carcinoma, since the age-adjusted incidence is the same in pregnant as in nonpregnant women. Despite increases in estrogen and progesterone levels, the natural history of cervical cancer is likewise unaffected by pregnancy, as the prognosis is the same in pregnant and nonpregnant patients (16,17,30). Precise survival data by stage for pregnancy complicated by invasive cervical carcinoma are difficult to ascertain, because more than 15 series reported a span greater than 30 years and their treatment, as well as staging, vary (31). Nonetheless, stage-for-stage, 5-year survival rates are the same for pregnant and nonpregnant patients, with rates approaching 100% for stage IA, 85% for IB, and 60% to 70% for stage II using aggregate data from more recent studies (17,32,33). The average age of patients with cervical cancer in pregnancy is 30 years, while the average parity is four, but neither variable has been shown to

Table 6 Cervical Carcinoma Associated with Pregnancy

	Trimester				Total	Average
	First	Second	Third	Postpartum		
Time of diagnosis	19.3	14.2	14.9	51.6	100	N/A
5-year survival	68.6	62.7	51.7	46.3	N/A	51.3
Stage						
IB	64.3	60.6	50.0	46.5	N/A	55.4
II	28.0	30.8	20.7	29.4	N/A	27.2
III/IV	7.7	8.6	29.3	24.1	N/A	17.4

Abbreviations: N/A, not applicable. *Source:* From Ref. 9.

be of prognostic value (17). Table 6 shows the breakdown by trimester (stage and 5-year survival) in cases of cervical cancer associated with pregnancy. Highlighted is the trend of decreased survival and increased likelihood of advanced stage at presentation as pregnancy progresses. Selection bias may influence the data. Patients who defer prenatal care and present later in pregnancy, or even during delivery, are more likely to ignore early symptoms of cervical cancer and not comply with regular cytologic screening. The distribution of histology is similar to the nonpregnant state; 95% or more are squamous cell carcinomas and 3% are adenocarcinomas.

The cornerstone of detection remains the Pap test. Biopsy is the requisite for diagnosis. Vaginal bleeding or abnormal discharge is the most frequent presenting symptom. Early-stage disease is often asymptomatic, but advanced disease may present with symptoms of urinary retention, pelvic pain, lymphedema, or weight loss. Once the diagnosis is made, thorough staging should be performed and may include cystoscopy, proctoscopy, and sigmoidoscopy. Imaging studies should be used judiciously; magnetic resonance imaging (MRI) may be the study of choice, as excellent soft-tissue delineation is obtained without ionizing radiation. Positron emission tomography (PET) imaging has newly recognized value in both the pretreatment and posttreatment management of nonpregnant cervical cancer patients (34–41). However, as the side effects the radioisotope required for the study may have on the developing fetus remains unclear, PET is considered contraindicated at this time during pregnancy. Single-exposure intravenous pyelography can be used and renal ultrasound may also be of value. Cervical malignancies tend to be understaged during pregnancy, because proper workup is oftentimes not performed and parametrial induration may be less prominent and more difficult to detect (32).

Although cervical cancer is not uncommonly found during pregnancy, the data regarding its treatment are limited secondary to the unique ethical considerations surrounding pregnancy that prevent many research methods. Treatment for invasive forms of cervical carcinoma depends on the stage of pregnancy and disease, as well as upon the wishes of the mother. It is also important to remember that most preinvasive lesions found during pregnancy do not progress and that oftentimes both high-grade lesions and low-grade lesions will regress during pregnancy and delivery to either low-grade lesions or normal appearance, respectively. As such, it is necessary to procure histologic confirmation of invasive carcinoma whenever feasible.

Treatment recommendations during pregnancy should be modified to the individual characteristics of the tumor and the patient's desires, and should involve multidisciplinary input. A thorough ultrasound should also be performed to rule out any fetal anomalies that could influence treatment choice. In general, the patient may be offered the same standard of treatment outlined for all nonpregnant cervical cancer patients with the understanding that only treatment of very early lesions allows future fertility, and significant fetal risks are involved that would require termination of the pregnancy. However, some suggest that other treatment options exist based on a lower level of evidence (42). The limit of 20 weeks of gestation is often used as a cutoff for deciding treatment timing, with termination and immediate treatment reserved for a confirmed gestational age of less than 20 weeks.

Microinvasive tumors confirmed by conization are considered to be either stage IA1 or IA2 with invasion less than 3mm below the basement membrane and negative margins, no greater than 7mm of lateral spread and the absence or presence of lymphovascular space involvement as defining criteria. Previous data exist exploring fertility-sparing treatment in nonpregnant patients with microinvasive disease and demonstrates low incidence of recurrence with conization (43–45). However, rarely is an excisional conization procedure currently recommended during pregnancy given the high rate of complications. If conservative treatment is desired, it should be reserved for those patients with stage IA1 disease and squamous cell histology. Conservative treatment would involve repeat cytology and colposcopy to exclude regrowth of the tumor after conization is indicated (17). Patients with stage IA2 cervical cancer are not considered to be the candidates for the same fertility-sparing excisional procedures offered to IA1 patients. Outside of pregnancy, standard of care is radical hysterectomy. These patients may be offered the aforementioned purposeful delayed management strategy versus pregnancy termination with immediate treatment. New data in the literature also offer the possibility of radical trachelectomy as a new fertility-sparing treatment option in this particular group of patients (46). If treatment is delayed until after delivery, route of delivery should be based primarily on obstetric indications. If cesarean section is indicated, a cesarean extrafascial or radical hysterectomy can be performed at delivery. Close postpartum follow-up without surgery is advocated by some when future childbearing is desired in selected patients with minimal microinvasive disease (16).

Frankly, invasive tumors of the cervix demand prompt treatment, although slight delay of up to 6–8 weeks has been shown not to alter prognosis (17,33). For stage IB1 and selected IIA tumors early in pregnancy, treatment options include radiation therapy and chemotherapy or radical hysterectomy with bilateral pelvic lymphadenectomy. Surgery does allow ovarian preservation, but the patient should be counseled prior that certain risk factors could lead to adjuvant radiation or chemotherapy. This option can be effective therapy with the fetus in situ up to 18–20 weeks (47); thereafter, hysterotomy and uterine evacuation should be performed. Radiation is equally efficacious, and no hysterotomy is necessary prior to 20 weeks of gestation with radiation therapy. In general, spontaneous abortion occurs rapidly after exposure to radiation in early pregnancy (48,49).

Some authors now recommend using misoprostol to promote expulsion of the pregnancy if it does not occur within an expected time frame to avoid further complications. If the pregnancy is advanced, hysterotomy is required prior to intracavitary radiation. For IB and IIA tumors found in the third trimester, classical cesarean section can be followed by radical hysterectomy with pelvic and para-aortic lymph node dissection. If radiation is planned, lymph node dissection alone can be performed, which may guide subsequent therapy.

With cervical cancer beyond stage IIA, radiation is the treatment of choice with chemosensitization now being routinely performed with radiosensitizing chemotherapy (50,51). Commencement of treatment is immediate, with the exception of late second- or third-trimester pregnancies when treatment may be delayed until after the documentation of fetal pulmonary maturity and delivery. It must be emphasized that the impact of treatment delay on maternal and fetal health is uncertain. Overall evidence suggests that some amount of delay is reasonable without greatly affecting maternal outcome (49,51–59) and allowing potential small but significant gains in fetal outcomes. The literature suggests that prognosis is unchanged over many weeks and patients can be counseled as such allowing the opportunity to delay treatment if so desired. Clearly, these patients must be closely followed for any evidence of disease progression.

In patients with advanced-stage cervical cancer who strongly desire delay of treatment, neoadjuvant chemotherapy is considered a reasonable option. Limited data suggest that platinum agents in association with either bleomycin or paclitaxel when administered in the second and third trimesters appear to have no fetal toxicity or long-term sequelae (60–62).

Route of delivery has not been shown to be of prognostic significance. Recent studies suggest that there may be a slight advantage to delivery by cesarean section (63–66). However, at this point, choice of route should be based on obstetric indications, extent of cervical tumor involvement, and therapy planned. In general, early lesions allow for vaginal delivery if otherwise indicated, while advanced disease favors abdominal delivery because of the risk of cervical laceration and hemorrhage or infection. Additionally, it is important to note that vaginal delivery through a malignant cervix has been associated with cancer implantation and recurrence at previous episiotomy scar sites (67–75).

Vulvar Carcinoma

Carcinoma of the vulva represents only about 4% of gynecologic malignancies and is quite rare in pregnancy, because the vast majority of vulvar malignancies occur in postmenopausal patients. Approximately 15% of vulvar cancers are found in women less than 40 years of age. Of these, about 90% of the cases are squamous cell cancers. Other cell types include melanoma, adenocarcinoma, basal cell carcinoma, and sarcoma. Presenting symptoms are similar to those of the nonpregnant state and include itching, irritation, discharge, and occasionally bleeding. The etiology of vulvar cancer is unknown, but common patient characteristics include obesity, diabetes, hypertension, and perhaps less-than-optimal vulvar hygiene. Recent evidence suggests that HPV infection is a causative or associative factor in preinvasive

vulvar intraepithelial neoplasia as well as in invasive vulvar cancer. Examination of the vulva will demonstrate areas of ulceration, exophytic growth, hyper- or hypopigmentation, or red or white discoloration. The key to early diagnosis is biopsy. All abnormal areas of the vulva, including raised, depressed, discolored, or warty lesions, deserve consideration for biopsy. Biopsy may be performed in the office under local anesthesia by simple excision or by utilizing the Keyes punch biopsy instrument. Toluidine blue staining and colposcopy may be used as adjunctive procedures, but should not substitute for biopsies, even in lieu of pregnancy.

A review of pregnancy-associated vulvar cancers in the literature by Barclay (76) revealed only 31 reported cases. Since this review, several other small series have been added. The youngest reported patient was 17 years old, while the average age was 27. Such a small number of patients presenting with vulvar carcinoma during pregnancy limits the development of guidelines for prognosis and treatment; nonetheless, certain conclusions can be drawn. Prognostically, these patients appear to do as well stage-for-stage with proper treatment as their nonpregnant counterparts. Treatment for vulvar intraepithelial neoplasia should be conservative with multiple biopsies to rule out invasion and then close follow-up, including colposcopy, until definitive therapy can be carried out postpartum. Invasive disease should be treated as in the nonpregnant state during the first and second trimesters, with radical or modified radical resection and groin node dissection. Lesions less than 2 cm in diameter and with invasion of 1 mm or less that are confined to the vulva with no evidence of nodal involvement may be considered for radical local excision. Bilateral or multiple ipsilateral positive groin nodules require adjunctive radiation to the groin and pelvis. Even if radiation is given after the period of organogenesis, the risk of spontaneous pregnancy loss is great. Thus, depending on the wishes of the patient, radiation treatment may be delayed until after delivery (3,77). Alternatively, in this unusual circumstance, consideration may be given to a pelvic node dissection, which, if negative, might allow omission of pelvic irradiation. Positive or close margins of resection, while also treatable with radiation, may be considered for re-excision during pregnancy to avoid the deleterious effects of radiation.

Invasive lesions presenting late in pregnancy (third trimester) may be widely excised and definitive treatment delayed until after delivery. These patients must be informed that these alternative forms of therapy during pregnancy deviate from the standard of treatment and may carry an increased risk of recurrence. The route of delivery is generally not altered by treatment, including radical vulvectomy and groin node dissection. Marked vaginal constriction and perineal fibrosis rarely necessitate cesarean section delivery. After treatment for vulvar cancer, there is no contraindication to future pregnancies. Past studies have showed successful pregnancies following treatment for vulvar carcinoma, with surgery-pregnancy intervals ranging from 6 months to 4½ years (76,78).

Vaginal Carcinoma

The occurrence of vaginal cancer has limited demographic overlaps with the reproductive age group, as the vast majority of cases are diagnosed in patients beyond 50 years

of age (25). Less than 2% of gynecologic malignancies are of primary vaginal origin. Metastatic disease from the cervix or vulva is far more common and must always be excluded. Up to 95% of cases are of squamous cell origin, while melanomas, sarcomas, and adenocarcinomas, including clear cell histologies, are also found.

The incidence of squamous cell carcinoma of the vagina during pregnancy is very rare, with fewer than 20 reported cases (1). Symptoms of vaginal cancers are bleeding or discharge. More advanced disease may present with symptoms of bladder or bowel dysfunction, including frequent urinary tract infections, urinary retention, constipation, or tenesmus. While a persistently abnormal Papanicolaou (Pap) smear may rarely provide initial evidence of vaginal cancer, thorough speculum examination with biopsy of suspicious gross lesions provides definitive diagnosis. Preinvasive disease, vaginal intraepithelial neoplasia, which is far more common than invasive disease in the pregnant population, is best diagnosed with the use of colposcopic-guided biopsies. If biopsy confirms preinvasive disease, treatment with laser, 5-FU, or other ablative therapy can be postponed until completion of the pregnancy.

In the exceptional event that invasive cancer of the vagina is discovered during pregnancy, treatment is generally unaltered, except possibly during the late second or third trimester, when postponement of treatment until after delivery may be considered. Therapy is dependent upon the location and stage of disease, but the primary mode of treatment is radiation. Surgery is a viable option when early-stage disease is confined to the upper one-third of the vagina and is thus resectable with radical hysterectomy and upper vaginectomy. Disease localized to the distal portion of the vagina has been reported as resectable with lower vaginectomy. Utilizing radiation or surgery, fetal loss is inevitable. However, there is one case report of stage I squamous cell carcinoma of the vagina treated by wide local excision at 23 weeks (79). The patient then underwent cesarean section at 33 weeks with pelvic lymphadenectomy and a second wide local excision with no evidence of recurrence.

Surgery allows preservation of ovarian function in this young population with postoperative radiation indicated only for close or positive margins (80). Advanced-stage disease of any histology requires prompt treatment, which may necessitate hysterotomy for removal of products of conception, thus allowing initiation of radiation therapy. It is important to note that even in patients with early-stage disease (I-II), the risk of pelvic lymph node metastases is high (20-35%) (81).

Several histologic types of vaginal cancer, although rare, tend to occur more commonly than squamous cell carcinoma in women of reproductive age. Adenocarcinoma, usually of the clear cell variety, may develop after in utero exposure to diethylstilbestrol. The link between diethylstilbestrol exposure and clear cell adenocarcinoma of the lower genital tract, including the cervix, was well established by 1971, after which the use of diethylstilbestrol during pregnancy was discontinued. The risk of developing adenocarcinoma of the vagina or cervix is actually less than 1 in 1000 for those exposed to the transplacental carcinogen diethylstilbestrol. Approximately one-third of diethylstilbestrol-exposed patients develop adenosis, which may be a precursor to clear cell

carcinoma. Such diethylstilbestrol-linked malignancies rarely occur before 14 years of age or after 30 years of age. Thus, frequent cervical and vaginal cytology with careful colposcopic evaluation for abnormal findings are indicated beginning at menarche. Most clear cell adenocarcinomas are diagnosed early (stage I) and thus have a good prognosis with an 80% 5-year survival. In pregnancy, treatment is largely unaltered, as surgery is performed without fetal regard, unless in the final trimester, in which case delay until after delivery may be contemplated.

Melanomas are very rare as primary tumors of the vagina. The lower posterior one-third of the vagina is the most frequent site of origin. Sarcoma botryoides of the vagina generally occurs in infants and children and presents as a group of cystic masses. The occurrence of both vaginal melanomas and sarcomas is exceedingly rare and reportable in pregnancy. Both tumors have a very poor prognosis, and management must be individualized according to the stage of disease, desires of the patient, and gestational age.

Endometrial Carcinoma

Endometrial carcinoma in pregnancy is extremely rare. There are fewer than 10 well-documented cases in the world literature and great care is necessary to exclude misdiagnosis secondary to an intense Arias-Stella phenomenon. Diagnosis is usually made at dilatation and curettage for spontaneous or therapeutic abortion. Treatment is unaltered by pregnancy.

Ovarian Neoplasia

Adnexal/Pelvic Mass

Pelvic masses in pregnancy present difficult management problems, because one must also consider the fetus as well as the patient. Therefore, the proper treatment of this problem is not always clear and requires clinical judgment. Pregnancy complicated by a pelvic mass has been reported with an incidence varying from 1 in 79 pregnancies to 1 in 2489; the average of 21 publications in the literature is 1 in 800 (82–103). The wide range of reported incidences is likely due to different detection methods, study populations, and types of masses reported. Of those publications, approximately 1 in 16,000 pregnancies is complicated by a malignant adnexal mass.

Prior to the advent of ultrasound, fibroids, ectopic pregnancies, appendicitis, and pelvic kidneys were frequently included in the diagnosis of pelvic mass. These entities are now diagnosed more accurately with ultrasound, avoiding unnecessary laparotomy (104–106). In general, simple, unilateral ovarian masses smaller than 5 cm during the first trimester are usually functional luteal cysts and oftentimes will resolve on ultrasound by 14 weeks of gestation. Those adnexal masses that are bilateral, greater than 5 cm, growing rapidly or persisting into the second and third trimesters, with solid, septate, or multicystic components need further imaging and/or evaluation (107). Bernhard et al. showed that out of 423 adnexal masses found in pregnancy, only 25 persisted and were surgically treated of which 2 were confirmed malignancies by histologic diagnosis. Ultrasound has been shown to be less accurate in characterizing malignant lesions (102). As such, MRI is useful for follow-up imaging on patients with concerning adnexal masses

initially identified by ultrasound (108,109). Computed tomography should probably be avoided during pregnancy.

It is important to note that most masses found during pregnancy are benign (110). Only up to 5% of pelvic masses during pregnancy are malignant versus 20% in the non-pregnant state (16). The most common masses found during gestation are serous or mucinous cystadenoma, mature teratoma, or a miscellaneous array of simple cysts, fibroids, and theca luteal cysts. Masses over 15 cm identified during pregnancy are seldom malignant (111–113). Of malignant pelvic masses found during pregnancy, the most common are germ cell tumors (45%), epithelial tumors (37.5%), sex cord-stromal tumors (10%), and other pathologies (7.5%) (114).

Masses discovered during pregnancy can be managed expectantly or surgically. Expectant management is frequently complicated by acute rupture, torsion, tumor previa, or malignancy. Grimes (115) reported that these complications occurred most commonly when masses were greater than 5 cm. Acute rupture or torsion resulting in an acute abdomen occurred in 34% of patients expectantly managed. Tumor previa occurred about 5% of the time, while malignancy occurred only in about 4.5% of cases. Surgical management seeks to avoid these complications and removes the mass under more controlled and less emergent conditions. If possible, surgery should be postponed to 16 to 18 weeks, as this timing is associated with a reduced risk of spontaneous abortion, hormonal independence of the corpus luteum of pregnancy, and the resolution of functional cysts.

Ovarian Cancer

Although rare, ovarian malignancies are the second most common gynecologic cancer diagnosed during pregnancy after cervical cancer (116). They are usually found as an incidental finding during routine prenatal care via ultrasound (117–119) and, as such, are generally found at an earlier stage than in nonpregnant women (116,117,120). Once a malignant adnexal mass is suspected, extensive preoperative discussion with the patient and family is required prior to laparotomy, and management should be multidisciplinary in conjunction with a high-risk obstetrician, gynecologic oncologist, and medical oncologist specialized in gynecologic cancers. If a malignancy is found, the patient should be staged and treated as if she were not pregnant. Pelvic washings should be obtained, extent of disease be assessed, and appropriate surgery be performed. Conservative surgery to preserve fertility and the current pregnancy is attempted where appropriate. However, the patient may always alter her treatment based on her desire to preserve the fetus. Of note, ovarian tumors do not spread to the fetus, in contrast to certain other malignancies.

Germ cell tumors, both benign and malignant, occur primarily in young women (121). The two most common malignant types are dysgerminomas and endodermal sinus (yolk sac) tumors. As dysgerminomas are the most common malignant germ cell tumors and most often occur in young women, it is not surprising that they are the most common malignant adnexal mass found in pregnancy. Approximately 10% to 15% of dysgerminomas occur bilaterally. A review of 27 reported cases of dysgerminomas reported all patients presented with large-size tumors ranging from 12 to 28 cm and most were stage IA (122). Because of their large size, obstetric

complications have been reported in association with dysgerminomas including obstructed labor and cesarean section (122). Surgical treatment is required as an initial management for all patients regardless of pregnancy status. Oftentimes, if appropriate, surgery will be postponed until 16 to 18 weeks when the risk for spontaneous abortion is minimized (83,123). Unilateral salpingo-oophorectomy with preservation of the contralateral ovary and of the uterus is adequate for early-stage disease of both germ cell and epithelial cancers.

Treatment of more advanced stages is controversial. It has been suggested that if the uterus and other ovary appear free of metastatic disease, then adequate staging can be performed with omental and peritoneal biopsies and sampling of suspicious lymph nodes (122). Biopsy of the contralateral ovary is recommended only if it seems to be affected by disease (124). Ipsilateral lymph node dissection may be considered as this is the most common site of first metastases. Adjuvant chemotherapy is considered unnecessary for stage IA and possibly stage IB, as the risk for recurrence is low, and there is a high cure rate for recurrent disease (123,125). Of note, serum lactate dehydrogenase levels are unaffected by pregnancy and can be used for initial diagnosis and follow-up response to treatment.

Endodermal sinus tumors comprise approximately one-fifth of the ovarian germ cell tumors and are the second most common (126,127). They are much less frequently encountered during pregnancy, but may be suspected when a serum alpha fetoprotein level is much higher than expected. Treatment for these tumors is more aggressive as the 5-year survival rate is only 13% (128). The best treatment strategy is early surgical resection followed by multiagent adjuvant chemotherapy. Adequate surgical treatment can also be achieved usually with the preservation of the contralateral ovary and uterus. The most common chemotherapy regimen used consists of bleomycin, etoposide, and cisplatin (BEP). There are several reports of pregnant women treated with combination chemotherapy who delivered normal infants (122). However, fetal complications have been reported as well (129). Some suggest that, if the mother desires, chemotherapy can be postponed until after early delivery with confirmed fetal lung maturity (130).

Ovarian epithelial tumors are rare in pregnancy as they are usually a disease of the elderly. They are categorized into three groups: benign, borderline, or invasive cancer. Borderline tumors or low malignant potential tumors are a disease of younger women and are more likely to be encountered in pregnancy. Standard of treatment for invasive cancers is upfront surgical cytoreduction followed by adjuvant chemotherapy. Unfortunately, this surgical approach precludes continuation of pregnancy. There have been reports in the literature of patients with invasive epithelial ovarian tumors of at least a stage III who underwent initial unilateral salpingo-oophorectomy with the completion of the surgical debulking postponed until after the delivery of the fetus (122,131–133). These women received platinum-based chemotherapy during pregnancy. All infants were delivered without any gross abnormalities or significant complications. One woman died of recurrence 29 months later, and others were disease free with follow-up periods ranging from 6 to 36 months. Overall,

management must be discussed with the patient with the understanding of the limited evidence in regard to the delay of treatment. The overall prognosis for advanced-stage ovarian cancer is low at approximately 30% at 5 years (134).

Borderline tumors are distinguished from their invasive counterparts by the histologic findings of papillary epithelial proliferation and atypia, but lack of stromal invasion (135,136). Treatment is primarily surgical. However, given their favorable prognosis, surgery to preserve fertility can oftentimes be achieved. Adjuvant chemotherapy is usually given only in the presence of confirmed invasive implants and, as such, can frequently be avoided during pregnancy.

Other less commonly found ovarian cancers include sex-cord stromal tumors. These tumors usually present with abdominal pain, torsion, and increased abdominal girth. Most patients are diagnosed with stage I disease and require only conservative surgical intervention due to their low-malignant potential. In cases of more advanced disease, adjuvant chemotherapy should be considered and usually consists of BEP (137–141). Another tumor rarely found in pregnancy is carcinosarcoma of the ovary also known as a “malignant mixed mesodermal tumor.” The prognosis is poor even with aggressive treatment (142,143) and only three cases have been reported in the literature (144–146). Given the aggressive nature of carcinosarcomas and the fact that an optimal debulking procedure at the time of initial surgery is an important determinant of future outcomes, there is no role for conservative surgery in their management plan (147). Lastly, metastatic tumors to the ovary are always a consideration in the differential for malignant adnexal masses. They are not uncommon and the most frequently identified primary sites include colon, breast, and gastric cancers (123,148). Treatment is based on the type of primary malignancy and is usually individualized based on different factors such as histologic type, gestational week, and the patient’s wishes.

In general, several principles can help guide the management of ovarian malignancies in pregnancy. Hysterectomy should be performed during pregnancy only if it contributes significantly to tumor debulking (116,149) and overall prognosis. Additionally, chemotherapy is contraindicated in the first trimester due to high rate of abortion (150) and abnormal fetal development (151), but it is compatible in the second or third trimester (150,152). Platinum-based chemotherapy regimens have the most scientific data supporting their safe use in pregnancy (153). An interval of 3 to 4 weeks between the last chemotherapy administration and the delivery is optimal due to both maternal and fetal hematologic risks from treatment (3). The majority of adverse fetal outcomes are likely due to prematurity with few reports of congenital anomalies (150,154,155). In the postpartum period, breast-feeding should be discouraged while receiving cytotoxic agents (156,157). As always, treatment strategy must be case dependent, and the patient must remain fully informed at all times.

GTD

The term “gestational trophoblastic disease” comprises a wide variety of pathologic entities, from the benign hydatidiform mole to the highly malignant choriocarcinoma. Hydatidiform mole has been observed since the era of Hippocrates.

Table 7 International Federation of Obstetrics and Gynecology Prognostic Scoring System for Gestational Trophoblastic Neoplasia

Risk factor	Score ^a			
	0	1	2	4
Age	<39	>39		
Prior pregnancy	Mole	Abortion	Term	
Interval (months) ^b	4	4–6	7–12	>12
Pretreatment hCG (log)	<3	<4	<5	>5
Largest tumor (cm)	<3	3–4	≥5	
Site of metastases		Spleen, kidney	Gastrointestinal tract	Brain, liver
Number of metastases	0	1–4	5–8	>8
Prior failed chemotherapy agents			Single	Multiple

^aPrognosis is determined by summing the scores for each individual factor. Total score <7=low risk, >7=high risk. ^bInterval is the time between the termination of prior pregnancy and the start of chemotherapy. *Abbreviation:* hCG, human chorionic gonadotropin.

Richardson and Hertig provided the first account of a hydatid mole in 1638, while in 1827 the midwife Bolvin was the first to ascribe moles as products of gestational origin. In 1895, Felix Morchand finally demonstrated that hydatidiform moles and their malignant sequelae derived from trophoblast, but his concept was not widely accepted until 1903 (158,159).

Trophoblast may be regarded as the first organ of the developing embryo. Normal trophoblast is a unique tissue that bears several characteristics of cancer. Among these is the ability to invade the myometrium and to embolize into the maternal circulation. Whether the trophoblast is normal or neoplastic, it contains both syncytiotrophoblast and cytotrophoblast and secretes human chorionic gonadotropin (hCG) in proportion to its volume. This fact allows clinicians to monitor this disease and predict eradication of trophoblastic tissue from the host (160).

Abnormal trophoblastic proliferation is manifested in two entities: partial and complete hydatidiform mole. The complete mole consists of abnormal trophoblast of paternal origin with a karyotype of 46,XX. This entity presents with abnormal bleeding 95% of the time between the 6th and 16th week gestational age. Other manifestations of molar gestation include pre-eclampsia, hyperemesis, and hyperthyroidism. Rarely, patients can present with trophoblastic embolization and symptoms of congestive heart failure or pulmonary edema. hCG levels are usually markedly elevated above those appropriate for the gestational age of the pregnancy. The diagnosis is generally made with ultrasound. Histologically, complete hydatid moles are characterized by hydropic villi, proliferation of both syncytiotrophoblast and cytotrophoblast, absence of fetal vessels, and no definitive fetal structures (161,162).

By contrast, the diagnosis of partial mole is usually made at the time of curettage for a presumed missed or incomplete abortion. The clinical features are similar to those of a complete mole, but less severe. In addition, partial moles are usually of polyploid karyotype and associated with fetal structures.

The incidence of complete hydatidiform mole varies throughout the world from a high of 1 in 450 in Japan to 1 in 2500 in the United States (163). These data are based on population-based studies. The treatment of choice for a complete mole is suction curettage. Blood products, such as packed red blood cells, should be made available preoperatively,

Table 8 International Federation of Obstetrics and Gynecology Staging of Gestational Trophoblastic Neoplasia

I Disease confined to the uterus
II Disease extends outside the uterus but is limited to the genital structures (adnexa, vagina, broad ligament)
III Disease extends to the lungs with or without genital tract involvement
IV Disease involves other metastatic sites
(1) <i>Good prognosis</i>
(a) Serum hCG <40,000 mIU/mL (random) or urinary hCG <100,000 IU (24 hr)
(b) Symptoms present less than 4 months
(c) No brain or liver metastases
(d) No prior chemotherapy
(e) Prior pregnancy: a mole or abortion of ectopic pregnancy
(2) <i>Poor prognosis</i>
(a) Serum hCG >40,000 mIU/mL (random) or urinary hCG >100,000 IU (24 hr)
(b) Symptoms present more than 4 months
(c) Brain or liver metastases
(d) Failure of prior chemotherapy
(e) Antecedent-term pregnancy

as blood loss can be unexpectedly high. Furthermore, a substantial risk of post-evacuation pulmonary edema from trophoblastic deportation or rapid fluid replacement is possible. The incidence of malignant sequelae of complete moles is about 15%. The incidence of malignancy following a partial mole is much less. All moles require careful follow-up with weekly hCG levels. A rising level or one that plateaus requires immediate attention to staging and initiation of cytotoxic therapy (164,165).

The malignant sequelae of molar gestation, categorized as gestational trophoblastic neoplasia (GTN), include invasive mole, choriocarcinoma, and placental site trophoblastic tumors. The prognosis for these entities is excellent, exceeding 90%, with proper treatment. Patients diagnosed with GTN are categorized into risk groups based on the International Federation of Obstetrics and Gynecology (FIGO) staging and scoring system (166,167) (Tables 7,8). The scoring system is based on a modified version of the World Health Organization (WHO) prognostic factor scoring system. Once malignant trophoblastic disease is diagnosed, staging studies consisting of computed tomography scans of the head, abdomen, and

Table 9 Chemotherapy Regimens for Low-Risk Gestational Trophoblastic Neoplasia

1	MTX, 0.4mg/kg (maximum 25mg)/day, IV or IM for 5 days. Repeat every 14 days
2	MTX, 30–50mg/m ² , IM weekly ^a
3	MTX, 1mg/kg, IM days 1, 3, 5, and 7; folinic acid, 0.1mg/kg, IM days 2, 4, 6, and 8. Repeat every 15–18 days or as needed
4	MTX, 100mg/m ² , IVP, then 200mg/m ² in 500mL of D ₅ W over 12 hours. Folinic acid, 15mg IM or orally every 12 hours for four doses beginning 24 hours after starting MTX. Repeat every 18 days or as needed ^a
5	Act-D, 10–12μg/kg, IV every day for 5 days. Repeat every 14 days
6	Act-D, 1.25mg/m ² , IV every 2 weeks ^a
7	Alternating MTX/Act-D regimens 1 and 5

^aShould not be used for metastatic or resistant disease or choriocarcinoma. *Abbreviations:* Act-D, actinomycin-D; D₅W, 5% dextrose in water; IM, intramuscularly; IV, intravenously; IVP, intravenous push; MTX, methotrexate.

Table 10 Etoposide, Methotrexate, Actinomycin-D, Cyclophosphamide, and Vincristine Chemotherapy for High-Risk Gestational Trophoblastic Neoplasia

	Drug	Dosing
Day 1	Etoposide	100mg/m ² IV over 30 min
	Actinomycin-D	0.5mg IVP
	Methotrexate	100mg/m ² IVP, then 200mg/m ² in 500mL of D ₅ W over 12 hours
Day 2	Etoposide	100mg/m ² IV over 30 min
	Actinomycin-D	0.5mg IVP
	Folinic acid	15mg IM or orally every 12 hours for four doses starting 24 hours after starting MTX
Day 8	Cyclophosphamide	600mg/m ² IV
	Vincristine	1.0mg/m ² IVP

Abbreviations: D₅W, 5% dextrose in water; IM, intramuscularly; IV, intravenously; IVP, intravenous push; MTX, methotrexate.

pelvis, serum chemistries including liver and renal function studies, and quantitative beta-HCG need to be performed. A chest X-ray is mandatory. Computed tomography of the chest may identify low-risk patients who are likely to fail primary single-agent therapy (168). Cure for patients with non-metastatic (stage I) and low-risk metastatic GTN (stages II and III, score < 7) disease approaches 100% in published studies (167). Patients classified as having high-risk metastatic GTN should receive multiagent chemotherapy plus adjuvant radiation or surgery to achieve survival rates of 80% to 90% (Tables 8,9). Of note, prior reports from the Brewer Center in Chicago, Illinois, have demonstrated the importance of having centralized trophoblastic disease centers to provide expertise in managing these patients. They noted that their successful secondary GTN treatment rates increased from 59% during 1962 to 1978 to 93% from 1979 to 2006 (169). They also noted that the most common reasons for unsuccessful GTN

treatment were using single-agent chemotherapy for high-risk disease and inappropriately using weekly methotrexate to treat patients with metastatic disease, FIGO scores ≥ 7, and/or non-postmolar choriocarcinoma. This highlights the importance of adhering to the FIGO staging and scoring system to administer chemotherapy regimens accordingly (Tables 9 and 10).

NONGYNECOLOGIC MALIGNANCIES

Breast Cancer

One in nine women will develop breast cancer during her lifetime, representing one-third of all cancers in women (170). Approximately 15% of breast cancers occur in women under the age of 41 years; 1 in 3000 pregnancies is complicated by breast cancer, with 3% of all breast cancer being diagnosed during pregnancy or lactation (1). The incidence of breast cancer in association with pregnancy is expected to continue to rise, owing to the trend toward delayed childbearing. It currently is the second most common malignancy diagnosed in pregnancy after cervical cancer (171).

Breast engorgement and hypertrophy during pregnancy may delay the detection of breast cancer. Some cases of inflammatory cancer, as well as some masses, can be confused with mastitis or other pregnancy-related changes. Most cases present with a painless lump often noted by the patient upon self-examination. If the woman is breast-feeding, she may note a “milk rejection sign” in which the infant refuses the breast affected by cancer (172). The initial prenatal visit should include a thorough breast examination with detailed instructions on breast self-examination.

More recent studies report an average delay in diagnosis of 1 to 2 months (173–177) although older studies noted delays of 6 months or greater (178–180). A 1-month delay in primary tumor treatment increases the risk of axillary metastases by 0.9% and a 6-month delay increases the risk by 5.1% (181). The presence of axillary metastases is a poor prognostic factor, and early detection despite pregnancy is essential.

Mammography should be limited during pregnancy to minimize radiation exposure. In addition, pregnancy changes, such as elevated water density, increase the rates of false-positive and false-negative mammographic examinations (182). Ultrasound is a recommended, good, inexpensive first step in the workup of a breast mass as it can distinguish between cystic and solid lesions in 97% of patients (175,176,183). For the diagnosis of metastases, MRI is preferred to ultrasonography especially for hepatic and brain imaging (184,185). Of note, gadolinium used during MRIs crosses the placenta, is associated with fetal abnormalities in rats, and its use during pregnancy should be limited to those cases where the benefits outweigh the risks to the fetus. Radioisotope bone scan, generally avoided during pregnancy, may be indicated only when metastases are clinically suspected. Adequate maternal hydration may increase fetal exposure to radiation.

For definitive diagnosis, any palpable mass should be biopsied. Stopping lactation beforehand reduces the risk for milk fistula formation. Fine-needle aspiration (FNA) has a specificity and sensitivity of about 95%, and no harmful effects upon the pregnancy have been reported (186). However, the accuracy of FNA is highly dependent on the pathologist's experience with pregnancy-associated breast cancer and is

important to avoid a misdiagnosis of hyperproliferative changes (185,187). If FNA is unsuccessful, open biopsy, preferably under local anesthesia, is performed. Core needle biopsy may also be a more cost-effective method as studies in nonpregnant women have shown it to also have a high sensitivity and specificity (188–191).

In the nonpregnant state, wide local excision with axillary node dissection and radiation is the preferred treatment for small unifocal masses. This alternative is less attractive during pregnancy, as radiation with boost doses to the tumor bed would cause internal scatter, resulting in fetal radiation exposure above acceptable levels (186). As such, mastectomy with axillary node dissection is traditionally the procedure of choice for stage I or II disease during pregnancy, as nodal metastases are commonly found in pregnancy-associated breast cancers, and the procedure may eliminate the need for postoperative irradiation. Treatment may be modified by delaying radiation until after delivery if the diagnosis is made in the late second trimester or beyond, while carrying out lumpectomy and axillary dissection during pregnancy at the time of initial diagnosis.

Patients with either node-positive disease or node-negative disease, but tumor greater than 1 cm, should receive 4 to 6 months of chemotherapy. If the woman is far from term, breast-conserving surgery can be followed by chemotherapy after the first trimester and irradiation after delivery (185). Chemotherapy is usually withheld until the second trimester, as at least half of infants have no complications when their mothers are treated after the first trimester (150,192–194). The most common side effects of chemotherapy during pregnancy are preterm delivery, low birth weight, transient infant leukopenia, transient tachypnea of the newborn, and intrauterine growth restriction. Long-term effects of chemotherapy on the newborn are unknown.

Advanced disease calls for careful individualization of treatments. Delay of palliative treatment until achievement of fetal viability is a reasonable option when the diagnosis is made late in pregnancy. Otherwise, aggressive palliative treatment should be instituted without delay. Such treatment, which includes radiation, multiagent chemotherapy, and hormonal therapy, separately or in combination, poses considerable risk to the fetus. If such advanced disease is diagnosed early in pregnancy, termination may be considered. Therapeutic abortion does not appear to enhance maternal remission or survival in early-stage disease; however, it does allow for prompt initiation of therapy in advanced disease.

Prognosis for pregnancy-associated breast cancer has been traditionally deemed dismal based on early reports. More recent studies have shown that the prognosis for breast cancer, stage-for-stage, is unchanged by pregnancy. Prognosis is most influenced by maternal age with 5-year survival rates of 75% for women over 40 years of age, but only 55% for those under 40 years of age (195,196). Pregnancy-associated breast cancer tends to present at later stages with twice the rate of lymph node involvement (74% vs. 37%), even when controlled for age (195). This worse prognosis may be due to delayed diagnosis and treatment of pregnant patients. In addition, pregnancy-induced hormonal changes may alter the behavior of tumors. Over 70% of women with pregnancy-associated breast cancer had estrogen-receptor-negative tumors thought

to be secondary to the downregulation of receptor status during pregnancy (195).

The traditional recommendation to wait 2 years after breast cancer treatment prior to a subsequent pregnancy is arbitrary as little scientific evidence exists in regard to this topic. The prognosis, both maternal and fetal, appears unaltered by subsequent pregnancy (196). However, some data now show that those women who do establish future pregnancies tend to demonstrate a “healthy mother effect” with better 10-year survival rates (197,198). A recent large population-based study of over 10,000 women demonstrated a reduced risk of dying in women who had a full-term pregnancy subsequent to breast cancer treatment (199). There was no evidence that a pregnancy after treatment for breast cancer has a negative influence on prognosis. Overall, future pregnancies appear to be safe unless the mother has an ER-positive cancer that has not been cured (197, 200, 201, 202). By contrast, there have also been studies evaluating the prognosis of a new breast cancer diagnosed after a pregnancy (203,204). The authors suggest that a new diagnosis of breast cancer within 2 years of a prior pregnancy is associated with decreased survival. The negative effect no longer persisted if the diagnosis was made greater than 10 years after the last pregnancy (204).

Colorectal Carcinoma

Colorectal carcinoma (CRC), one of the leading causes of cancer death in females, occurs only in 1 in 50,000 to 1 in 100,000 pregnancies, with approximately 300 total reported cases. Most originate distally below the level of the peritoneal reflection (205,206). The mean age of diagnosis is 32 years (207). CRC represents a serious threat not only to the mother, but also to the fetus as one prior study showed that only 25 of 32 women diagnosed with CRC during pregnancy went on to have healthy live born infants (208). Additionally, CRC is uncommon in young women and, when diagnosed within this age group, is oftentimes associated with predisposing factors such as hereditary nonpolyposis CRC (Lynch syndrome), familial adenomatous polyposis, Gardner syndrome, and chronic history of ulcerative colitis (209).

Presenting symptoms include constipation, obstipation, abdominal pain, rectal or abdominal mass, rectal bleeding, nausea, and vomiting. Many of these signs and symptoms represent common complaints of normal pregnancy and therefore a delay in diagnosis until it has progressed to advanced-stage disease is common. Rectal bleeding of guaiac-positive stool is an alarming symptom, which requires full evaluation. Routine digital examination should be performed during prenatal evaluation. Distribution of lesions appears to be similar to that in the nonpregnant population, with 57% arising in the rectum, 20% in the sigmoid colon, and 23% in the remainder (207).

Workup of a colorectal lesion normally requires colonoscopy with biopsy, a serum carcinoembryonic antigen level, and abdominal imaging (210,211). However, little data exist for colonoscopy during pregnancy and is still considered experimental. As such, risks and benefits should be fully disclosed to the patient and oftentimes only a partial colonoscopy will be performed to confirm the diagnosis while minimizing risk. Barium enema should be avoided if possible. Levels of the serum tumor marker, carcinoembryonic antigen, are generally

Table 11 Dukes Staging for Colorectal Carcinoma

B	Penetration through the bowel wall
C	Positive lymph node involvement
D	Distant metastasis

not affected in normal pregnancy and provide prognostic value (212,213). In regard to abdominal imaging during pregnancy, ultrasonography or MRI is the modality of choice.

Treatment during the first two trimesters is generally immediate surgery with limited regard for the pregnancy, although frequently the pregnancy is unharmed if cancer had not metastasized to other pelvic structures. Even distal tumors may be resected with primary re-anastomosis using automatic staplers and abdominoperineal or low anterior resection procedures. If optimal resection is prevented by the gravid uterus, hysterectomy may at times be necessary; such a possibility must be addressed with the mother prior to surgery. If tumor is not resectable, diverting colostomy for decompression and palliation is the treatment of choice to allow the pregnancy to progress toward term. During the third trimester, one can await fetal maturity and perform cesarean section with subsequent tumor excision or diverting colostomy, depending on the extent of the disease. If the tumor is discovered near term, vaginal delivery may be considered, provided that tumor is not obstructing the pelvic outlet. With advanced-stage and surgically unresectable tumor identified at any stage of pregnancy, consideration may be given to awaiting fetal maturity, thus delaying palliative treatment until after delivery (207). Irradiation for colorectal cancer during pregnancy has a limited role due to the colon's close proximity to the uterus, with no evidence of prolonging survival. Chemotherapy is recommended for Dukes C and D CRC. Several studies have shown a survival advantage if chemotherapy is administered within 5 weeks of resection of Dukes C CRC (213). Recently, research into new chemotherapeutic agents has also demonstrated survival benefits for Dukes D CRC (213).

Pregnancy has not been shown to affect maternal prognosis or the natural source of colorectal cancer. The prognosis of pregnant women with CRC is dismal likely due to its delayed diagnosis. There are no reported 5-year survivors for colon cancer. Few with rectal carcinoma are reported, owing to the advanced stage at presentation. Over one-half of pregnant patients with CRC present with Dukes stage C or a more advanced stage (see Table 11 for staging) (206) and 25% of pregnant women with CRC have ovarian metastases compared with 3% to 8% in nonpregnant women (214,215). Theoretically, the estrogen-binding capacity of cells derived from CRCs may indicate accelerated cancer growth during pregnancy. However, survival data between pregnant and nonpregnant patients are comparable stage-for-stage. Information regarding fertility after CRC is limited and has focused on those cancers treated with 5-fluorouracil. The general consensus is to wait at least 1 to 2 years before pursuing a subsequent pregnancy to allow the body sufficient time to recover.

Melanoma

Melanoma represents 1% of all cancers diagnosed in the United States, with approximately 30% occurring in women of

reproductive age (216). It complicates pregnancy with an estimated incidence of 0.14 to 2.8 cases per 1000 pregnancies (217). In general, incidence rates have increased dramatically over recent decades in the United States (218) and, as such, could increase the incidence rates during pregnancy.

The majority of patients present with a change in the size and color of a preexisting nevus. More advanced melanomas may present with ulceration and bleeding. Excisional biopsy of the entire suspicious pigmented lesion is the diagnostic procedure of choice. Microscopic measurement of the actual tumor thickness, as outlined by Breslow, most accurately reflects the prognostic index and is of utmost importance in the clinical management of patients (219). The Clark level, which describes the anatomic level of invasion, should also be assessed. Following histopathologic evaluation of the biopsy, the patient should be clinically staged with a thorough history and complete physical examination. The most common clinical staging system defines stage I as local disease without clinically palpable regional lymph nodes, stage II as having suspiciously palpable regional lymph nodes, and stage III as having distant metastases (220). Further tests, such as serum liver function studies, or radionuclide or computed tomography scans of the liver, bone, or brain, should be performed only for specific signs or symptoms suggesting metastatic disease.

Local excision with wide margins is the only effective cure for melanoma and this approach should not be influenced by pregnancy (221). Regional lymphadenectomy has not proven to be beneficial when lymph nodes are not palpable, but clinically involved lymph nodes should be excised. Distant metastatic disease may be treatable with systemic chemotherapy with a response rate of 20% to 25%. Metastatic melanoma is resistant to most forms of therapy. Immunotherapy or radiotherapy are unproven modalities during pregnancy.

Pregnancy-associated increases in pigmentation and melanocyte-stimulating hormone, presence of estrogen receptors on 46% of melanomas, reports of rapidly fatal courses in pregnancy, and reports of tumor regression postpartum or with hormonal therapy have led to the speculation that the course of malignant melanoma may be adversely affected by pregnancy (222). Additionally, incidence rates are higher in females compare with males only during the first four decades of life. However, two population-based studies showed that the number of incident melanoma cases diagnosed during pregnancy did not differ from the number expected based on current estimated prevalence rates (223,224). Overall, research has failed to demonstrate a clear association between estrogen and melanoma or between pregnancy-associated factors and subsequent development of melanoma (225).

Melanoma is one of the most unpredictable cancers. Extensive research had failed to provide conclusive evidence for either a beneficial or deleterious effect of pregnancy on its clinical course. Most recent studies that control for prognostic factors have demonstrated similar survival between pregnant and nonpregnant patients. When controlling of tumor site, age, Breslow thickness, and Clark level, an overall mortality of 25% in the pregnancy group was found during a 7-year mean follow-up period (226). For all patients, melanoma prognosis is closely related to Breslow thickness (the depth of the lesion from the granular cell layer of the epidermis to the deepest

identifiable tumor cells) (227,228) as well as anatomic site and presence of tumor ulceration (229).

Early-stage disease is managed surgically while more advanced-stage disease is often treated with combination chemotherapy. Although Reintgen and colleagues (216) reported no difference in survival for patients who developed melanoma during pregnancy or for those who became pregnant within 5 years of diagnosis, most clinicians advise patients to avoid a subsequent pregnancy for 2 to 5 years after diagnosis, since 60% to 86% of melanomas recur during this period (216,221).

In addition, when melanoma complicates pregnancy, both the fetus and the placenta should be examined closely after delivery because melanoma is the most common tumor metastasizing to the fetus and the placenta. The presence of metastases to the placenta is classified as stage IV disease, and all patients with placental metastases, except one, have died within 7 months (230). Overall, this phenomenon is exceedingly rare, with fewer than 20 reported cases. Termination of the pregnancy is not warranted, as infant survival, even with metastatic melanoma, is 75% (221,222). Of note, no cases of fetal metastases have been reported when the placenta did not demonstrate malignant transformation (225). Such information may prove useful in counseling couples after delivery.

Hematologic Malignancies

Hematologic malignancies are the third most common cancer complicating pregnancy (25% of cases) after cervical cancer and breast cancer (231–233). The three most common include Hodgkin's lymphoma, non-Hodgkin's lymphoma, and leukemia.

Leukemia

The development of leukemia during pregnancy is rare, with an incidence of 1 in 75,000 pregnancies (234). Acute and chronic leukemias occur with equal frequency, although acute leukemias are more frequently diagnosed during pregnancy (235,236). Among the acute forms, acute myelogenous leukemia (AML) is more common than acute lymphocytic leukemia (ALL). Ninety percent of the chronic leukemia cases are myelocytic, with the remainder being chronic lymphocytic leukemia (237).

The majority of pregnant women found to have leukemia are diagnosed during routine prenatal care. Signs and symptoms of acute leukemia include anemia, granulocytopenia, thrombocytopenia, splenomegaly, fatigue, fever, infection, and evidence of a bleeding diathesis. Physical exam may demonstrate pallor, petechiae, or ecchymoses. The diagnosis of leukemia oftentimes is confirmed by bone marrow examination. However, it can be initially suspected when a peripheral blood smear demonstrates a normocytic, normochromic anemia with a mild to severe thrombocytopenia. Blast cells are virtually always present despite a normal or low white blood cell count (238). Additionally, if the patient presents with a leukocytosis, flow cytometry and cytogenetics of a peripheral blood sample can be sufficient for diagnosis.

ALL in adults is seen in the 30- to 40-year-old age group. While anemia and splenomegaly are common, only 25% of patients will have white blood cell counts greater than

50,000/mm³ (239). By contrast, AML most commonly occurs in 30- to 60-year-old women and 75% will have white blood cell counts greater than 50,000/mm³. The usual age of presentation of acute leukemia during pregnancy ranges from 23 to 28 years (237). As such, it is not unexpected that AML is more commonly encountered during pregnancy (240).

Chronic leukemia usually presents with lymphadenopathy, splenomegaly, leukocytosis, and constitutional symptoms. Chronic myelocytic leukemia (CML) accounts for the majority of chronic leukemias complicating pregnancies, with a median age of 35 years (241). CML is generally indolent, with a median age onset of 60 years, which accounts for its relative rarity during gestation.

Treatment of acute leukemia with chemotherapy is based on the ultimate goal of eradicating all leukemic clone cells from the bone marrow with subsequent prevention of future emergence of resistant clone cells. As such, the treatment strategy is based on divided phases classified as induction, consolidation, and maintenance (242,243). For those patients who do not achieve remission, allogeneic hematopoietic stem cell transplant is an option. Common chemotherapy induction regimens for ALL include anthracyclines, cytarabine, and vincristine in combination with steroids and L-asparaginase. AML is treated with anthracyclines and cytarabine only. Additionally, induction-induced morbidities must be prevented and treated as needed, such as cotrimoxazole for *pneumocystis carinii* prophylaxis and fluconazole for prevention of *Candida albicans* infections.

Experience in the treatment of leukemia during pregnancy is limited. Without treatment, the median survival time for patients with acute leukemia is 2 months. With treatment, 65% to 75% of adults with ALL will gain complete remission; however, recurrence is common and only one-third of patients with ALL will be long-term survivors. A similar proportion of individuals less than 60 years of age treated for AML will achieve complete remission, with 40% of these experiencing eventual cure (241). Chronic leukemia is more indolent and can be successfully controlled with chemotherapy for a long period of time.

The patient diagnosed with acute leukemia during pregnancy poses a difficult problem. Due to the poor prognosis and rapid progression of this disease, immediate treatment is needed. Since there is no evidence that pregnancy alters the natural course of leukemia, terminating the pregnancy will not improve survival of the patient. Additionally, expert opinion holds that the outcome of pregnant patients with acute leukemia is adversely affected only when appropriate therapy is withheld for more than a few weeks (244).

Combination chemotherapy has become the therapeutic management of choice in patients with acute leukemia. Children who were exposed to chemotherapeutic agents in utero showed normal growth and development from 1 to 17 years of age (235). If given after the second trimester, chemotherapy is not associated with an increased rate of fetal malformations (240). Remission rates of pregnant women treated with combination chemotherapy compare favorably with those in comparable nonpregnant women. Standard anti-leukemic agents, such as cytarabine and anthracyclines, can be safely administered during the second and third trimesters. However, antifolates should be avoided during the first

trimester, owing to a 10% to 20% risk of congenital anomalies (245). Use of L-asparaginase during pregnancy should always be done with caution as it has been shown to decrease the levels of certain thrombosis inhibitors and is associated with a significantly increased risk of thromboembolism (246–249). It is important to note that evidence shows that delaying appropriate chemotherapy for more than a few weeks at any time other than the latter part of the third trimester is associated with excessive fetal mortality (235,250,251).

Intrathecal chemotherapy and whole-brain radiation may safely be performed during any trimester of pregnancy (252). There is an increased risk of infection, stillbirth, and spontaneous abortion associated with leukemia treatment (250). Patients diagnosed with leukemia during the first half of pregnancy have only a 50% to 60% chance of producing a healthy live infant. Intrauterine growth restriction is seen in approximately 8% of infants of mothers treated for leukemia during pregnancy (244).

Chronic leukemia is generally a more indolent disease and treatment should be withheld until after delivery if possible. As seen with acute leukemia, pregnancy does not appear to alter the natural course of chronic leukemia. Maternal and fetal outcomes are generally excellent, with survival rates of 96% and 84%, respectively (253), and are not significantly different from that expected for nonpregnant women. Interferon- α has been used in at least 10 cases of chronic leukemia-complicated pregnancy without adverse maternal effects with only one case of transient neonatal thrombocytopenia (254,255). The main goal of treating chronic leukemias during pregnancy is to control splenomegaly, leukocytosis, and constitutional symptoms.

Lymphoma

Lymphoma is a relatively common malignancy presenting during the reproductive years. It occurs in 1 in 1000 to 1 in 6000 pregnancies. Approximately 25% to 40% of lymphomas are Hodgkin's type, with the average age of onset being 32 years. Hodgkin's disease is the most common type of lymphoma associated with pregnancy (256).

The majority of women with lymphoma are asymptomatic. On physical examination, 80% will have superficial lymphadenopathy. Those with Hodgkin's disease are more likely to have localized lymphadenopathy, most often involving cervical, submaxillary, or axillary nodes. A small percentage of patients have fever, night sweats, weight loss, or pruritus, which are associated with poor prognosis. Biopsy is the "gold standard" of diagnosis. The histology of Hodgkin's lymphoma often shows multinucleated Reed–Sternberg cells with a pattern that is most commonly nodular sclerosing or lymphocytic. Histology is no longer thought to contribute to overall prognosis, as recent evidence demonstrates that the two most important prognostic factors are stage of disease and patient's age (244). Hodgkin's lymphoma is staged by the Ann Arbor staging system.

Patients with non-Hodgkin's lymphoma commonly present with high- or intermediate-grade diffuse histologic patterns and have a poorer prognosis than those with a nodular pattern (53). They are histologically distinguished from Hodgkin's lymphoma by the absence of Reed–Sternberg cells. They comprise a heterogeneous group of lymphoid

malignancies and differ in their presentation, stage at diagnosis, and prognosis. The classification system now used is based on the WHO classification system and uses morphologic, genetic, immunophenotypic, and clinical features. This has been shown to provide a higher degree of diagnostic accuracy and reproducibility (257).

The treatment of lymphoma depends on accurate staging, and minimal evaluation requires examination by the physician, chest radiographs, bone marrow biopsy with aspirate and core, and imaging of the abdomen usually with MRI. Abdominal ultrasound examination for retroperitoneal adenopathy or hydronephrosis may be helpful in staging. Lymphangiograms are rarely used in the current evaluation of lymphoma.

Once staging is complete, treatment generally should not be compromised because of the pregnancy. In the nonpregnant woman, nodal radiotherapy and combination chemotherapy result in cures for 70% of patients with Hodgkin's disease and 50% of patients with non-Hodgkin's lymphoma (256). Patients in the third trimester with localized Hodgkin's disease can be allowed to deliver prior to therapy (245). Treatment during the first and second trimesters and in patients with advanced disease or high-grade tumors is more complex. Localized disease above the diaphragm can be treated with radiotherapy with abdominal shielding. More extensive disease is best treated with combination chemotherapy to reduce the large fetal radiation exposure. The same considerations concerning combination chemotherapy as discussed with leukemia apply to lymphoma.

Placental metastases have been reported in both leukemia and lymphoma patients and, as such, the placenta should be closely examined after delivery as well as be sent to pathology for histologic evaluation. As a group, they account for 19% of the malignancies metastatic to the products of conception and 50% of those metastatic to the fetus (232,258). Postpartum contraception is important as many patients often require prolonged maintenance therapy. Breast-feeding should be avoided as little data exist regarding the specific chemotherapy agents used to treat these malignancies and their potential for neonatal adverse effects.

Thyroid Cancer

Thyroid cancer is the most frequently encountered cancer in the reproductive age group, with 50% of cases occurring in women of 15 to 44 years of age. In the general population, it is the most common endocrine cancer, with an estimated incidence of 9 per 100,000 (259). Approximately 10% of thyroid cancers that occur during the reproductive years are diagnosed during pregnancy or in the first year after birth (260,261). Some case-control studies suggest that hormonal factors may play an etiologic role in the development of thyroid cancer (262). This theory is supported by isolated studies showing an increased incidence in pregnancy and a decreased incidence, equal to that in males, following menopause. Clinically detectable thyroid nodules are three to four times more likely in pregnant women, and although most are benign, there are reports that up to 39% to 43% of these nodules are malignant (261). Thyroid stimulation is thought to be caused by the high levels of beta-hCG, which also has thyroid-stimulating activity. However, there is currently no

consensus about the impact of pregnancy on thyroid cancer, and the precise incidence of thyroid cancer in pregnancy is unknown (263).

The most common histologic type is papillary, followed by follicular and mixed papillary–follicular. These histologies have a favorable prognosis, whereas the less commonly occurring medullary and anaplastic patterns do not. The usual clinical presentation is that of a single thyroid nodule that has up to a 20% chance of being malignant. Rapid growth and fixation of the nodule to the surrounding structures or cervical lymphadenectomy are common findings for advanced disease. Risk factors for developing thyroid cancer are prior head or neck irradiation and a family history of multiple endocrine neoplasms.

Diagnosis is often made by palpation, but must be confirmed by biopsy. FNA has been shown to be a safe and effective technique in pregnant women, with false-positive results being exceedingly rare and false-negative results occurring in only 5% to 10% of cases (252). Some advocate fine-needle aspiration of all thyroid nodules prior to 20 weeks of gestation, and after 20 weeks, only those that grow during suppressive therapy should be sampled (264). Radioisotope nuclear scanning is contraindicated in pregnancy, because radioactive isotopes are taken up by the fetus. Other methods, such as ultrasound, can be used to distinguish solid-form cystic nodules. Thyroid function tests may also be helpful and can diagnose unsuspected thyroiditis. If medullary thyroid cancer is suspected, a calcitonin level should be checked as well. Normally, pregnancy witnesses a hypertrophy of the thyroid gland from follicular cell hyperplasia, and total triiodothyronine and thyroxine levels are elevated while triiodothyronine resin uptake is decreased secondary to increased thyroid-binding globulin. Thyroid-stimulating hormone is in the normal to slightly elevated range.

Treatment of choice for all primary carcinomas is surgery. Thyroidectomy is safe in the midtrimester and does not appear to increase the risk of adverse perinatal outcomes (265). Cancer discovered during the first or early second trimester should prompt immediate surgery (263). In the third trimester, a brief delay to allow fetal pulmonary maturity may be acceptable, and even malignant nodules diagnosed at any time after 20 weeks may be followed unless noted to be rapidly growing or of undifferentiated histology (261,266). Similarly, surgery for indeterminate findings on FNA can be delayed until after delivery as well unless the nodule is increasing in size (261). Well-differentiated forms of papillary and follicular histology are treated with subtotal thyroidectomy. Extensive neck dissection performed for cervical lymphadenectomy carries an increased incidence of spontaneous abortion. Poor prognostic medullary or anaplastic forms may present at very advanced stages, in which case regard for fetal development may predominate. Treatment with radioactive iodine, which is often used for adjuvant therapy in follicular thyroid cancers, is contraindicated, since it crosses the placenta and is trapped by the fetal thyroid.

Overall, prognosis during pregnancy appears unchanged when controlling for stage and histology; thus, abortion or prevention of subsequent pregnancy is unwarranted. When surgery is performed, vigilance for hypothyroidism and hypoparathyroidism should be maintained throughout

pregnancy as well as postpartum. After surgery and iodine treatment, hormonal replacement therapy is suggested to suppress thyroid-stimulation hormone. Thyroid hormone replacement is safe and effective in pregnancy. Subsequent pregnancy after treatment with radioactive iodine is safe as the gonadal impairment is only temporary and reversible, and there have been no reports of stillbirths, malformations, early deaths, or malignancies (267). In general, it is recommended to wait 1 year after treatment prior to pursuing another pregnancy to avoid all potential adverse side effects.

Bone and Soft-Tissue Sarcomas

Bone and soft-tissue sarcomas are relatively common malignancies in the reproductive age group. Their presence in association with pregnancy, however, is very rare, as there are less than 50 such recorded cases in the literature (268). The majority of these cases are osteosarcomas, followed by Ewing's sarcomas. Genital sarcomas of the cervix, vagina, and vulva include liposarcomas, histiocytomas, myosarcomas, and leiomyosarcomas, with and without peritoneal dissemination.

The majority of patients present with symptoms of localized pain or a mass. Diagnostic procedures commonly used to assess sarcomas include radiographs with abdominal shielding during pregnancy. Osteogenic sarcomas may require radioisotope bone scanning, which is thought to be of low risk to the fetus (269). Definitive diagnosis of any type of sarcoma requires biopsy. Although pregnancy has no proven deleterious effects on the natural course of sarcomas, delayed diagnosis results in postponed treatment. These tumors present at advanced stages, which may explain isolated reports of worsened prognosis for sarcomas in pregnancy (270). The aggressive biologic behavior of pelvic sarcomas may be enhanced by hypervascularity or hormonal stimulus; however, an impaired prognosis for most sarcomas associated with pregnancy remains unsubstantiated.

Owing to the diversity of histologic types, anatomic locations, stages of disease, and forms of treatment for different types of sarcomas, it is difficult to generalize treatment options. Since maternal prognosis for all types of sarcomas is poor, a combination of surgery, irradiation, and aggressive multiagent chemotherapy is warranted (271). Most clinicians recommend that the pregnant woman should be managed without regard for the pregnancy during the first two trimesters of gestation. In cases presenting in the third trimester, the fetus may be delivered vaginally or by cesarean section for obstetric indications as soon as pulmonary maturity is documented, so that aggressive treatment can be initiated. Although based on limited experience, more recent reports advocate the initiation of multiagent chemotherapy for control of systemic disease during any stage of gestation. Such therapy is based on the rationale that mortality in sarcomas often results from distant metastases and not local recurrence, and chemotherapy is relatively well tolerated by the fetus with the exception of the first trimester.

Tumors of the Central Nervous System

The Third National Cancer Study indicates that 21% of brain tumors affect women in the childbearing years (2); however, only 220 cases of central nervous system (CNS) tumors occurring during pregnancy have been reported in the world's

literature over the past 90 years (272). Intracranial tumors occur in pregnancy with a reported frequency of 3.6 per 10 (25) births (273). The most common neoplasms are glial neoplasms, followed by meningiomas and acoustic neuromas (274) and have similar frequencies in pregnant and nonpregnant women. Certain CNS tumors, such as meningiomas, pituitary adenomas, and vascular neoplasms, have a slightly increased incidence during pregnancy.

Although not well established, the fact that meningiomas predominate in women, enlarge rapidly during pregnancy, and express estrogen and progesterone receptors suggests a causal relationship between the tumors and pregnancy (275). Pregnancy normally results in pituitary enlargement secondary to hyperplasia of prolactin-secreting acidophilic cells and it also appears to stimulate the growth of pituitary microadenomas, making them clinically apparent (276). The relative frequency of CNS vascular tumors is also increased during pregnancy, with hemangioblastomas and spinal hemangiomas predominating. This increased incidence is attributed to retrograde engorgement of vascular channels in the tumor secondary to increased venous pressure from compression of the inferior vena cava in the gravid uterus, as well as an overall increased blood volume (277). These factors permit occult vascular tumors to become clinically apparent. Additionally, growth of residual lesions or recurrence is possible during pregnancy in previously treated patients (274).

Symptoms of brain tumors manifesting during pregnancy, such as nausea and vomiting, can be mistakenly attributed to the pregnancy. In addition, headache and visual disturbances commonly caused by brain tumors may be misinterpreted as signs of pre-eclampsia or optic neuritis. Spinal cord tumors cause symptoms of spinal cord compression, depending on the level involved. Early symptoms, such as fatigue, backache, and nerve-root irritation, may also be confused with common pregnancy-related complaints.

The diagnosis of CNS tumors can be established by radiographic studies, such as computed tomography scans, MRI, myelography, and angiography. Prolactin levels are useful in assessing pituitary tumors, and examination of the cerebrospinal fluid is helpful with spinal cord tumors. Definitive diagnosis of any tumor requires histologic examination. The coexistence of a CNS tumor and pregnancy should not preclude diagnostic studies.

The management of CNS tumors must be considered on an individual basis. In general, immediate treatment is necessary when symptoms are severe or progressive. Once the diagnosis of a CNS tumor is established, the patient should be closely observed for sudden increase in intracranial pressure, loss of visual fields, or progressive neurologic deficits. The treatment of choice for most CNS tumors, including meningiomas and spinal cord tumors, is surgery. Other tumors may respond to radiation therapy, which is not contraindicated during pregnancy provided the tumor is above the thoracic region and the fetus can be appropriately shielded. Prolactinomas can be treated with bromocriptine even during pregnancy, but surgical management is still preferred. When symptoms are mild or occur during the third trimester, careful observation with conservative medical treatment aimed at reducing intracranial pressure until fetal maturity is suggested (278). When symptoms are severe, treatment is mandatory without

regard to the pregnancy to prevent further neurologic deficits or death. Neurosurgery is particularly safe in the third trimester. The best mode of delivery in the presence of increased intracranial pressure remains to be determined.

CHEMOTHERAPY IN PREGNANCY

Oftentimes, chemotherapy treatment cannot be delayed until after delivery for pregnant women diagnosed with certain cancers. Most chemotherapeutic agents have been associated with adverse fetal side effects (279). However, safe use of chemotherapy has also been reported in the second and third trimesters with little evidence for adverse neonatal outcomes. The risks regarding chemotherapy use during pregnancy depend on the timing of exposure, the dose, and the characteristics affecting placental transfer. Those factors that most readily affect placental transfer from mother to fetus are high lipid solubility, low molecular weight, and loose binding to plasma proteins. It is also thought that genetic predisposition to teratogenicity might explain why some women have increased susceptibility compared with others (279). Risks of chemotherapy vary depending on the gestational age. Use of chemotherapy in the first trimester carries the risk of spontaneous abortion, fetal death, and major malformations. The gestational weeks 2 to 8 comprise the period of organogenesis and, as such, represent the time when the fetus is most vulnerable to teratogenic insults. Chemotherapy administered during the second and third trimesters increases the risk for intrauterine growth restriction and low birth weight. Unfortunately, transplacental studies have been unsuccessful in effectively monitoring fetal exposure to the administration of chemotherapeutic agents to the mother (280).

Pharmacokinetic changes associated with pregnancy are largely unknown, and pregnant women receive similar weight-based doses as those who are not pregnant. Given the increased blood volume and renal clearance that occurs with pregnancy, these women may receive decreased doses of the active agent. There is also a thought that a faster hepatic mixed-function oxidase system combined with decreased plasma albumin levels may also affect drug absorption. Currently, no pharmacokinetic studies have been done in pregnant women receiving chemotherapy.

Overall, delivery should be avoided during the maternal nadir period, which occurs 2 to 3 weeks after treatment. Chemotherapy should not be administered after 35 weeks of gestation as spontaneous delivery could occur before the bone marrow has recovered. The ability of an agent to cross the placenta correlates poorly with its ability to pass into breast milk, and breast-feeding is considered contraindicated while undergoing chemotherapy. As always, the decision to use chemotherapy in pregnancy must be weighed against the effect of treatment delay on maternal survival and the overall risk to the fetus.

36 Chemotherapy in pregnancy

Mark I. Hunter

INTRODUCTION

Fortunately, both the diagnosis of cancer during pregnancy and the diagnosis of pregnancy during the active treatment of a previously diagnosed cancer are rare occurrences, with cancer affecting approximately 1 in every 1000 pregnancies (1). However, with such a large population of females within the reproductive age range, the number of patients and providers having to face such difficult treatment decisions is not insignificant. Fortunately, there are a growing number of options besides pregnancy termination, based on an increasing understanding of the effects of various chemotherapeutic agents on the growing fetus, at different stages of development.

The cancers occurring most commonly in pregnancy include cancers of the breast, uterine cervix, ovary, colon, and the lymphomas (2). Alternatively, the cancers most likely to occur in a woman of reproductive age include thyroid cancer and cervical cancer. As more women are waiting until into their 30s and 40s to have children, age-dependent cancers occurring in pregnancy may be of increasing importance. Regardless of the type of cancer diagnosed, patients are often left with difficult choices. They frequently have the incorrect assumption that they cannot simultaneously make the decision to save their own life, while preserving the life and health of their unborn child. Naturally, a team of support staff and counselors should be available to work through these issues as patients are educated and decisions are made.

COMMON CANCERS IN PREGNANCY

Breast Cancer

It is estimated that breast cancer affects between 19 and 33 per 100,000 pregnancies (3–5). The pathologic distribution of these tumors appears to coincide with other young non-pregnant patients and is predominantly ductal invasive carcinoma (6). They tend to be less likely to be estrogen or progesterone receptor positive, and there are mixed data on whether the pregnant state alters the likelihood of Her-2/neu positivity (7,8). The prognosis for women with breast cancer diagnosed in pregnancy is similar to that of other nonpregnant young women (9,10).

Treatment for patients with breast cancer may include surgery, chemotherapy, and radiation. The use of radiation treatment is best avoided whenever possible at any time during pregnancy. Doses lower than 1Gy have been associated with increases in the rate of mental retardation and are most pronounced when the fetus is exposed in the first trimester (11). Surgery, however, is thought to be safe and can be performed at any time during the pregnancy. As with all cancers, it is generally preferred to wait until after 12 weeks of gestation to perform surgery, avoiding the coincident association with a spontaneous abortion.

The use of cytotoxic chemotherapy in pregnancy has been reported for a number of different tumor types. While most of these studies have a limited number of patients, the data would suggest that many of these agents are quite safe in pregnancy, particularly in the second and third trimesters. In breast cancer, the use of a combination of 5-fluorouracil (5-FU), doxorubicin, and cyclophosphamide was found to be without complication to the fetus or infant when given in the second or third trimester (12). Taxanes have been used to treat patients with breast cancer. However, published studies at this time are limited to a small number of case reports (13,14). Other drugs used to treat breast cancer include vinorelbine, capecitabine, gemcitabine, trastuzumab, and tamoxifen, many of which are discussed subsequently.

Cervical Cancer

Owing to the adoption of a revolutionary screening program, most cervical cancers are caught early. However, there are many women who either fail to participate in cervical cancer screening or are failed by the inherent false-negative rate of modern screening techniques. Indeed, as many as 40% of women diagnosed with cervical cancer are of childbearing age, with the incidence of cervical cancer in pregnancy estimated to be between 1.5 and 12 per 100,000 (5,15,16).

Surgical options for the treatment of women with cervical cancer include cold knife conization and extrafascial hysterectomy for microinvasive disease, and radical hysterectomy for more advanced stages. Although conization has been performed safely in pregnancy, it has also been associated with severe bleeding and preterm labor, and is generally discouraged (17). It may be appropriate to delay treatment until after the completion of pregnancy for patients with microinvasive disease. It is recommended that these patients then undergo cesarean section, with or without hysterectomy. Hysterectomy can be performed at the time of diagnosis with the fetus in utero if pregnancy termination is desired.

In cases where cervical cancer is diagnosed early in pregnancy and termination is not an acceptable option, investigators have described the use of neoadjuvant chemotherapy. Significant responses have been reported in some cases, with reductions in tumor volume, enabling both delays in delivery and effective postpartum treatments (18,19). Agents used include combinations of cisplatin with vincristine or bleomycin (19,20). Delays in definitive treatment of up to 32 weeks have been reported, with patients who have gone on to achieve surgical resection without further recurrence (21).

Ovarian Cancer

As the use of ultrasound has become exceedingly common in the evaluation of early pregnancies and is, in fact, the standard of care in the midtrimester, an increasing number of ovarian

masses are being incidentally discovered. Although the majority of these masses are benign, a reported 2% to 3% are found to be malignant (22). The estimated incidence of ovarian cancer is 7 to 8 per 100,000 pregnancies (22,23). If reasonable, it is best to delay the surgical evaluation of an adnexal mass until after the rate of spontaneous abortion has dropped and the pregnancy has become independent of the corpus luteum, with an optimal target window of 16 to 18 weeks of gestation. If the mass is found to be cancer on frozen section, then surgical staging and optimal cytoreduction can be performed without significant risks to the fetus.

Adjuvant chemotherapy for the treatment of ovarian cancer currently includes the use of a platinum and a taxane, such as carboplatin and paclitaxel. The use of a platinum with paclitaxel has been reported in pregnancy with normal growth and development in infants and children at follow-up (24,25).

Malignant Melanoma

Unlike most other cancers developing in pregnancy, transplacental spread of malignant melanoma from mother to fetus has been described (26). Treatment of early-stage lesions is focused on surgical excision and can be performed safely in pregnancy as described previously. It is now quite common to perform sentinel lymph node mapping on patients at risk of having regional metastasis. Overall, it is thought that the use of radioactive tracers in pregnancy exposes the fetus to a very low dose of radiation (<0.5cGy) and can be used safely (27). Alternatively, for lesions excised later in the pregnancy, lymph node mapping and excision can be delayed until the postpartum period.

For patients with distant metastatic spread of melanoma, the use of chemotherapy has not met with impressive results. Agents administered during pregnancy include dacarbazine, temozolomide, cisplatin, vinblastine, and interferon alpha2b (28,29).

Lymphoma

Lymphoma, including both Hodgkin's lymphoma (HL) and non-Hodgkin's lymphoma (NHL), has been estimated to affect 8 to 16 per 100,000 pregnancies (5,30). Patients with NHL tend to have more aggressive histologic subtypes and advanced-stage disease. Staging for the pregnant patient with lymphoma may include history and physical examination, blood tests, bone marrow biopsies, and chest X-ray with abdominal shielding. Although CT scans are well below the levels that might be considered teratogenic, such scans may be replaced with ultrasound or MRI where appropriate.

The use of radiation in the treatment of lymphoma is fairly routine. Although for reasons discussed previously, it may be omitted in the treatment of a pregnant patient. Furthermore, pregnancy termination should be considered at least for the patient diagnosed with aggressive NHL in the first trimester, when immediate treatment is critical.

HL is commonly treated with regimens such as ABVD (adriamycin, bleomycin, vinblastine, dacarbazine). Other regimens include BEACOPP (bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisone), the Stanford V protocol (mechlorethamine, doxorubicin, vinblastine, vincristine, bleomycin, etoposide, and prednisone), and MOPP (mechlorethamine, vincristine,

procarbazine and prednisone). Rituximab with combined chemotherapy has also been described (31).

Thyroid Cancer

While thyroid cancer is not the most commonly diagnosed malignancy occurring in pregnancy, it is more likely to be diagnosed during pregnancy because of its predilection for females of reproductive age. Imaging studies commonly used in the evaluation of a possible thyroid cancer include CT scans to evaluate both the extension of the tumor into adjacent tissues and the presence of cervical lymphadenopathy, and ultrasound, to delineate lesion size, and its cystic and solid characteristics. Fine-needle aspiration is of varying accuracy depending on histologic type, although it can generally be performed safely in pregnancy.

Surgery remains the most important treatment modality for patients with differentiated thyroid cancer, and total thyroidectomy is preferred to hemithyroidectomy (32). However, surgical timing must be weighed against risks to the fetus and the inherent and often coincidental rate of spontaneous miscarriage in the early trimester, as previously discussed. Unique to thyroidectomy, however, is the careful consideration of neurologic development in a fetus exposed to improper levels of thyroid hormone following complete removal of the thyroid. After about 18 weeks of gestation, fetal thyroid production begins, and the effects of a maternal thyroidectomy become less important. However, it should be noted that several retrospective studies have failed to demonstrate a significant difference in disease progression or outcomes for patients in whom thyroidectomy was delayed until after delivery, when compared with those performed during the second trimester (32). Radioactive iodine is a commonly used adjuvant therapy for patients with thyroid cancer. It is frequently given 3 to 6 months after thyroidectomy and is not recommended during pregnancy.

SYSTEMIC CHEMOTHERAPY

Introduction

The overall incidence of congenital malformations after the use of cytotoxic drugs during pregnancy has been reported to be approximately 3%, which does not differ significantly from the baseline risk of malformations in the general population of 2% to 3% (33). Naturally, the risk of exposure to the fetus from these agents differs depending on the stage of organogenesis, with the risk of malformations following the first-trimester exposure as high as 10% to 20%, in contrast to 1% to 3% for the second and third trimesters (34–36).

The pharmacokinetics of standard chemotherapies administered during pregnancy would be expected to depart from well-investigated standards due to changes in renal clearance, large increases in circulating blood volumes, lower serum albumin, and third spacing of many chemotherapeutic compounds into the amniotic fluid. Overall, drug clearances are higher, although there have been few studies that have investigated the differences in chemotherapy pharmacokinetics in pregnancy and it is thus unclear what proper dose adjustments are necessary in this population (37). Most chemotherapeutic compounds are lipid soluble and can easily cross the placenta. As a result, it is expected that the fetus or amniotic fluid will have a similar or even a higher

concentration of the drug, or its active metabolite, than that in the maternal circulation.

The risk of exposure to chemotherapy can be stratified based on the age of the gestation, with the greatest risk of physical defects coinciding with the exposure during the period of organogenesis, from 2 to 8 weeks. For practical purposes, most report on the timing of exposure as being based on the first, second, or third trimester. As noted previously, there is some suggestion that second-trimester exposure has been linked to low birth weight. Chemotherapy given in the third trimester can predictably cause side effects in the newborn, which are similar to that expected in the adult, such as neutropenia, anemia, and thrombocytopenia.

Taxanes

Taxanes, including agents such as paclitaxel, docetaxel, ortataxel, and tasetaxel, are compounds originally derived from the bark of yew trees. They affect their antineoplastic properties by stabilizing tubulin, which blocks the function of microtubules essential for cell division. These agents are considered first-line therapy for the treatment of many cancers including those of the lung, ovary, and breast.

In rabbit and rat studies, fetal exposure to both docetaxel and paclitaxel have been associated with an increase in intrauterine deaths, increased fetal resorption, reduced fetal weight, and delayed ossification. Human studies have been limited to a scant number of case reports. In one report, docetaxel, cisplatin, and gemcitabine were given to a patient in the first and second trimesters of an unrecognized pregnancy (38). A healthy infant was delivered by cesarean section at 33 weeks, without congenital malformations. Sood et al. reported on the use of paclitaxel and cisplatin in a patient diagnosed with stage IIIC ovarian cancer at 27 weeks. After surgical debulking, she was given three cycles of chemotherapy prior to delivery. The child was 30 months of age, at the time of the publication, without any known abnormalities or developmental delays (24). Morris et al. reported on a patient with recurrent metastatic breast cancer diagnosed at 29 weeks of gestation. She received a total of six cycles of weekly paclitaxel and delivered a normal infant by elective cesarean section at 38 weeks (39). Additionally, a normal infant was delivered after three 21-day cycles of docetaxel given to a patient diagnosed with recurrent breast cancer at 15 weeks of gestation (13). Other reports have further confirmed that taxanes can be used safely in the second and third trimesters of pregnancy without significant risk of fetal malformations (14,40,41).

Alkylating Agents

Alkylating agents include the subclass of nitrogen mustards, of which the compounds in most common use today include cyclophosphamide, ifosfamide, and melphalan, and chlorambucil. To exhibit their antineoplastic properties, many of these agents, such as cyclophosphamide, must be converted to an active metabolite in the liver. The compounds then attach to the alkyl groups in DNA, causing cross-linking between double-helix strands and preventing the uncoiling of DNA that is necessary for replication. Alkylating agents are used in several different tumor types including, but not limited to, breast cancer, NHL, chronic

lymphocytic leukemia, ovarian cancer, bone and soft-tissue sarcomas, and rhabdomyosarcomas.

Cyclophosphamide has been demonstrated to have significant absorption through the skin and mucous membranes, and great care should be taken by fertile women when administering this drug (42). Exposure to cyclophosphamide in the first trimester has been associated, in a small number of reports, with growth deficiency, developmental delay, cranio-synostosis, blepharophimosis, flat nasal bridge, abnormal ears, and distal limb defects including hypoplastic thumbs and oligodactyly (43). Zemlickis et al. reported on a patient with acute lymphocytic leukemia who received cyclophosphamide daily in the first trimester of a twin gestation (44). Interestingly, the male twin was diagnosed with papillary thyroid cancer at 11 years of age and neuroblastoma at 14 years of age. The female twin was unaffected. While no fetal deformities have been noted from exposure in the second and third trimesters, growth restriction, microcephaly, and neonatal pancytopenia have been described (45).

There have been several detailing the use of ifosfamide in the second and third trimesters, most commonly in multiagent combinations (46–48). No fetal anomalies have been noted and the infants appeared to be developing normally. One report, however, described the development of fetal growth restriction and anhydramnios after the first cycle of combination chemotherapy including ifosfamide, which was initiated in the second trimester for a maternal diagnosis of rhabdomyosarcoma of the face (49). The effects of ifosfamide given to humans during the first trimester are unknown. However, animal studies have demonstrated increased resorption and lethal anomalies when the drug has been given at high doses early in the pregnancy.

In animal studies, there has been some suggestion that there may be inheritable chromosomal aberrations caused by exposure of germ cells to chlorambucil and melphalan (50). In humans, cardiac and renal defects, including renal agenesis, have been reported with fetal exposure to chlorambucil in the first trimester (51,52). Still, others have described the use of chlorambucil throughout pregnancy with delivery of normal infants (51).

Platinum Agents

In a manner similar to the alkylating agents, platinum compounds, including among others cisplatin, carboplatin, and oxaliplatin, cross-link DNA and prevent uncoiling, however, without the use of an alkyl group. They have been described as being alkylating-like. They have been approved for the treatment of many cancers including those of the ovary, uterus, bladder, head and neck, esophagus, lung, lymphoma, leukemia, and choriocarcinoma. Representing one of the only reports of a platinum compound being administered in the first trimester, Li et al. described a single case of microphthalmos following the use of the Dartmouth regimen (dacarbazine, carmustine, cisplatin, and tamoxifen) to treat a patient with metastatic melanoma (53).

Tabata et al. reported on the use of carboplatin as a single agent for four cycles, with delivery of a normal infant at 33 weeks, who demonstrated normal development at 1 year (54). Another child exhibited normal development at 18 months following two cycles of single-agent carboplatin in the

treatment of stage III ovarian cancer diagnosed at 22 weeks of gestation (55). Carboplatin has also been combined with paclitaxel, resulting in normal development at 6 months of a child following three cycles of the combination prior to delivery (56). Mir et al. reviewed more than three dozen reports on the use of cisplatin or carboplatin, alone or in combination, to treat malignancies in the second and third trimesters (57). They report no fetal malformations in any patient treated with either compound when started after the first trimester, with the exception of one case of ventriculomegaly, diagnosed in a fetus in close proximity to chemotherapy administration.

Antimetabolites

Antimetabolites include methotrexate and 5-FU. Methotrexate, a folic acid antagonist, is indicated for use in the treatment of many cancers, including breast cancer, head and neck cancer, acute lymphocytic leukemia, NHL, bladder cancer, colorectal cancer, and gestational trophoblastic disease. It is an abortifacient and should not be given at any time during pregnancy. When given in the first trimester, this class of agents is associated with a constellation of severe fetal anomalies known as “aminopterin syndrome.” The syndrome includes growth deficiency, patent cranial sutures, craniosynostosis, unusual skull shapes, dysmorphic facies, hydrocephalus, mental retardation, and skeletal defects (35).

There are few reports on the use of methotrexate in the second and third trimesters. One patient presented at 25 weeks of gestation with metastatic breast cancer and was treated with two cycles of doxorubicin, methotrexate, and vincristine prior to delivery of a female without anomalies, who was developing normally at 2 years (58). Nabers et al. reported on the use of methotrexate initiated at 27 weeks in a patient with choriocarcinoma metastatic to the lung, with a coincident normal pregnancy (59). Additionally, Ring et al. reported on 12 patients treated with cyclophosphamide, methotrexate, and fluorouracil in the second and third trimesters, with no adverse fetal outcomes (60).

Much like methotrexate, 5-FU, a pyrimidine analog, has been associated with multiple congenital abnormalities when it has been used during the first trimester, including radial dysplasia, absent digits, and hypoplasias of the lungs, aorta, esophagus, duodenum, and ureters (61). However, Berry et al. reported on 24 patients treated for breast cancer in pregnancy. They noted no fetal abnormalities or neonatal complications with the use of a combination of fluorouracil, doxorubicin, and cyclofosfamide (12). Fluorouracil is also used in topical form to treat conditions of the vulva and vagina. Several patients have been inadvertently treated with this preparation in the first trimester, without any report of deformities (62).

Antibiotics

The most common antineoplastic antibiotics include dactinomycin-D and bleomycin. The former exerts antitumor activity by inhibiting DNA synthesis and function, and promotes the accumulation of intracellular free radicals that further damage DNA. It is approved for the treatment of Wilms' tumor, rhabdomyosarcoma, germ cell tumors, gestational trophoblastic disease, and Ewing's sarcoma. Exposure of the fetus to this compound has been limited to a few case reports in

the second and third trimesters, resulting in intact infants with normal development (63–65).

Bleomycin is a peptide that binds to iron and creates oxygen free radicals, damaging DNA. It is indicated for cancers of the head and neck, squamous cell carcinomas of the skin, vulva, and cervix, germ cell tumors, HL, and NHL. As with dactinomycin-D, no case reports of malformations from the first-trimester exposure have been reported for this drug. Second- and third-trimester exposures have been associated with the delivery of infants without deformities, and normal development has been reported (66,67). Nantel et al. reported on the use of 12 weekly cycles of methotrexate, doxorubicin, cyclophosphamide, vincristine, prednisone, and bleomycin in the treatment of NHL in a patient. The patient went into preterm labor and delivered twins without congenital abnormalities (68). Another patient with an endodermal sinus tumor diagnosed at 18 weeks was treated with three cycles of cisplatin, vinblastine, and bleomycin and delivered a healthy infant without abnormalities at 31 weeks (69).

Nucleoside Analogs

Nucleoside analogs, including cytarabine and gemcitabine, exhibit their antineoplastic properties by causing incorporation of either the drug or its metabolite into DNA and terminating replication. Cytarabine is indicated in the treatment of multiple types of leukemias, as well as in leptomeningeal carcinomatosis. The compound has been associated with otic and auditory canal anomalies, digital anomalies, lobster claw hand, and lower limb defects (70,71). Unlike most other chemotherapies, cytarabine has been associated with in utero fetal death, when given in the later trimesters, and should be avoided in pregnancy altogether, when alternative agents are available (72).

Gemcitabine is indicated in the treatment of cancers of the ovary, pancreas, bladder, lung, and in sarcomas. There are little data regarding the intrapartum use of gemcitabine in the literature. Studies in mice have demonstrated teratogenicity including decreased fetal weight, cleft palate, and increased mortality (73). Kim et al. reported on a woman with non-small cell lung cancer, treated with palliative docetaxel, gemcitabine, and cisplatin from weeks 9 to 22 of an unrecognized pregnancy. A healthy infant was delivered at 33 weeks with no recognizable anomalies (38). Hematologic toxicity is commonly dose limiting and the compound should be used with caution toward the end of the third trimester. In the absence of more case reports, or perhaps a series of patients, other compounds might be considered prior to choosing gemcitabine during pregnancy.

Topoisomerase Inhibitors

Topoisomerase I and II are involved in the cleaving of DNA strands for the purpose of replication. Topoisomerase inhibitors bind to the DNA–topoisomerase complex and prevent the advancement of the replication fork. Topotecan and irinotecan are examples of compounds specific to topoisomerase I, while etoposide binds specifically to the topoisomerase II–DNA complex.

Both topotecan and irinotecan are derivatives from the *Camptotheca acuminata* tree. As with the nonpregnant population, the most pronounced maternal toxicity associated

with topotecan is myelosuppression. To date, there have been no human studies evaluating the teratogenicity of this compound, and unlike most other antineoplastic agents, there are no reports of any pregnant patients receiving this drug. However, animal studies have been concerning. At levels equivalent to human doses, topotecan has been associated with reduced fetal body weight, fetal demise, fetal resorption, and brain, skull, and vertebrae malformations. Most commonly, malformations of the eyes were noted, including microphthalmia, anophthalmia, retinal defects, and ectopic orbits. Granted, most fetal effects are seen by early pregnancy exposure, in the absence of any human data, it is not recommended that topotecan be used at any time during pregnancy.

Irinotecan has also demonstrated animal embryotoxicity at doses equivalent to recommended human levels. Teratogenic effects include visceral and skeletal abnormalities, as well as some external defects. Furthermore, rats administered irinotecan after organogenesis and through weaning had decreased learning ability and decreased fetal weights in the female offspring (74). Unlike topotecan, there has been a single report of the use of irinotecan in pregnancy. A 34-year-old patient was diagnosed with recurrent colon cancer, metastatic to a single ovary at 15 weeks of gestation. She underwent surgical resection and, starting at 18 weeks, was treated with 10 courses of 5-FU and irinotecan over the next 5 months. She delivered a healthy infant at 37 weeks, with no appreciated teratogenic or developmental effects at 4 months (75).

Unlike the topoisomerase I inhibitors, there are dozens of published reports detailing the use of etoposide in pregnancy. Many of these patients have been diagnosed with endodermal sinus tumors, although a variety of other tumors have also been treated with this agent in pregnancy (76). Animal studies have demonstrated multiple fetal abnormalities when the drug is administered during organogenesis, including fetal loss, exencephaly, encephalocele, hydrocephalus, gastroschisis, microphthalmia or anophthalmia, dextrocardia, and axial skeleton defects (77). Etoposide is most frequently given with other agents such as bleomycin and cisplatin (BEP), and the reports occurring in the pregnant patients are no exception. One fetus developed ventriculomegaly and the child now has cerebral atrophy following a single course of BEP (78). Another patient had two cycles of BEP starting at 18 weeks and delivered a normal infant during laparotomy for metastatic disease at 31 weeks. Yet another patient, diagnosed at 26 weeks of gestation with Burkitt's lymphoma, was treated with cyclophosphamide, vincristine, doxorubicin, cytarabine, etoposide, ifosfamide, mesna, and intrathecal cytarabine and delivered a healthy baby at 32 weeks (46). Another patient was treated with BEP at 26 weeks for a metastatic tumor of unknown primary. She developed septicemia and delivered prematurely. The infant has moderate sensorineural hearing loss (79). Several other reports describe the delivery of normal, healthy infants following etoposide administration.

Doxorubicin is indicated in the treatment of many cancers, including, but not limited to, breast cancer, HL, and NHL, soft-tissue sarcoma, ovarian cancer, lung cancer, bladder cancer, thyroid cancer, and gastric cancer. The drug is an

anthracycline antibiotic isolated from *Streptomyces* species. It intercalates into DNA, which inhibits DNA synthesis. Doxorubicin also inhibits transcription, by inhibiting DNA-dependent RNA polymerase, and the function of topoisomerase II. Myelosuppression is dose limiting, but both acute and chronic cardiotoxicity have been well described. When given in the first trimester, in combination with other agents, doxorubicin has been associated with imperforate anus, rectovaginal fistula, and microcephaly (80). In the largest series to date, Hahn et al. reported on the use of doxorubicin in combination with 5-FU, and cyclophosphamide in 57 pregnant women (81). They reported three congenital anomalies, including Down syndrome, clubfoot, and bilateral ureteral reflux. Several others have reported the use of doxorubicin alone or in combination with other therapies, starting as early as the second trimester, without obvious effects on the fetus. There have been no reports of fetal or infant cardiotoxicity associated with doxorubicin use in pregnancy (67,82,83).

Epirubicin is sometimes used instead of doxorubicin as it can have faster elimination and fewer side effects. It has been used in breast cancer, ovarian cancer, lymphomas, gastric cancer, and lung cancer. There have been a few larger series describing the use of epirubicin in pregnancy. Azim et al. described the second-trimester administration of either doxorubicin or epirubicin to a total of 3 and 23 patients, respectively (84). They reported two preterm deliveries, no fetal anomalies, and normal development in all children.

Vinca Alkaloids

Vincristine is a vinca alkaloid antimicrotubule agent derived from the periwinkle *Catharanthus roseus* plant. It is indicated for the treatment of choriocarcinoma, brain tumors, thyroid cancer, leukemia, lymphoma, sarcomas, and several other malignancies. As noted above, vincristine has been used in combination with bleomycin and other agents, delivering infants without abnormalities. Tewari et al. reported on the neoadjuvant treatment of cervical cancer with cisplatin and vincristine in two pregnant women, both of whom experienced significant reductions in tumor volume (19). No adverse fetal effects were noted. Bader et al. also reported on the use of cisplatin and vincristine in a patient for the neoadjuvant treatment of a cervical cancer beginning in the 23rd week of pregnancy (85). At 33 weeks, the patient then underwent a cesarean radical hysterectomy, delivering a normal infant. There have been some sporadic reports of atrial septal defects, renal hypoplasia, and pancytopenia following the use of vincristine in pregnancy (45,86,87). Several other authors have reported the successful use of vincristine, most frequently in combination with other agents, leading to the delivery and normal development of healthy infants (88,89).

Vinblastine is also a vinca alkaloid derived from the periwinkle plant. It is indicated for the treatment of HL and NHL, breast cancer, Kaposi's sarcoma, and renal cell carcinoma. It exerts its antitumor effect by inhibiting tubulin polymerization and disrupting microtubules during the M-phase of the cell cycle. As with most agents described here, animal studies in early pregnancy have demonstrated increased resorption, spontaneous abortion, and gross fetal abnormalities. However, some human studies have reported

no teratogenic effects from first-trimester exposure (90). At 18 weeks of gestation, a patient was diagnosed with an endodermal sinus tumor of the ovary, and following laparotomy, she received three courses of cisplatin, vinblastine, and bleomycin (69). She delivered a healthy and normal infant at 31 weeks. To date, there have been more than half a dozen other patients who have received vinblastine in combination regimens, followed by the delivery of normal, healthy infants (91,92).

Vinorelbine is a synthetic derivative of vinblastine. It is indicated in the treatment of non-small cell lung cancer, breast cancer, ovarian cancer, and HL. When administered to a patient with lung cancer from the 27th to 39th week of pregnancy, a healthy and normal infant resulted (93). Several other patients have reportedly received vinorelbine during pregnancy, with therapy being initiated between 15 and 29 weeks of gestation. In this setting, the drug has most commonly been administered as part of a combination of chemotherapies, being paired with 5-FU, cisplatin, or trastuzumab. All infants have been delivered without congenital abnormalities, had normal birth weights, and have been developing normally (94–96).

Biologic and Growth Factor Agents

Trastuzumab is an antibody indicated for the treatment of patients with HER2 overproducing breast cancers. The antibody exerts its effect on cancer cells both by activating the body's immune response against the cells and by shutting down the signal that tells the cancer cells to grow and divide uncontrollably. Trastuzumab was given to six pregnant patients for the treatment of breast cancer. Anhydramnios developed in three out of the six patients treated (97). Another patient with recurrent metastatic breast cancer was treated with trastuzumab for the first 23 weeks of an undiagnosed pregnancy (98). The patient was delivered by cesarean section at 27 weeks due to severe vaginal bleeding. This pregnancy was also noted to have oligohydramnios. The infant was noted to have uncommonly strong capillary leak syndrome, persisting infections, and necrotizing enterocolitis. The baby died due to multiple organ failure 21 weeks after delivery. Other patients have received trastuzumab in the second and third trimesters without complication to the fetus (96).

Bevacizumab inhibits tumor angiogenesis by binding directly to vascular endothelial growth factor (VEGF). It is currently indicated for the treatment of glioblastoma, renal cell carcinoma, breast cancer, lung cancer, and colon cancer. Rabbit studies at human doses have demonstrated teratogenicity including gross and skeletal malformations, as well as low fetal body weights and increased resorption. Reports on the use of this compound in human pregnancies are very limited. Petrou et al. described two early pregnancy losses at 6 weeks of gestation 7 and 10 days following intravitreal injection of bevacizumab (99). Rosen et al., however, reported the use of the therapy in the second trimester without significant fetal effects (100).

Rituximab is a monoclonal antibody against CD20, which exerts its effect by selectively depleting CD20+ B cells. It is indicated in the use of rheumatoid arthritis and in lymphomas. Kimby et al. reported on the unintentional use of rituximab in

a patient with recurrent NHL in the first trimester of pregnancy (101). She delivered a normal, healthy infant without evidence of hematologic or immunologic abnormalities. Other reports of first-trimester administration have also demonstrated no teratogenic or immunologic effects on the fetus or neonate (102). Pellkofer et al. reported on the use of rituximab for the treatment of neuromyelitis optica 1 week prior to conception (103). The patient delivered a healthy infant with normal development at 15 months. Another patient with idiopathic thrombocytopenic purpura was treated with rituximab weekly for 4 weeks in the third trimester (104). A healthy infant was born 1 month after the last administration of the drug. However, the child had no detectable B lymphocytes. Six months following delivery, her B-lymphocyte counts were normal, and at 10 months, she had normal vaccination titers. Other authors have confirmed this finding of significant rituximab concentrations in the neonate, transient B-lymphocyte depletion, quick recovery, and an absence of immunologic or other neonatal consequences (105–107).

Imatinib is a specific inhibitor of a number of tyrosine kinase enzymes and is indicated for the treatment of chronic myelogenous leukemia. It has been associated with a high rate of teratogenicity (108). However, Skoumalova et al. reported on its administration throughout the first trimester of pregnancy, followed by the use of interferon for the remainder of the gestation, with the delivery of a normal and healthy child (108). Neither the drug nor its active metabolite appears to cross the placenta in significant concentrations (109). Nonetheless, Pye et al. reported on the evaluation of 125 pregnancies complicated by the use of imatinib (110). They reported that 3 of the 35 patients who terminated their pregnancies did so because of detected fetal malformations. Of the remaining infants delivered, 12 had malformations, and 3 of them had similar complex malformations including renal and vertebral anomalies.

Sunitinib is an oral inhibitor of multiple receptor tyrosine kinases including VEGF receptors. It is indicated for the treatment of refractory metastatic renal cell carcinoma and gastrointestinal stromal tumors. Rats and rabbits were given the drug during the periods of organogenesis and demonstrated malformations including thoracic and lumbar vertebral alterations, cleft lip and palate, and increased resorption (111). To date, there have been no reports of this drug administered during a human pregnancy.

Several interferon compounds have now been developed and marketed for the treatment of many kinds of diseases and malignancies. A thorough discussion of the fetal and neonatal effects of each of these drugs is beyond the scope of this chapter. However, there have been several reviews and case reports suggesting that interferon alpha appears to be associated with the delivery of normal and healthy infants (112–114). Mubarak et al. reported on the use of interferon alpha for the treatment of chronic myeloid leukemia beginning in the first trimester (115). Although one child was born with transient thrombocytopenia, all three infants were without abnormalities and developing appropriately. It should be noted that there have been reports of maternal postpartum cardiomyopathy developing in women who have been treated with interferon prior to pregnancy (116).

Birth Weights, Development, and Long Term Follow Up

Some authors have suggested that birth weights for infants born to mothers with breast cancer were significantly lower than those of healthy controls (117). However, in one of the largest series to date, Aviles et al. reported on the long-term follow-up of 84 children and grandchildren of patients treated with chemotherapy for hematologic malignancies during pregnancy (118). The median follow-up was 18 years and ranged from 6 to 29 years. They reported normal birth weights, normal learning and educational performance, no congenital abnormalities, and no cancer or leukemia, with a median follow-up of 18 years and a range of 6 to 29 years.

Infant Hemotoxicities

Some authors suggest that patients should not be treated after 35 weeks of gestation, as many infants may be born with neutropenia, thrombocytopenia, and profound anemia under these circumstances (117). Indeed, infants have been born with severe anemia requiring prolonged ICU admissions, following chemotherapy administered during pregnancy (119). Progenitor studies in these infants have revealed severe bone marrow suppression. Infants should be monitored following delivery for such effects for a prolonged period of time.

SUMMARY

With such a large and growing population of women of reproductive range, the absolute number of women who will be diagnosed with a pregnancy during cancer treatment or diagnosed with a cancer during the course of her pregnancy is far from negligible. The contrast that can occur when the happiest time in a woman's young life is shattered by the finding of often metastatic disease is universally devastating for the patient, her family, and all of those who are involved with her care. Significant moral and ethical dilemmas arise, and questions regarding teratogenicity, pregnancy termination, and disease prognosis have to be approached and considered by a team of physicians, nurses, social workers, counselors, and loved ones. Fortunately, it is clear that there are a number of such malignancies that are curable, and it is further understood that most chemotherapies can be well tolerated in the second and third trimesters without effects on the fetus or on the future development of the child.

With a growing number of chemotherapeutic compounds available, and at least some differences among their effects in pregnancy, multiagent and single-agent combinations should be custom-tailored to provide patients with the best possible treatment of their neoplasm, while exposing the fetus to the least teratogenic, growth restricting, and hemotoxic regimens. Fortunately, it is evident that at least some patients will emerge from this difficult situation disease free and raise healthy and developmentally normal children.

37 Maternal obesity

D. Yvette LaCoursiere and Thomas R. Moore

EPIDEMIOLOGY

Obesity is recognized as a major increasing health threat in the United States. In the year 2000, 117 billion dollars in health-care costs and 300,000 deaths were attributed to obesity (1,2). In 2003 to 2004, 62% of women were overweight or obese, 33% were obese, and 7% were severely obese (3). Women suffer a disproportionate burden of disease compared with men as a result of the increases in morbidity (4).

Regrettably, the obesity epidemic has spilled over into the obstetric population. In fact, recent statistics have shown a marked increase in the prevalence of pregravid overweight and/or obesity over the past few decades (5,6). In a study of 66,000 women in nine states, 22% of women were obese prepregnancy, a 70% increase in the study period (6). As a testament to the pervasiveness of maternal obesity, no subgroup had less than 43% increase in obesity over the interval. The greatest increases in obesity were seen in those who were >20 years of age, black, parous (three or more children), with a high school education, nonsmokers, and enrolled in WIC.

The rising prevalence would not be problematic if it were not for the sequelae for mother and baby. Obesity has been associated with infertility, spontaneous abortion (SAB), intrauterine fetal demise (IUFD), inaccurate fetal imaging, gestational diabetes mellitus (GDM), pre-eclampsia, cesarean delivery, anesthetic complications, deep vein thrombosis/pulmonary embolus (DVT/PE), wound complications, mood disorders, breast-feeding difficulties, contraceptive failures, and longer-term issues such as excess gestational weight gain (GWG), later-life obesity, diabetes, and heart disease (5,7–16). Likewise, the fetus incurs risks of macrosomia, associated complications, and pediatric obesity (11,17) (Table 1).

Increasing maternal obesity has potential public health implications as well. As an example, a study in Utah revealed a 40% increase in overweight and obesity between 1991 and 2001 (5). While this study described a smaller overall increase in body mass index (BMI) compared with Kim's data, it described the impact to the community as a whole. An estimate of the attributable fraction of cesarean delivery in the state revealed that one in seven were attributable to obesity after controlling for other factors. Additionally, after assessing trends among potential confounders including maternal age, ethnicity, chronic hypertension, and renal disease, the study described a parallel rise in pre-eclampsia among nulliparous women from 5% to 8% in the same interval in which obesity increased (5).

ETIOLOGY

The etiology of maternal obesity is complex and multifactorial. While not classically discussed in perinatal textbooks, the ecologic context in which a patient lives is important to

include in a chapter on maternal obesity, given that some management is dependent on lifestyle interventions. Access to healthy foods and physical activity (PA) opportunities have a potential effect on maternal and fetal well-being. Living more than 4 miles from a supermarket doubles the likelihood of having the lowest quartile of food quality (18). This type of research has recently been linked to adverse birth outcomes. Lane and colleagues documented that mothers living near markets without fresh produce and dairy were at significant risk of delivering low-birth weight infants (19). Also living in areas with social spaces lowers the risk of low or excess GWG (20). Inquiring about the environment may guide counseling for obese women.

PATHOPHYSIOLOGY

Complex alterations in glucose and lipid metabolism, inflammation, adipokines, and vascular dysfunction occur in obese women. Significant endocrinopathies are associated with obesity, and examples from nonpregnant populations are relevant as they describe the milieu into which a fetus is exposed. Obese individuals are more likely to develop insulin resistance and hyperinsulinemia (21). Adult twins who were discordant with respect to weight were studied and the obese twin of the dyad had significantly higher insulin levels and less insulin sensitivity to maintain normal glucose levels (21). At a cellular level, obesity causes post-receptor binding defects, impaired second messengers, and enzymatic defects, which diminish the ability of the cells to import glucose into the cell. This is exacerbated by the production of human placental lactogen during pregnancy. Additionally, obesity causes abnormal lipogenesis and protein synthesis and increases lipolysis, which then increases free fatty acids (FFAs). At the muscle, this results in FFA oxidation and decreased glucose use leading to hyperglycemia, and at the liver, the increased FFA oxidation increases gluconeogenesis also resulting in hyperglycemia. Thus, at least three mechanisms result in hyperglycemia associated with obesity. These pathophysiologic changes in the overweight and obese translate into increased relative risks of developing diabetes mellitus both during pregnancy and outside of pregnancy (22). In a meta-analysis of over 20 studies, increasing BMI increased the odds of having GDM. The unadjusted ORs of developing GDM were 2.14 (95% CI 1.82–2.53), 3.56 (3.05–4.21), and 8.56 (5.07–16.04) among overweight, obese, and severely obese compared with normal-weight pregnant women, respectively (23). Likewise, obese women with GDM were twice as likely to develop type 2 after pregnancy.

Hypertensive consequences also increase with overweight and obesity. Nurse's Health Study data show a 1.7-fold increase in the risk of hypertension in overweight women compared with normal-weight women (24). A fivefold

increase is seen in obese women and abdominal obesity doubles the risk. Likewise, both weight gain and loss modify these risks. Thus, obese women entering pregnancy are at risk for chronic hypertension. The literature supports the association between obesity and pre-eclampsia, even lacking chronic hypertension. Sibai et al. reported a threefold increase in pre-eclampsia to 12% of women with a BMI of $\geq 34 \text{ kg/m}^2$ compared with lean women (25).

Unlike hyperinsulinemia and hyperglycemia, the mechanism remains to be elucidated. The vascular volume is increased in obesity and in pregnancy, but peripheral resistance is only slightly elevated in obesity and decreased in pregnancy. Other theories include increased renal sodium and water, activation of the sympathetic system, alteration in the function of sodium-hydrogen ATPases and changes to the vascular wall, and subclinical inflammation (22,26).

Overall, the data regarding preterm birth (PTB) and obesity are conflicting. In a large European cohort, the rate of PTB was increased (aOR 1.6) (10), others have reported a decrease (7), and yet some report that postdate pregnancy is increased by obesity (27). Nohr and colleagues suggest that actually indicated PTB is increased as a result of maternal medical conditions, not spontaneous PTB (28).

Obesity increases multiple aspects of parturition including induction, duration of labor, oxytocin requirement, and cesarean delivery (29,30). Cesarean delivery is performed in up to half of obese women and increases as BMI rises. As an example, cesarean delivery rates are shown in Figure 1 for women with and without the risk factors of diabetes and hypertension (31). Obesity has been shown to similarly decrease the success of women undergoing a trial of labor after cesarean. Juhasz and colleagues demonstrated that overweight and obese women were 50% less likely to have a successful vaginal birth after cesarean (VBAC), and a weight gain of over 40lb decreased a woman's chance of VBAC 40% when compared with underweight women (32). Similar failure rates with trial of labor were described by Durnwald et al. even after controlling for other additional factors (normal BMI 70.5%, obese 54.6%, $p = 0.003$) (33).

Psychosocial Factors and Obesity in Pregnancy (Table 2)

issues in their children, this makes identifying and treating those at greatest risk essential (34,35). Obesity is one of the factors that has recently been found to be a risk marker for depressed mood during pregnancy and postpartum.

The link between BMI, eating attitudes, and depression and anxiety during pregnancy and at 4 and 14 months postpartum was first described by Carter et al. (8). A recent analysis showed that depression, one of six negative psychologic states assessed, was associated with pregravid BMI. While the relationship was seen in all overweight and obese women, a BMI of >40 was strongly associated with depressive and anxiety symptoms, locus of control, perceived stress, powerful others, restrained eating and dieting, and weight cycling (9).

In a 2010 study of over 1000 predominantly Caucasian women, recruited immediately postpartum, prepregnancy BMI was associated with depressive symptoms (12). The percentage of women screening positive for postpartum depression was 14.4% in normal-weight women with an increase in all other BMI strata: underweight, 18.0%; overweight, 18.5%; obese class 1, 18.8%; obese class 2, 32.4%; and obese class 3, 40.0%. In a regression model, class 2 and class 3 obesity were strongly associated with screening positive for depression.

Not all studies have found this association. A secondary analysis of overweight and obese women enrolled in a postpartum weight loss intervention did not find a link between obesity and depressed mood. However, by virtue of the recruitment into an intense trial, obese women with depression could have been excluded (36).

Long-Term Consequences

While an increasing number of studies have focused attention on the immediate maternal and neonatal complications associated with prepregnancy overweight and obesity, less attention has been paid to the long-term consequences of excess maternal weight gain and postpartum weight retention, which may contribute to midlife obesity and subsequent development of diabetes and heart disease (5,14,15). Olson demonstrated that only 42% of women had attained their prepregnancy weight and 26% of women had retained over 10 lb 1 year after delivery (37). They estimated that 69% of incident cases of obesity could have been prevented by decreasing weight gain during pregnancy. This excess weight gain and postpartum retention translated into an increase in long-term obesity and subsequent development of obesity-related illnesses. One decade after delivering, women who gained less than recommended during pregnancy were 4kg heavier on average, compared with 6 and 8kg in women gaining the recommended and greater-than-advised, respectively. A weight gain of 16kg during pregnancy was a significant predictor of long-term weight retention (14,15,38).

Bariatric Surgery

Between 1998 and 2005, bariatric surgery has increased 800% with the majority of the procedures performed on women (39). Overall, women who have successfully lost weight after bariatric surgery appear to have lower rates of GDM, hypertension, cesarean delivery, and macrosomia (40). Maggard and colleagues reported a GDM rate of 22% in obese women and 0% in the post-bariatric surgery group. Pre-eclampsia rates were lower as well (3% obese women vs. 0% post-bariatric surgery group). There was no evidence of increased growth restriction or preterm deliveries in the post-bariatric surgery group compared with the obese controls (39).

Some women after bariatric surgery experience deficiencies of iron, folate, vitamin B₁₂, and calcium, particularly in those with malabsorptive procedures. Additionally, there are reports in the literature of complications during pregnancy after bariatric surgery including anastomotic leaks, internal hernias, intestinal obstruction, gastrointestinal bleeding and erosion, band migration, and maternal death (41). Population-level data comparing the benefits and risks of bariatric surgery compared with pregnancy in the severely obese are not readily available.

Breast-Feeding

Interesting work reveals an association between obesity and breast-feeding failures even after controlling for socioeconomic status (42,43). Increased prepregnancy BMI is associated with shorter breast-feeding duration (42). This is unfortunate as both maternal obesity and short duration of breast-feeding are independent risk factors for childhood overweight (43). Recently, biologic data support this epidemiologic association between obesity and short duration of breast-feeding. Increased prepregnancy BMI predicts a lower prolactin response to suckling at 48 hours. Prolactin is responsible for stimulating milk production and thus a decrease in responsiveness could lead to a diminished ability to make milk and perhaps contribute to breast-feeding discontinuation (44). Perhaps interventions that improve

pregnancy BMI and or maternal weight gain might improve a woman's ability to breast-feed.

Effects on the Offspring (Table 3)

Fetal anomalies are reportedly increased in fetuses of obese women. Specifically, neural tube, cleft palate, and cardiac defects are increased, and concomitantly the ability to detect defects is impaired in this population by at least 20% (45). Stothard and colleagues attempted to determine how the decreased detection rate might contribute to the overall increase in anomalies by a decrease in pregnancy terminations in obese women. They included pregnancy terminations in their analyses and found no change in the odds (46).

IUFD and Infant Mortality

An increasing number of studies have described an increase in IUFD among obese women. Denison and colleagues reported a threefold increase in IUFD in women with a BMI≥35 (aOR 3.90, CI 2.44–6.22) (27) (Table 3). In a study of 24,000 women, after adjusting for antepartum complications, the association was attenuated but still present for IUFD and neonatal death (47). Mortality after delivery is also increased in neonates born to obese women (48). It is unclear whether this increase in IUFD warrants aggressive antepartum monitoring, given the rising prevalence of obesity and the relatively small risk of fetal demise.

Macrosomia and Childhood Obesity

Birth weight increases with maternal obesity. In a secondary analysis of the hyperglycemia and adverse pregnancy outcomes, Metzger reported that 13.6% nondiabetic obese women developed macrosomia (>4000g birth weight) compared with 6.7% of non-obese normal-weight women (49) (Table 3). In a study of 116,976 macrosomic infants, after controlling for antepartum risk factors, those born to obese mothers were more likely to experience hyaline membrane disease (aOR 2.14, CI 1.73–2.66), extended assisted ventilation (aOR 1.71, CI 1.44–2.04), birth injury (aOR 1.58, CI 1.37–1.84), and meconium aspiration (aOR 1.42, CI 1.09–1.89) (50). The consequences of maternal obesity persist: large-for-gestational-age (LGA) babies and maternal obesity have been shown to have a twofold increase in the risk of metabolic syndrome in children (hazard ratios LGA 2.15, CI 1.25–3.82, maternal obesity 1.81, CI 1.03–3.19) (51). GWG likewise increases macrosomia and is worse in overweight and obese women. It is hypothesized that GWG and maternal obesity lead to

Table 3 Fetal, Neonatal, and Pediatric Consequences of Maternal Obesity and Excess Gestational Weight Gain (GWG)

maternal insulin resistance and glucose intolerance, which increase fetal glucose, insulin, steroid and growth hormones, amino acids, and lipids (Fig. 2). The resultant increase in fetal fat deposition leads to accelerated birth weights, neonatal complications, and childhood obesity (52).

DIAGNOSIS

Defining Obesity and Measuring GWG

In nonpregnant adults, BMI is commonly used as a measure of adiposity. The World Health Organization defines normal BMI as a BMI between 18.5 and 24.9, underweight as <18.5, overweight as 25 to 29.9, and obesity as >30. For more detailed assessments and risk stratification, it defines class 1 obesity as 30 to 34.9, class 2 obesity as 35 to 39.9, and class 3 obesity as >40. In obstetrics, it is the practice to use a woman’s prepregnancy BMI for risk assessment and to follow their GWG. Using a measured prepregnancy BMI is preferable. Alternatively, a first-trimester measured BMI or self-reported prepregnancy BMI can serve as a proxy. Notably, a self-reported pregravid BMI will underestimate a woman’s actual BMI category. Table 4 provides formulas for calculation and two online references. BMI can be calculated by (i) dividing

the individual’s weight in kilograms by height in meters squared or (ii) multiplying their weight in pounds by 703 and dividing this by the height in inches squared. Waist circumference is measured in the horizontal plane at the level of the iliac crest at the end of inspiration.

After extensive review, new recommendations for weight gain during pregnancy were released in 2009 by the Institute of Medicine (52). The document states that “Although the guidelines ... are not dramatically different ... fully implementing them would represent a radical change in the care of women of childbearing age.” In fact, the recommendations are not significantly different. Only women in the obese category saw a reduction in the recommended weight gain to 11 to 20lb. The Institute of Medicine (IOM) based the limited changes on the fact that there are limited data on metabolic profile, diet patterns, and eating behaviors of those without weight gain. The IOM cautioned that insufficient gain (<15lb) would imply mobilization of adipose and protein stores and could result in ketonemia with the potential to result in neurologic deficits in the infant (52). The guidelines presented in Table 5 drew some frank criticism from prominent obstetricians who suggested that this decrease in GWG was insufficient.

The IOM modified its recommendations for special populations. Women of short stature, adolescents, and all race/ethnicities are encouraged to gain the standard amount by their prepregnancy BMI category. Additionally, they changed the weight gain recommendations for twins to 37 to 54lb for normal-weight women, 31 to 50lb for overweight women, and 25 to 42 lb for obese women. They were unable to stratify the recommendations for obese women carrying singletons or twins by class 1, class 2, or class 3 obesity citing insufficiency of representative published data.

MANAGEMENT

Logistical Considerations

In order to provide compassionate care, clinicians should recognize the challenges obese women face in obtaining medical care. Simple strategies to make the clinical setting more hospitable will facilitate effective communication and development of rapport. While the following recommendations may seem straightforward and perhaps inconsequential, they in fact set the stage for effective and compassionate communication. Office staff can assist clinicians in making the office more comfortable by evaluating a few key pieces of the patient’s visit (53).

- Chairs with armrests may be constraining to overweight and obese women. Consider making benches available or having access to seating without armboards or wider seats.

	BMI	Total weight gain (lb)	Rates of weight gain in second and third trimesters (lb/week)
Underweight	<18.5	28–30	1 (1–1.3)
Normal weight	18.5–24.9	25–35	1 (0.8–1)
Overweight	25.0–29.9	15–25	0.6 (0.5–0.7)
Obese (includes all classes)	≥30.0	11–20	0.5 (0.4–0.6)

Source: Institute of Medicine, 2009.

- Weight is considered a private issue by many women. Obese women may be embarrassed by having their weight measures in a public location, especially if they are heavier than the maximum capacity of the scale. Weigh women in a *private* location.
- Large blood pressure cuffs should be available at each location where blood pressures are taken to avoid unnecessary embarrassment to the patient. Have larger sized gowns and sheets in each examination room.
- Limited mobility may make it difficult for obese women to get onto an examination table or place their feet securely on the footrests. Provide adequate assistance for accessing the table and consider performing the pelvic examination without footrests.
- Large speculums should be available in each examination room.

Lifestyle Interventions—Nutrition, PA, and Successful Interventions

Currently, attempts are being made to identify interventions improving nutrition and PA during pregnancy. Clearly, there is room for improvement. There are no nationally representative data available on pregnant women, thus using reproductive-aged women as a proxy, women are not eating a diet rich in fruits and vegetables. Less than 2% of women aged 19 to 30 eat the recommended amounts of fruits and vegetables. Even when the requirement is lowered to the essential five-a-day servings of fruits and vegetables, less than 30% of women aged 19 to 30 and less than 40% of women aged 31 to 50 meet the target (54).

We perform no better in the realm of PA. When measured by accelerometry, only 5% of adults meet the recommended 30 minutes of moderate PA per day, 5 days per week (55). Data

in pregnancy are limited; however, DiNallo and colleagues reported that <12% of women meet PA recommendations in pregnancy (56). This is despite more recent data supporting that moderate PA in pregnancy is not associated with preterm labor, low birth weight, or pregnancy loss, and most studies show an inverse association between PA and GWG (57). Lifestyle interventions in overweight and obese women are limited, but none yet in the United States has been completely successful. Of the four intensive interventions, one showed no effect on GWG in obese women, one lowered GWG in low-income women, the other in normal weight, and the last showed that dietary and lifestyle changes resulted in a 7% decrease in GWG. The Europeans have more consistent success with 2- to 3-kg improvements in GWG and improvements in dietary practices. Currently, interventionists are attempting to determine what works and in which populations.

These research interventions clearly include an entire curriculum and consume a significant amount of resources that are not available to most clinicians. If available, clinicians should consider referrals to nutritionists in early pregnancy and each trimester. Alternatively, free online resources for nutritional plans are available for pregnant mothers on mypyramid.gov (Fig. 3).

Assessing current level of PA and encouraging continued exercise and active choices is a simple intervention a physician can perform in clinic. Tables 6 and 7 describe the American College of Obstetricians and Gynecologists recommendations and contraindications and precautions.

Management Plan

A management plan for obese pregnant women is included in Table 8. Acknowledging that half of pregnancies are unintended, the discussion about appropriate weight during pregnancy and consequences of obesity should begin at the well-woman examination. Currently, only one-quarter of

Figure 3 “MyPyramid Plan for Moms.” Source: From MyPyramid.gov.

Table 6 Physical Activity Recommendations in Pregnancy

≥30 min/day moderate exercise 5 days/week
 Avoid supine position with exercise
 Avoid trauma, fall risk, and scuba

Source: ACOG, 2006.

Table 7 Contraindications and Precautions for Physical Activity in Pregnancy**Absolute contraindications**

Significant heart disease or restrictive lung disease
 Incompetent cervix
 Multiple gestation
 Second- and third-trimester bleeding
 Previa, PROM, PTL, or pre-eclampsia

Relative contraindications

Anemia
 Arrhythmias
 Poorly controlled DM 1
 BMI>40
 Underweight
 IUGR
 Poorly controlled HTN or thyroid disease

Precautions

Loss of fluid, vaginal bleeding, cramping, regular contractions, chest pain, shortness of breath dizziness, decreased fetal movement

Abbreviations: PROM, premature rupture of membranes; PTL, preterm labor; DM 1, diabetes mellitus 1; BMI, body mass index; IUGR, intrauterine growth restriction; HTN, hypertension. Source: ACOG, 2006.

providers address weight among overweight and obese women at annual examinations (58). Documentation of BMI should be performed and overweight and obese patients should be referred to available PA and nutrition counseling. Women who are contemplating pregnancy should be encouraged to take folic acid as obesity is a risk factor for inadequate folic acid supplementation. Also they should be educated regarding the increased risks that obese women and their infants experience and screened for diabetes.

In early pregnancy, BMI should be calculated, recorded, and used to assess risks and set a GWG target. Throughout prenatal care, the GWG should be described and patient be given appropriate feedback, an important point being that clinicians and ancillary services should be providing consistent messaging. Folic acid supplementation should be encouraged. The Royal College of Obstetricians and Gynaecologists recommends increasing folic acid supplementation to 5 mg; however, the IOM concludes that the increased rate of neural tube defects may result from inadequate folate use not inadequate dosing (59,60). Serum screening and first-trimester ultrasonographic screening should be encouraged, as second-trimester screening is less efficacious at detecting anomalies. It is unclear whether fetal surveillance for obese women is cost-effective; however, consideration should be made for antenatal testing in the severely obese as they are at greatest risk for IUFD.

Intrapartum care should include anesthesia consultation and assessment of an early epidural, given that a 1-cm increase in neck circumference translates to a 1.13 increase in unsuccessful or complicated intubations (61). VBAC counseling should be modified to include the decrease in success.

Table 8 Management Plan**Preconception care (including gynecologic care and well-woman examinations)**

Measure height and weight, calculate BMI
 Address weight, physical activity, and nutrition (referral)
 If considering conception
 Folic acid 400 mcg
 Weight loss before conception
 Risk counseling by prepregnancy BMI
 Screen for diabetes

Antepartum

Calculate prepregnancy or early pregnancy BMI
 Set weight gain goal and review risks (2009 IOM recommendations)
 Monitor gain and provide feedback
 Consistent messaging—GWG, nutrition, and PA
 Nutrition website, nutrition referral
 400 mcg folic acid
 Serum screening—first, second, and integrated screens are BMI corrected
 Ultrasonographic screening
 Offer first Δ US for NT (no \downarrow in detection rate)
 Second Δ scan 20–30% \downarrow common anomalies
 Antenatal testing 36 weeks if BMI>40*

Intrapartum

Anesthesia consult, consider early CLE (BMI>35)
 Avoid elective induction
 Modify VBAC counseling

\downarrow 50%
 >40# GWG \downarrow 40%

Vaginal delivery

Low threshold to deliver in OR—BMI>35
 Steps

Cesarean delivery

Table limit
 Air mattress and sufficient staff
 Incision placement
 Surgical incise drape or tape (for cephalad retraction of pannus)
 360-degree protected edge
 In situ uterine closure
 Subcutaneous layer 3.0 vicryl closure (if >2 cm)
 Compression stockings or prophylactic heparin

Immediately postpartum

Early ambulation
 Lactation consultation
 Early outpatient visit (7–14 days)
 Wound
 Breast-feeding
 Edinburgh Postnatal Depression Scale (EPDS)

Postpartum visit (6 weeks)

Weight management
 Mood
 Contraception

Abbreviations: BMI, body mass index; IOM, Institute of Medicine; GWG, gestational weight gain; PA, physical activity; NT, nuchal translucency; VBAC, vaginal birth after cesarean. *Consider

The gynecologic, general surgery, and anesthesia literature supports the increased risk of surgical morbidity. Surgical complications include increases in operative time, blood loss, transfusions, length of stay, pressure sores, nerve injuries, deep vein thromboses, wound complications, difficult intubations, and associated pulmonary complications (62–65).

Table 9 Key Points for Women after Bariatric Surgery

Post-op counseling regarding increased fertility
 Delay contraception for 12–18 months after bariatric surgery
 Assess for vitamin and mineral deficiency (Fe, Folate, B₁₂, calcium, vitamin D)
 High suspicion for band/bypass complication
 Co-manage with general surgery

Source: ACOG 2009, Kirshtein 2010.

For cesarean deliveries, the provider must know the weight limit of the OR table and prepare accordingly; table extensions must be available. Sufficient staff and/or air mattress lift devices should be available. Incision placement requires assessment of the location of the anterior superior iliac spine and the pannus. In severely obese women, the pannus tends to deviate the abdominal wall caudally and as such vertical peri- and supra-umbilical incisions might be required to access the lower uterine segment. Two additional techniques that may be useful include taping the pannus to a bar that resides at shoulder level with tape or a surgical incise drape to retract the pannus cephalad and using a cesarean o-ring retractor. Often, it is not possible to exteriorize the uterus and an in situ closure is performed. To decrease the likelihood of these complications, surgeons should be aware of the operating table weight limit, administer an adequate dose of preoperative antibiotics (if BMI > 35 or > 220# double the Ancef dose to 2g), and close the subcutaneous tissue (66). Early ambulation, sequential compression devices, or prophylactic heparin should be used to protect against deep vein thromboses.

Immediately, postpartum women should be encouraged to ambulate and be provided with lactation assistance. Inviting women to return to clinic 1 to 2 weeks postpartum provides an opportunity to assess wounds, support breast-feeding, and ensure that mood is stable. Clinicians should begin a weight management dialogue at 6 weeks postpartum, evaluate mood, and discuss the importance of adequate contraception.

Bariatric Surgery

Even if a woman has a history of infertility, she should be counseled that spontaneous conception is possible after bariatric surgery. It is important that women acknowledge this and delay contraception for the first 12 to 18 months to avoid pregnancy in the rapid weight loss phase to protect the fetus from growth restriction. When pregnancy does occur, women should be screened for vitamin and mineral insufficiency each trimester and supplemented as needed using rapid release or oral solutions in lieu of extended release medications. Some women may not tolerate a 1-hour glucose tolerance test and may require fasting and 1 to 2 hours postprandial glucose levels for 1 week at 25 to 28 weeks. Clinicians should have a high index of suspicion for band or bypass complications when women present with abdominal pain, nausea/vomiting, and anorexia. Consultation with bariatric or general surgeons should be sought readily and early (Table 9) (40,41).

Future Directions

Unanswered questions abound in the care of the obese pregnant patients. Well-designed prospective studies are needed to answer these research questions. Potential topics include

identifying (i) whether modest decreases in weight (5–10%) preconception elicit significant improvement in obstetric outcomes, (ii) appropriate GWG recommendations by class of obesity, (iii) successful interventions to improve GWG, and (iv) the effects of PA on obstetric and psychologic outcomes. Future research should inform best practices.

38 **Medicolegal considerations**

Erol Amon and Gilad Gross

INTRODUCTION

It is important to initially view the professions of medicine and law from the perspective of the roles they serve in a civilized society. In many ways, the professions are quite similar and yet have important differences. We do not rely on the practice of voodoo medicine, nor do we rely on capriciousness in the practice of law. Each profession has a well-developed set of values, norms, and methods taught within a higher educational system. The final practical step is that each professional is granted a license by the state in which they practice based on personal achievement, professionalism, and meeting obligations to the public.

Analogous to the physician–patient relationship is that of the attorney–client. Both share the duty of confidentiality and to place their patients’ or clients’ interest before their own. In most instances, clients or patients are extremely vulnerable and in need of professional assistance. This asymmetric relationship and need for profound levels of duty call for high degrees of professionalism from members of both professions.

Alternatively, there are marked differences. Medicine employs an open, cooperative, yet tightly constrained scientific methodology invested in discovering the truth. By contrast, the American legal system uses a relatively hidden, more creative, adversarial approach in which the courts and jurors unearth the truth to best meet the needs of the justice system. The attorney’s goal is to use the adversarial system to win their case for their client rather than a thorough searching for truth. While scientific studies generally advance a physician’s purpose to care for and remedy his patient’s illness, some of these studies may actually detract from an attorney’s theory on an alleged malpractice case. This occurs because in all circumstances attorneys have the ethical duty to advocate zealously for their client. In medicine, scientific unknowns remain as inconclusive unanswered questions, whereas legal disputes are always conclusively decided upon and finality reached regardless of the quality and quantity of evidence presented. Physicians are trained in the traditional sciences and the scientific method while attorneys are generally schooled in disciplines of advocacy, debate, and political science (1).

There are multiple opportunities for the two professions to interface. Broadly, there are two major meeting grounds: (i) professional liability litigation and (ii) contractual or regulatory aspects of medical practice (2). This chapter will focus on several aspects of professional liability and its litigation.

Most physicians will be called on during their career to provide legal testimony in one context or another. They could be a party to a lawsuit either as plaintiff or defendant. They could be a fact witness providing first-hand knowledge about a patient’s condition, treatment, and records. In this capacity, personal testimony relates to what the physician observed,

heard, or did in the case being litigated. They may also be called upon to provide expert testimony and opine on past events relating to a malpractice lawsuit, in which they often have no first-hand knowledge about the patient’s condition or care. They could also be called upon to predict future medical outcomes, including life expectancy, and in a psychiatric context to discern whether a patient is dangerous enough to be involuntarily committed (homicidal or suicidal) by a judicial decision.

LITIGATION FOR ALLEGED MEDICAL MALPRACTICE

The American legal system is known as the adversarial system having its origin in English law. This method of litigation is the foundation of the American justice system. In theory, it has potential to perform quite well. Accordingly, the logic is as follows (3):

1. *if* two equally matched attorneys (with intelligence, experience, and resources)
2. zealously and competently represent their clients,
3. within the bounds of ethical and legal rules,
4. with neutral judges and juries,
5. *then* the correct results should be reached.

It is noteworthy that judges do not often take active roles; rather, they simply are a neutral referee ruling on admissibility of evidence and other legal issues as they arise. The court will not be interested in reviewing evidence the parties do not present. Jurors are also passive participants usually unable to ask clarifying questions (3).

As a result, attorneys for each side bear an enormous responsibility. Each side is presumed to look after their own interests. They must investigate, prosecute, and defend their clients by collecting, organizing, and presenting the evidence (4). Each party to the litigation will attempt to advance its own favorable evidence (interpretation of historical facts) while attempting to limit the admissibility and credibility of its opponent’s evidence. In contrast to medical practice, there is no obligation to present all the facts, only those favorable to a particular side. Opposing attorneys examine and cross-examine the witnesses and, by using the rules of evidence, attempt to convince a relatively passive court of the correctness of their client’s position.

Each side defines the scope of relevant evidence. Evidence law states that evidence is relevant if it has “any tendency to make the existence of any fact that is of consequence to the determination of the action more probable or less probable than it would be without the evidence” (5). This evidence must be pertinent to the case and help the judge or jury make a final decision based on a “preponderance of the evidence.” The trier of fact (judge or jury) assesses the evidence presented and unearths the “real truth.” Regardless of how close the

pro and con evidence stacks up, ultimately, a conclusion must be reached and one side must win.

To assist the court in making its final decision, attorneys will call upon expert witnesses to help explain to the lay jury the applicable standards of care, whether they were breached, whether the breach caused the injury, and the measure of the past and projected monetary damages based on the nature of the injury (6).

PROVING PROFESSIONAL NEGLIGENCE

The burden of proof rests with the plaintiff in the American judicial system; the degree to which this must be demonstrated, however, is variable. In criminal cases in which a defendant's life or liberty is at stake, the burden is to provide evidence that is "beyond a reasonable doubt," which typically translates to a 95% likelihood. However, in professional negligence cases where the compensation for injury secondary to negligence is money, the courts apply a *mere* "preponderance of the evidence" standard (6). This often equates to proving only 51% likelihood or as common parlance as "more likely than not."

There are four elements that must be demonstrated in a professional negligence lawsuit. These are duty, breach, causation, and injury. Each element must be proved by the preponderance of evidence standard (2).

The first of these elements, a legal duty, is created by the physician–patient relationship. The obligation arising out of this relationship is the duty to provide the standard of medical care that would be exercised by other similarly situated physicians under similar circumstances with comparable resources (6). These standards of care refer to appropriate conduct (behavior), that is, actions or inactions by the defendant. It does not refer to a mind-set (character) to harm or help the plaintiff.

It is imperative to understand the contrast of legal duty from ethical duty. A legal duty is what *must or must not* be done that a court of law may or will enforce. An ethical duty is what someone *should or should not* do and a court may not or will not find it enforceable. Consider a physician who happens to be shopping at a mall and the person standing in front of him collapses and stops breathing. The physician ethically should assist that person. However, in the absence of a preexisting physician–patient relationship, he has no legal duty, no legal requirement, to help and cannot be haled into a court for failing to provide medical care. However, once this physician takes action to help, he must do so nonnegligently. To encourage these selfless acts, almost all states have enacted "Good Samaritan" statutes to protect these good people from lawsuits (7).

The second element that has to be proved by the plaintiff is the defendant's breach of the standard of care (the legal duty). Here the physician's conduct is at issue. The alleged negligent (breached) conduct is either an omission of an owed duty or commission of a negligent act. To prove this element, expert witness testimony is generally required (2) to provide admissible evidence for the benefit of the court by answering two questions:

1. what is or should of been the standard of medical care and

2. whether the duty to provide that standard was breached by the defendant physician.

The legal principle of *Res Ipsa Loquitur* is an exception to the plaintiff's requirement for expert witness testimony (2). This legal doctrine addresses the adverse outcome that could only have come about by the defendant's negligence. It is a rule of circumstantial proof (6). A prime example is the unintentional leaving of a sponge in a patient's abdomen after a surgical procedure. Here the lay person may use their common sense and reason that this was clearly negligence.

The third element to prove is legal causation. There must be a reasonably close and causal connection between the breach of the standard care and the alleged injury. The legal question asked of and answered by the expert witness is "but for" the defendant's breach, would the plaintiff suffered the claimed injury (6). In other words, the breach must be a necessary condition that leads to the injury. Furthermore, the attorney will often be required to ask the expert witness that "within a reasonable degree of medical certainty" whether the alleged breach resulted in the alleged injury (2).

In medicine, causation is complex and depends on multiple factors. To establish scientific proof using "evidenced-based" medicine, physicians often rely on controlled clinical trials with mathematical probabilities. Scientific studies minimize the occurrence of happenstance or chance by quantifying a probability of error to <5%. Causation is further strengthened if these results are independently reproducible.

In law, however, the notion of legal cause is generally quite different than medical causation. The focus is not scientific truth. The heart of the legal matter is the attribution of responsibility (8). Therefore, by necessity, the law commences a retrospective investigation of particular conduct of particular persons and uses the somewhat complex rules of legal evidence to help the jury make a final decision. In these situations, the probability of error in malpractice litigation (<50%) can be much higher than that in science (<5%). Thus, the 51% standard proof (i.e., preponderance of the evidence) is invoked to persuade the jury.

The final element that requires legal proof is the development of an injury. The purpose of awarding monetary damages is to make the victim "whole" from a legal standpoint. If there is no injury, there is no recovery on which damages can be based. Compensatory damages are usually of two types: economic (measurable) and non-economic (nonmeasurable). Economic damages include case-related past, present, and future medical expenses and related loss of past, present, and future wages. An economic expert known as a "life planner" will testify as to the amount of economic damages. Noneconomic damages include those related to "pain and suffering," loss of consortium, and mental anguish. Unfortunately, these cannot be accurately quantified and thus are subject to sizable degrees of variation among juries. Many state legislatures, through tort law reforms, have enacted or are attempting to enact a hard cap on noneconomic damages to protect against runaway jury awards, to improve the predictability of judgment amounts, and to stabilize insurance premiums and maintain access to medical care (9).

Ultimately, all four elements must be linked together for the plaintiff to prevail by proving each element by a

preponderance of the evidence (2). If a physician defendant has no legal duty to the patient, that suit will automatically fail. If the defendant can show that the standard of care was met despite an adverse outcome (maloccurrence), the defendant should prevail. Even if the defendant did breach a standard of medical care owed to the plaintiff, but the breach did not cause or was unrelated to the injury, the plaintiff should not recover any damages.

Legal *duty* is hardly ever litigated because in most cases there is usually a well-defined physician–patient relationship. On the other hand, evidence pertaining to the other three elements is inevitably controversial, often litigated, and most often introduced into court through the testimony of experts.

GUIDELINES FOR EXPERT WITNESS TESTIMONY

An expert witness is defined as a person who, by reason of education, special training, and/or experience possesses knowledge of a particular subject area at greater depth than the judge or lay jury. The judge will often decide on the admissibility of this evidence (expert’s testimony) by assessing the proffered expert’s qualifications and opposing counsel’s objections. Once allowed to testify in the courtroom, the jury will weigh the expert’s testimony about their interpretation (opinions) of the facts of the case (6).

Multiple experts may be used to prove each element independently. In contrast to fact witnesses, expert witnesses are permitted to reflect, opine, and pontificate in court. Initially, experts on standard of care through testimony educate the jury on what the appropriate medical practice is or should be, and whether or not the defendant’s conduct falls within the standard of care. Causation experts may be used to establish whether the alleged breach “within a reasonable degree of medical certainty” caused the alleged injury. A single expert witness can provide testimony on both standard of care and causation, or alternatively and more likely, multiple experts will be utilized. Economic experts are separate individuals who make claims regarding the degree of damages, life expectancy, and projected future costs.

Expert witnesses are employed by opposing parties of a malpractice claim. Physicians who accept both plaintiff and defense cases are thought to be less biased. Depending on individualized State Tort Law, an expert may render appropriate opinions by virtue of similar practice and does not need to practice an identical discipline of medicine. Nonetheless, the expert must have knowledge of the standard of care and be familiar with the locality of the case setting. A favorable expert is one who is active clinically. While it helps to be familiar with current literature, it is very important that they have an understanding of the standards of care during the time period that the case actually took place. Oftentimes, years, and even decades, have passed before a case is filed. Also it is important that experts understand the setting by region and facility and how these factors can impact the evidence of a case.

Obstetric cases stemming from alleged neurologic birth injuries attract a relatively small group of physician experts who testify in a large portion of cases. Many witnesses tend to establish themselves as plaintiff or defendant “friendly” (10). Although specific qualifications can vary from state to state, the American College of Obstetricians and Gynecologists has

Table 1 American College of Obstetricians and Gynecologists Qualifications for the Expert (11)

1	The physician expert witness must have a current, valid, and unrestricted license to practice medicine in the state in which he or she practices
2	The physician expert witness should be currently certified by a board recognized by the American Board of Medical Specialties, as well as by experience or demonstrated competence in the subject of the case
3	The specialty, training, and experience of the physician expert witness should be appropriate to the subject matter in the case
4	The physician expert witness should be familiar with the standard of care provided at the time of the alleged occurrence. In addition, the physician expert witness should have been actively involved in the clinical practice of the specialty or the subject matter of the case within 5 years from the time the expert was retained to provide an expert opinion in the matter
5	The physician expert witness should be able to demonstrate evidence of continuing medical education relevant to the specialty or the subject matter of the case
6	The physician expert should be prepared to document the percentage of time that is involved in serving as an expert witness. In addition, the physician expert should be willing to disclose the amount of fees or compensation obtained for such activities and the total number of times the physician expert has testified for the plaintiff or defendant

offered a guide in an attempt to promote the integrity of the individual expert witness and his professional organization (11). Their recommendations are found in Table 1.

As stated previously, the expert witness who testifies on behalf of both plaintiff and defendant is considered less ethically biased (12). The expert should distinguish maloccurrence from malpractice. Maloccurrence is an adverse outcome unrelated to the quality of care provided, whereas malpractice is substandard care causing harm. It is unethical for a physician expert to accept compensation that is contingent on the outcome of litigation (13).

Additional ethical principles for expert testimony (12) include the following:

1. The physician’s review of medical facts must be thorough, fair, and impartial and must not exclude any relevant information. It must not be biased to create a view favoring the plaintiff, the government, or the defendant. The goal of a physician testifying in any judicial proceeding should be to provide testimony that is complete, objective, and helpful to a just resolution of the proceeding.
2. The physician’s testimony must reflect an evaluation of performance in light of generally accepted standards, neither condemning performance that falls within generally accepted practice standards nor endorsing or condoning performance that falls below these standards. Medical decisions often must be made in the absence of diagnostic and prognostic certainty.
3. The physician must make every effort to assess the relationship of the alleged substandard practice to

the outcome, because deviation from a practice standard is not always substandard care or causally related to a bad outcome.

4. Finally, the physician must be prepared to have testimony given in any judicial proceeding subjected to peer review by an institution or professional organization to which he or she belongs.

When called upon to testify, most physicians bring a high degree of professionalism to the legal process and play a very important role in the administration of justice (13). Unequivocally, a patient injured by genuine medical malpractice deserves due compensation. When true malpractice has occurred, the individual (patient) and society (all of us) will benefit by professional testimony that assists a court in reaching that conclusion (9).

Most physicians desire the best for their patients. More often than not, unfortunate maloccurrence is the nature of an adverse outcome rather than true medical malpractice. Physicians can benefit and avoid litigation by application of the principles of risk management.

SELECTED ASPECTS OF RISK MANAGEMENT

Maloccurrence is defined as a bad or undesirable outcome that is unrelated to the quality of care provided. In some cases, these outcomes are anticipated and unavoidable. In other cases, they are unanticipated yet unavoidable. Fully informed consent goes a long way to preventing litigation in these situations. Malpractice, on the other hand, is essentially the provision of substandard medical care that causes significant harm (12).

Basic risk management principles include listening carefully to patients, documenting their complaints, comments, and responses, as well as timely documentation of how physicians respond both verbally and physically. While this communication and documentation will confer some degree of protection from claims, it remains a basic tenet that errors must be avoided.

Practicing the principles of patient safety minimizes medical errors. Open and extensive communication among caregivers is paramount to this process. It builds trust and respect through such endeavors as team training, structured sign outs, team huddles that anticipate problems, mock drills, and clinical simulations. Significant improvements in the management and outcomes of obstetric emergencies such as shoulder dystocia and hemorrhage have been reported. The concept of full disclosure to patients following adverse outcomes has also been shown to reduce the risk of malpractice claims. Physicians who demonstrate compassion by being available to discuss, answer questions, and importantly apologize as appropriate are less apt to be the target of claims. Still some physicians appear to be prone to lawsuits.

Frequently sued obstetricians demonstrate a pattern of behavior that is fairly predictable. They are often rushed and unavailable. When present, they often are poor communicators and do not take the time to listen or offer pertinent information. They seem unconcerned and show disrespect to their patients. Despite these shortcomings, the outcomes of lawsuits in the setting of these contextual risk factors still seem to favor the lawsuit-prone physicians (14). Although there may be unprofessional behavior, the alleged acts of negligence acts are often not as claimed. They may turn out not breaches

of the standards of care; furthermore, the untoward outcome may be a temporary injury that resolves with minimal effects or no injury at all.

In contrast to cases that result in no payment, the greatest predictor of a professional liability payment to a patient is the severity of outcome, namely an unanticipated death or permanent disability. Being a great communicator, being personable, and being well liked by your patient is very important but does not provide complete immunity from a lawsuit. If there is a significantly bad outcome due to substandard care, and there are appropriate expert plaintiff attorneys and expert witnesses, there is a high likelihood that when litigation does happen, it will rightfully result in favor of the plaintiff.

What can institutions do? Current initiatives to reduce liability via vigorous quality improvement (QI) programs are being developed. QI endeavors can be implemented in solo locations or system-wide entities. A series of "triggers" are identified that when encountered, set off an automatic review by select representatives on the committee. Examples from the field of obstetrics include postpartum hemorrhage, a return to the operating room, and maternal readmission. These reviews are done to identify variables that contribute to adverse outcomes or near misses. Events are deemed avoidable or unavoidable and action items are created. Responsible parties are then tasked with addressing deficiencies and propagating progressive change.

CONCLUSION

In conclusion, we reviewed the four elements of medical malpractice case, the importance of expert witness testimony, the guidelines for integrity and ethical physician expert witness testimony, and some practical aspects of risk management and litigation avoidance.

39 Drug abuse in pregnancy: Marijuana, LSD, cocaine, amphetamines, alcohol, and opiates

Jacquelyn C. Howitt and Anita Publik-Anderson

INTRODUCTION

Most health professionals will at some time encounter the issue of substance abuse in pregnancy, as increasing numbers of pregnant women cope with the aid of illicit drugs or continue established substance abuse patterns despite pregnancy. The drug-abusing population includes women from every portion of society, every ethnic group, and every socioeconomic stratum. In 2007, 19.9 million Americans aged 12 or older were current (past month) drug users; 6.9 million people aged 12 and older were classified as having a dependence on, or abuse of, illicit drugs. Among pregnant women aged 15 to 44 years, 3.9% reported using illicit drugs in the past month (1). Familiarity with drugs of abuse, recognition of the hallmarks and subtleties of drug use, and the ability to be prepared for possible complications of drug use in mother, fetus, and neonate is therefore essential for those caring for pregnant women and their offspring.

Relatively little is known about the direct effects of specific illicit drugs on human pregnancy. Since most women who abuse drugs use more than one drug, studies are rarely "pure." As polydrug use complicates even the best of human studies, and as malnutrition, anemia, and infection are frequently confounding factors, most authors caution against too narrow an interpretation of data regarding the effects of a single drug. Nevertheless, inferences can be drawn from human studies and data extrapolated from animal studies. The following pages contain a review of some of the more common drugs of abuse in pregnancy.

MARIJUANA

Marijuana is the most commonly used illicit drug; its use has increased in reproductive-aged women (1). Delta-9-tetrahydrocannabinol (D9THC) is its main pharmacologically active component. Cannabidiol and cannabiol, other components of marijuana that can affect the metabolism and activity of D9THC, do not possess significant pharmacologic activity of their own (2). The primary site of marijuana metabolism is the liver; the lung also affords some metabolic action (3). The primary metabolite of D9THC (11-hydroxy D9THC), which may also be pharmacologically active, is in turn converted to more polar metabolites that are excreted through bile, feces, and urine (2). Two weeks after the marijuana use, D9THC may still be detected in urine (4). Smoking marijuana leads to rapid onset of drug action (within minutes), yielding effects that usually last less than 2 to 3 hours (3). Marijuana is lipophilic and readily distributed to organs with relatively high blood flow (liver, lung, kidney, spleen). However, the brain, which also has a good blood supply, receives comparatively small amounts of marijuana (2), which accumulates mainly in the gray matter. Physiologic effects of

marijuana use include tachycardia, slight decrease in blood pressure, reddening of the conjunctiva, fine hand tremors, and a modest reduction in muscle strength. Marijuana also possesses analgesic activity, has antiemetic properties, and causes hallucinations in high doses (3). Following marijuana administration, users experience a brief stimulatory phase in which they may become anxious and restless or euphoric. They typically report enhanced perception of the five senses. A period of sedation follows in which users seem to move in and out of a "dream-like" state, during which they have a shortened attention span, an altered sense of time and distance, and impairment of short-term memory.

The placenta can accumulate significant amounts of D9THC. Placental transfer has been documented in monkeys (5), sheep, and mice and rats (2). Maternal administration of D9THC in these animals yields lower concentrations of marijuana in the fetus than in the mother (5).

The actual effect of marijuana use on human pregnancy outcome and on the fetus is controversial. Suggested effects include a higher occurrence of preterm labor and abruptio placentae (6) (possibly dose dependent), an increased risk of precipitous labor (4), an increased risk of abnormal antenatal tests (4), a higher likelihood of meconium staining of amniotic fluid at the time of delivery (4), and an increased risk of prolonged, protracted, or arrested labor (4). Few authors have confirmed the findings of an increased risk of preterm labor or precipitous labor, and the increased incidence of meconium is not a universal finding (7). The incidences of miscarriage, obstetric complications, or major fetal physical anomalies in human pregnancies complicated by marijuana use are the same as those of controls (8). There is no increased risk of perinatal death, nor is there a need for special care of human babies prenatally exposed to inhaled cannabis (9). A consistent relationship between marijuana use and the incidences of premature rupture of membranes, fetal distress, and fetal malposition has not been demonstrated (6). Frequent and regular use of marijuana throughout pregnancy is associated with a detectable, though not statistically significant, decrease in birth weight (9). Fried et al. found no effect of maternal marijuana use on infant weight, length, head circumference, or Apgar scores (8).

A significant amount of research has been done to evaluate the impact of marijuana on brain development, learning, and behavior of the prenatally exposed fetus. Cannabinoid (CB) receptors identified in the white matter of the brain of fetal rats have an influence on early brain development (10) through the expression of dopamine (11), serotonin, and glutamate (12), involving glial cells and axonal linkages and the hypothalamic-pituitary axis (13). In the fetal, neonatal, and adult human

brain, CB receptor-binding sites are found throughout the frontal cortex; there is an increase in receptor binding in developing brains. Rats injected with CB-1 agonists demonstrate learning disruption and changes in emotional reactivity; authors postulate that an impairment in cortical glutamatergic neurotransmission is associated with the observed reduction in cortical neurons and impaired neurite branching (12). Human fetuses exposed in utero to marijuana at 18 to 22 weeks were found to have a significant reduction of the D2 gene expression in the amygdala (11). Decreased D2 mRNA expression in the amygdala (linked to emotional behavior and mood states) provides a possible explanation for observed cognitive and behavioral states of older children exposed in utero to marijuana, according to Wang et al. (11).

Purported neurobehavioral effects following prenatal exposure to marijuana include an increase in fine tremors and exaggerated and prolonged startle responses in newborn infants. These infants may have a poorer habituation response to visual stimuli (8), but they show a normal response to auditory stimuli (5). By 12 and 24 months of age, infants exposed prenatally to marijuana are similar to controls when assessed for visual, mental, motor or language capabilities. At 48 months, memory and verbal parameters of children exposed to more than regular marijuana use are affected, and 3-year-olds also have poorer abstract and visual reasoning (14). Head circumference is negatively impacted at 9 to 12 years of age (14). While there is no uniform decrease in intelligence, certain processes of executive function such as complex visual-perceptual tasks, planning, and attention are affected into adolescence (14).

Although controversy remains about the effects of perinatal marijuana use on pregnancy, research supports a long-lasting effect on the developing brain. This may help guide in counseling the marijuana user about potential effects of in utero exposure. Increased vigilance in the reproductive-aged population is warranted, as marijuana use is so prevalent, concomitant use of other drugs is so common, and self-reporting is often incomplete.

LYSERGIC ACID DIETHYLAMIDE

The hallucinogen lysergic acid diethylamide (LSD) reached its peak popularity in the late 1960s. Since that time, the overall use of LSD has declined dramatically (1,15). After oral administration, LSD is rapidly absorbed into the blood. Physiologic effects in humans are generally sympathomimetic in character: pupillary dilation, an increase in blood pressure, tachycardia, hyperreflexia, piloerection, and increased temperature (3). LSD induces states of altered perception. Initial symptoms, which occur within minutes following ingestion, include dizziness, weakness, nausea, and paresthesias. Within 2 to 3 hours, the user experiences visual illusions and affective symptoms. Within 4 to 5 hours, users may experience major panic attacks or merely feel detached. Drug effects may differ among users as well as with the same person on different occasions. The half-life of LSD is approximately 3 hours and symptoms begin to abate after 12 hours. There is no withdrawal syndrome, and no deaths have been attributed to the direct effects of LSD.

In 1968 and 1969, three case reports suggested human teratogenicity from prenatal LSD exposure. These involved limb

defects, specifically finger abnormalities, and occasionally toe abnormalities of either or both the feet (16,17). In all three reports, each fetus had also been exposed to marijuana. McGlothlin et al. (18) studied the effects of parental LSD exposure and observed an increased risk of spontaneous abortion among women exposed to LSD. Several authors have suggested a causative association between LSD intake and chromosomal damage while others have disputed this correlation (17,19).

COCAINE

Cocaine is a stimulant drug derived from the coca plant, *Erythroxylon coca*. Cocaine use in pregnancy was widely publicized in the 1980s with reports of the urban phenomenon of "crack babies" flooding maternity wards and burdening society. While harm from cocaine to multiple organ systems is clear, and much of the risk in pregnancy is known, there are numerous confounders that make effects directly attributable to cocaine difficult to isolate; the mania of the media blitz may be unfounded (20,21). A retrospective study of 139 cocaine-abusing women revealed concomitant use of other drugs such as alcohol, tobacco, marijuana, diazepam, heroin, and methadone to occur in 92.8% of users (20). Cocaine use has increased, but its use still pales when compared with that of marijuana and alcohol. In the United States, 1.5 million persons over the age of 12 met the criteria for the abuse or dependence of cocaine or crack cocaine over the past year (1).

Cocaine is an alkaloid related to topical anesthetic agents. Hydrochloride can be added to the alkaloid and then heated to yield the free base known as "crack." Cocaine can be sniffed, injected, or smoked as the freebase form. Cocaine causes a "rush" of intense euphoria, which lasts 20 minutes after injection and 60 to 90 minutes following intranasal use. Mood is elevated along with energy and alertness, and the appetite is decreased. When this effect wears off, the user may "crash" and become lethargic, depressed, and somnolent. Finally in an "extinction" phase, an episodic intense craving for the drug will gradually decrease in frequency and severity, but can last months or years after last use (22).

Cocaine blocks the presynaptic reuptake of catecholamines at neuron terminals, which then increases postsynaptic levels of norepinephrine, dopamine, and epinephrine (23). The plasma half-life of cocaine is approximately 40 minutes, and it is then metabolized by the liver, plasma esterases, and the cytochrome P450 enzymes (22,23) and then excreted in the urine. Cocaine can be detected for 8 hours in the urine and its metabolites detected in urine for up to 7 days.

The major physiologic effects of cocaine relate to its sympathomimetic characteristics: hypertension, tachycardia, hyperglycemia, hyperpyrexia, and mydriasis. Coronary vasoconstriction can cause spasm, angina, acute myocardial infarction, arrhythmias, and sudden death. Acute vasoconstriction can cause subarachnoid hemorrhage, ischemic or hemorrhagic stroke (24), and intestinal necrosis (23). Sniffing or snorting cocaine can cause anosmia, chronic rhinitis, septal degeneration, necrosis, and perforation (22). Smoking cocaine can cause direct lung damage, pulmonary edema, spontaneous pneumomediastinum, and pneumopericardium (22). Higher doses of cocaine can cause disinhibition, disturbances in judgment, grandiosity, impulsive behavior, hypersexuality, and paranoid psychosis (22).

Perinatal effects associated with gestational cocaine use are fogged by confounding risk factors such as polysubstance abuse, malnutrition, and lifestyle. Associations include an increase in spontaneous abortions (25,26), preterm premature rupture of membranes (21,27), chorioamnionitis (21), meconium-stained amniotic fluid (20,21), and precipitous labor (21,28). The most commonly cited perinatal effects of prenatal cocaine exposure are prematurity, growth restriction, low birth weight, and placental abruption. Most of these effects are thought to be related to cocaine's vasoconstrictive properties.

In 1983, Acker et al. reported two cases of abruptio placentae associated with cocaine use (29). While other investigators had similar findings (25,26), some of these have low statistical significance and other reports dispute them altogether (27,28,30). In one study, infants whose urine tested cocaine positive (exposure shortly before delivery) had a similar rate of abruptio placentae as infants with cocaine-negative urine (no recent exposure) (21). The rate of abruption in both groups was, however, higher than that of the general population. Several case reports have noted an association of cocaine use and uterine rupture (31–33), thought to be related to the increase in contractile force of the myometrium (34).

Most authors agree that cocaine use increases the likelihood of preterm labor (28,35) and of preterm birth (20,27,28) although there is no significant difference when controlled for polydrug use. While prematurity and low birth weight both increase the risk of intracerebral events, the risk appears to be higher in cocaine-exposed babies, as compared with controls (36). Decreased birth weight (28), low birth weight (LBW) (less than 2500g) (27,28), intrauterine growth retardation (IUGR), and small-for-gestational-age (SGA) infants occur following prenatal cocaine exposure (20,28,35), though there is not a statistically significant difference in IUGR if multiple drugs are used (28). Cocaine use is predictive of low birth weight even when other variables such as age, race, gravidity, socioeconomic status, and lack of prenatal care are controlled (27). The use of other drugs is additive with respect to LBW. Burkett et al. found that the combination of cocaine with tobacco and other drugs, excluding alcohol, had more effect on the incidence of SGA and LBW infants than cocaine alone (21). Zuckerman et al. found the use of marijuana and cocaine to be independently associated with impaired fetal growth (37).

Neonatal effects of cocaine exposure are varied and without a typical presentation. Cocaine has no consistent effect on 5-minute Apgar scores (20,28) or umbilical artery pH values (28). Neonatal neurobehavioral abnormalities include tremulousness, irritability and muscular rigidity, sleeping problems, feeding difficulties, vomiting, diarrhea, fever, hypotonia, a high-pitched cry, tachypnea, hyperreflexia, tachycardia, seizures, and hyperresponsiveness (20). A poor sucking response and neurologic deficits are frequently prominent features in these infants (21). Apneic spells and abnormal pneumograms have been noted (21), and some authors report an increased incidence of sudden infant death syndrome (SIDS) (25) although this association has been debated (38).

Congenital anomalies associated with cocaine exposure have included skull defects (26), urogenital anomalies (39), urinary anomalies without genital defects (40), and congenital cardiovascular defects such as atrial septal defects, ventricular septal defects, cardiomegaly (20), transposition of the great vessels, hypoplastic right heart (26), and polydactyly (21). Many investigators have found no statistical increase in cocaine-induced congenital anomalies (28,30).

Animal studies have been particularly helpful in exploring potential effects of prenatal cocaine use. Woods et al. were able to demonstrate dose-dependent cardiovascular effects in pregnant and fetal sheep following intravenous injection of cocaine (41). The authors suggest that cocaine given to the pregnant ewe may produce fetal hypoxemia via uterine artery vasoconstriction as well as direct fetal cardiovascular effects via transplacental passage of cocaine into the fetal circulation.

Webster and Brown-Woodman administered cocaine to pregnant rats as single or multiple doses, during specified gestational periods, and examined the fetuses at various times for evidence of hemorrhage or malformation (42). They found no evidence of teratogenicity when cocaine was given during the main organogenic period, even at toxic maternal doses. However, when given at later specific gestational ages, cocaine exposure was associated with damage to fetal limbs and tail, and hemorrhage in the genital tubercle. In general, cocaine administration was followed by the occurrence of edema and hemorrhage at certain sites. When involved fetuses were reinspected at a later date, reduction anomalies were identified at these sites. It appears, then, that the malformations are a direct result of hemorrhage and edema, followed by necrosis, and subsequent disruption and/or amputation. The authors postulate that the fetal vasculature must attain a certain degree of maturation prior to being able to respond to hypoxia, thereby protecting developing tissues during organogenesis.

Other investigators have been particularly interested in neurobehavioral effects of prenatal cocaine exposure. Spear et al. found that cocaine-exposed rat offspring had cognitive defects in some, but not all, conditioning situations (43). These authors have offered the suggestion, based on their work in the animal model, that chronic exposure to cocaine during gestation results in downregulation of dopaminergic systems, conferring later hyperactivity and attention deficit disorders. Fetal cocaine exposure during synaptogenesis, even at doses well below maternal toxicity, results in long-term changes in the neurochemistry of dopaminergic systems (44). The exact duration of those changes and the impact is still not fully understood.

AMPHETAMINES

Use of methamphetamine (MA) and its derivatives increased significantly in the 1990s. Approximately 10.4 million (4.3%) of the adult population in the United States reported at least one-time use (1). The Infant Development, Environment, and Lifestyle study reported a 5% use rate in pregnant women (45).

MA, the most popular amphetamine, can be smoked, snorted, injected, orally ingested, or administered anally. Smoking and injection allow rapid uptake of the drug into the brain, and the user experiences a "rush" that lasts only a few minutes. Snorting and ingestion produce euphoria, which lasts longer. Amphetamines stimulate the release of

neurotransmitters and interfere with their reuptake at the nerve terminal (3,46). The catecholamine excess accounts for amphetamine's peripheral alpha and beta actions and central nervous system (CNS) stimulant effects of vasoconstriction and bronchodilation, increased systolic and diastolic blood pressures, and an increased respiratory rate. An enhanced perception of environmental stimuli, mood elevation, and a decrease in hunger and fatigue are thought to result from amphetamine's ability to stimulate the reticular activating system. High doses of amphetamines can cause hypertension, retinal damage, cardiac seizures, stroke, and death. Chronic use can lead to anxiety, insomnia, hallucinations, confusion, psychosis headache, pallor or flushing, palpitations, blood pressure instability, and cardiac arrhythmias (3).

"Designer drugs," synthetic analogs, and amphetamine derivatives, which share many of the effects of the parent drugs, are powerful psychostimulants with often unpredictable side effects. Illegal manufacturing of these derivative drugs may involve the inclusion of contaminants, which may pose further dangers.

Most investigators who have studied antenatal amphetamine abuse have found polydrug abuse to be the norm (47,48). Because of the confounding effects of multiple drugs, the possibility of drug impurities, malnutrition, and psychosocial environments, it has been difficult to isolate adverse perinatal and pediatric effects attributable to amphetamine use during pregnancy. Amphetamines cross the placenta and directly affect the fetus. In sheep studies, MA was found to cross the placenta, with resulting fetal drug levels equilibrating with maternal levels within 20 minutes (49).

Amphetamine use during pregnancy has inconsistently been associated with preterm delivery (47,48,50) and inconsistently associated with an increase in congenital heart defects and cleft lip (51). Findings of altered growth parameters including SGA (50), overall smaller birth weights and birth lengths, and smaller head circumferences (47) occur more consistently. Infant withdrawal symptoms have been reported (50). Because amphetamines directly affect the monoaminergic systems of the brain, it has been postulated that amphetamines are capable of causing long-term CNS changes to the developing fetus (46). In a prospective study of children who had been prenatally exposed to amphetamine, Eriksson et al. found the children to exhibit normal physical health parameters (including growth) and normal IQs, but they show a statistically significant increase in aggressive behavior, peer-related problems, and an increased risk of learning disabilities lasting into school ages (48).

ALCOHOL

Alcohol use in pregnancy may well be the largest preventable cause of birth defects and developmental disorders. Alcohol use is prevalent around the world; moderate use during pregnancy was accepted behavior until very recently. In the past, intravenous drips of alcohol were even prescribed as a tocolytic for preterm contractions. Controversy exists today on the topic of what constitutes a "safe" amount of alcohol in pregnancy. In 1981, the U.S. Surgeon General recommended that pregnant women "limit the amount of alcohol they drink." This warning was updated in 2005 to the following:

"No amount of alcohol consumption can be considered safe during pregnancy. Alcohol can damage a fetus at any stage of pregnancy," and "The cognitive deficits and behavioral problems resulting from prenatal alcohol exposure are lifelong" (52). Despite warnings from the Surgeon General and massive public health campaigns, alcohol use during pregnancy continues to be a common problem. More than 1 in 5 pregnant women report alcohol use in the first trimester, 1 in 14 consume alcohol in the second trimester, and 1 in 20 in the third trimester (53). One in 30 pregnant women report high-risk drinking, defined as seven or more drinks a week or five or more drinks on any one occasion. One in nine pregnant women binge-drink in the first 3 months of pregnancy; 8.8% of pregnant women aged 15 to 17 and 3.8% of pregnant 26- to 44-year-olds report binge-drinking (54). Alcohol use in pregnancy is also found more frequently in women who are unmarried, over 30 years old, with a higher parity, and with co-use of tobacco and other substances (1,54). Alcohol use and abuse include every ethnic group, every socioeconomic strata, every age group. The most well-known screen for alcohol use is the CAGE (Cut-down, Annoyed, Guilty, Eye-opener) questionnaire (55), which has a sensitivity of 75% in women, but does not assess tolerance. The TWEAK (Tolerance, Worried, Eye-openers, Amnesia, Cut-down) scale, with an 87% sensitivity in women, was developed as a screen for risk-drinking in pregnancy (56).

Alcohol, a small molecule that is readily absorbed from the gastrointestinal tract and distributed throughout the body, is oxidized in the liver by the enzyme alcohol dehydrogenase (3) and metabolized to acetaldehyde, acetate, and then to acetyl coenzyme A. It is further oxidized via the citric acid cycle or is utilized in various anaerobic reactions. Metabolism of alcohol results in increased production of lactate and fatty acids. The consumption of excessive alcohol can result in hypertension, slurred speech, staggering gait, ketoacidosis, myopathy, hepatomegaly, pancreatitis, other upper gastrointestinal disorders, malabsorption and vitamin deficiencies, mood swings, memory lapses, blackouts, other neurobehavioral disorders, hematologic disorders, and cardiac dysfunction (3,57). Evaluation of complete blood count, red blood cell indices, liver function tests, and urine assessment for ketones is recommended.

Ethanol readily crosses the placenta and can interfere with active transport of amino acids across the placenta (58). Acetaldehyde is also a mutagen and is also capable of altering placental transport of nutrients (57).

Perinatal effects associated with alcohol consumption include an increased risk of spontaneous abortion (57), stillbirth (59), lower birth weight (60,61), and IUGR (62). Because alcohol use is associated with many comorbidities, it is difficult to interpret the data. For example, the occurrence of decreased birth weight is not always statistically significant when results are controlled for smoking (59). Also the IUGR infants are born to those classified as heavy drinkers as opposed to the occasional or moderate drinkers (58). Indeed, the evidence is inconsistent when low-to-moderate use of alcohol is considered. A review article revealed that small amounts of alcohol may have a paradoxically protective effect on outcomes such as stillbirth, IUGR, and birth weight (63). The amount and timing of drinking seem to be important too. Women with three or more binge episodes had an increased

risk of stillbirth, but there was no effect on fetal survival if alcohol intake is low (64). There is a statistically weak association with heavy alcohol use and fetal distress, placental abruption, and 5-minute Apgar scores of less than 6 (59). Antenatal testing may also be affected by alcohol as seen in a transient effect on fetal heart rate (FHR) reactivity (65). Fetal breathing may also be affected for up to 3 hours after alcohol ingestion, according to McLeod et al., but this change does not coincide with the changes in fetal movement or FHR (66).

In 1968, Lemoine, a French pediatrician, published his observations of children whose mothers drank heavily (67). These children displayed characteristic craniofacial abnormalities, growth retardation, and delayed psychomotor maturation. In 1973, Jones and Smith coined the term "fetal alcohol syndrome" (FAS) (68). FAS is characterized by maternal exposure to alcohol, prenatal and/or postnatal growth retardation (weight, length, <10th percentile), CNS involvement (deficient brain growth, structural abnormalities, microcephaly, signs of neurologic abnormality, developmental delay, or intellectual delay), and characteristic facial dysmorphism (microcephaly, microphthalmia and/or short palpebral fissures, poorly developed philtrum, or flattening of the maxillary area). Neonatal features associated with heavy prenatal alcohol exposure include cardiac abnormalities, neonatal irritability and hypotonia, hyperactivity, genitourinary abnormalities, skeletal and muscular abnormalities, ocular problems, or hemangiomas (57).

Fetal effects from alcohol are now considered to fall within a larger diagnostic category of alcohol-related birth defects (ARBD). A minority of exposed children will qualify as having FAS; most will fall into the spectrum of disorders. Birth prevalence of FAS ranges from 0.2 to 2.0 per 1000 live births in the United States with a higher incidence in certain groups (e.g., up to 9 per 1000 live births found in certain Native American groups) (54).

In a 10-year follow-up study of FAS infants in Germany, most children identified as having FAS had persistent features into adolescence (69). Growth deficiency and mental and developmental retardation persisted in patients with mild-to-moderate FAS. Children with FAS and ARBD display a large range of mental abilities in both IQ values and in the extent of developmental disability (69). In an Italian study, children diagnosed with FAS had deficiencies in nonverbal and abstract reasoning, language comprehension, and displayed greater levels of inattention and hyperactivity than their peers (70).

Certain progenitor cells that give rise to craniofacial structures are especially vulnerable in the first trimester (71). According to Sulik et al., craniofacial malformations may be caused by abnormal development of the neural plate and its derivatives, suggesting that the time of critical exposure is at approximately the third week of human gestation (Fig. 1) (72). Mice studies of alcohol have shown that a single exposure of alcohol to the developing brain can cause neuroapoptosis. Prolonged high blood levels of alcohol can cause neuronal loss on a massive scale (71). The combination of alcohol and CBs appears to be especially toxic, with disseminated and severe neuronal degeneration after exposure to mildly toxic ethanol doses (73). Peak vulnerability in humans to ethanol-induced neuroapoptosis is in the last half of gestation, with effects lasting to several years after birth (71).

Figure 1 A and B Fetal alcohol syndrome in children. C and D Fourteen-day-old mouse fetuses from ethanol-treated and control mothers, respectively.

OPIATES

Opiates act by binding to various endogenous opioid receptors, activating euphorogenic effects. After opioid injection, a user experiences warmth and flushing of the skin and sensations described as orgasmic (3,74). Physical dependence and tolerance can develop with regular use, leading the addict to increase doses to get the desired effects.

Opioid overdose causes stupor, a decrease in body temperature, flaccid muscles, eventually coma, convulsions, and cardiorespiratory arrest (74). Opioid withdrawal, on the other hand, is marked by dilated pupils, irritability and restlessness, insomnia, anorexia, tachycardia, weakness, depression, nausea, vomiting, stomach and muscular cramps, muscle twitching, "gooseflesh," chills, hypertension and tachycardia, tearing, rhinorrhea, and yawning. Withdrawal, though distinctly uncomfortable, is usually not life-threatening (3). Opioid abuse in pregnancy has both direct and indirect effects on the fetus. There is a direct opiate effect due to the transplacental passage of opiates, while indirect effects are a result of related maternal malnutrition or infection, and other sequelae of polydrug abuse and high-risk behaviors. For example, heroin addicts have higher rates of infections, including sexually transmitted diseases (75,76); intravenous drug use increases the risk of contracting such diseases as HIV and hepatitis (76). Opiates readily cross the placenta and have been identified in

amniotic fluid, umbilical cord blood, neonatal urine, and meconium (76).

In the pregnant abuser, withdrawal may be marked by uterine irritability and increased fetal activity, which may precede other maternal withdrawal symptoms. Perinatal risks of opiate abuse include spontaneous abortion, stillbirth (75), abruptio placentae (76), preterm birth (75,77), low birth weight (77–79), smaller head circumference (78,79), and low birth length (77–79), although birth lengths are similar when controlled for smoking and maternal weight gain, according to at least one author (78). At the ages of 12, 18, 24, and 36 months, short stature was not more prevalent among the infants of opiate addicts (78,79). Likewise, infant weights at 12 through 24 months of age did not differ from those of controls (79). Teratogenic effects following opiate abuse have not been reported (75,80). Dispute remains in regard to respiratory distress syndrome occurring less frequently in the opiate-addicted neonate (75). There is a reported increased risk of SIDS in infants prenatally exposed to opiates (81,82).

As many as 90% of newborns of opiate addicts will demonstrate some degree of postnatal withdrawal (74). Signs and symptoms of neonatal heroin withdrawal, which typically appear 24 to 48 hours after birth, are hyperactivity, irritability, tremors, convulsions, persistent high-pitched crying, hypertonia alternating with periods of hypotonia, gastrointestinal dysfunction, respiratory distress, sneezing, sweating, tearing, mottling, and fever (74). Untreated infants with neonatal abstinence risk death from respiratory depression.

Methadone maintenance has been the gold standard for treatment of pregnant opiate addict since the 1970s. Methadone is a synthetic mu receptor agonist that blocks the euphoric effects of heroin, decreases the cravings for heroin, and prevents the symptoms of withdrawal. Methadone programs in pregnancy offer several advantages over no treatment. Methadone-maintained women have more prenatal visits and less anemia than other drug abusers (80,83); and methadone can reduce the use of nonprescribed opiates and of related criminal behavior (84). Methadone also has the advantage of providing a more steady concentration of drug, the advantage of which is prevention of recurrent fetal withdrawals.

Methadone for the treatment of opiate abuse is highly regulated: it must be administered at a specially licensed facility. Patients typically present weekly to get their medication, which is usually in the range of 60 to 150 mg. (In pregnancy, the lowest dose possible to prevent withdrawal symptoms is recommended.) Methadone is usually taken orally and has a half-life of 24 to 36 hours. It has a long duration of action and extensive, nonspecific tissue binding. Peak plasma levels occur about 4 hours after the ingestion of a maintenance dose (74). Metabolism occurs primarily in the liver, and methadone is excreted in feces and urine (85). Both the placenta and the fetus can further metabolize methadone (85). Neonatal withdrawal from methadone may be more severe than that from other opiates (83), may be prolonged (80,83), and may not occur until 2 to 4 weeks after birth.

It has been suggested by some investigators that fetal opiate withdrawal may be causally related to hypoxia and to meconium passage in utero. Substantiating this idea is the increased incidence of meconium-stained fluid during

labor (75). An increased likelihood of shortened gestation has been reported (75), though the clinical significance of 0.6 weeks (77) is questionable. A decrease in frequency of fetal movements and FHR accelerations after methadone ingestion has been reported (86). In a retrospective study of 30 infants of drug-abusing mothers with birth weights less than 1500g (of which 15 were infants of methadone addicts), and matched drug-free controls, a lesser probability of intraventricular hemorrhage (IVH) was noted in infants having had prenatal opiate exposure as compared with infants of drug-free women with similar risk factors (87). This suggests that gestational opiate exposure may actually offer protection against IVH in these very small infants. In a study by Edelin et al., rates of occurrence of LBW (birth weights less than 2500g) were similar in the methadone group and the polydrug group (29.6% and 34% respectively), but they differed significantly from the rates in drug-free controls (16.7%) (83). This finding has been confirmed by others (80).

Newborn infants of opiate addicts often exhibit neurobehavioral abnormalities (79,88). It has been postulated that downregulation of opiate receptors in the fetus exposed prenatally to opiates is a likely mechanism of these neurobehavioral changes. Methadone-exposed infants are more likely than infants without opiate exposure to have affected motor behaviors at 1 day and at 1 month of age, demonstrating hypertonia, tremulousness, and jerky movements (88). These abnormalities may persist. At 1 year of age, fine motor coordination of methadone-exposed infants is significantly less than that of drug-free controls (80). As young children, those exposed to prenatal methadone may be hyperactive, with difficulty in fine motor coordination and with difficulties relating socially (88).

Data from studies of methadone exposure in the rat tend to support clinical findings. Rat pups perinatally exposed to methadone demonstrate behavioral changes also in that they are abnormally slow to respond to hot-plate stimulation (89). Prenatal methadone exposure in the rat leads to downregulation of opioid receptors in the cerebral cortex and hypothalamus and to a decrease in alpha-adrenergic receptors in the cerebral cortex (90).

Buprenorphine is a partial mu-opioid agonist and kappa antagonist, which was approved for the treatment of nonpregnant, opioid-dependent adults in 2002. Buprenorphine is labeled as an FDA pregnancy category C drug (91). Buprenorphine also crosses the placenta, but possibly to a lesser degree than does methadone (92). Data are limited on its use in detoxification and maintenance therapy in pregnant women, but it appears that buprenorphine may offer some advantages over methadone for prenatal opioid management. Buprenorphine, in contrast to methadone, can be prescribed by physicians who meet specific certification requirements, such as the completion of a training course, thereby potentially increasing access and treatment availability for the opiate dependent (91). Dosing of buprenorphine depends on the type of opioid used and the stage of treatment (91). No statistically significant differences in Apgar scores, in occurrence of neonatal abstinence (requiring treatment), or in the dose of morphine required to manage neonatal withdrawal, were apparent in a Cochrane review of available studies in which outcomes following buprenorphine therapy

were compared with outcomes in pregnancies involving methadone treatment (93).

The care of the pregnant opioid abuser during labor can be quite complicated. Specific recommendations include continuation of usual maintenance doses of methadone or buprenorphine in labor. (Methadone is used only to prevent withdrawal; it will not provide adequate analgesia.) Methadone or other opiates (e.g., morphine) should be given when evidence of maternal withdrawal exists. Agonist-antagonist combinations should not be given, as they will provoke withdrawal. Similarly, naloxone should not be given to infants of opiate addicts in the delivery room, as it may provoke neonatal withdrawal.

40 Tobacco and alcohol use during pregnancy

Beth A. Bailey and Robert J. Sokol

INTRODUCTION

Substance use, including the most common behaviors of smoking and drinking, is a major health issue for women, regardless of age and reproductive or pregnancy status. Health risks to women can be substantial, and during pregnancy, these risks are shared with the developing fetus. Even with the recognition of the adverse impact of these substances on maternal and fetal health, obstetric clinicians, many of us who might be said to have “surgical personalities,” often have difficulty dealing effectively with these “behavioral medicine” issues. Our goal in this concise chapter is to highlight the magnitude of the problems these substances pose during pregnancy and the adverse consequences of the use of these substances on the mother and the offspring, briefly noting some plausible mechanisms for effect. We then turn our attention to the practical issues of how to identify pregnant women who are smoking or consuming alcohol and how to help her make changes in her behavior to benefit both her own health and that of her unborn child.

EPIDEMIOLOGY

Cigarettes

Nationally, approximately 11% to 13% of women report smoking throughout pregnancy (1,2). However, rates of pregnancy smoking vary considerably by region. For example, many Southern states have rates of pregnancy smoking near 20% (2), with rural regions seeing rates from 30% to 40% (3–5).

Smoking during pregnancy can occur in any subpopulation; however, certain women are statistically more likely to smoke while pregnant. Research has revealed that white women are significantly more likely to smoke during pregnancy than their African-American or Hispanic counterparts (1,6). Additionally, women who live in poverty, who have lower levels of education, and who receive Medicaid are more likely to be pregnancy smokers than other women (6–8).

Alcohol

Each year in the United States, approximately half a million pregnant women are thought to drink alcohol (9). This translates into a prevalence rate of nearly 13% and is consistent with the more than 10% of pregnant women who reported current alcohol use as part of the 2002 Behavioral Risk Factor Surveillance Survey (10) and the 15% to 20% identified in a large-scale study conducted more than 15 years ago (11). While estimates vary, anywhere from 2% to 6% of women engage in heavy, frequent, or binge-drinking while pregnant (9,10,12).

Drinking during pregnancy occurs across diverse populations and sociodemographic conditions. However, certain racial groups see higher rates of pregnancy drinking, including African-Americans and American Indians/Alaskan

Natives (13). Additionally, women over the age of 30, those who are unmarried, and those who have lower incomes are also at a statistically increased risk of pregnancy alcohol consumption (14). Finally, smoking and drinking often go hand in hand during pregnancy. Women who smoke more than half a pack of cigarettes per day during pregnancy are more than twice as likely as nonsmokers to consume alcohol (38% vs. 17%) (14).

ETIOLOGY AND PATHOPHYSIOLOGY

Cigarettes

A significant amount of evidence has accumulated documenting the deleterious effects of pregnancy smoking. The potential short- and long-term effects for the mother have been well reported and include significantly increased risk of respiratory, cardiovascular, and cancer-related diseases. The potential for harmful fetal effects is also profound. Tobacco use in pregnancy is associated with significantly increased rates of pregnancy complications and adverse birth outcomes (15). Ectopic pregnancy, placenta previa and abruption, stillbirth, premature rupture of membranes, and intrauterine growth restriction have all been associated with gestational exposure to cigarettes (16–19). For a smoke-exposed fetus that survives to delivery, the increased likelihood of low birth weight and preterm birth is substantial, with risk increasing with the number of cigarettes smoked per day (6,20). Nationally, smoking accounts for 20% to 30% of all low birth weight births (20), and research indicates that infants born to women who smoke are 200 to 300g lighter than those born to nonsmokers (4,21). Smoking in pregnancy also nearly doubles the risk of preterm birth (22,23), producing a significant economic cost through neonatal intensive care unit (NICU) admission and treatment. Indeed, babies born to smokers are twice as likely to be admitted to the NICU as those born to nonsmokers (4). Smoke-exposed newborns have an increased risk for respiratory dysfunction, intraventricular hemorrhage, necrotizing enterocolitis, and retinopathy (15). Finally, an increased likelihood of infant mortality is associated with heavy pregnancy smoking, with exposure accounting for 5% of perinatal deaths (24).

Prenatal exposure to cigarettes has also been shown to have long-term developmental consequences. Physical health effects well into childhood include growth restriction, abnormal neuromotor tone, increases in respiratory infections, asthma, otitis media, and obesity (25–30). Long-term effects on cognitive development, including learning problems and delayed academic achievement, have also been reported (31–33). Finally, prenatal exposure to cigarettes has been implicated in significantly increased rates of behavioral and mental health problems, including attention deficit hyperactivity disorder, conduct disorders,

depressive and anxiety disorders, criminal behavior, and substance use, abuse, and dependence (34–44).

While not yet completely understood, the mechanisms by which maternal smoking leads to fetal harm and longer term developmental problems have been explored in both animal and human models. The most often cited compounds in cigarettes known to cause harm to the fetus are nicotine, carbon monoxide, and cyanide. Cyanide has been shown, in multiple studies, to be harmful to rapidly dividing cells (45). Carbon monoxide combines with hemoglobin to produce carboxyhemoglobin thus lowering blood oxygen tension and likely contributing to fetal hypoxia (46). In addition, nicotine and carbon monoxide both reduce placental blood flow, impacting fetal growth. A recent study suggested that maternal smoking leads to decreased concentrations of fetal insulin, insulin-like growth factor (IGF), and IGF binding protein, which all may be involved in the pathway by which prenatal cigarette exposure impacts development (47). Thus, both hypoxia and chemicals responsible for growth may be responsible for cell death, structural alterations, and consequent delayed development when prenatal cigarette exposure occurs. Still other studies have focused on the potential impact of nicotine on the developing nervous and neurochemical systems (48). Fetal exposure to smoking, and nicotine in particular, has been proposed to impact serotonin uptake, changes in dopaminergic systems, and changes in DNA and RNA synthesis in the brain during critical developmental periods (49,50). Any one of these potential pathways could impact both structural and functional development, leading to the negative outcomes that have been observed in children exposed to smoking during gestation (51). However, further study is needed.

Alcohol

It has been four decades since the characteristics of children born to women who consumed alcohol during pregnancy were described in the medical literature (52). The term “fetal alcohol syndrome” (FAS) describes children with prenatal alcohol exposure and resultant growth restriction, central nervous system/neurodevelopmental delays, and facial malformations. In addition to typical or classic FAS, terms such as “alcohol-related neurodevelopmental disorder” and “fetal alcohol spectrum disorder” characterize a range of problems associated with prenatal alcohol exposure (53). Research has clearly documented the adverse outcomes associated with alcohol exposure during gestation. Full FAS is characterized by prenatal and postnatal growth deficiency, including reduced overall height and microcephaly, and being born small for gestational age with little catch-up seen into childhood; specific facial dysmorphology including long smooth philtrum, thin upper lip, midfacial hypoplasia, small eyes, and inner epicanthal folds; and central nervous system and neurodevelopmental abnormalities including decreased cognitive abilities (52,53).

Even in the absence of diagnosable FAS, alcohol consumption during pregnancy increases the risk of poor outcomes in children. Prenatal alcohol consumption is a strong predictor of low birth weight. Early studies clearly identified a link between even moderate consumption and low birth weight (54), and recent large-scale studies have reported strong associations between exposure and birth weight (55). Consuming one or more drinks

per day was associated with a fivefold increase in the likelihood of a low-birth weight delivery (56), while three or more drinks per week were associated with a nearly 150-g reduction in birth weight (57). Recent evidence suggests that some of the lowered birth weight associated with pregnancy alcohol consumption is accounted for by an increased risk of preterm birth. One or more drinks per day have been found to more than double the risk of preterm birth (56). Even lesser levels of consumption have been linked to 10-fold or more increases in the risk of extreme preterm birth (prior to 32 weeks of gestation) (58). Mild prematurity was also linked to pregnancy alcohol consumption, particularly in women over the age of 30 (58).

The link between prenatal alcohol exposure and low birth weight and preterm birth is of significant consequence as these are leading causes of neonatal morbidity and mortality in the United States and the strongest biologic predictors of immediate and long-term developmental outcomes (59). In addition to the pathway through birth weight and gestational age, gestational alcohol exposure, even in the absence of full FAS, appears to independently impact a multitude of outcomes into childhood. Continued growth restriction, delays in gross and fine motor development, and impairments in visual motor integration have all been reported (30,60–62). Decreases in overall cognitive performance and general intelligence quotient scores have been associated with even moderate levels of prenatal alcohol exposure (63), in addition to specific deficits including slowed mental processing (64), delayed language and reading abilities (65,66), and increased learning problems (63). Studies have shown that children with prenatal alcohol exposure have problems with organizing and maintaining attention, and with impulsivity (67). Behavioral problems, including hyperactivity and delinquent behavior, have also been reported (68,69). Finally, long-term studies have described associations between prenatal alcohol exposure and many specific psychiatric disorders (70).

The mechanism by which prenatal exposure to alcohol leads to adverse pregnancy, newborn, and longer term developmental outcomes is not yet thoroughly understood. As has been recently reviewed, neuroimaging studies have shown overall and region-specific surface area and volumetric reductions, structural alterations, and white and gray matter density abnormalities (71). These alterations could all be involved in the physical and neurobehavioral effects of exposure. In addition, both animal and human studies have suggested that exposure to alcohol during gestation may cause hypothalamic–pituitary–adrenal (HPA) axis hyperactivity, thereby leading to significant adverse cognitive and behavioral outcomes (72). Furthermore, animal models have shown alcohol intake to decrease blood flow to the placenta, impacting cell growth and death (73). Finally, alcohol consumption increases the production of prostaglandins during pregnancy (74), resulting in decreased cell division (75). Any one, or a combination of these processes, could explain the mechanism by which prenatal alcohol exposure impacts development and outcomes, but further study is clearly needed.

DIAGNOSIS

Cigarettes

In a 2000 bulletin (updated in 2005), the American College of Obstetricians and Gynecologists (ACOG) recommended

screening all pregnant women for smoking (76). Recent reports suggest that prenatal care providers vary widely in rates of screening all pregnant patients for smoking. For example, one study found that 98% of Ohio obstetricians reported asking all patients about smoking (77), while another study found that only 28% of obstetricians in rural southern Appalachia reported always asking (78). Reasons providers have given for failure to screen for pregnancy smoking have included lack of time, other issues taking priority, lack of confidence in skills, lack of referral sources, and beliefs that attempts to intervene will not be successful (77,78).

The most common method of determining smoking status during pregnancy has been via self-report, either by oral or written questioning. Self-report data have the advantage of being inexpensive and easy to collect, with responses immediately available (79), and a handful of studies involving pregnant women have suggested that self-reported smoking status is accurate (80,81). Others have suggested, however, that self-report of smoking status during pregnancy is unreliable and results in significant misclassification and underestimation of prevalence rates (82). An examination of the numerous studies that have investigated the association between self-report of pregnancy smoking status and biochemical verification has revealed false denial or deception rates as low as 1% and as high as 35%. A recent review of this literature concluded that measuring smoking status during pregnancy by self-report alone significantly underestimates smoking rates and misclassifies a significant proportion of women (79).

Several factors likely contribute to inaccuracies in self-report of smoking status during pregnancy, including faulty recall and intentional deception (79). As greater attention is given to the health effects of smoking, both in general and during pregnancy, and as efforts to regulate and reduce smoking increase, smoking becomes stigmatized and individuals are sensitized to socially desirable forms of behavior (83). As this occurs, it is likely that concealment of smoking during pregnancy in particular may increase (84). Multiple studies have shown that many factors may help reduce false denial of smoking among pregnant women, including appropriate wording, timing, and setting of inquiries of smoking status (85,86). For example, we know that the use of a structured multiple choice format in a private confidential setting may increase disclosure (87). Indeed, studies have shown that use of a five-response choice question (Box 1) increases disclosure over asking "Do you smoke?" by 40% (87).

Given the drawbacks of self-report, determination of pregnancy smoking status in both clinical and research settings often relies on biochemical assessment. Cotinine, a major metabolite of nicotine, is a commonly used biomarker of exposure to tobacco smoke, and cotinine levels in saliva, blood, and urine are often considered the best measure of nicotine consumption (88). Compared with self-report, cotinine levels have been shown to be more accurate indicators of smoking (79) and to be better predictors of pregnancy outcomes (89). Biochemical assessment of smoking behavior is not without limitations, however (83). In addition to the factors of cost and inconvenience, acceptance of appropriately sensitive and specific cutoff points is far from universal. Varying cotinine cutoff levels

Box 1 Pregnancy Smoking Screening Question

- Please choose the response that best describes your smoking
- (A) I have *never* smoked or I have smoked fewer than 100 cigarettes in my lifetime
 - (B) I stopped smoking *before* I found out I was pregnant, and I am not smoking now
 - (C) I stopped smoking *after* I found out I was pregnant, and I am not smoking now
 - (D) I smoke some now, but I *cut down* on the number of cigarettes I smoke since I found out I was pregnant
 - (E) I smoke regularly now, about the *same* as before I found out I was pregnant

If the patient responds A, no further follow-up is needed
 If the patient responds B or C, reinforce her decision to quit, congratulate her on the success of quitting, and encourage her to remain smoke free
 If the patient responds D or E, she should be classified as a smoker. Document and intervene

Source: From Ref. 87.

have been proposed to distinguish smokers from nonsmokers and from those exposed to environmental tobacco smoke (ETS) (90–92). Given varying cut-point recommendations, the use of biochemical assessment may not ever be completely accurate in distinguishing those who smoke, especially intermittently, from those who are only exposed to ETS (93). Thus, using both self-report and biochemical assessment is likely to yield the most accurate information about pregnancy smoking status.

Alcohol

For many years, ACOG has consistently advised clinicians to question all pregnant women at their first prenatal visit about current and past alcohol use (94). A recent survey of more than 600 practicing ACOG members revealed that over 90% asked all women at their first prenatal visit about alcohol use (95). Barriers noted by those who failed to routinely screen prenatal patients for alcohol use included time limitations, patient sensitivity, lack of confidence in skills, and inadequate referral sources.

Even when providers do assess pregnancy alcohol consumption, detection is complicated by many of the same factors that impact the determination of smoking status. Pregnancy alcohol consumption has also become increasingly stigmatized as public awareness of the dangers has increased, leading to the potential for high rates of denial via self-report (96). In addition, and unlike biochemical assessment of smoking status, no reliable biologic marker is available to reveal alcohol use. Although analysis of both meconium and hair samples for fatty acid ethyl esters has been proposed, neither would practically detect alcohol use during pregnancy, and no large population-based studies have validated these methods (97). Similarly, other biochemical markers, such as ethanol metabolites, that reveal only very recent use have not yet been well validated or have not been shown to have adequate diagnostic sensitivity and/or specificity in identifying drinking in pregnant women (98). Thus, most researchers and physicians rely on self-report of maternal alcohol use during pregnancy (53).

Box 2 T-ACE Screening Tool for Pregnancy Risk Drinking^a*Tolerance*

“How many drinks does it take to make you feel high?”

A positive answer, scored a 2, is more than two cans of beer, two glasses of wine, or two mixed drinks. This suggests tolerance of alcohol and very likely a history of at least moderate-to-heavy alcohol intake

Annoyed

“Have people annoyed you by criticizing your drinking?”

Cut Down

“Have you felt you ought to cut down on your drinking?”

Eye-Opener

“Have you ever had a drink first thing in the morning to steady your nerves or get rid of a hangover?”

^aThe first question is scored 0 or 2 points. The last three questions are scored 1 point if answered affirmatively. A total score of 2 or more is considered positive for risk drinking. *Source:* From Ref. 100.

Studies indicate that obstetricians often obtain inaccurate alcohol consumption information from their patients. For example, in a prospective study that included high-risk women, almost twice as many admitted to drinking during a research interview compared with indications from maternal medical records (99). While tools are available to assist prenatal care providers in accurately identifying women who consume alcohol during pregnancy, a recent study revealed that fewer than one quarter who screen for pregnancy alcohol consumption use a standardized screening tool (95). The T-ACE, a modification of a traditional alcohol screening test, the CAGE, but specifically adapted for use before and during pregnancy, consists of four questions that may be asked as part of the medical history by physicians or office personnel (Box 2) (100). It typically identifies 90% or more of potential pregnancy risk drinkers, and follow-up questions can rule out false positives (101). The CAGE, also a four-item scale commonly used in obstetric practices, was developed for and validated with men and has not been shown to be valid with pregnant women (100). The TWEAK, a five-item scale, was developed for and validated with pregnant women (102). However, this tool appears to have lower sensitivity for detection of drinking among minority women and has no additional validity over the T-ACE. The AUDIT-C is a three-item scale to screen for alcohol use during pregnancy, rather than consequences of use as queried in the previously described screens. While this tool includes assessment of quantity and pattern of alcohol use, and initial data suggest good sensitivity across different samples, additional validation of the AUDIT-C is needed. Consequently, ACOG and the National Institute on Alcohol Abuse and Alcoholism have both recommended the T-ACE as the best tool for screening all reproductive-aged women and pregnant women specifically for alcohol use.

MANAGEMENT**Cigarettes**

Addressing cigarette exposure with pregnant smokers should be a top priority for all prenatal care providers, as research has shown that when women quit smoking during pregnancy, the risk of adverse outcomes is nearly reduced to levels experienced by nonsmokers (103). Furthermore, growing

Box 3 The 5 A's Intervention for Pregnant Smokers*Ask*

Tobacco status is queried with a multiple-choice question format and answers are documented in the patient chart

Advise

Urge all tobacco users to quit in a clear, strong, personalized manner. Discuss the benefits of quitting including the potential harms of smoking to the fetus and the long-term health consequences of the mother. Provide pregnancy-specific educational materials

Assess

Determine the patient's willingness to quit in the next 30 days and encourage the patient to minimize exposure to secondhand smoke. If the patient declines smoking cessation or is ambivalent, work to increase the patient's motivation to quit

Assist

Provide aid for the patient to quit. Set a quit date. Provide counseling with skills building, pregnancy-specific self-help and smoking cessation materials, and social support. Develop a contract to quit smoking. Encourage a patient diary to record successes, problems, and triggers. Discuss alternate behaviors, potential problem situations, and how to handle slipups

Arrange

Provide follow-up contact, either in person or by telephone soon after the quit date, and further follow-up encounters as needed. Congratulate success during each visit. Review circumstances if relapse occurred and use it as a learning experience for the patient. Consider referral or more intensive treatment. Begin postpartum relapse prevention counseling late in pregnancy

Source: From Ref. 108.

evidence suggests that clinically proven interventions can lead to significant successes in smoking cessation (104). Increasingly, obstetric providers are implementing brief interventions (BIs)—low-cost, time-efficient, and effective self-help treatments involving counseling—with their prenatal smokers. The five A's BI method of smoking cessation counseling (ask, advise, assess, assist, and arrange), which can be administered in as few as 3 minutes, is considered best practice and has been adapted for use during pregnancy (Box 3) (105). Most physicians have found this model effective and easy to use in the course of a regular prenatal visit.

When properly implemented, the five A's method results in cessation rates up to four times higher than the rates for those who attempt to quit on their own (106), and 70% higher than traditional physician advice (105). To date, nearly 100 published studies have detailed the effectiveness of various office-based smoking cessation interventions for pregnant women. A 2008 Cochrane Review of clinical trials showed a significant reduction in pregnancy smoking intervention groups compared with controls (107). The most effective interventions were those based on or similar to the five A's, with these “low-intensity” interventions just as effective as those of higher intensity (i.e., longer and more frequent sessions conducted by counseling professionals encompassing

Box 4 Brief Intervention for Reducing Alcohol Use During Pregnancy—FRAMES Approach

- F: *Feedback* of personal risk. Compare the patient's level and drinking patterns with pregnancy-recommended abstinence. The patient may not be aware that what she considers normal activity is actually risky
- R: *Responsibility* for personal control. Stress to the patient that it is her responsibility to make the change for the health of her baby
- A: *Advice* to change. Give direct advice (not insistence) to the patient to change her drinking behavior
- M: *Menu* of ways to reduce/stop drinking. Identify when the patient is likely to drink and solicit alternate ways that she might handle these situations
- E: *Empathy*. Use a style of interaction that is understanding and involved. Remain positive and encouraging and avoid being judgmental and preachy
- S: *Self-efficacy*. Elicit and reinforce self-motivating statements such as "I am confident that I can stop drinking." Encourage the patient to develop strategies, implement them, and commit to change

Source: From Ref. 111.

multiple types of efforts). In a 2005 bulletin, ACOG established the five A's as a standard component of prenatal care for all smokers (108). And in a 2009, the U.S. Preventive Services Task Force reaffirmed that the net benefit of using a five A's office-based intervention with pregnant smokers is substantial (109).

Alcohol

Once a prenatal patient had been identified as consuming alcohol, the management options available to the provider will depend upon training, expertise, and available resources. For women who drink but are not alcohol dependent, an in-office BI may be all that is needed to reduce the risk of an alcohol-exposed pregnancy. For alcohol-dependent women, a BI, coupled with referral to specialized treatment programs, is recommended (110). BIs, including the structured five A's approach described above for use with smokers, can be delivered by health professionals who are not specialists in the treatment of substance use and dependence. Increasing numbers of physicians have obtained continuing education training in motivational interviewing for use with pregnant women who consume alcohol. Motivational interviewing, a type of BI, helps empower the patient to make lifestyle changes while minimizing resistance (111). Using this approach with pregnant alcohol users specifically, the physician can illustrate the importance of abstinence or decreased alcohol intake and the avoidance of binge-drinking, and offer encouragement and optimism about change (112). The most successful interventions follow the FRAMES approach (Box 4).

Research has suggested that women, even those identified as heavy drinkers, respond to motivational interviewing (113,114). In a multicenter randomized controlled trial to reduce the risk for alcohol-exposed pregnancies, 830 at-risk women received educational information plus motivational interviewing or information alone (115). The intervention

consisted of four counseling sessions and one contraceptive consultation. The intervention group had a 70% decrease in risk for alcohol-exposed pregnancies, more than twice the risk reduction for the information-only group at 3-, 6-, and 9-month follow-up (ORs 2.3, 2.2, and 2.1, respectively). In another randomized controlled trial involving only pregnant women, 255 patients who reported alcohol consumption were recruited from a community-based setting and randomly assigned to receive intervention or assessment only (116). The intervention consisted of multiple BI sessions with a nutritionist that included education and feedback, cognitive behavioral procedures, goal setting, and contracting. Compared with women in the control group, women who received the intervention were five times more likely to report abstinence by the end of the pregnancy. In addition, their newborns had significantly higher birth weights and lengths, and a three times lower fetal mortality rate. In another study, a BI administered by nurses and physicians during a prenatal care visit was evaluated with 300 alcohol-consuming women (117). The BI in this study was a single session, averaging 25 minutes, which included knowledge assessment with feedback, goal setting and contracting, behavioral modification, and tips for handling difficult situations. Although pregnancy alcohol consumption decreased for both those who received the intervention and those who received only an assessment, those who received the BI had the most significant decrease. In addition, the greatest decreases were seen among women with the highest initial consumption and those whose partners also participated in the BI. Still other studies have shown that follow-up is critical, as a series of BIs is generally more effective than a single suggestion to stop drinking (118).

CONCLUSIONS

As many as 20% of pregnancies are complicated by smoking and/or alcohol consumption. Exposure to either substance significantly increases the risk of poor pregnancy outcomes including low birth weight and preterm birth. Prenatal smoke exposure in particular is implicated in substantial health problems early in life, while both smoke and alcohol exposure can lead to long-term growth delays and cognitive and behavioral problems. While biochemical assessment can be used to identify women who smoke during pregnancy, no reliable biomarker for alcohol consumption is yet clinically applicable. Self-report of smoking and alcohol use is typically relied upon in clinical settings, and reliable and well-validated tools are available and recommended for use with all prenatal patients. Once women who smoke or drink during pregnancy are identified, brief proven interventions can aid the busy clinician in working with patients to reduce or eliminate these pregnancy risk behaviors.

41 Exercise and pregnancy

Raul Artal

The epidemic of obesity that began in 1980 continues to proliferate. The sedentary lifestyle and gestational weight gain of many pregnant women has become a major contributor to the obesity epidemics. Lifestyle factors play a significant role particularly during pregnancy when pregnant women gain additional weight over prepregnancy weight. The health-related benefits of exercise are well documented in the general population (1–4). Although exercise is being promoted to the general population, health providers are still reluctant to prescribe lifestyle programs to pregnant women. However, pregnancy is a unique period in a woman's and her family's life; health awareness increases and women are particularly inclined to accept lifestyle modifications of judicious diets and exercise. During their pregnancies, even previously sedentary women may seek to modify their lifestyle and initiate exercise activities. The potential health benefits, safety, and feasibility of different amounts and intensities of physical activity in pregnancy have been endorsed by several organizations. In 2002, the American College of Obstetricians and Gynecologists (ACOG) published recommendations and guidelines for exercise during pregnancies, which have been recently reaffirmed (5,6); the guidelines mirror those issued to the general population by the Centers for Disease Control and Prevention. The American College for Sports Medicine (7) and the Society of Obstetricians and Gynecologists of Canada (8) have each published guidelines similar to the ACOG guidelines. Data obtained in 2000 indicate that 15.8% of pregnant women meet minimum physical activity recommendations and indications are that it has not changed (9). Studies and reviews evaluating the effects of physical activity on pregnancy outcome have identified certain beneficial trends and very few complications (9–11). Physically active pregnant women benefit by engaging in physical activities: among the benefits, they have less macrosomic babies and caesarian sections and develop significantly less gestational diabetes. For patients who require insulin, insulin requirements decrease significantly and frequently could be replaced to a diet and exercise regimen alone. Dissemination of such information could only lead to safe conduct of an active lifestyle.

It has been recognized that lifestyle modification in pregnancy can result in persistent habits that could influence close family and offspring; this has important public health implications, particularly since exercise has been recognized as an effective adjunctive to management of diabetes in pregnancy and postpartum.

Health-care providers should familiarize themselves with the general principals of exercise prescription and be cognizant of the physiologic changes associated with pregnancy and potential maternal and fetal risks (6,12). Exercise guidelines for healthy pregnant women do not differ significantly from those to the general population; however,

pregnancy is associated with significant physiologic alterations that could affect both mother and fetus. These alterations are in response to the increased metabolic demands for both mother and fetus.

BIOMECHANICAL AND ANATOMICAL CONSIDERATIONS FOR EXERCISE GUIDELINES IN PREGNANCY

Several changes in pregnancy affect the biomechanics of movement. Under the influence of estrogen, progesterone, and elastin, there is a generalized connective tissue relaxation leading to ligamentous laxity and joint instability. The increase in weight gain increases the load on the musculoskeletal system, producing higher reaction forces. Additional strain on the musculoskeletal system comes from the continuous change in the body center of mass or point of gravity. The immediate consequence is a combination of progressive lordosis and a limiting in the range of hip joint motion (13). The change in the point of gravity will require greater muscular effort with certain movements, for example, raising from squatting or sitting positions. One way to reduce the muscular effort of the lower extremity muscles is to utilize the upper extremity muscles when rising from the above-mentioned positions. The progressive lordosis in pregnancy frequently results in lower back pain. The above limitation could frequently result in lower back pain. This limitation could be prevented or reduced by improved muscular strength, preferably prior to pregnancy. Most significant, as it relates to exercise guidelines and prescription, is that the biomechanical changes of pregnancy could create balance problems and orthopedic injuries. In addition to back and hip pain, common orthopedic injuries in pregnancy are a consequence of accumulation of interstitial fluid that could result in nerve compression syndromes such as carpal tunnel syndrome.

CARDIOVASCULAR RESPONSES TO EXERCISE IN PREGNANCY

The major hemodynamic response to exercise is redistribution of blood flow away from the visceral organs and toward the working muscles. During exercise, the cardiac output to the brain and heart remains unchanged, while the uterine blood flow is significantly restricted depending on the intensity of the exercise.

Pregnancy is characterized by a significant increase in blood volume, compensated in part by increased venous capacitance and reduced peripheral vascular resistance (16). Early in pregnancy, the cardiac output increases in excess of the increment in uterine blood flow. Cardiac output reaches maximum values by midpregnancy and becomes highly variable in the third trimester. Increases in heart rate, stroke volume, and cardiac output are observed not only at rest but

also during submaximal exercise until the third trimester of pregnancy (17).

During cycle ergometry in pregnancy, different kinetic adjustments to the increased maternal mass have been demonstrated (18,19). The relative increases in cardiac output and stroke volume during exercise are similar in pregnant and nonpregnant subjects.

However, during strenuous exercise, the cardiac output response appears to be blunted in pregnancy, a possible reflection of impaired cardiac mechanical functions (20). These findings are significant from the clinical point of view as the preferential redistribution of blood flow during strenuous exercise does not meet the expected requirements, limiting physical performance. Anecdotal observations indicate that such responses may differ and some elite athletes are capable of overcoming such limitations. At lower exercise intensity, the increase in cardiac output is primarily due to higher heart rates, whereas at higher exercise intensities the contribution is primarily due to increased stroke volume. Hemodynamic changes during rest or exercise in the upright position in pregnancy are influenced significantly by the venous return. Venous return can be significantly impaired in the supine position in pregnancy, even at rest, and can cause symptomatic reduction in cardiac output in about 5% or more of pregnant women (21).

In one invasive study conducted in pregnant women, uterine blood flow during mild cycle exercise was reduced by 25% in healthy women, during their third trimester of pregnancy (22). A further progressive reduction in blood flow and cardiac output occurs as the intensity of exercise increases. Confirmation for such hemodynamic changes can be found in studies conducted in nonpregnant adults (23). It is plausible that most of the hemodynamic responses to exercise in pregnancy are a reflection of the hemodynamic changes of pregnancy combined with progressive detraining.

Health benefits could be derived from mild to moderate exercise routines at an intensity of training of 12 to 14 on the 20-point Borg Scale of Rating of Perceived Exertion (RPE). The RPE scale was first introduced by Borg (24). An RPE of 12 to 14 will correspond to a physical activity that will be perceived "somewhat hard" at the most by the exercising subject and could be more easily monitored than target heart rates.

PULMONARY RESPONSES TO EXERCISE IN PREGNANCY

Significant changes in pulmonary functions parallel the other anatomical and physiologic changes of pregnancy. The increase in inspiratory capacity of 300 mL (inspiratory volume + tidal volume) is paralleled by an increased chest circumference and an increase in the resting oxygen consumption by 10% to 20%. The physiologic purpose of the pregnancy state of hyperventilation appears to be aimed at reducing the $p\text{CO}_2$ and maintaining pH at 7.44. The increases in tidal volume result in an increase in ventilation, which is the cause of a common subjective feeling of dyspnea. The resulting mild maternal alkalosis facilitates placental gas exchange and prevents fetal acidosis (25). Many conditions such as strenuous exercise may alter these interactions and affect fetal oxygenation.

Comparison of pulmonary responses during mild, moderate, and VO_2 max exercise (Fig. 1) indicates that only a modest increase in VO_2 max is achieved in pregnancy (26). This limitation appears to be primarily related to the progressive increase in weight. It does appear that both pregnancy and exercise increase the respiratory demands in the presence of reduced maternal ventilatory reserve. Ventilatory responses and aerobic conditioning have been studied in longitudinal studies in pregnancy, and it appears that during submaximal exercise, the differences are reflected predominantly in a significant increase in tidal volume during exercise in pregnancy (26).

Another study (27) found that in recreational athletes who maintain a moderate to high level of exercise performance during and after pregnancy, pregnancy is followed by a small increase in VO_2 max.

FUEL UTILIZATION DURING EXERCISE IN PREGNANCY

The combined needs of pregnancy and exercise evoke complex hormonal interactions. Stress hormones play an essential role in this process and notably release of catecholamines, glucagon, and cortisol increases while insulin secretion is suppressed (Figs. 2,3) (28,29). Changes in fuel metabolism are modulated to satisfy the requirements of pregnancy (Figs. 2,3). The heavier the workload, the higher the sympathoadrenal activity. Catecholamines promote both glycogenolysis and lipolysis. Epinephrine is recognized to play an essential role in maintaining normoglycemia. Normoglycemia is one of the most guarded physiologic functions in pregnancy. Assessing fuel utilization during exercise in pregnancy is essential

Figure 1 Oxygen consumption during mild, moderate, and VO_2 max exercise. Source: From Ref. 26.

because of the possible metabolic effects of exercise-induced maternal hypoglycemia. Such events are unlikely to occur during mild-moderate exercise, but might occur during prolonged exercise (Fig. 4) (29).

Measurements by indirect calorimetry indicate preferential use of carbohydrates during non-weight-bearing exercise in pregnancy (31). Studies have demonstrated that there is a tendency for higher respiratory exchange ratios (RERs) during pregnancy and during exercise in pregnancy, which suggests a preferential utilization of carbohydrates (31) (Fig. 5).

The RER is a variable that reflects the ratio between carbon dioxide output (CO₂) and oxygen uptake (VO₂). The RER will provide information on the proportion of substrate derived from various foodstuffs. For carbohydrates to be completely oxidized to CO₂ and H₂O, one volume of CO₂ is produced for each volume of O₂ consumed. An RER value of 1.0 would indicate that only carbohydrates are being utilized.

The increases in norepinephrine that parallel the exercise intensity have clinical relevance since norepinephrine has restrictive effects on the splanchnic, renal, and uterine blood flow and could precipitate uterine activity (28).

Figure 2 Effect of exercise on maternal glucose, glucagon, and insulin concentrations. The asterisks indicate a significant difference for that value when compared with the pre-exercise value. Source: From Ref. 28.

On occasions, uterine activity has been demonstrated to occur during and after physical activity in pregnancy (28); however, it could potentially have clinical significance only in patients who are at risk for premature labor. And indeed, patients at risk for premature labor are advised to refrain from exercise during pregnancy (Boxes 1-3).

NUTRITION FOR THE ACTIVE PREGNANT WOMAN

The nutritional needs of active pregnant women are not currently defined; however, the recommended dietary intake for pregnant women at large has been well researched. It has been estimated that the caloric cost of pregnancy is approximately 85,000 calories, approximately 300 extra calories per day above prepregnancy requirements. The average weight gain during pregnancy is approximately 12.5kg, a 20% increase in body weight for most women, with most of the weight gain occurring during the second half of pregnancy.

About 40% of the total gain is represented by the products of conception—fetus, placenta, and amniotic fluid (33). Due to methodology difficulties, it has not yet been determined what the true change in body composition during pregnancy is. However, it appears that there is a modest (less than 5%) increase in the percentage of body fat while the remainder is interstitial accumulation of fluids (34). It is well recognized that individual weight gain in pregnancy can affect the outcome of pregnancy. Obese women (20% above standard weight for height) more frequently deliver large infants (greater than 4.0kg); conversely, women who begin pregnancy 15% below standard weight for height frequently deliver low-birth weight infants.

Many active women will begin pregnancy underweight. Among these women, there is an increased awareness of body image, and many of them will continue to consume inadequate low-calorie diets during their pregnancies. To compensate for these low-calorie diets, they will frequently turn to excessive use of vitamins. Excessive intake of vitamins can result in an increased incidence of congenital malformations. Excessive ingestion of vitamin D could result in a neonatal syndrome consisting of supravalvular aortic stenosis, elfin facies, and mental retardation (35). Hypervitaminosis A

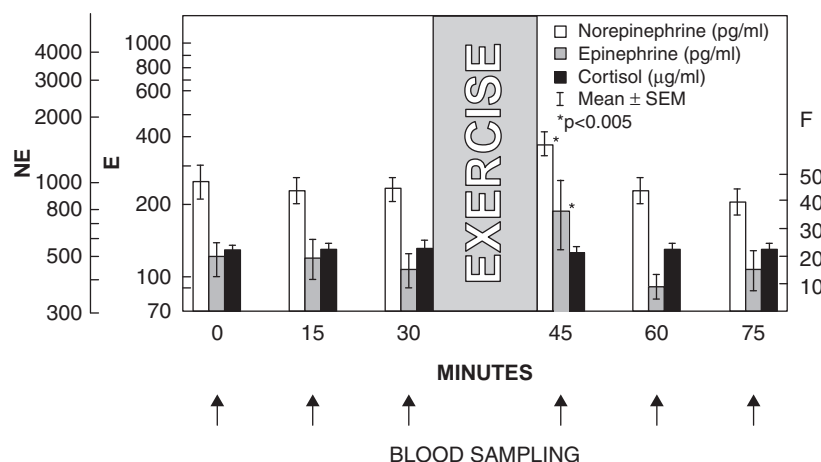

Figure 3 Comparison with pre-exercise and post-exercise concentrations of norepinephrine, epinephrine, and cortisol. The data for norepinephrine (NE) and epinephrine (E) are illustrated on a logarithmic scale to the left of the Figure and those for cortisol (F) are on a separate scale to the right of the figure. The asterisks indicate a significant statistical difference for that value when compared with the pre-exercise value. Source: From Ref. 28.

may cause urogenital anomalies, ear malformations, cleft palate, and neural tube defects (36). The iron status should be assessed since many of these women may have preexisting depleted iron stores.

The daily nutritional requirements should include an additional 300 cal/day, which is required to provide for the increased basal metabolic needs of pregnancy. Additional calories will be needed depending on the activities conducted. Furthermore, in the postpartum period, lactating women will require an additional 400 to 600 cal/day to meet the metabolic needs. The Institute of Developmental Biology and Molecular Medicine has published in 2009 guidelines for the rate of weight gain during pregnancy by prepregnancy BMI (37). The Institute of Medicine (IOM) recommendations of a single standard of weight gain for all obesity classes has come under criticism since higher body mass index levels combined with additional weight gain are associated with more severe pregnancy complications, such as pre-eclampsia and

gestational diabetes (38). The IOM recommendations retained the 1990 focus on the theoretical association between poor gestational weight gain and low birth weight. Important to point out that most causes for low birth weight are the consequences of other conditions than poor nutrition; there is lack of evidence in developed countries that dietary supplementation increases birth weight.

FETAL RESPONSES TO MATERNAL EXERCISE

The main concerns related to exercise in pregnancy are focused on the fetus and any potential maternal benefits that could be offset by fetal injuries. In the uncomplicated pregnancy, such events are highly unlikely. It appears now that with mild-moderate exercise, the risks for pregnant women are not different from the nonpregnant.

It is well recognized that during other obstetric events, transient hypoxia could result initially in fetal tachycardia and an increase in fetal blood pressure. These fetal responses are protective mechanisms for the fetus to facilitate transfer of oxygen and decrease the CO₂ tension across the placenta. Any acute alterations could result in fetal heart rate (FHR) changes, causing possible fetal distress, whereas chronic effects may result in intrauterine growth retardation. Though fetal demise may be associated with either of the above events, there has never been a report in literature to link them with maternal exercise.

The crux of the theoretical risk is related to the selective redistribution of blood flow during exercise to the exercising muscles and away from the visceral organs. Studies conducted in nonpregnant (23) and pregnant (16) subjects confirm that blood flow selectively redistributes during exercise. In experimental animal studies, a reduction in uterine blood flow by 50% or more could lead to fetal respiratory acidosis. Theoretically, such events could occur during either strenuous or prolonged exercise. Most of the studies addressing fetal responses to exercise have examined FHR changes during or after exercise (39–41). The summary and results of these studies is listed in Table 1 (39–63). Most of the studies demonstrate a minimum or moderate increase in FHR by 10 to 30 beats/min over baseline during or following maternal exercise. FHR decelerations has been reported to occur spontaneously with a frequency of 8.9% and recorded on rare occasions during and after exercise (62). On few occasions when FHR was measured during exercise in labor with a fetal scalp electrode attached, no FHR abnormalities were recorded either in the presence or absence of uterine activity (60). The mechanism leading to fetal bradycardia during maternal exercise can only be speculated upon: most likely are either vagal reflex, cord compression, or fetal head malposition with no known consequences.

Due to the inaccessibility of the fetus, validation of events of FHR responses could ultimately be obtained only with direct internal FHR monitoring (60) or two-dimensional ultrasound (63,64).

Several studies (58) have attempted to assess umbilical blood flow during maternal exercise with Doppler velocimetry, demonstrating various or no changes. Doppler velocimetry studies are technically difficult to conduct during exercise, so most measurements are taken before and after exercise, by which time any changes could have returned to normal.

The presence of fetal activity has often been interpreted as a reflection of well-being. The same is true for fetal breathing,

Box 1 Absolute Contraindications of Aerobic Exercise During Pregnancy

- Hemodynamically significant heart disease
- Restrictive lung disease
- Incompetent cervix/cerclage
- Multiple gestation at risk for premature labor
- Persistent second- or third-trimester bleeding
- Placenta previa after 24 weeks of gestation
- Premature labor during the current pregnancy
- Rupture membranes
- Pregnancy-induced hypertension

Source: From Ref. 32.

Box 2 Relative Contraindications to Aerobic Exercise During Pregnancy

- Severe anemia
- Unevaluated maternal cardiac arrhythmia
- Chronic bronchitis
- Poorly controlled type I diabetes
- Extreme morbid obesity
- Extreme underweight (body mass index <12)
- History of extremely sedentary lifestyle
- Intrauterine growth restriction in current pregnancy
- Poorly controlled hypertension/pre-eclampsia
- Orthopedic limitations
- Poorly controlled seizure disorder
- Poorly controlled thyroid disease
- Heavy smoker

Source: From Ref. 32.

Box 3 Warning Signs to Terminate Exercise While Pregnant

- Vaginal bleeding
- Dyspnea before exertion
- Dizziness
- Headache
- Chest pain
- Muscle weakness
- Calf pain or swelling (need to rule out thrombophlebitis)
- Preterm labor
- Decreased fetal movement
- Amniotic fluid leakage

which is related to the stage in gestation, diurnal variations, maternal plasma glucose, and catecholamine concentration. And, indeed, a direct relationship has been demonstrated between the sympathetic activity of the mother and the frequency of occurrence of both fetal breathing movements and fetal body movements.

Numerous studies have examined the effects of exercise on pregnancy outcome since 2002. The results of these studies are summarized in Table 2 (74).

Epidemiologic studies have suggested for a long time that a link exists between strenuous work and the development of intrauterine growth retardation. Working mothers have a tendency to deliver earlier and small-for-gestational-age infants (75,76). Uncontrolled studies done in elite athletes

indicate conflicting evidence (76,77). Most of the studies conducted in pregnant athletes report a very low incidence of complications, but at least one study (79) found that the number of newborn babies of Olympian mothers weighing 2600 to 3000g (potentially growth restricted or born prematurely) was greater in their investigations than those weighing in excess of 3500g. The evidence in the literature is too limited to allow risk assignment for either premature labor or fetal growth restriction for exercising mothers. However, anecdotal clinical observations indicate that patients at risk for premature labor may have labor triggered by exercise. Furthermore, women who are diet conscious often do not receive the minimum required nutrients. The combined energy requirements of pregnancy and exercise coupled with poor weight gain may lead to fetal retardation.

Exercise, hyperthermia, and risk for malformations

During exercise, the working muscles generate heat, which could increase the body core temperature to levels that are considered teratogenic. Data obtained in studies conducted in research animals indicate that hyperthermia in excess of 39°C could be teratogenic and frequently result in neurotubular defects (80–82).

Human data implicating hyperthermia as teratogenic include primarily case reports (83–87) that may suggest an association, but cannot prove causality. The only prospective study, which was conducted with 165 women exposed to first-trimester hyperthermia, has failed to confirm its teratogenic effects (85). Nevertheless, the theoretical risk cannot be dismissed easily, and pregnant women should be advised to avoid hyperthermia during the first weeks of gestation. The malformations implicated are the result of a failure of closure of the neural tube in the phase of embryogenesis that occurs 25 to 27 days after conception or 50 days from last menstrual period.

CLINICAL APPLICATIONS FOR EXERCISE IN PREGNANCY

Gestational diabetes occurs in 4% to 7% of the obstetric population. Insulin therapy and diet may not be the optimal treatment to attain euglycemia. The hormonal changes of pregnancy reduce insulin peripheral sensitivity and are further amplified in patients affected by gestational diabetes. Reduced insulin sensitivity may be reversed most efficiently with exercise. Exercise has been recognized for a long time as an adjunct or alternative therapeutic modality for type II diabetic patients. Pregnant diabetics have been denied this option in the past, primarily because of the potential fetal risks. Published studies on fetal responses to exercise have removed the initial concerns (Table 1).

Exercise training results in sustained insulin sensitivity and improves glucose clearance. Because these functions are altered in gestational diabetes, exercise should be considered not only optional, but also preferable, because it obviates insulin therapy. During exercise, plasma concentrations of glucose counter-regulatory hormones play an important role in maintaining glucose homeostasis.

Studies conducted in pregnant diabetics indicate that these patients' physiologic and metabolic responses to exercise are similar to healthy nondiabetics (88). No maternal or fetal adverse responses have been reported to date in pregnant

Table 2 (continued) Studies Examining the Effects of Exercise on Pregnancy Outcome

Author, year, and outcome	Study type	Activity type	Activity period	Size of study population	Main findings: relative risks, odds ratios, and 95% CI
Weight-gain restriction Artal et al., 2007 (72)	Intervention	Moderate exercise Program equivalent to 60% symptom- limited to VO ₂ max	Enrolled <33 weeks Gestation to delivery	Obese with GDM Exercise + diet (ED) <i>n</i> = 39 Diet (D) <i>n</i> = 57	Percentage gaining weight during study ED vs. D (53.8% vs. 78.9%, <i>p</i> < 0.01) Mean weight gain/week ED vs. D (0.1 ± 0.4 kg vs. 0.3 ± 0.4 kg, <i>p</i> < 0.05) Percentage macrosomic infants born to women gaining weight during study (ED or D) vs. to women losing weight or having no mean weight change during study (17.9% vs. 4.2%, <i>p</i> = 0.12)
Normalization of blood glucose Bung et al., 1991 (73)	Randomized clinical trial	Moderate exercise Program equivalent to 50% symptom limited to VO ₂ max	Enrolled <33 weeks Gestation to delivery	Hispanic women with GDM Exercise + diet (EXE) <i>n</i> = 17 Insulin + diet (INS) <i>n</i> = 17	Normalization of blood glucose Achieved and maintained in EXE and INS groups within 1 week

Abbreviations: GDM, gestational diabetes mellitus; BMI, body mass index. Source: From Ref. 74.

diabetics engaging in mild-to-moderate physical activities. Nor have there been reported significant complications in non-diabetic, physically active pregnant women.

To date, several studies have tested several exercise prescription regimens for pregnant diabetics. These studies have assessed maternal and fetal safety, and the efficacy of exercise prescription to improve carbohydrate tolerance and obviate insulin therapy.

The prescribed exercise regimens include the following:

1. Artal R (89)—20 minutes of bicycle ergometry (18 subjects at 50% VO₂ max after each meal (three times/day) for at least 5 days/week for 6 weeks prior to expected date of confinement (EDC).
2. Jovanovic-Peterson (90)—20 minutes arm ergometry (10 subjects) at less than 50% VO₂ max daily for 6 weeks prior to EDC.
3. Bung P (73)—45 minutes of bicycle ergometry (21 subjects) at 50% of VO₂ max three to four times/week for at least 6 weeks prior to EDC.

All the above studies have demonstrated that exercise prescription is feasible in about 25% of pregnant diabetics and may be utilized as an optional therapeutic approach even in previously sedentary gestational diabetics. The rate of complications observed was similar in the study and control groups. In one study, two patients experienced premature labor of which one was successfully tocolyzed (73). The type, frequency, and intensity of exercise utilized in the above studies were sufficient to attain and maintain euglycemia. Non-weight-bearing exercise appears to be particularly suited for these types of patients.

It appears that in the absence of either medical or obstetric complications, exercise prescription can be an optional adjunct therapy for gestational diabetes. This concept has been well accepted, but not widely prescribed.

SUMMARY

Exercise in pregnancy conducted in moderation appears to be beneficial to both mother and fetus, by and large, safe. Questions remain as to the safety and potential benefits for strenuous exercise.

The current published literature includes the following consistent findings (3):

1. Women who exercised before pregnancy and continued to do so during pregnancy tend to weigh less, gain less weight, and deliver by and large normal size and fewer macrosomic babies.
2. All women, regardless of initial level of physical activity, decrease their activity as pregnancy progresses.
3. Active pregnant diabetic women can prevent or ameliorate gestational diabetes.
4. Physically active women appear to tolerate labor pain better.
5. Lifestyle modification in pregnancy has a beneficial effect on mothers, their families, and future generations.

Pregnancy should not be a state of confinement, and cardiovascular and muscular fitness can be reasonably maintained. Restriction or modification of physical activity routines should be dictated by obstetric and medical indications only.

42 Ethical considerations

Frank A. Chervenak and Laurence B. McCullough

INTRODUCTION

Ethics is an essential dimension of maternal–fetal medicine (1–3). In this chapter, we develop a framework for clinical judgment and decision-making about the ethical dimensions of clinical practice and research in maternal–fetal medicine. We emphasize a preventive ethics approach that appreciates the potential for ethical conflict and adopts ethically justified strategies to prevent those conflicts from occurring. Preventive ethics helps to build and sustain a strong physician–patient relationship. We first define ethics, medical ethics, and the fundamental ethical principles of medical ethics, beneficence, and respect for autonomy. Second, we show how these two principles should interact in clinical judgment and practice in maternal–fetal medicine, with emphasis on the core concept of the fetus as a patient. Third, we set out an ethical framework for innovation and research in maternal–fetal medicine, with an emphasis on ethically justified criteria to guide the initiation and implementation of research in maternal–fetal medicine.

ETHICS, MEDICAL ETHICS, AND ETHICAL PRINCIPLES

Ethics is the disciplined study of morality. Medical ethics is the disciplined study of morality in medicine and concerns the obligations of physicians and health-care organizations to patients as well as the obligations of patients (4). It is important not to confuse medical ethics with the many sources of morality in a pluralistic society. These include, but are not limited to, law, our political heritage as free people, the world's religions (most of which now exist in our country), ethnic and cultural traditions, families, the traditions and practices of medicine (including medical education and training), and personal experience. Medical ethics since the eighteenth-century European and American Enlightenment has been secular (5). It makes no reference to God or revealed tradition, but to what rational discourse requires and produces. At the same time, secular medical ethics is not intrinsically hostile to religious beliefs. Therefore, ethical principles and virtues should be understood to apply to all physicians, regardless of their personal religious and spiritual beliefs (6).

The traditions and practices of medicine constitute a major source of morality for physicians. They provide an important reference point for medical ethics because they are based on the obligation to protect and promote the health-related interests of the patient. This obligation tells physicians what morality in medicine ought to be, but in very general abstract terms. Providing a more concrete, clinically applicable account of that obligation is the central task of medical ethics, using ethical principles (4).

The *ethical principle of beneficence* in its general meaning and application requires one to act in a way that is expected reliably to produce the greater balance of benefits over harms in the

lives of others (6). To put this principle into clinical practice requires a reliable account of the benefits and harms relevant to the care of the patient, and of how those goods and harms should be reasonably balanced against each other when not all of them can be achieved in a particular clinical situation, such as a request for an elective cesarean delivery (7). In medicine, the principle of beneficence requires the physician to act in a way that is reliably expected to produce the greater balance of clinical benefits over harms for the patient (4).

Beneficence-based clinical judgment has an ancient pedigree, with its first expression found in the Hippocratic Oath and accompanying texts (8). Beneficence-based clinical judgment makes an important claim: to interpret reliably the health-related interests of the patient from medicine's perspective. This perspective is provided by accumulated scientific research, clinical experience, and reasoned responses to uncertainty. As rigorously evidence based (9), beneficence-based judgment is thus not the function of the individual clinical perspective of any particular physician and therefore should not be based merely on the clinical impression or intuition of an individual physician. On the basis of this rigorous clinical perspective, focused on the best available evidence, beneficence-based clinical judgment identifies the clinical benefits that can be achieved for the patient in clinical practice based on the competencies of medicine. The clinical benefits that medicine is competent to seek for patients are the prevention and management of disease, injury, handicap, and unnecessary pain and suffering, and the prevention of premature or unnecessary death. Pain and suffering become unnecessary when they do not result in achieving the other goods of medical care, for example, allowing a woman to labor without effective analgesia (4).

Nonmaleficence means that the physician should prevent causing harm and is best understood as expressing the limits of beneficence. This is also known as *Primum non nocere* or “first do no harm.” This commonly invoked dogma is really a Latinized misinterpretation of the Hippocratic texts, which emphasized beneficence while avoiding harm when approaching the limits of medicine (4). Nonmaleficence should be incorporated into beneficence-based clinical judgment: when the physician approaches the limits of beneficence-based clinical judgment, that is, when the evidence for expected benefit diminishes and the risks of clinical harm increase, then the physician should proceed with great caution. The physician should be especially concerned to prevent serious, far-reaching, and irreversible clinical harm to the patient. It is important to note that there is an inherent risk of paternalism in beneficence-based clinical judgment. By this, we mean that beneficence-based clinical judgment, if it is *mistakenly* considered to be the sole source of moral responsibility and therefore moral authority in medical care, invites the unwary

physician to conclude that beneficence-based judgments can be imposed on the patient in violation of her autonomy. Paternalism is a dehumanizing response to the patient and, therefore, should be avoided in the practice of obstetrics and gynecology.

The preventive ethics response to this inherent paternalism is for the physician to explain the diagnostic, therapeutic, and prognostic reasoning that leads to his or her clinical judgment about what is in the interest of the patient so that the patient can assess that judgment for herself. This general rule can be put into clinical practice in the following way: the physician should disclose and explain to the patient the major factors of this reasoning process, including matters of uncertainty. In neither medical law nor medical ethics does this require that the patient be provided with a complete medical education (10). The physician should then explain how and why other clinicians might reasonably differ from his or her clinical judgment. The physician should then present a well-reasoned response to this critique. The outcome of this process is that beneficence-based clinical judgments take on a rigor that they sometimes lack in maternal–fetal medicine and the process of their formulation includes explaining them to the patient. It should be apparent that beneficence-based clinical judgment will frequently result in the identification of a continuum of clinical strategies that protect and promote the patient's health-related interests, such as indications for cesarean delivery for fetal distress. Awareness of this feature of beneficence-based clinical judgment provides an important preventive ethics antidote to paternalism by increasing the likelihood that one or more of these medically reasonable, evidence-based alternatives will be acceptable to the patient. All beneficence-based clinical alternatives should be identified and explained to all patients, regardless of how the physician is paid, especially those that are well established in evidence-based obstetrics and gynecology.

One advantage for the physician in carrying out this approach to communicating with the patient would be, we believe, to increase the likelihood of compliance (11). This is an especially pertinent consideration in the management of pregnancy, where the pregnant patient often must monitor herself for clinical changes, for example, self-observation for unusual weight gain or bleeding. Another advantage would be to provide the patient with a better-informed opportunity to make a decision about whether to seek a second opinion. The approach outlined above should make such a decision less threatening to her physician, who has already shared with the patient the limitations on clinical judgment.

In contrast to the principle of beneficence, there has been increasing emphasis in the literature of medical ethics on the *ethical principle of respect for autonomy* (6). This principle requires one always to empower the patient in the informed consent process by providing her with information about the beneficence-based alternatives for managing her or the fetus's condition and then implement the value-based preferences of the pregnant patient, unless there is compelling ethical justification for not doing so. The pregnant patient increasingly brings to her medical care her own perspective on what is in her interest. The principle of respect for autonomy translates this fact into autonomy-based clinical judgment. Because each patient's perspective on her interests is a function

of her values and beliefs, it is impossible to specify the benefits and harms of autonomy-based clinical judgment in advance. Indeed, it would be inappropriate for the physician to do so, because the definition of her benefits and harms and their balancing are the prerogative of the patient. Not surprisingly, autonomy-based clinical judgment is strongly antipaternalistic in nature (4).

To understand the demands of this principle in clinical practice, we need an operationalized concept of autonomy to make it relevant to clinical practice. To do this, we identify three sequential autonomy-based behaviors on the part of the patient: (i) absorbing and retaining information about her condition and alternative diagnostic and therapeutic responses to it, (ii) understanding that information (evaluating and rank-ordering those responses and appreciating that she could experience the risks of treatment), and (iii) expressing a value-based preference. The physician has a role to play in each of these. They are, respectively, (i) to recognize the capacity of each patient to deal with medical information (and not to underestimate that capacity), provide information (disclose and explain all beneficence-based alternatives), and recognize the validity of the values and beliefs of the patient; (ii) not to interfere with but, when necessary, to assist the patient in her evaluation and ranking of diagnostic and therapeutic alternatives for managing her condition; and (iii) to elicit and implement the patient's value-based preference (4).

The legal obligations of the physician regarding informed consent were established in a series of cases during the twentieth century. In 1914, *Schloendorff v. The Society of The New York Hospital* established the concept of simple consent, whether the patient says "yes" or "no" to medical intervention (10,12). To this day in the medical and bioethics literature, this decision is quoted: "Every human being of adult years and sound mind has the right to determine what shall be done with his body, and a surgeon who performs an operation without his patient's consent commits an assault for which he is liable in damages" (12). The legal requirement of consent further evolved to include disclosure of information sufficient to enable patients to make informed decisions about whether to say "yes" or "no" to medical intervention (10).

There are two accepted legal standards for such disclosure. The professional community standard defines adequate disclosure in the context of what the relevantly trained and experienced physician tells patients. The reasonable person standard, which has been adopted by most states, goes further and requires the physician to disclose "material" information, what any patient in the patient's condition needs to know and the layperson of average sophistication should not be expected to know. Patients need to know what the physician thinks is clinically salient, that is, the physician's beneficence-based clinical judgment. This reasonable person has emerged as the ethical standard, and we therefore urge perinatologists to adopt it. On this standard, the physician should disclose to the patient her or the fetus's diagnosis (including differential diagnosis when that is all that is known), the beneficence-based (and therefore medically reasonable) alternatives to diagnose and manage the patient's condition, and the short-term and long-term benefits and risks of each alternative.

THE INTERACTION OF BENEFICENCE AND RESPECT FOR AUTONOMY IN CLINICAL JUDGMENT AND PRACTICE IN MATERNAL—FETAL MEDICINE

The ethical principles of beneficence and respect for autonomy play a complex role in obstetric clinical judgment and practice. There are obviously beneficence-based and autonomy-based obligations to the pregnant patient: the physician's perspective on the pregnant woman's health-related interests provides the basis for the physician's beneficence-based obligations to her, whereas her own perspective on those interests provides the basis for the physician's autonomy-based obligations to her. Because of an insufficiently developed central nervous system, the fetus cannot meaningfully be said to possess values and beliefs. Thus, there is no basis for saying that a fetus has a perspective on its interests. There can therefore be no autonomy-based obligations to any fetus. Hence, the language of fetal rights has no meaning and therefore no application to the fetus in obstetric clinical judgment and practice despite its popularity in public and political discourse in the United States and other countries. Obviously, the physician has a perspective on the fetus's health-related interests, and the physician can have beneficence-based obligations to the fetus, *but only when the fetus is a patient*. Because of its importance for obstetric clinical judgment and practice, the ethical concept of the fetus as a patient requires detailed consideration (4).

The *ethical concept of the fetus as a patient* is essential to obstetric clinical judgment and practice. Developments in fetal diagnosis and management strategies to optimize fetal outcome have become widely accepted, encouraging the development of this concept. This concept has considerable clinical significance because when the fetus is a patient, directive counseling, that is, recommending a form of management, for fetal benefit is appropriate, and when the fetus is not a patient, nondirective counseling, that is, offering but not recommending a form of management for fetal benefit, is appropriate. However, there can be uncertainty about when the fetus is a patient. One approach to resolving this uncertainty would be to argue that the fetus is or is not a patient in virtue of personhood or some other form of independent moral status. We now show that this approach fails to resolve the uncertainty, and we therefore defend an alternative approach that does resolve the uncertainty.

One prominent approach for establishing whether or not the fetus is a patient has involved attempts to show whether or not the fetus has *independent moral status*. Independent moral status for the fetus means that one or more characteristics that the fetus possesses in and of itself and, therefore, independently of the pregnant woman and physician, generate and therefore ground obligations to the fetus on the part of the pregnant woman and her physician. Many fetal characteristics have been nominated for this role, including moment of conception, implantation, central nervous system development, quickening, and the moment of birth. It should come as no surprise that there is considerable variation among ethical arguments about when the fetus acquires independent moral status. Some take the view that the fetus has independent moral status from the moment of conception or implantation. Others believe that independent moral status is acquired in degrees, thus resulting in "graded" moral status. Still

others hold, at least by implication, that the fetus never has independent moral status so long as it is in utero (13,14).

Despite an ever-expanding theologic and philosophical literature on this subject, there has been no closure on a single authoritative account of the independent moral status of the fetus. This is an unsurprising outcome because, given the absence of a single method that would be authoritative for all of the markedly diverse theologic and philosophical schools of thought involved in this endless debate, closure is impossible. For closure ever to be possible, debates about such a final authority within and between theologic and philosophical traditions would have to be resolved in a way satisfactory to all, an inconceivable intellectual and cultural event. The concept of the independent moral status of the fetus has no stable or clinically applicable meaning. We therefore abandon these futile attempts to understand the ethical concept of the fetus as a patient in terms of independent moral status of the fetus and turn to an alternative approach that makes it possible to identify ethically distinct senses of the fetus as a patient and their clinical implications for directive and nondirective counseling.

Our analysis of the ethical concept of the fetus as a patient begins with the recognition that being a patient does not require that one possesses independent moral status. Rather, being a patient means that one can benefit clinically from the applications of the clinical skills of the physician. Put more precisely, a human being without independent moral status is properly regarded as a patient when two conditions are met: that a human being (i) is presented to the physician and (ii) there exist clinical interventions that are reliably expected to be efficacious, in that they are reliably expected to result in a greater balance of clinical benefits over harms for the human being in question (15). This is the sense in which the ethical concept of the fetus as a patient should be understood, what we call the dependent moral status of the fetus.

The authors have argued elsewhere that beneficence-based obligations to the fetus exist when the fetus is reliably expected *later* to achieve independent moral status as a child and a person (4). That is, the fetus is a patient when the fetus is presented for medical interventions, whether diagnostic or therapeutic, that reasonably can be expected to result in a greater balance of goods over harms for the child and the person the fetus can later become during early childhood. The ethical significance of the concept of the fetus as a patient, therefore, depends on links that can be established between the fetus and its later achieving independent moral status.

The Viable Fetal Patient

One such link is viability. Viability, however, must be understood in terms of *both* biologic and technologic factors. It is only by virtue of *both* factors that a viable fetus can exist ex utero and thus achieve independent moral status. When a fetus is viable, that is, when it is of sufficient maturity so that it can survive into the neonatal period and achieve independent moral status given the availability of the requisite technologic support, and when it is presented to the physician, the fetus is a patient.

Viability exists as a function of biomedical and technologic capacities, which are different in different parts of the world. As a consequence, there is, at the present time, no worldwide

uniform gestational age to define viability. In the United States, we believe, viability presently occurs at approximately 24 weeks of gestational age (16,17).

When the fetus is a patient, directive counseling for fetal benefit is ethically justified. In clinical practice, directive counseling for fetal benefit involves one or more of the following: recommending against termination of pregnancy, recommending against nonaggressive management, or recommending aggressive management. Aggressive obstetric management includes interventions such as fetal surveillance, tocolysis, cesarean delivery, or delivery in a tertiary care center when indicated. Nonaggressive obstetric management excludes such interventions. Directive counseling for fetal benefit, however, must take account of the presence and severity of fetal anomalies, extreme prematurity, and obligations to the pregnant woman.

It is very important to appreciate in obstetric clinical judgment and practice that the strength of directive counseling for fetal benefit varies according to the presence and severity of fetal anomalies. As a rule, the more severe the fetal anomaly, the less directive counseling should be for fetal benefit. In particular, when lethal anomalies such as anencephaly can be diagnosed with certainty, there are no beneficence-based obligations to provide aggressive management. Such fetuses are dying patients, and the counseling, therefore, should be nondirective in recommending between nonaggressive management and termination of pregnancy, but directive in recommending against aggressive management for the sake of maternal benefit (18). By contrast, third-trimester abortion for Down syndrome, or achondroplasia, is not ethically justifiable, because the future child with high probability will have the capacity to grow and develop (19,20).

Directive counseling for fetal benefit in cases of extreme prematurity of viable fetuses is appropriate. In particular, this is the case for what we term just-viable fetuses, those with a gestational age of 24 to 26 weeks, for which there are significant rates of survival but high rates of mortality and morbidity. These rates of morbidity and mortality can be increased by nonaggressive obstetric management, whereas aggressive obstetric management may favorably influence outcome. Thus, it appears that there are substantial beneficence-based obligations to just-viable fetuses to provide aggressive obstetric management. This is all the more the case in pregnancies beyond 26 weeks of gestational age. Therefore, directive counseling for fetal benefit is justified in all cases of extreme prematurity of viable fetuses, considered by itself. Of course, such directive counseling is appropriate only when it is based on documented efficacy of aggressive obstetric management for each fetal indication. For example, such efficacy has not been demonstrated for routine cesarean delivery to manage extreme prematurity.

Any directive counseling for fetal benefit must occur in the context of balancing beneficence-based obligations to the fetus against beneficence-based and autonomy-based obligations to the pregnant woman. Any such balancing must recognize that a pregnant woman is obligated only to take reasonable risks of medical interventions that are reliably expected to benefit the viable fetus or child later. A unique feature of obstetric ethics is that the pregnant woman's autonomy influences whether, in a particular case, the viable fetus ought to be regarded as presented to the physician.

Obviously, any strategy for directive counseling for fetal benefit that takes account of obligations to the pregnant woman must be open to the possibility of conflict between the physician's recommendation and a pregnant woman's autonomous decision to the contrary. Such conflict is best managed preventively through the informed consent process as an ongoing dialogue throughout a woman's pregnancy, augmented as necessary by negotiation and respectful persuasion (21).

The Previable Fetal Patient

The only possible link between the previable fetus and the child it can become is the pregnant woman's autonomy. This is because technologic factors cannot result in the previable fetus becoming a child. The link, therefore, between a fetus and the child it can become when the fetus is previable can be established only by the pregnant woman's decision to confer the status of being a patient on her previable fetus. The previable fetus, therefore, has no claim to the status of being a patient independently of the pregnant woman's autonomy. The pregnant woman is free to withhold, confer, or, having once conferred, withdraw the status of being a patient on or from her previable fetus according to her own values and beliefs. The previable fetus is presented to the physician as a function of the pregnant woman's autonomy (4).

Counseling the pregnant woman regarding the management of her pregnancy when the fetus is previable should be nondirective in terms of continuing the pregnancy or having an abortion if she refuses to confer the status of being a patient on her fetus. If she does confer such status in a settled way, at that point beneficence-based obligations to her fetus come into existence, and directive counseling for fetal benefit becomes appropriate for these previable fetuses. Just as for viable fetuses, such counseling must take account of the presence and severity of fetal anomalies, extreme prematurity, and obligations owed to the pregnant woman.

For pregnancies in which the woman is uncertain about whether to confer such status, the authors propose that the fetus be provisionally regarded as a patient. This justifies directive counseling against behavior that can harm a fetus in significant and irreversible ways, for example, substance abuse, especially alcohol, until the woman settles on whether to confer the status of being a patient on the fetus.

In particular, nondirective counseling is appropriate in cases of what we term near-viable fetuses, that is, those that are 22 to 23 weeks of gestational age, for which there are anecdotal reports of survival (16,17,22). In our view, aggressive obstetric and neonatal management should be regarded as clinical investigation (a topic addressed in the next section of this chapter), not a standard of care. There is no obligation on the part of a pregnant woman to confer the status of being a patient on a near-viable fetus, because the efficacy of aggressive obstetric and neonatal management has yet to be proven (17).

ETHICS OF RESEARCH IN MATERNAL FETAL MEDICINE

Definition of Research

The definition of research in the federal regulations in the United States is the following: "an activity designed to test a hypothesis, permit conclusions to be drawn, and thereby to develop or contribute to generalizable knowledge" (23).

Three Components of Research Ethics

The history of human experimentation appears to be coincident with the history of medicine. Concern about the scientific and ethical quality of research with human subjects begins to emerge in eighteenth-century medical ethics. One of major figures of that period, Dr. John Gregory (1724–1773) of Scotland, wrote the first modern medical ethics in the English language (24). He developed a research ethics to address the potential abuse of patients in the Royal Infirmary of Edinburgh by younger physicians anxious to establish their reputations. These physicians would pronounce Infirmary patients incurable, not to abandon them (which was the common practice), but to justify introducing experimental medicines into patient care.

Gregory condemned this practice. His first concern was that such experimentation was premature: standard remedies had not yet been attempted and shown to be ineffective in a patient's care. His second concern was that experimentation was often poorly designed. For example, compound drugs would be used without attention to the question of which elements of the compound might cause observed clinical effects. His third concern was that such physicians used the sick poor to advance their own reputational interests, subjecting them to unnecessary risk of clinical harm (a violation of the ethical principle of beneficence) out of personal self-interest. Gregory called this "sporting" with the sick poor; we now call it exploitation.

Gregory's research ethics introduced one of the key components of any adequate research ethics: the protection of research subjects. Such protection was gained by ensuring that there is a clinical justification for research and that the research is scientifically well designed. A second key component of any adequate research ethics, the consent of research subjects, was introduced in the nineteenth century.

Making a reasonable effort to prevent what is known as the *therapeutic misconception* is one of the major responsibilities of clinical investigators in the informed consent process. The therapeutic misconception occurs when potential subjects fail to appreciate that some aspects of what they will experience in a study are not justified by a clinical judgment of what is in the patient's health-related interest but by scientific considerations. Subjects, instead, confuse these scientific study design issues with regular medical care (25). For example, pregnant women being asked to enroll in a randomized fetal research trial should understand that intervention will be randomly selected rather than individually tailored by their physician's clinical judgment.

The need for both scientific and ethical integrity as components of research ethics was reinforced by the scientific and ethical catastrophe of the Nazi medical war crimes. A major result of the trials of the Nazi physicians was the promulgation of the Nuremberg Code. This is regarded as the founding document of contemporary research ethics and insists on sound scientific method and consent, which have become two of the three main components of research ethics globally (26).

The third and final key component of research ethics was introduced by the Declaration of Helsinki. It requires independent overview of clinical investigation, for both its scientific and its ethical integrity (26).

As a result of this centuries-long history of medical ethics, there has emerged an international consensus that there are three key components of research ethics: (27)

1. Clinical research with human subjects must be clinically justified and scientifically sound. The clinical need for research should be well established on the basis of a critical, evidence-based evaluation of current clinical practice. Clinical research should be well designed scientifically, with clearly stated research questions and testable hypotheses and a method adequate to test the hypotheses and this answers the research questions.
2. Informed consent is required. The Nuremberg Code did not allow any exceptions to this requirement, a position that is no longer part of the international consensus. It has been recognized in recent decades that there are populations of patients for whom we need to improve the quality of medical care but who cannot consent to becoming research subjects. This may be a result of the clinical circumstances of research (e.g., in emergencies where there is no time for the consent process) or the inability of the potential subject to engage in the informed consent process (e.g., fetuses).
3. Oversight of research is required. Investigators are obligated to prepare research protocols that establish clinical need, meet standards of scientific integrity, and describe the informed consent process (or justify its waiver) and submit protocols for prospective review by independent committees established for this purpose (known in the United States as Institutional Review Board and in most of the rest of the world as Research Ethics Committees).

Ethical Criteria for Innovation in Maternal–Fetal Medicine

Innovation in maternal–fetal medicine should begin with the design of an intervention and its implementation in animal models, followed by a single case and then case series. This rigorous approach is required to determine the feasibility, safety, and efficacy of innovations in fetal research. It is a basic tenet of research ethics that potential subjects should be protected from potentially harmful innovation. Three criteria must be satisfied in order to conduct such preliminary investigations in fetal research in an ethically responsible fashion, by taking into account beneficence-based obligations to the fetal patient and beneficence-based obligations to the pregnant woman. The previsible fetus is a patient in these cases because, as explained above, the woman has made a decision to continue her pregnancy, in order to have the opportunity to gain the potential benefits of the innovation. She remains free to withdraw that status before viability:

1. the proposed fetal intervention is reliably expected on the basis of previous animal studies either to be life-saving or to prevent serious and irreversible disease, injury, or handicap for the fetus;
2. among possible alternative designs, the intervention is designed in such a way as to involve the least risk of mortality and morbidity to the fetal patient (which is required by beneficence and will satisfy

the U.S. research requirement of minimal risk to the fetus); (23) and

3. on the basis of animal studies and analysis of theoretical risks both for the current and for the future pregnancies, the mortality risk of the fetal intervention to the pregnant woman is reliably expected to be low and the risk of disease, injury, or handicap to the pregnant woman is reliably expected to be low or manageable (28).

The first two criteria are based on beneficence-based obligations to the fetal patient. Research on animal models should suggest that there would be therapeutic benefit without disproportionate iatrogenic fetal morbidity or mortality. If animal studies result in high rates of mortality or morbidity for the animal fetal subject, then innovation should not be introduced to human subjects until these rates improve in subsequent animal studies.

The third criterion reflects the fact that fetal intervention in the form of fetal surgery is necessarily also as maternal surgery and that ethically and clinically the fetal patient is not a separate patient. This criterion reminds investigators that the willingness of a subject, in this case, the pregnant woman, to consent to risk does not by itself establish whether the risk/benefit ratio is favorable. Judgments about an acceptable risk/benefit ratio should not be autonomy based, but beneficence based. This is because investigators have an independent beneficence-based obligation to protect human subjects from unreasonably risky research and should use beneficence-based, not autonomy-based, risk–benefit analyses. Phrases such as “maternal–fetal surgery” are useful if they remind investigators of the need for such comprehensive analysis. If they are used systematically to subordinate fetal interests to maternal interest and rights, and therefore to undermine the concept of the fetus as a patient in favor of the concept that the fetus is merely a part of the pregnant woman, such phrases lack ethical utility.

Ethical Criteria in Randomized Trials in Maternal–Fetal Medicine

Preliminary innovation should end and randomized clinical trials begin when there is clinical equipoise. Until recently, equipoise has meant that there is “a remaining disagreement in the expert clinical community, despite the available evidence, about the merits of the intervention to be tested” (26). Brody notes that one challenge here is identifying how much disagreement can remain for there still to be equipoise (26). Lilford has suggested that when two-thirds of the expert community, measured reliably, no longer disagree, equipoise is not satisfied (29).

This older concept of equipoise is based on the distribution of opinion in the clinical community, which may or may not be evidence based. To make judgments of equipoise more rigorous, it has been argued that it should be evidence based. This is known as normative equipoise or evidence based, which is the preferred concept (27). When evidence-based evaluation of clinical experience and the current literature supports the judgment that the experimental intervention is more harmful than nonintervention, equipoise cannot be achieved.

The satisfaction of the previous three criteria for innovation, with slight modifications, should count as equipoise in the expert community:

1. the initial case series indicates that the proposed fetal intervention is reliably expected either to be life-saving or to prevent serious and irreversible disease, injury, or handicap;
2. among possible alternative designs, the intervention continues to involve the least risk of morbidity and mortality to the fetus; and
3. the case series indicates that the mortality risk to the pregnant woman is reliably expected to be low and the risk of disease, injury, or handicap to the pregnant woman, including for future pregnancies, is reliably expected to be low or manageable (28).

One good test for the satisfaction of the first and third criteria is significant trends in the data from the case series. When evidence-based equipoise has been achieved on the basis of these three criteria, randomized clinical trials should commence. They must have relevant and clearly defined primary and secondary endpoints and a design and sample size adequate to measure these endpoints.

The above three criteria can be used in a straightforward manner to define stopping rules for randomized clinical trials in fetal research. When the data support a rigorous clinical judgment that the first or third criterion is not satisfied, the trial should be stopped.

Criteria for Making the Transition from Research to Clinical Practice

When a clinical trial in fetal research is completed, its outcome can be assessed to determine whether the investigational fetal intervention should be introduced into clinical practice. Trial results should meet the following three criteria in order to make this important transition:

1. the fetal intervention has a significant probability of being lifesaving or preventing serious or irreversible disease, injury, or handicap for the fetus;
2. the fetal intervention involves low mortality and low or manageable risk of serious and irreversible disease, injury, or handicap to the fetus; and
3. the mortality risk to the pregnant woman is low and the risk of disease, injury, or handicap is low or manageable, including for future pregnancies (28).

Brody has underscored the value of data safety and monitoring boards to prevent investigator bias and to protect subjects (26). Such boards should be used in fetal research, especially to ensure adherence of the above-mentioned ethical criteria as a basis for monitoring such research.

CONCLUSION

Ethics is an essential dimension of clinical practice and research in maternal–fetal medicine. An understanding and clinical application of the ethical principles of beneficence and respect for autonomy and of the ethical concept of the fetus as a patient should guide clinicians and investigators, to better serve pregnant and fetal patients.

43 Basic genetics and patterns of inheritance

Dorothy K. Grange

INTRODUCTION

The field of medical genetics is rapidly expanding. Genetics is becoming increasingly important in the general practice of medicine. Thus, the primary care physician has a responsibility to acquire adequate knowledge of genetics to provide his or her patients with the most up-to-date medical care. In addition to advances in the understanding of the genetic basis for many of the more frequent chromosomal, single-gene, and multiple anomaly syndromes, there is greater knowledge of the role of genetics in common disorders such as hypertension, diabetes, heart disease, cancer, psychiatric disorders, and other medical problems. Medical genetics has a particularly great impact on the practice of obstetrics and on the evaluation and the management of fetal abnormalities, resulting in a need for close working relationships between clinical geneticists and specialists in maternal–fetal medicine. As the growth of information and technology continues, it is anticipated that new forms of genetic therapy, at the somatic cell level and possibly at the germ cell level, will be developed. Some of these treatments may be employed preconceptually and during pregnancy, requiring the involvement of obstetricians and gynecologists.

The human genome contains three billion base pairs of DNA, packaged into units known as chromosomes and encoding an estimated 20,000 to 25,000 genes (1,2). At the present time, over 12,000 human genes have been mapped and almost 3000 single-gene disorders have been described for which the molecular genetic basis is known (3). The Human Genome Project, begun in the late 1980s and completed in 2003, produced a haploid human genome sequence, which was a composite of the DNA sequence of several individuals. As a result, new genes and new information about the genetic basis for many disorders have been discovered. This has already begun to have a huge impact on the practice of medical genetics and medicine in general.

CYTOGENETICS

Cytogenetics is the study of chromosomes and their abnormalities (4,5). The field of cytogenetics is a relative newcomer in clinical laboratory medicine. It was not until the mid-1950s that chromosome analysis could be done. Soon after it was determined that the normal number of chromosomes in humans is 46, rapid discoveries in the area of human cytogenetics were made. In 1959, LeJeune identified the cytogenetic basis of Down syndrome, and around the same time, sex chromosome abnormalities were found in patients with anomalies of sexual development. Techniques for the analysis of chromosomes have continued to be improved and refined, allowing more subtle abnormalities to be identified. Newer molecular cytogenetic methods have revolutionized the identification and confirmation of microdeletions, microduplications, and cryptic translocations.

Humans have a total of 46 chromosomes, including 22 pairs of numbered chromosomes, or autosomes, and one pair of sex chromosomes. Each chromosome comprises a single length of double-stranded DNA, ranging in size from 50 million to 250 million base pairs. This genetic information is tightly compressed and packaged in the formation of the chromosomes. The DNA molecules are complexed with proteins called histones. The histones are packaged into nucleosomes, which are further compacted into a helical structure known as a solenoid. Finally, the solenoids are wound in a helical fashion and compressed to form the chromatin loops. Chromatin is packaged into chromosomes, which can be viewed microscopically during the metaphase stage of cell division.

Performing cytogenetic analysis has become an integral part of many areas of medical practice, including obstetrics, pediatrics, and oncology. Traditional chromosome analysis first involves obtaining a sample of living tissue. This can be blood, skin, amniotic fluid, products of conception, bone marrow, or any viable solid tissue. Blood is the most frequently analyzed tissue for routine chromosome analysis. For blood, the lymphocytes are isolated. For amniotic fluid, the amniocytes are obtained by spinning down the fluid and removing the cell pellet. For solid tissues, the tissue is minced and/or sonicated. For all tissue types, the cells are cultured in tissue culture for 48 to 72 hours. Cell division is arrested at metaphase by the addition of colcemid. The cells are then harvested and placed on a microscope slide. The cell nuclei are ruptured by adding a hypotonic solution, then stained to show the bands, and images of the metaphase chromosome spreads are analyzed. Each chromosome is studied by looking at the banding pattern to identify not only numerical abnormalities, but also structural problems. Newer computerized technology allows karyotype analysis by digital imaging methods. By convention, the 22 autosome pairs are arranged by size, from the largest to the smallest, in four rows, with the pair of sex chromosomes in the lower right corner (Fig. 1). Ideograms are schematic representations of banding patterns used by cytogeneticists to standardize numbering of specific bands (Fig. 2).

Chromosomes have distinctive structural appearances when viewed microscopically. There are two arms with a central narrowing called the centromere. The shorter arm is termed “p” for “petit,” while the longer arm is denoted “q,” because q comes after p alphabetically. The p arm is always shown at the top on karyotypes. There are three types of chromosomes structurally (Fig. 3). Metacentric chromosomes have p and q arms that are almost equal in length, with the centromere located in the middle. Submetacentric chromosomes have a shorter p arm with the centromere placed closer to the top of the chromosome and acrocentric chromosomes have small p arms called satellites with the centromere located near the top of the chromosome. The ends of chromosomes are called the telomeres.

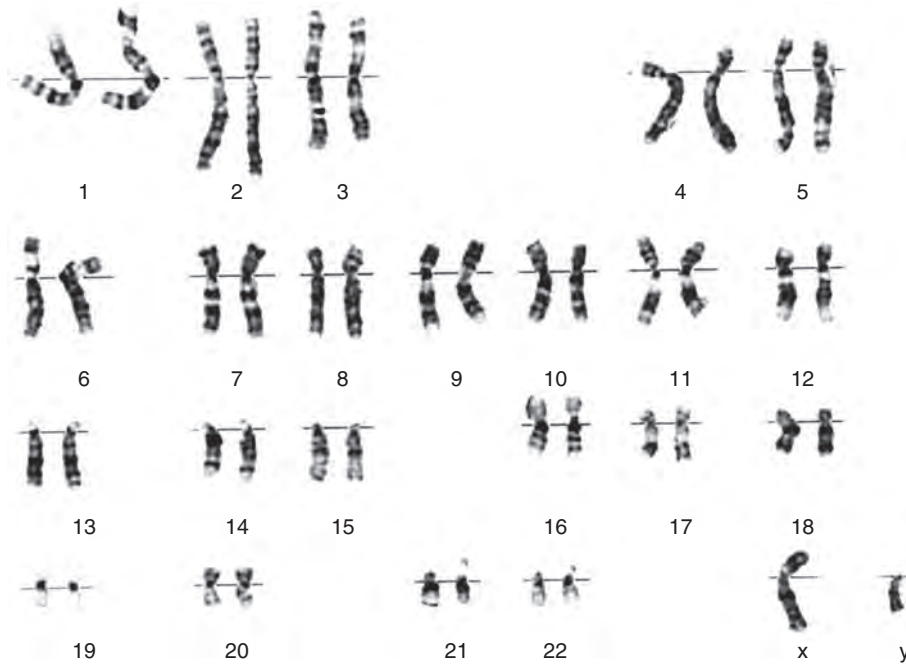

Figure 1 Normal male karyotype.

Figure 2 Ideogram of human chromosome showing Giemsa banding patterns. Source: From Ref. 6.

Various banding techniques are used to visualize the chromosomes. The most frequently used method is Giemsa banding or G-banding, which results in a specific pattern of dark and light bands on each chromosome. The older method, quinacrine banding, or Q-banding, produces the same dark and light patterns, but requires the use of a fluorescence microscope and is not used routinely. Reverse banding or R-banding, results in the opposite of the dark and light pattern seen with G-banding; this may be used to

better see the ends of the chromosomes. C-banding stains the constitutive heterochromatin, which is near the centromeres and NOR stain visualizes the nucleolar organizing regions of the satellites and stalks of acrocentric chromosomes. For routine karyotype analysis, G-banding is typically used by most laboratories. Routine karyotyping cannot detect gains or losses of cytogenetic material smaller than about 4Mb in size and therefore can miss significant abnormalities.

Figure 4 Example of fluorescence in situ hybridization analysis in a patient with Williams syndrome. On the left panel, an interphase cell is shown with a deletion of one copy of the elastin (ELN) gene within the critical 7q11.23 Williams syndrome region; there is only one red ELN signal and there are two green control signals. On the right panel, a metaphase cell is shown indicating a deletion on chromosome 7 with a missing red signal. Source: Courtesy of Dr. Shashikant Kulkarni.

Fluorescence in situ hybridization (FISH) is a technique in which DNA probes attached to fluorescent dyes are hybridized to specific chromosome regions from patient samples, either interphase cells or metaphase chromosome spreads, most often from lymphocytes or amniocytes. The chromosomes are then visualized by fluorescent microscopy. Probes can be designed to hybridize to whole chromosomes, specific chromosome segments of interest, centromeres, or telomeres. FISH is widely used for the diagnosis of suspected recognizable microdeletion syndromes (Fig. 4). Multicolor FISH is useful for analyzing submicroscopic structural rearrangements undetectable by classic cytogenetic techniques or for identifying marker chromosomes. FISH is also used for rapid screening for aneuploidy including trisomy 13, 18, or 21 and abnormalities of X and Y.

Chromosome microarray analysis using array-based comparative genomic hybridization (aCGH) is a powerful new technique for the detection of genomic copy number alterations, including deletions and duplications (7–9). It was originally developed as a research tool, but is rapidly replacing traditional cytogenetic methods of analysis for the diagnosis of chromosomal defects. With this method, DNA

from the patient's DNA and DNA from a normal control are each labeled with different tags for analysis by fluorescence (Fig. 5). The patient and control DNA are mixed together along with unlabeled human cot-1 DNA to suppress repetitive DNA sequences, and the mix is hybridized to a slide containing thousands of defined DNA probes. The (fluorescence) color ratio along the chromosomes is used to evaluate regions of DNA gain or loss in the patient sample as compared with the control DNA. Clinically available arrays include focused arrays that are designed to identify all microdeletions detectable by FISH, bacterial artificial chromosome arrays that can detect rearrangements greater than 1 Mb, oligonucleotide arrays using DNA probes that can pick up imbalances as small as 20 to 80 kb, and single-nucleotide polymorphism arrays. Diagnosis of alterations in DNA dosage or genomic copy number that are known to be associated with a variety of syndromic and non-syndromic pediatric and adult genetic disorders can be found by aCGH analysis. Copy number variations (CNV) or polymorphisms that are not known to be associated with an abnormal phenotype or are considered to be benign are often detected. In addition, previously undescribed deletions or duplications with unclear clinical

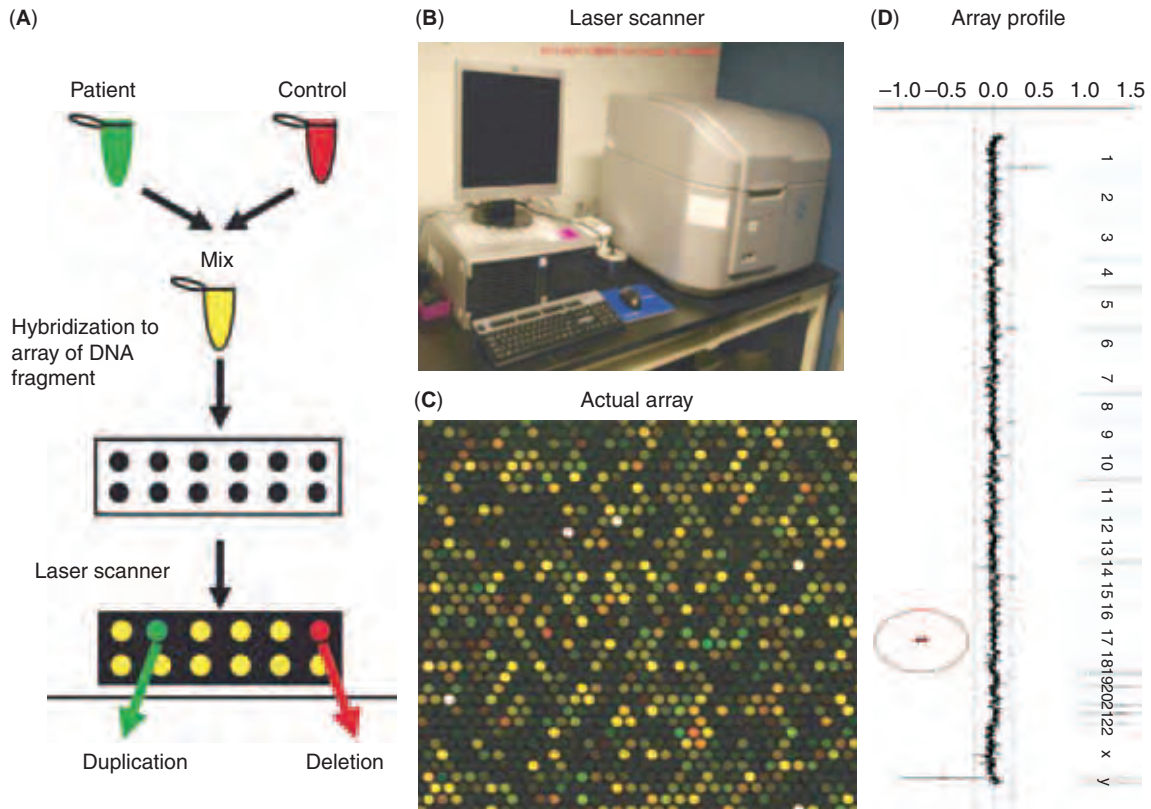

Figure 5 Array comparative genomic hybridization (chromosome microarray) technology. (A) DNA from the patient sample is labeled with a green fluorescence dye and a control DNA is labeled with a red fluorescence dye. The two samples are mixed and co-hybridized to an array of genomic DNA targets on a slide. The ratios of fluorescence intensities are proportional to the ratio of copy numbers of DNA sequences in the patient versus the control samples. Green area indicates duplication and red area indicates deletion. (B) The slides are scanned into image files using a microarray scanner. (C) The output shows hundreds of spots with different ratios of fluorescence intensities. (D) The array profile is analyzed; shown here is a patient profile indicating a deletion of three DNA markers within the neurofibromatosis type 1 critical region on chromosome 17p11.2. *Source:* From Ref. 7.

significance may be identified, requiring parental analysis to determine inheritance of the abnormality and often making genetic counseling for the family difficult. Another caveat of using chromosome microarray analysis is that it cannot detect balanced chromosome rearrangements such as translocations or inversions if there is no gain or loss of a chromosome segment.

CHROMOSOMAL ABNORMALITIES

Chromosome abnormalities are seen in 1 in 150 to 1 in 170 live births and thus, as a group, contribute significantly to morbidity and mortality among neonates and infants (1). Any baby that has two or more congenital anomalies should have a karyotype performed (Table 1). Some of the more frequent chromosome anomalies will be reviewed, as well as the categories of chromosome abnormalities.

Aneuploidy

The term “aneuploidy” refers to an abnormal total number of chromosomes (10). For example, an individual who has either a missing or extra copy of one of the chromosomes is said to have aneuploidy. Aneuploidy is the most common type of chromosome aberration found in humans and arises by a process known as “nondisjunction.” Nondisjunction occurs when there is a failure of proper distribution of chromosome pairs into daughter cells during meiosis, leading to gametes that have either an extra copy of a given chromosome or a missing copy of that chromosome. Meiosis is the process by

Table 1 Indications for Chromosome Analysis

- Suspected recognizable chromosome abnormality
- Infant with two or more malformations
- Mental retardation or developmental delay of unknown etiology, with or without malformations
- Relatives of people with known translocation, deletion, or duplication
- Stillborn infants with malformations or no known reason for fetal demise
- Females with short stature
- Males with infertility, small testes, or gynecomastia
- Women and their partners who have experienced recurrent miscarriages

which the chromosomes in the gamete are reduced from the diploid state (46 chromosomes) to the haploid state (23 chromosomes). There are two cell divisions in meiosis, called meiosis I and meiosis II. In meiosis I cell division, which is also known as the reduction division stage, two haploid cells are formed from one diploid cell. Meiosis II division results in replication of each haploid cell. Nondisjunction can occur in either meiosis I or meiosis II, although 80% of the time it occurs during meiosis I (11). There is a clear association between advancing maternal age and an increased risk for nondisjunctional events (12). However, regardless of parental ages, it has been shown that the extra number 21 in children with trisomy 21 is of maternal origin in 95% of cases and of paternal origin in only 5% of cases (13). In general, if a zygote

Figure 6 Two-year-old boy with Down syndrome. Note brachycephaly, dysplastic ears, epicanthal folds, and upslanting palpebral fissures.

Figure 7 Karyotype of trisomy 21 karyotype. The arrow indicates extra chromosome 21.

has monosomy for an autosome, early embryogenesis will fail and a spontaneous pregnancy loss will occur, sometimes even before the first missed menstrual period. On the other hand, trisomy for an autosome may result in a longer surviving embryo or fetus, or even a liveborn infant. Trisomy 13, trisomy 18, and trisomy 21 (Down syndrome) are the only autosomal trisomies that can result in viable infants in the non-mosaic state. However, mosaicism for many different autosomal trisomies, that is, the presence of both normal and trisomic cells in one individual, has been described in viable infants. Sex chromosome aneuploidy has, in general, less deleterious effects on the affected individual.

Down Syndrome

Down syndrome, or trisomy 21, is the most common autosomal chromosome abnormality seen in liveborn infants (Fig. 6). It occurs in approximately 1 in 700 newborns. As mentioned above, the risk of nondisjunction increases with advancing maternal age. The American College of Obstetrics and Gynecology has recommended that invasive prenatal

testing for Down syndrome and other trisomies should be offered to all women, regardless of age, and not limited to those over age 35 (14). Down syndrome is caused by the presence of three copies of chromosome 21 (Fig. 7). In 95% of cases, there is straightforward trisomy 21 (denoted 47,XX,+21 in a female and 47,XY,+21 in a male), with an extra 21 in every cell of the body, arising by nondisjunction. About 2% to 3% of patients have mosaicism, with some portion of cells having a normal chromosome complement; mosaicism is caused by postzygotic nondisjunction. The features of Down syndrome may be milder in the mosaic form, depending on what percentage of cells are normal. About 2% of Down syndrome cases are caused by a translocation, usually a Robertsonian translocation involving another acrocentric chromosome, such as the number 14 (14;21) or the number 21 (21;21). Karyotyping on all newborns with clinical features of Down syndrome will identify those who have the translocation form. Approximately 25% of translocation cases are inherited from a parent, with a high risk of recurrence in future pregnancies (15,16). Therefore, chromosome analysis should be done

Figure 8 Newborn infant with trisomy 18, showing dysmorphic faces, flexion contracture of fingers, and rocker bottom feet.

on the parents of all cases of translocation-type Down syndrome. If a woman is a 14;21 Robertsonian translocation carrier, there is a 15% risk of Down syndrome in each pregnancy, as well as a high risk of recurrent spontaneous abortions due to the other possible unbalanced chromosome complements in the offspring. If a man is a carrier, the risk of a liveborn baby with trisomy 21 is only about 5% (15,16).

Individuals with Down syndrome usually have a moderate degree of mental retardation, with IQ in the 50 to 60 range. Some have milder mental retardation, while others fall into the severe range. The degree of mental retardation cannot be determined at birth. Early intervention, with involvement in infant stimulation and parent training programs, can improve the developmental outcome. Most people with Down syndrome are educable and many can be mainstreamed in regular classrooms in school. Increasing numbers of individuals with Down syndrome are able to live semi-independently and hold jobs in supervised settings (17, 18).

There are a number of associated birth defects and medical problems in Down syndrome. Approximately 40% to 50% of babies with trisomy 21 have a congenital heart defect, frequently an atrioventricular canal or septal defect (19). About 12% of these babies have a malformation of the gastrointestinal tract, most often duodenal atresia, but occasionally Hirschsprung's disease, imperforate anus, or

tracheoesophageal atresia. Other birth defects include congenital cataracts (3%), syndactyly, 11 pairs of ribs, and urinary tract anomalies (2–3%) (20). Anomalies can be detected by prenatal ultrasound, particularly the heart defects and duodenal atresia. If either of these types of anomalies is seen, prenatal testing for Down syndrome should be considered.

Postnatal medical problems, in addition to developmental delay and mental retardation, include poor feeding and hypotonia in infancy, obesity later in life, visual impairment (myopia in 70%), recurrent otitis media and hearing loss, hypothyroidism (20%), atlantoaxial or atlanto-occipital instability (5–10%), and childhood leukemia (1%) (20).

Trisomy 18

Trisomy 18 (Edward syndrome) is a much less common autosomal trisomy, seen in approximately 1 in 7000 liveborn infants (21). It has been estimated that at least two-thirds of trisomy 18 conceptuses are lost by spontaneous abortion. Trisomy 18 is caused by the presence of three copies of the number 18 chromosome, again arising by nondisjunction in meiosis I or meiosis II.

The prognosis for trisomy 18 is extremely poor and the majority of infants die within the first 3 months of life. There are, however, a few individuals who have survived to their teens and twenties. The associated mental retardation is severe to profound. In general, the birth defects seen in trisomy 18 are more frequent and much more severe than that in trisomy 21 (Fig. 8). Most infants have significant intrauterine growth retardation, which may be identified by prenatal ultrasound. Approximately 85% of infants have a congenital heart defect, including septal defects, multivalvular dysplasia, and complex anomalies. Other anomalies are dysmorphic facial features, short sternum, joint contractures, overlapping digits, rocker bottom feet, renal abnormalities, and occasionally gastrointestinal tract anomalies and neural tube defects.

Trisomy 13

Trisomy 13 (Patau syndrome) is the third autosomal trisomy, which can be seen in liveborn infants. It is less common than trisomy 18 and occurs in about 1 in 12,000 live births (19). As in trisomy 18, the prognosis for trisomy 13 is very poor, with most infants dying within the first 3 months. Depending on the severity of the associated birth defects, longer-term survival is possible. Infants with trisomy 13 tend to be better grown than those with trisomy 18 (Fig. 9). However, they are more likely to have microcephaly, which can be seen by prenatal ultrasound. Congenital heart defects are present in 80% to 85%, again often of a complex nature. Those with less significant heart defects may survive longer. Holoprosencephaly, cleft lip and palate, renal anomalies, and omphalocele are frequent abnormalities in trisomy 13, which may be detected by prenatal ultrasound.

Sex Chromosome Abnormalities

Sex chromosome abnormalities as a group are very common. Approximately 1 in 500 individuals has a sex chromosome abnormality, although it has been suggested that the true incidence may be higher. Some cases may never be ascertained due to the relatively mild signs and symptoms associated with most of the common sex chromosome problems. Many patients

Figure 9 Newborn infant with trisomy 13, showing microphthalmia, bilateral cleft lip and palate, and postaxial polydactyly of the hands.

are not diagnosed until adulthood when they may undergo evaluation for infertility or other reproductive problems.

Turner Syndrome

Turner syndrome is one of the most familiar sex chromosome abnormalities. It is caused by the presence of only one X chromosome (45,X) in phenotypic females. This classic Turner karyotype is seen in 50% of cases; other cases may be mosaic (45,X/46,XX), or may be caused by an abnormal X chromosome, such as an isochromosome or ring X (1). There may be portions of a Y chromosome present or mosaicism for a 46,XY cell line in some cases. FISH testing for SRY is recommended for detection of Y chromosome material. Turner syndrome is seen in about 1 in 2500 newborn girls. However, it is well known that the incidence is much higher in early pregnancy, with more than 98% of 45,X embryos and fetuses being lost by spontaneous miscarriage. This would suggest that the incidence among conceptuses could be as high as 1.5%, an extraordinarily high frequency (5).

Features of Turner syndrome detectable by ultrasound include cystic hygroma, lymphedema, or hydrops fetalis; when these abnormalities are seen, the prognosis for survival of the pregnancy is poor (22). Smaller cystic hygromas may resolve during pregnancy, leaving a webbed neck or excess nuchal skin. Other anomalies seen in Turner syndrome include

congenital heart defects, frequently coarctation of the aorta, and renal anomalies, often horseshoe kidney. Lymphedema may be seen at birth, often involving the dorsum of the hands and feet, as well as a shield-shaped chest and wide-spaced nipples. For surviving girls with Turner syndrome, the prognosis for good health and a normal lifespan is excellent. Intelligence is normal, although there may be some specific learning disabilities. However, due to the “streak” ovaries, puberty and the onset of menses will not usually occur without hormone therapy and the average adult height without growth hormone treatment is 57 inches. The long-term outcome with estrogen/progesterone replacement and growth hormone therapy is very good. A number of successful pregnancies in women with Turner syndrome have been reported, with the use of ovum donation and in vitro fertilization techniques (23).

Klinefelter Syndrome

Klinefelter syndrome is caused by the presence of an extra X chromosome in a phenotypic male (47,XXY) and occurs in approximately 1 in 500 to 1 in 1000 males. If Klinefelter syndrome is detected prenatally, it is usually by chance, when an amniocentesis is being done for other reasons. There are no expected fetal anomalies in Klinefelter syndrome and most cases are not diagnosed in infancy. The diagnosis may be suspected in a boy with tall thin body habitus and mild learning disabilities. Testicular size is usually normal in prepubertal boys. However, boys with Klinefelter syndrome fail to go through puberty normally and eventually have small, firm testes and relatively hypoplastic external genitalia. They are usually sterile, and the diagnosis is sometimes made in an adult infertility or urology clinic.

47, XXX Syndrome

This chromosome abnormality is thought to occur in 1 in 1000 women, although the true incidence may be higher. Many cases are probably never ascertained because of the mild nature of the associated signs and symptoms. There is no recognizable phenotype, except perhaps tall stature and mild learning problems. Fertility is normal and the risk of sex chromosome aneuploidy in the offspring of an affected woman appears to be low.

47, XYY Syndrome

This chromosome abnormality is also fairly common, occurring in about 1 in 800 men. Again, there is no definite phenotype except taller than expected stature, slightly long facies and long digits. Most individuals have normal intelligence, but there have been reports of personality disorders and antisocial behavior. The incidence may be underestimated due to the nonspecific phenotype. This condition is most often diagnosed serendipitously.

Structural Alterations

In addition to aneuploidy, in which there is loss or gain of an entire chromosome, rearrangements, deletions, or duplications of portions of chromosomes can occur. These structural alterations can result in either balanced or unbalanced chromosome abnormalities. In unbalanced abnormalities, there is missing and/or additional chromosome material, which often causes multiple birth defects and developmental problems. Balanced chromosome abnormalities involve rearrangements of

the chromosomes without loss or gain of chromosome material and are usually found in normal individuals.

One frequent cause of structural alteration is a translocation. There are two basic types of translocations. A reciprocal translocation occurs when two chromosomes break and the pieces exchange places (Fig. 10). The resulting abnormal chromosomes are called "derivative chromosomes." If the reciprocal translocation is balanced, the individual is usually

Figure 10 Reciprocal translocation between chromosomes 3 and 21. The break points on the long arm of each chromosome are indicated by the wavy line. Source: From Ref. 6.

normal. Translocations such as these are found in approximately 1 in 500 normal individuals in the general population and are usually never detected. However, if a parent carries a balanced translocation and passes only one of his or her derivative chromosomes to an offspring, along with the other normal chromosomes, the child will have an unbalanced chromosome complement and will likely have multiple problems as a result (Fig. 11). Inheritance of a derivative chromosome in this situation causes a partial duplication (partial trisomy) of one chromosome and a partial deletion (partial monosomy) of another chromosome.

In Robertsonian translocations, the satellites of two acrocentric chromosomes are lost and the q arms of the chromosomes fuse at the centromeres, resulting in a single chromosome (Fig. 12). Thus, a carrier of a Robertsonian translocation has a total of only 45 chromosomes, but has a balanced chromosome complement and is a normal individual. The loss of the satellites poses no problems since these regions of chromosome material encode repetitive sequences that are not essential. A Robertsonian translocation in a parent can result in an unbalanced chromosome abnormality in his or her offspring. If the zygote inherits the translocation chromosome along with either one of the parents' corresponding normal chromosomes, the child will have trisomy for that chromosome. If the zygote receives the translocation chromosome alone, a normal carrier would be produced. If the zygote does not receive the translocation chromosome, and thus has one of the single involved chromosomes, a monosomy would be produced, which would cause a miscarriage. As previously discussed, most autosomal trisomies are lethal. The only unbalanced Robertsonian translocations seen in liveborn babies with trisomies are in Down syndrome and trisomy 13. Other trisomies for acrocentric autosomes, such as trisomy 14, trisomy 15, or trisomy 22 are lethal abnormalities and

Figure 11 Meiotic segregation in a reciprocal translocation involving chromosomes 3 and 21. Source: From Ref. 6.

would cause miscarriages. The most frequent Robertsonian translocation encountered in the general population is a 13;14 translocation, followed in frequency by a 14;21 translocation (22). The former would place a carrier at high risk for having a child with trisomy 13, while the latter would result in a high risk for trisomy 21, and both would be expected to cause a higher risk for recurrent pregnancy loss due to lethal trisomies and monosomies.

Another type of structural abnormality is a deletion, in the absence of a translocation. Deletions can be terminal, that is, at either end of the chromosome, or interstitial, within the short or long arm of the chromosome. As can be imagined, there is an almost infinite number of possible deletions that can occur as a result of accidents during meiosis. However, some specific deletions are seen more frequently. One such relatively common terminal deletion is 5p- or cri du chat syndrome. Cri du chat syndrome is associated with microcephaly and mental retardation in all cases, congenital heart defects in about 30%, and craniofacial dysmorphic features, including a round face, epicanthal folds, hypertelorism, and dysplastic ears (19). Newborns with cri du chat syndrome have a mewing or cat-like cry, for which the syndrome was named. Another fairly frequent terminal deletion is 4p- or Wolf-Hirschhorn

syndrome, a disorder associated with mental retardation, growth deficiency, and distinctive craniofacial dysmorphic features. Patients with Wolf-Hirschhorn have microcephaly, a prominent glabellar region, hypertelorism, strabismus, cleft lip and/or palate, and micrognathia (19). They may have associated cardiac, renal, and genital anomalies. These types of deletions are usually visible on routine karyotype analysis due to their large size. However, deletions can obviously vary widely in size; some are too small to be seen on routine studies and will require FISH analysis or chromosome microarray analysis to be detected.

There are an increasing number of recognizable microdeletion syndromes (Table 2). For example, Prader-Willi and Angelman syndromes are microdeletion syndromes, both involving a deletion at 15q11q13. Prader-Willi syndrome is a complex disorder associated with hypotonia and failure to thrive in early infancy, followed by rapid weight gain after about 2 years of age and severe obesity, mental retardation, hypogonadism, and craniofacial dysmorphic features. By contrast, the Angelman syndrome phenotype is very different, even though both syndromes are associated with the same microdeletion. Angelman syndrome, also called the “happy puppet” syndrome, presents with severe mental retardation,

Figure 12 Meiotic segregation in Robertsonian translocation involving chromosomes 14 and 21. Source: From Ref. 6.

Table 2 Microdeletion Syndromes

Syndrome	Clinical features	Chromosome deletion
Alagille	Cholestasis, pulmonary atresia, vertebral anomalies, dysmorphic facial features	20p11.23-p12.2
Angelman	Mental retardation, seizures, ataxic gait	15q11.2q13
DiGeorge/velocardiofacial	Characteristic facies, cleft palate, heart defect, thymic hypoplasia	22q11.2
Langer-Giedion	Characteristic facies, sparse hair, exostoses, mental retardation	8q24
Miller-Dieker	Lissencephaly, characteristic facies	17p13.3
Prader-Willi	Mental retardation, obesity, short stature, hypotonia, hypogonadism	15q11.2q13
Smith-Magenis	Dysmorphic facies, sleep disturbance, mental retardation, self-destructive behavior	17p11.2
Williams	Mental retardation, supravalvular aortic stenosis, characteristic facies	7q11.23
Retinoblastoma	Eye tumor	13q14
Wilms tumor/aniridia	Mental retardation, aniridia, Wilms tumor, genital defects	11p13

Figure 13 Two unrelated boys with Williams syndrome. Note epicanthal folds, upturned nose, and wide mouth with full lips. Source: From Ref. 25.

seizures, ataxia, and inappropriate laughter. It is now known that genomic imprinting is responsible for the phenotypic differences between these two syndromes. Genomic imprinting implies that maternally and paternally derived genetic information at the same locus is not identical and interchangeable, at least for some portions of the genome. In Prader-Willi, the deletion always occurs on the paternally derived number 15 chromosome, resulting in lack of genetic influence from the father in this region. About 70% to 75% of Prader-Willi patients have such a deletion, while the remainder have no visible abnormalities; virtually all of these remaining patients have maternal disomy, meaning that they have two copies of the mother's chromosome 15 and neither of the father's, again resulting in lack of paternal genetic influence in this region (1). The disomy can be either isodisomy, in which there are two identical copies of one of the maternal 15 chromosomes, or heterodisomy in which the two copies represent one of each of the maternal number 15 chromosomes. The mirror image situation exists in Angelman syndrome; if a deletion is found, it is always on the maternally derived number 15, and if there is no deletion, there is paternal disomy for 15, both cases resulting in loss of maternal genetic influence in this region of 15 (1). Thus, genomic imprinting of the genes in this area at 15q11q13 is taking place, since lack of influence from either parent can result in two very different syndromes.

Many other microdeletion syndromes have been identified (24). Many of these conditions were well recognized by clinical geneticists for years before the microdeletion could be detected. With the improvement of cytogenetic technology, smaller fragments of missing chromosome material can be identified using FISH. Studies in this area have been aided by the use of chromosome microarray analysis. Microdeletion syndromes have also been referred to as contiguous gene syndromes because of the loss of multiple adjacent genes. It is understandable that the phenotypes of these patients may vary depending on the size of the deletion and the number and importance of the deleted genes. One good example of this is Williams syndrome, which is readily diagnosed by FISH (Fig. 4). Williams syndrome is a well-recognized multiple

anomaly syndrome characterized by moderate mental retardation, craniofacial dysmorphic features, hypercalcemia, and cardiovascular abnormalities. Facial features include epicanthal folds with periorbital fullness, stellate iris pattern, long philtrum, and wide mouth with prominent lips (Fig. 13). The cardiovascular abnormalities typically involve supravalvular aortic stenosis, but other blood vessels, such as pulmonary and renal arteries, may be affected. Most cases are sporadic, but there is autosomal dominant inheritance in some families. There is a separate, clearly autosomal dominant disorder of isolated supravalvular aortic stenosis, which is not associated with the other features of Williams syndrome. It has been discovered that the supravalvular aortic stenosis and other vascular abnormalities in both of these disorders are due to abnormalities in the gene for elastin, which is located on chromosome 7 at 7q11.23 (26). In the case of Williams syndrome, one copy of the elastin gene is deleted, along with other genes in the surrounding regions. Williams syndrome patients without deletion of the elastin gene do not have arterial disease. Thus, variable expression of contiguous gene or microdeletion syndromes can be directly related to the extent of the deleted genes, but all patients share an overlapping area of involvement.

In addition to deletions, duplications of chromosome material can occur in the absence of a translocation, and again there are an increasing number of newly recognized microduplication syndromes detectable with the use of chromosome microarray analysis. Duplications can be interstitial, within the body of the chromosome, or terminal, at the end of the chromosome. Duplication of a portion of chromosome material results in partial trisomy for that region. As with deletions, there are an almost endless number of possible duplications that could result from errors in meiosis during gamete formation. Some of the common duplications have been found in regions associated with deletions of the same region, including the 22q11.2 microduplication syndrome at the same locus as the DiGeorge/velocardiofacial syndrome deletion (Fig. 14) and the 7q11.23 microduplication syndrome at the same locus as the Williams syndrome deletion.

Figure 14 Array comparative genomic hybridization for 22q11.2 microdeletion and microduplication syndromes. (A) A 3Mb loss of chromosomal material in a patient with the 22q11.2 microdeletion syndrome (DiGeorge/velocardiofacial syndrome) is shown on the left and its reciprocal gain in a patient with the 22q11.2 microduplication syndrome is shown on the right. (B) Deletion confirmed by metaphase fluorescence in situ hybridization (FISH) analysis, with a single red 22q11.2 signal and two green control signals. (C) Duplication confirmed by interphase FISH showing three red signals and two control green signals. Source: From Ref. 7.

Another type of structural rearrangement is a ring chromosome. A ring occurs when the terminal p and q arms are deleted and the “sticky ends” anneal to each other. This can occur with any chromosome, perhaps most frequently with

the X chromosome. The seriousness of the effects is related to the extent of the deletions produced.

Inversions refer to breakage of a chromosome at two places with secondary inversion and reinsertion of the

Figure 15 Structural abnormalities of chromosomes (see text for details).
Source: From Ref. 6.

material back into the same chromosome. If this occurs within either the p arm or the q arm, it is said to be a paracentric inversion, since the centromere is not affected. If it occurs on either side of the centromere, it is a pericentric inversion (Fig. 15). Most individuals with inversions are

normal. Sometimes, an inversion results in a deletion or duplication of chromosome material, leading to phenotypic or developmental abnormalities. If a parent has an inversion, his or her offspring could have an unbalanced chromosome constitution if proper pairing does not occur during meiosis and abnormal gametes are formed. If an inversion is present, a loop forms during chromosome pairing in meiosis I. Recombination, or crossing over, which normally occurs in meiosis I, can take place in the loop as well, potentially leading to unbalanced gametes. However, normal carriers of paracentric and pericentric inversions have different risks of producing abnormal offspring. If the inversion is paracentric, the unbalanced gametes produced are likely to be acentric or dicentric, with a very low chance of resulting in a viable liveborn child with a chromosome abnormality. If the inversion is pericentric, the centromere is not affected by recombination and abnormal gametes with duplication and deletion of material distal to the inversion can be produced, potentially leading to viable offspring with chromosome anomalies. The larger the pericentric inversion, the more likely it is that abnormal offspring can be produced, since the duplicated or deleted segments are smaller. The overall risk that a pericentric inversion carrier will have karyotypically abnormal children is estimated to be between 1% and 10% (16).

Finally, isochromosomes result from loss of either the p arm or the q arm of a metacentric or submetacentric chromosome, with duplication of the remaining arm, thus causing trisomy for the p or q arm of a pair of chromosomes and monosomy for the opposite arm. This is seen most commonly in some cases of Turner syndrome, when the X chromosome is involved. Isochromosomes for the autosomes would be expected to cause very severe and likely lethal abnormalities in most cases.

Chromosome Abnormalities in Spontaneous Abortions

Chromosomes examined from products of conception from pregnancy losses at various stages of gestation show an exceptionally high rate of chromosomal abnormalities. In fact, as many as 10% to 15% of early embryos have a chromosome abnormality, usually leading to a spontaneous pregnancy loss (27). Approximately 50% to 60% of spontaneous abortions are caused by a chromosome anomaly in the embryo or fetus (28). At the time of live birth, approximately 1 in 150 newborns is chromosomally abnormal. Thus, as stated by John Opitz, "it seems established that most of, 'humanity' dies before, rather than after birth, and that perhaps only a third survive from the earliest beginnings till [sic] birth..." (29). The most frequent abnormalities seen are autosomal trisomies (52%), especially trisomy 16 (15%), trisomy 13, 18, and 21. 45,X accounts for 18% of abnormalities and triploidy is found in 17% (30). There is a steady loss of these abnormal pregnancies throughout the first trimester. By 20 weeks, the incidence has fallen to 27 in 1000 or 2.7%, and by full term, the incidence is 6 in 1000 or 0.6% (28).

In the vast majority of cases, the occurrence of a chromosomally abnormal pregnancy with spontaneous abortion does not increase the risk of recurrence in a future pregnancy. A general rule of thumb is that products of conception should be evaluated by karyotype analysis on the third pregnancy loss. Parental blood chromosomes should also be analyzed at this point, looking for a balanced translocation in

Table 3 Common Single-Gene Disorders

Disease	Incidence
<i>Autosomal dominant</i>	
Adenomatous polyposis coli	1 in 6000
Adult polycystic kidney disease	1 in 1000
Familial hypercholesterolemia	1 in 500
Hereditary nonpolyposis colorectal cancer	up to 1 in 200
Huntington disease	1 in 20,000
Marfan syndrome	1 in 10,000 to 1 in 20,000
Myotonic dystrophy	1 in 7000 to 1 in 20,000
Neurofibromatosis type I	1 in 3000 to 1 in 5000
Osteogenesis imperfecta	1 in 10,000 to 1 in 15,000
<i>Autosomal recessive</i>	
A1-Antitrypsin deficiency	1 in 2500 to 1 in 10,000 Caucasians
Cystic fibrosis	1 in 2000 Caucasians
Hemochromatosis	1 in 5000
Phenylketonuria	1 in 10,000 to 1 in 20,000
Sickle cell disease	1 in 400 African-Americans
Tay-Sachs disease	1 in 3000 Ashkenazi Jews
Thalassemia	1 in 50 to 1 in 100 Asians and in Mediterranean populations
<i>X-linked</i>	
Duchenne muscular dystrophy	1 in 3500 males
Fragile X syndrome	1 in 1200 males; 1 in 2500 females
Hemophilia A	1 in 10,000 males
Color blindness	8% of males
Glucose 6-phosphate dehydrogenase deficiency	10-15% of African-American males

one of the partners. A translocation is found in approximately 5% to 10% of couples with recurrent miscarriages (31).

MENDELIAN INHERITANCE

In 1865, an Austrian monk named Gregor Mendel published his now-famous treatise on the inheritance of characteristics in garden peas, leading eventually to the modern study of genes and inheritance, including human genetic disorders. However, Mendel’s original work was largely ignored during his lifetime. In fact, his contemporary, Charles Darwin, apparently never knew of Mendel’s research and hypotheses. Mendel’s work was “rediscovered” at the beginning of the 20th century. In 1902, Archibald Garrod reported the first known human Mendelian disorder, alkaptonuria. Over the last century, thousands of human single-gene traits and disorders have been described (Table 3). These conditions were catalogued over many years by Victor McKusick in his *Mendelian Inheritance in Man* and now in an online version OMIM (Online Mendelian Inheritance in Man) (3).

Since humans have two copies of each chromosome, we also have two copies of each gene. Alternative forms of the same gene are called “alleles.” Each chromosome contains hundreds of different genes. At the time of conception, we inherit one of each pair of genes from our mother and the other of each pair from our father. Thus, we receive an equal amount of genetic information from each parent.

There are four basic inheritance patterns of human single-gene disorders. These include autosomal dominant and

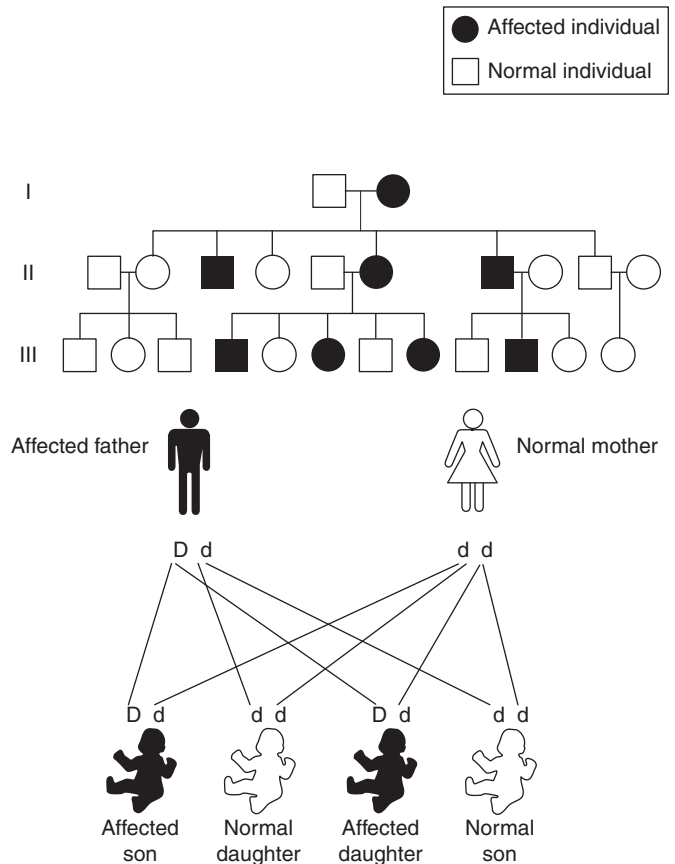

Figure 16 Autosomal dominant inheritance. Both males and females are affected and there is male-to-male transmission of the disorder. Source: From Ref. 25.

autosomal recessive inheritance, in which the mutant gene is on an autosome, and X-linked dominant and X-linked recessive inheritance, in which the mutant gene is on the X chromosome. Individuals can be heterozygous for a given gene, meaning that they have two different forms, or alleles, of the gene at the same locus on each of the two different chromosomes. Individuals can also be homozygous for a gene, in which the two alleles are identical. Males are said to be hemizygous with respect to genes on the X chromosome, since they have only one copy of the X.

In autosomal dominant genetic disorders, only one copy of a mutant allele is necessary for expression of the disease (Fig. 16). Thus, heterozygotes will be affected. The risk of passing on the mutation to an offspring is 50% for each pregnancy. Vertical transmission of the disorder is seen on pedigree analysis, and the condition can often be traced back many generations. However, there are certain caveats to keep in mind when evaluating autosomal dominant disorders. First, there is a high degree of variability of expression of dominant conditions. Even within the same family, some individuals may be severely affected while others may have very mild and medically insignificant features. Thus, thorough review of medical histories and physical examinations on multiple family members are often parts of a genetic evaluation. Second, there may be reduced penetrance of a dominant disorder. Thus, a heterozygote may not show any manifestations of the mutant gene after a complete medical evaluation. Finally, many autosomal dominant disorders have a high new spontaneous mutation rate and a dominant condition may

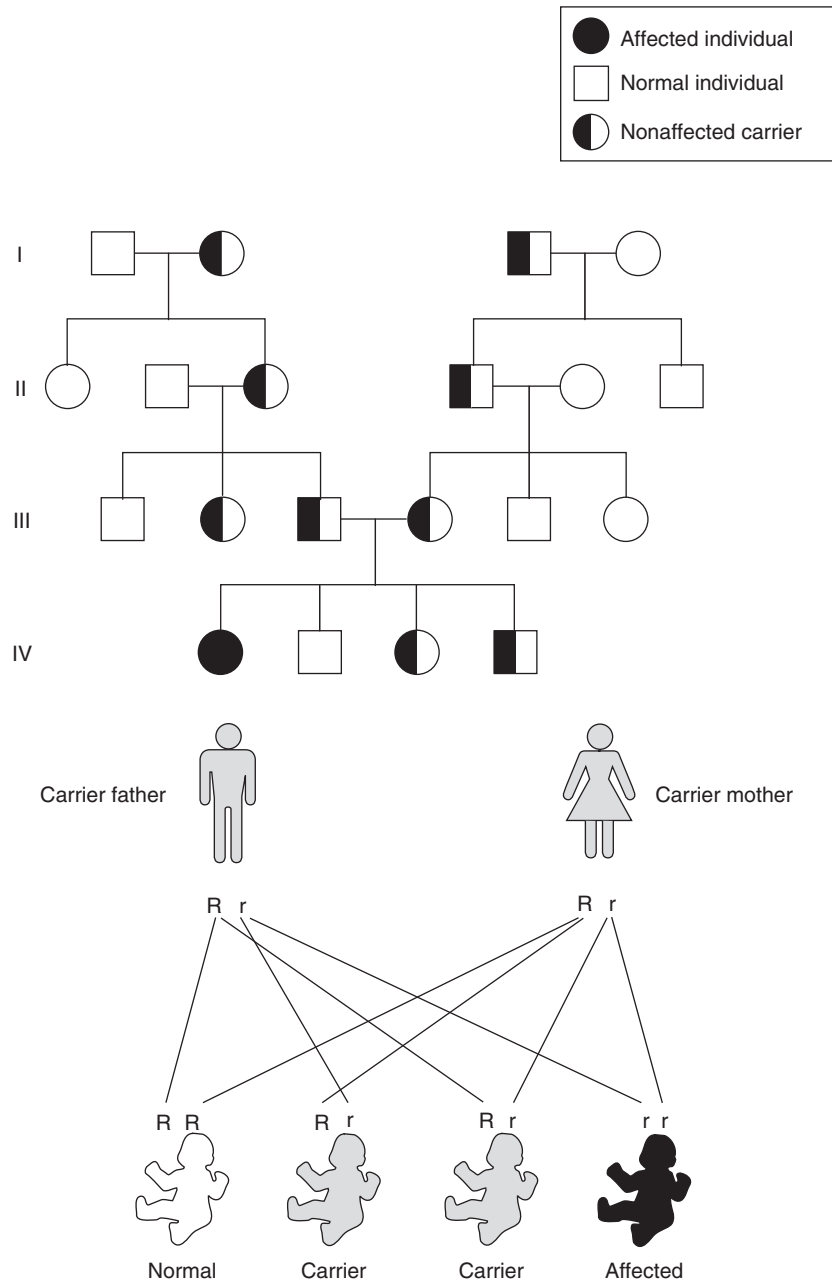

Figure 17 Autosomal recessive inheritance. Note that both parents must be carriers and the affected offspring may be male or female. Source: From Ref. 25.

appear de novo in an isolated individual in a pedigree. However, once present, it can be passed on to subsequent generations. In general, abnormal genes in autosomal dominant disorders likely encode structural proteins, such as collagen, which is abnormal in osteogenesis imperfecta, or fibrillin, which is mutant in Marfan syndrome.

In autosomal recessive conditions, two copies of a mutant allele are necessary for expression, and only homozygotes will be affected (Fig. 17). Heterozygotes for recessive genes are usually normal and do not have any manifestations of the disease, but they are carriers. Autosomal recessive disorders manifest only if both parents are carriers of the same mutant gene and the offspring receives one mutant allele from each parent. Individuals with autosomal recessive disorders are often compound heterozygotes, meaning that they have two different mutant alleles of the same gene, resulting in expression of the disorder. Recurrence risk for a recessive

disorder is 25% for each pregnancy. There is a 25% chance of having a normal noncarrier child and a 50% chance of having a carrier child. Pedigree analysis usually does not reveal other affected family members outside of the nuclear family group, unless there is consanguinity. The incidence of an autosomal recessive disorder in a population is related to the frequency of heterozygotes. The carrier rate for some conditions is high, while it is very low for others. Recessive conditions have a higher incidence in isolated or inbred populations. Recessive disorders show little variation in expression among affected members within a pedigree, although there may be inter-familial variation due to different mutant alleles. In general, recessive disorders more likely involve genes that encode enzymes or molecules important in cellular functions. Examples include inborn errors of metabolism caused by enzyme deficiencies, hemoglobinopathies, and defects in cellular membrane transport mechanisms, as in cystic fibrosis.

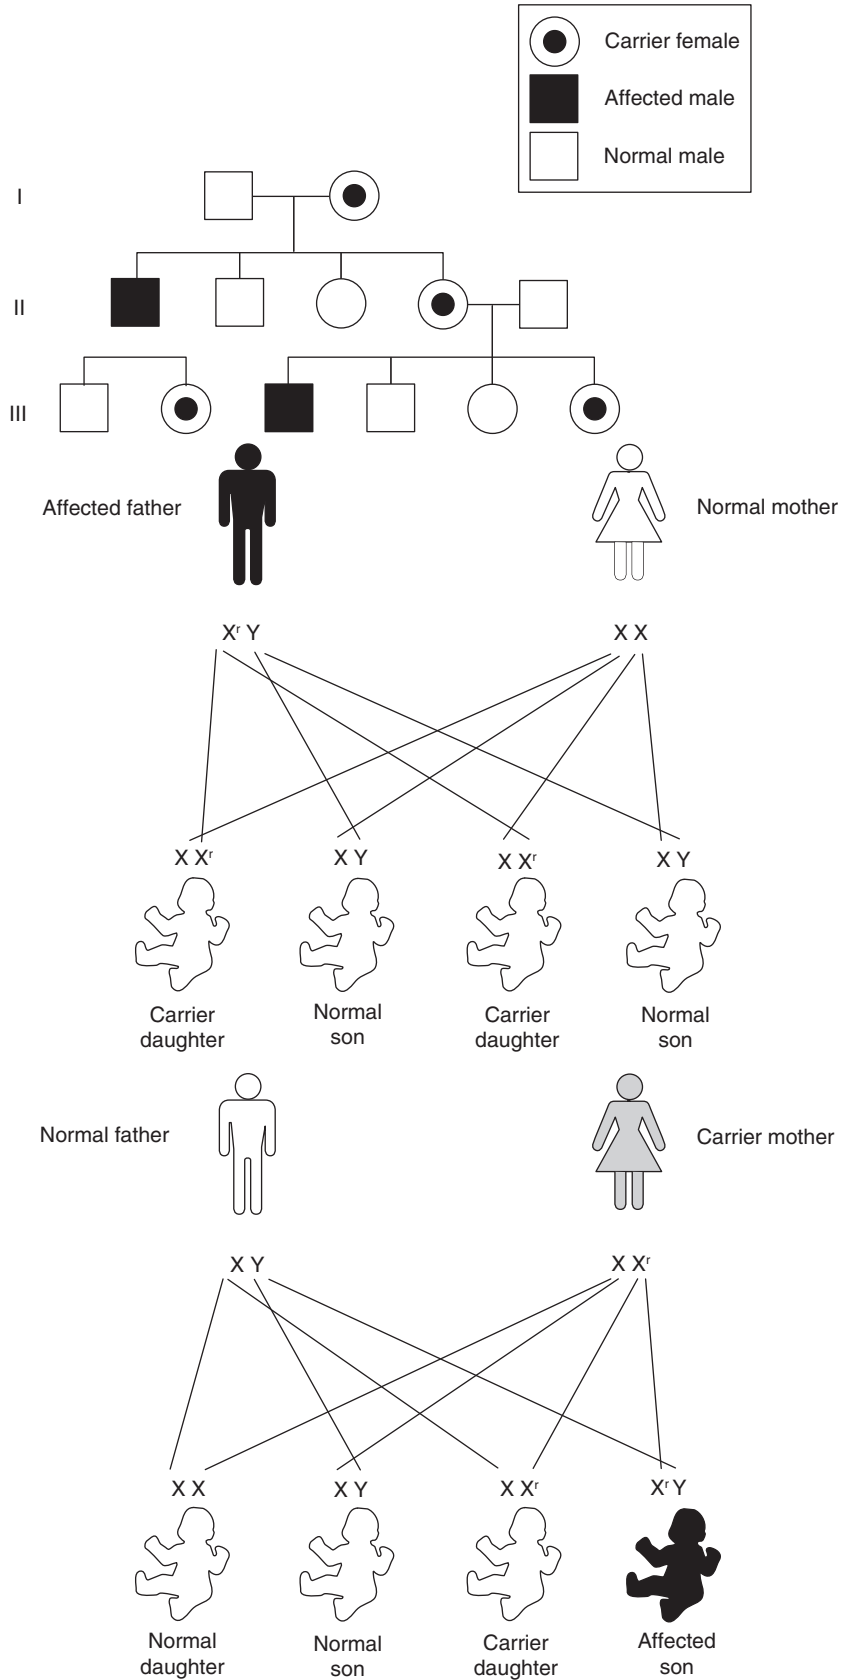

Figure 18 X-linked recessive inheritance. Males can be affected in multiple generations and they inherit the trait from their mothers. Source: From Ref. 25.

X-linked recessive conditions are caused by mutations in genes on the X chromosome. Since males are hemizygous for X-linked genes, they will express such mutations, while females with a mutant recessive gene on one X chromosome will be carriers with a normal phenotype (Fig. 18). There are

exceptions to these rules. For example, if the X-inactivation process results in a larger proportion of active X chromosomes carrying the mutant allele, a female may show expression or partial expression of the disorder. In X-linked dominant conditions, only one copy of the mutant allele is needed for full

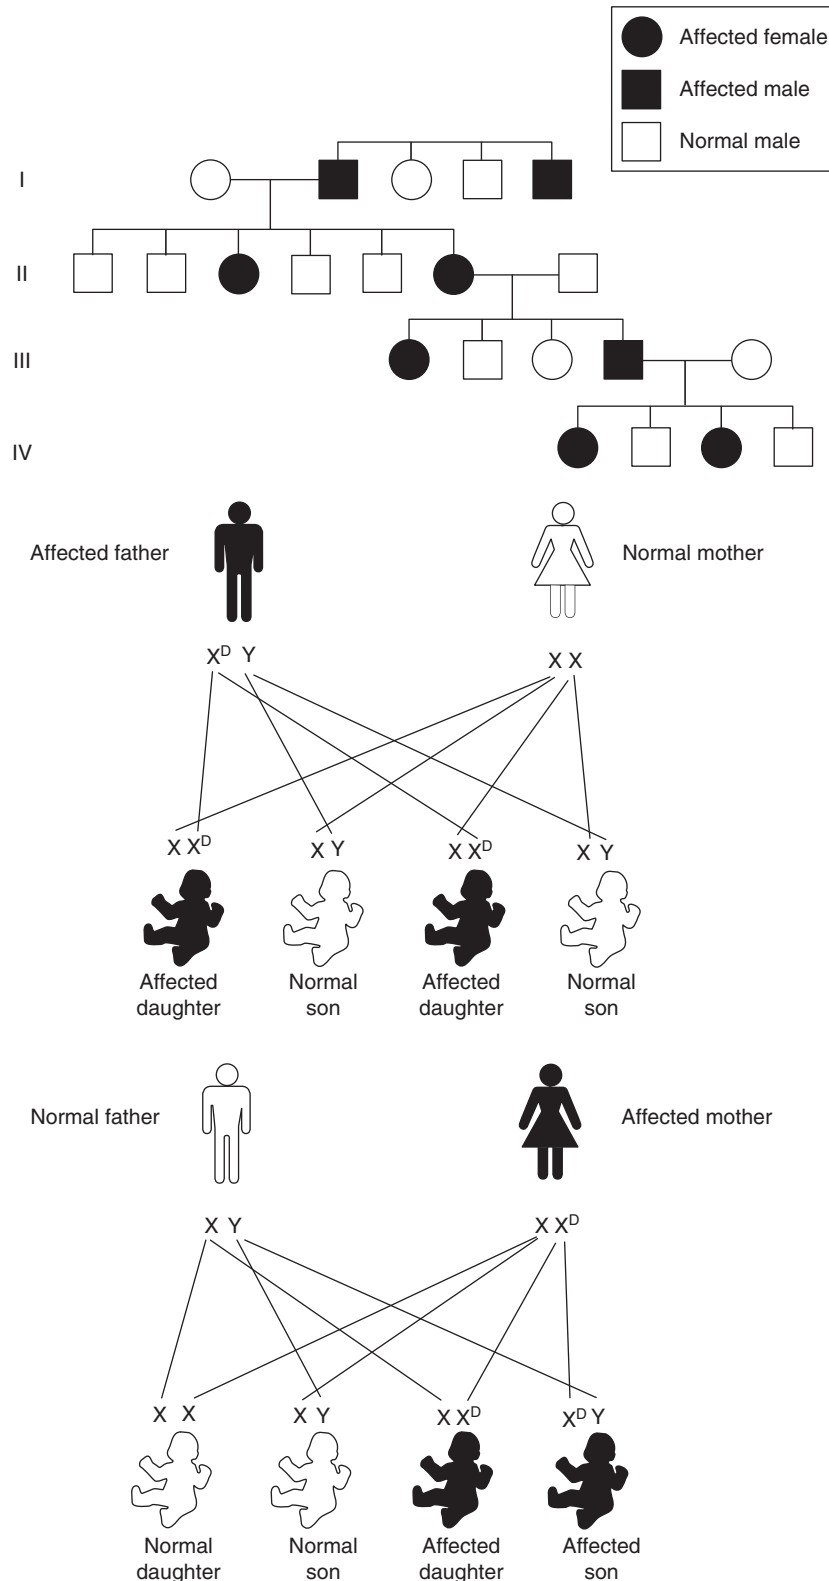

Figure 19 X-linked dominant inheritance. Males and females are affected, but male-to-male transmission does not occur.

expression of the disorder (Fig. 19). In this situation, males and females are both affected, but males will show much more severe manifestations than females, or the mutation may even be lethal in males.

There are fewer Y-linked genes known at this time. The most recent update on OMIM lists 59 genes identified on the Y chromosome, including the *SRY* gene, which is involved in male sex determination (3). Y-linked, or holandric,

conditions, such as maleness itself, are passed exclusively from father to son.

MULTIFACTORIAL AND POLYGENIC INHERITANCE

In multifactorial inheritance, it is postulated that genetic influences from both parents, in combination with environmental factors, lead to a specific birth defect or disorder. In polygenic inheritance, multiple genetic influences in

Table 4 Multifactorial Disorders

Disorder	Incidence
<i>Congenital malformations</i>	
Cleft lip with/without cleft palate	1 in 500 to 1 in 1000
Cleft palate	1 in 1000
Club foot	1 in 1000
Congenital heart defects	1 in 200 to 1 in 500
Neural tube defects	1 in 500 to 1 in 1000
Pyloric stenosis	1 in 300
<i>Adult diseases</i>	
Alcoholism	1 in 10 to 1 in 20
Alzheimer's disease	1 in 10
Bipolar affective disorder	1 in 100 to 1 in 200
Cancer	1 in 3
Diabetes (types I and II)	1 in 10
Coronary artery disease	1 in 3 to 1 in 5
Schizophrenia	1 in 100

combination act together to produce a disorder. Examples of birth defects with multifactorial inheritance include isolated congenital heart defects, cleft lip with or without cleft palate, cleft palate, neural tube defects, pyloric stenosis, and congenital dislocation of the hips (Table 4). In multifactorial disorders, there is no evidence to suggest simple Mendelian inheritance. For example, the defect does not necessarily appear in sequential generations of a family, as would an autosomal dominant condition due to a single-gene mutation. However, there may be clustering of the defect in more than one member of a pedigree. The appearance of multifactorial disorders has been explained by a threshold model in which certain genes present in an individual, along with prenatal environmental factors, accumulate toward a threshold. If an individual has enough of these genes and factors, a threshold will be crossed and the defect will appear (32).

Multifactorial disorders often show an increased incidence in one sex or the other. Pyloric stenosis is much more common in males, while dislocation of the hips is more common in females. These sex differences have been explained by a shift in the threshold depending upon the sex.

Once a couple has had a child with a multifactorial condition, the risk of having a second child with the same disorder is increased over the background population risk. Recurrence risk figures can be estimated for a given defect based on population studies. For example, the incidence of cleft lip with or without cleft palate is 1 in 700 to 1 in 1000 newborns. This risk increases to approximately 4% or 1 in 25 after a family has had one child with cleft lip, representing a 40-fold increased risk. However, the risk is still relatively small, with a 96% chance of having a normal child.

The exact environmental factors contributing to multifactorial conditions remain unknown in most cases. Regional factors must play a role, since it is well known that some areas of the world have a markedly increased risk for certain defects. For example, the incidence of neural tube defects is approximately 1 in 1000 in the general population, but in parts of Great Britain, especially Ireland and Wales, the rate is as high as 7 to 9 in 1000 births (1). Genetic influences must also play a role, since immigrants from these areas to other parts of the world still have a somewhat higher rate of neural tube defects (1). However, other

Table 5 Diseases Caused by Mitochondrial DNA Mutations

Kearns–Sayre disease, due to large mtDNA deletion
Leber hereditary optic neuropathy, due to G3460A, G11778A, or T14484C mutation in complex I subunits
Leigh syndrome (subacute necrotizing encephalopathy), due to T8993G or C mutation in complex V in 10% of cases
Mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes, due to A3243G or T3271C mutations in Leucine tRNA
Mitochondrial myopathy, due to mutations in various mt-tRNA genes
Myoclonic epilepsy and ragged-red fiber disease, due to A8344G in Lysine tRNA
Neurogenic muscle weakness, ataxia, and retinitis pigmentosa, due to T8993G or C mutation in complex V

environmental variables such as diet must also be important. It has been shown that folic acid consumption in the diet of pregnant women can significantly reduce the recurrence risk of neural tube defects in subsequent pregnancies. The current recommendation by the Centers for Disease Control states that all women of childbearing age who are capable of becoming pregnant should consume 400 mg of folic acid per day (33). All women who have had a previous child with a neural tube should take 4 mg of folic acid per day, beginning 2 to 3 months prior to conception and continuing for the first 3 months of gestation (34). Flour and other grain products are now supplemented with folic acid in the United States to ensure proper intake for all women, since it is difficult to obtain more than 200 mg of folic acid a day from a typical American diet.

MITOCHONDRIAL INHERITANCE

There are an increasing number of recognized human genetic disorders caused by mutations in the mitochondrial genome (Table 5) (35). Within the cytoplasm of each cell are several hundred mitochondria, which are involved in energy production for the cell. Each mitochondrion has multiple copies of its own circular DNA (mtDNA), which is 16.5 Mb in size, encoding 37 genes for tRNA, rRNA, and some of the enzymes of oxidative phosphorylation. Because mtDNA is cytoplasmic in location, inheritance is exclusively maternal. Sperm contain very few mitochondria and, therefore, both males and females inherit essentially all of their mtDNA from their mothers. There is variable expression of mitochondrial disorders due to heteroplasmy; this term refers to the variability of the proportion of mutant mtDNA within each cell. The proportion of abnormal mtDNA at the somatic level may change over time due to replicative segregation. This can account for the apparent degenerative nature of these disorders noted clinically, which corresponds to an increase in the percentage of abnormal mitochondria (36,37). A woman who has a mitochondrial DNA disorder will pass it on to all of her offspring. However, because of the highly variable expression of these conditions, not all offspring would be expected to be affected to the same degree. Offspring of men with mitochondrial DNA disorders cannot inherit the condition because all mitochondria originate from the mother. It is important to remember that there are also many disorders associated with mitochondrial dysfunction that are inherited in a Mendelian fashion, since most

proteins active within the mitochondria are encoded by nuclear DNA genes.

COMMON METABOLIC DISORDERS

Inborn errors of metabolism are due to enzyme deficiencies that cause abnormal elevations of intermediary compounds of biochemical pathways in tissues and body fluids, with resultant medical problems. Most have an autosomal recessive inheritance pattern, but a few are X-linked recessive disorders. There are several hundred known inborn errors of metabolism, most of which are very rare (38). However, they are collectively common and affect about 1 in 1000 newborns.

One of the most common metabolic disorders is the autosomal recessive aminoacidopathy phenylketonuria (PKU), which has an incidence of 1 in 10,000 to 1 in 15,000 newborns (38). It is caused by a deficiency of the enzyme phenylalanine hydroxylase, which normally converts phenylalanine to tyrosine. Patients with PKU have elevated blood levels of phenylalanine and excretion of phenylketones in the urine. If left untreated, affected individuals will develop microcephaly and profound mental retardation due to the toxic effects of the elevated compounds. However, if diagnosed within the first few weeks of life, with institution of a low phenylalanine diet, mental retardation can be prevented. PKU is the first genetic disorder for which there has been generalized population screening. Since the 1960s, all newborns in the United States have been tested for the disorder. This has nearly eliminated PKU as a cause for mental retardation. However, a new problem has emerged; women who were allowed to stop the dietary restriction of phenylalanine after age 6 years are now of childbearing age. The elevated blood level of phenylalanine in a pregnant PKU woman has deleterious effects on the developing fetus, with increased risk for spontaneous pregnancy loss, congenital heart defects, severe microcephaly, and mental retardation. Therefore, the PKU diet must be reinstated prior to conception and continued throughout pregnancy. New guidelines state that all people with PKU should remain on the diet for life.

The United States and most developed countries of the world perform newborn screening for many inborn errors of metabolism, endocrine disorders including hypothyroidism and congenital adrenal hyperplasia, cystic fibrosis, hemoglobinopathies, and hearing loss. All states now have significantly expanded newborn metabolic disease screening, largely due to the development of tandem mass spectrometry methods to detect many amino acid disorders, organic acid disorders, and disorders of fatty acid oxidation. For most of these disorders, it has been shown that early diagnosis in the newborn period can significantly reduce morbidity and mortality. As mentioned above for PKU, institution of dietary restriction of phenylalanine before 1 month of age can prevent mental retardation. For other inborn errors of metabolism, such as fatty acid oxidation defects, maple syrup urine disease and galactosemia, illness, mental retardation, and even death can be prevented by early detection and treatment.

POPULATION SCREENING FOR GENETIC DISEASE

Screening tests are a routine part of medical care, with the goal of early identification and treatment of specific and common diseases. For genetic diseases, population screening involves

not only affected individuals, but also additional family members. Screening for genetic disease has been defined as the “search in a population for persons possessing certain genotypes that (i) are already associated with disease or predisposition to disease or (ii) may lead to disease in their descendants” (39). As outlined in the previous section, newborn screening for metabolic diseases exemplifies the first type of screening, which will result in proper identification of infants with these disorders and institution of treatment. Other examples include presymptomatic genetic testing for Huntington disease, breast cancer, or colon cancer.

The second type of screening includes testing of targeted ethnic or racial populations to identify carriers of genetic disease. Examples are cystic fibrosis in Caucasians, Tay–Sachs disease in Ashkenazi Jews, and hemoglobinopathies in African-Americans (10). On a smaller scale, genetic screening can involve karyotype analysis on family members at risk for having a chromosome translocation. Carrier testing is also available for women who are at risk to be carriers for X-linked disorders such as Duchenne muscular dystrophy or Fragile X syndrome. This type of population screening will not affect the health of the carrier, but will have a significant impact on reproductive choices for the family. It is essential that appropriate genetic counseling accompany the information given regarding carrier status.

GENETIC COUNSELING

Genetic counseling is an important part of the practice of medical genetics. The field of genetics is unique in that a diagnosis of a genetic disorder in an individual has an impact on his or her entire family. Multiple family members and their present or future offspring may be at risk for the genetic disorder as well. Genetic counseling involves the explanation of the manifestations of the disorder, the natural history and treatment, the inheritance pattern, the risks of recurrence, and the methods of prenatal and postnatal diagnosis. The genetic counselor also helps the family make the best possible adjustment to the disorder and the risks of recurrence. This often involves referral to a support organization through which the family can make contact with other affected individuals. The vast majority of genetic counselors and clinical geneticists seek to provide nondirective counseling, whereby information about the disorder and the recurrence risk is given in an unbiased and neutral way, and the family makes decisions about reproductive options in accordance with their own beliefs and values.

Reasons for referral for genetic counseling include a family history of a known or suspected single-gene disorder, chromosomal disorder, or multifactorial condition, carrier status for a genetic disease, consanguinity, advanced maternal age during pregnancy, abnormal screening tests during pregnancy, repeated pregnancy loss or infertility, or teratogen exposure during pregnancy.

In the prenatal clinic setting, the genetic counseling session often precedes any diagnostic testing. During the session, the family history is reviewed in detail, as well as the reasons for referral, the information obtainable by the prenatal testing, and the risks of the procedure. If fetal abnormalities are detected, then additional counseling sessions may be required to explain the findings to the family and to discuss options for

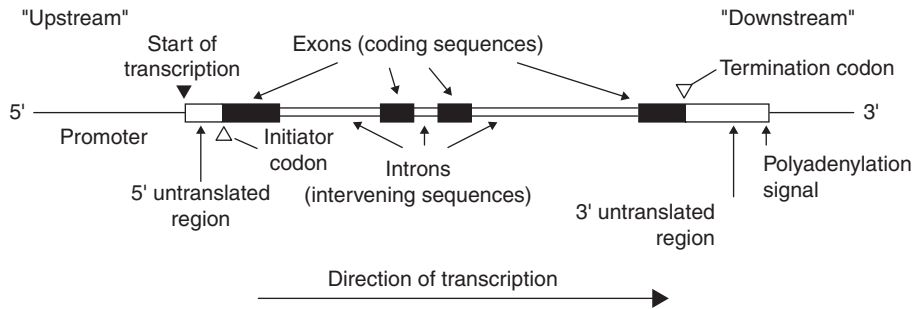

Figure 20 General structure of a typical human gene. Source: From Ref. 40.

pregnancy management. If special care or surgery will be needed for the baby immediately after birth, the genetic counselor and the obstetrician may help arrange meetings with the appropriate surgeons or pediatric specialists so that the family is optimally prepared. For cases that are likely to be lethal, it is best to introduce the idea of a postmortem examination before the birth of the baby. In the event of death, a complete autopsy is recommended to search for additional anomalies and to confirm the diagnosis. This helps ensure that accurate genetic counseling, especially with respect to recurrence risk, can be provided in subsequent pregnancies.

MOLECULAR GENETICS

Genes are the basic units of inheritance. As mentioned previously, there are several thousand single-gene diseases with a known molecular genetic cause, representing only a fraction of the estimated total 20,000 to 25,000 genes in the human genome. Over the past 5 to 10 years, there has been a dramatic increase in the number of identified, cloned, and sequenced disease genes. With this new knowledge has come increased availability and demand for both prenatal and postnatal molecular genetic testing. Molecular genetic testing is done for diagnostic purposes to confirm the presence of a disorder, as well as to identify conditions presymptomatically.

Genes are composed of deoxyribonucleic acid (DNA) and are contained on the chromosomes. Each strand of DNA has a specific sequence of four nucleotides, each containing a different base, adenine, thymine, cytosine, or guanine. Adenine pairs with thymine and cytosine pairs with guanine as two complementary strands of DNA are wound together to form a double helix. Genes have a common basic structure (Fig. 20). First, there are upstream sequences that regulate transcription, known as promoters and enhancers. Then, there is a transcription initiation site, followed by a series of alternating exons and introns. The DNA sequence serves as a template from which messenger RNA (mRNA) is made; this process is known as transcription. As transcription proceeds, a primary mRNA is made from the DNA sequence of the gene, which includes the introns. The intron sequences are then spliced out and the exons are linked together to form the mature mRNA molecule. Thus, the exons are the only portions of the gene that specify the final protein product. The mature mRNA molecule is used to make the protein product by the process of translation. Groups of three nucleotides, called codons, code for specific amino acids. Transfer RNA (tRNA) and ribosomal RNA (rRNA) interact with the mRNA to assemble the amino acids into a polypeptide chain to form the final protein molecule.

Errors in the sequence of nucleic acids of the DNA produce mutations in genes and often lead to genetic diseases. There are a variety of different kinds of mutations that can occur in genes. Some result in genetic disorders, while others may have no detrimental effect. The most common type of mutations include missense (single amino acid change), nonsense (insertion of stop codon with premature termination of translation), frameshift (insertion or deletion of nucleotides that alters downstream codons), splice site (incorrect splicing of introns), and promoter mutations (decreased transcription of mRNA). An expansion mutation occurs when there is insertion of many extra copies of a trinucleotide repeat; examples of disorders with this type of mutation are fragile X syndrome, Huntington disease, and myotonic dystrophy.

Diagnosis is possible for many genetic disorders using molecular genetic techniques. Genomic DNA can be obtained from peripheral blood leukocytes, solid tissues, or cultured cells. Testing can be accomplished by either direct mutation analysis or by linkage analysis (Fig. 21). In linkage analysis, information about nondisease producing variation, or polymorphisms, such as restriction fragment-length polymorphisms, variable number of tandem repeats, or microsatellite repeat polymorphisms, can trace inheritance of a chromosome containing a disease-producing gene through a family. This method of testing has disadvantages. First, multiple family members are needed to establish the phase of linkage. Second, some families may not be informative for some linked markers. Third, recombination between the marker and the disease gene may occur, causing inaccuracies in the test results.

In direct DNA testing, the disease gene must have been isolated and disease-producing mutations are identified. Specific mutations can then be sought by a variety of methods. Segments of DNA from the gene of interest is amplified by (PCR) polymerase chain reaction and then sequenced, or deletions or rearrangements of the gene can be identified by Southern blotting. Direct testing is advantageous, since it is likely to be more accurate than linkage analysis, and a single individual can be tested without requiring family information. For example, molecular genetic testing for sickle cell disease is highly accurate, since all affected individuals have the same missense mutation at position six of the beta-globin chain, which results in a substitution of valine for glutamic acid. This point mutation results in a loss of one MstII restriction enzyme site in the mutant gene, making direct DNA diagnosis very straightforward. For other genetic disorders characterized by a number of common mutations, such as cystic fibrosis, allele-specific oligonucleotide probes (ASOs) of 18 to 20 nucleotides in length complementary to known normal and

Figure 21 Linkage of the gene for neurofibromatosis 1 to a marker locus. The mother (I-1) is affected with this dominant disease and is heterozygous at the NF1 locus (*Dd*), as well as at two other loci, 1 and 2, on chromosome 17. She carries the *A* and *B* alleles on the same chromosome as the mutant NF1 allele (*D*). The unaffected father is homozygous normal (*dd*) at the NF1 locus, as well as at the two marker loci (*AA* and *BB*). All three affected offspring have inherited the *A* allele at marker 1, whereas the three unaffected offspring have inherited the *a* allele. Thus, all six offspring are nonrecombinant for NF1 and marker locus 1. However, individuals II-1, II-3, and II-5 are recombinant for NF1 and marker locus 2, indicating that meiotic crossing over has occurred between these two loci. Source: From Ref. 40.

mutant DNA sequences can be devised. ASOs are then hybridized to patient DNA samples to identify homozygotes or heterozygotes for specific mutations. Thus, a panel of ASOs for the most common mutations seen in a disorder can be used to rapidly screen patient DNA samples. For disorders in which there are no common mutations or when common mutations have been ruled out, the entire gene can be sequenced to look for rare or new disease-causing mutations. In the future, identification of the molecular basis for genetic defects or syndromes may be achieved by exome sequencing, in which all of the exons in the genome are sequenced to identify mutations in candidate genes, or by whole genome sequencing. Up-to-date information about genetic disorders for which molecular genetic testing is clinically available can be found at the GeneTests website (<http://www.ncbi.nlm.nih.gov/sites/GeneTests/?db=GeneTests>).

TREATMENT OF GENETIC DISEASES

With the isolation of disease genes and an increasingly better understanding of the molecular genetic bases for many disorders, it has become feasible to consider treatments and potentially cures for genetic disease (41).

Gene therapy involves insertion of normal copies of genes into individuals who have genetic diseases. This can potentially be accomplished by either somatic cell or germ cell gene therapy. Most work thus far has focused on somatic cell gene therapy. There are two ways to approach somatic cell gene therapy. *Ex vivo* gene therapy involves removing a patient's cells from the body, inserting the normal gene copy into the cells, and then returning the cells to the body. In *in vivo* gene therapy, cells are treated while inside the patient's body. For successful gene therapy, the cell requiring treatment must be easily accessible and relatively long-lived. Some of the earliest human gene therapy trials were performed for severe combined immune deficiency due to adenosine deaminase deficiency, using bone marrow stem cells. Other cells under consideration for therapy have included lymphocytes, hepatocytes, muscle cells, and respiratory epithelial cells. More

recently, gene therapy for Leber's congenital amaurosis has been accomplished by replacement of the defective gene locally to the retina of the eye. Types of genetic diseases that are amenable to somatic cell gene therapy are primarily autosomal recessive or X-linked disorders that result in almost total lack of normal protein. Reconstitution of even 5% to 10% of normal protein levels appears to be sufficient to treat these diseases. Dominant disorders that are caused by heterozygosity for mutant and normal genes (dominant-negative mutations) are not likely to be treatable by gene replacement; methods to block production of the mutant protein will be required.

In conditions associated with an enzyme deficiency, methods have been developed to provide systemic delivery of the missing enzyme to the patient. Enzyme replacement therapy for lysosomal storage diseases, such as Gaucher disease, Fabry disease, Hurler syndrome, and Pompe disease, has been very successful. Enzyme replacement therapy for other enzyme deficiency disorders is under development. Another approach has been to decrease the substrate for the deficient enzyme by giving a drug that inhibits an upstream enzyme in the pathway, thus decreasing accumulation of the toxic compound. This type of drug treatment has been approved for Gaucher disease and is being developed for other conditions.

With the elucidation of the molecular genetic pathways involved in certain genetic disorders, it has been possible to devise new uses for FDA-approved drugs. Examples of this include the experimental use of farnesyltransferase inhibitors in progeria, a premature aging syndrome, and an angiotensin II type 1 receptor antagonist for treatment of the dilated aortic root in Marfan syndrome. Pharmacologic chaperones are also being developed to help stabilize mutant proteins and enhance residual activity.

Finally, methods for manipulating the expression or splicing of mutant genes are being investigated. Drugs that induce read-through of a stop codon during translation of a mutant gene can result in increased expression of full-length protein. This approach has been tried experimentally with cystic fibrosis and Duchenne muscular dystrophy. In other studies, antisense oligonucleotides have been used to induce skipping

during mRNA splicing of exons that contain mutations; this approach will produce a smaller protein, but one that might retain some residual function. This method of therapy has been investigated for Duchenne muscular dystrophy. It is anticipated that more such opportunities will become available in the future for targeted therapy of the disease manifestations of genetic disorders.

44 Principles of teratology of drugs and radiation

Frank R. Witter

Teratology is the study of birth defects. In this chapter, the potential of drugs and radiation to produce birth defects in humans will be explored. Wilson (1) has estimated that of all human malformations, less than 1% are due to radiations and 4% to 6% are due to drugs and environmental chemicals.

Whether an agent produces a teratogenic effect is dependent on the timing of the insult. The teratologic literature is usually reported in post-conception weeks. Clinical dating is always 2 weeks greater than post-conception dating as it is based on the patient's last menstrual period or ultrasound measurements, which are reported in menstrual weeks. To avoid confusion, all timing of teratogenic exposure will be discussed in menstrual weeks. The conceptus is relatively resistant in the first 2 weeks of its existence (menstrual weeks 3 and 4) when either no effect or loss of the pregnancy is the major outcome of exposure to teratogenic agents. During this time period, the embryo has sufficient reparative powers, if not destroyed, to recover and few malformations occur. The most likely times for chemical teratogenesis are menstrual weeks 5 to 12 inclusive, which corresponds to the time of major organ differentiation. For radiation injury, the most likely times for exposure are menstrual weeks 10 to 17 inclusive (2), which correspond to the time of maximum neuronal cell proliferation and migration to the cerebral cortex. No gross malformations due to radiation have been seen in humans without the child exhibiting growth retardation, microcephaly, or gross eye malformations. After the time of gestation of maximal sensitivity, the effects of teratogens in general are to produce growth retardation (3–6). After 27 menstrual weeks, based on atomic bomb survivors, there is no proven risk of central nervous system effects, specifically severe mental retardation from the radiation (7,8).

The criteria for a human teratogen are listed in Table 1 (9). In addition to these criteria, the existence of a dose–response relationship supports the contention that an agent is a teratogen. Thus, for a teratogen with increasing dose of the exposure, there should be an increase in the number or severity of defects produced. Also it should produce similar defects in experimental animal systems.

DRUGS AS TERATOGENS

Drugs that fulfill the criteria for a human teratogen may produce their effect directly, indirectly, or through a toxic intermediate. Direct-acting teratogens cause damage in their native form and require only access to the conceptus to do harm. An example of direct-acting teratogens are cytotoxic antineoplastic agents, which cause direct cell damage leading to cell death, which may result in malformation or pregnancy loss.

Indirect-acting teratogens act by perturbing maternal homeostasis to produce damage. Narcotic analgesics are not

themselves teratogens; however, they can act as indirect teratogens when taken in sufficient doses to produce maternal hypoxia from respiratory depression. Hypoxia then acts directly to produce malformations by causing cell death in the developing conceptus. Therefore, by acting to compromise maternal respiration, narcotics may act as indirect teratogens.

Unlike the first two methods by which a drug can act as a teratogen, those drugs whose teratogenic potential is expressed through a toxic intermediate are not as readily predicted by animal experiments. This is because there are many pathways by which drugs may be metabolized and these may vary between species or even between individuals of the same species. The developing field of pharmacogenetics is expanding our knowledge of these differences. However, because of this variation, the toxic intermediate may not be produced in all individuals or species. A teratogen acting through a toxic intermediate may be a human teratogen and not one in animal species usually tested, or vice versa. An example of a human teratogen that would fit into this class is thalidomide, which is not a teratogen in the guinea pig.

In addition to the difficulty in extrapolating from animal experiments to man, there are other difficulties with fulfilling the criterion of Table 1. The drug in question might prevent the loss of an already malformed fetus. The condition for which the drug is used might produce the malformation. The fetal malformation might cause maternal symptoms for which the drug is taken. Finally, the drug may be commonly used in combination with other drugs that produce the malformation or only a combination of agents, not the individual agents by themselves, might produce the malformation.

Because of these difficulties and the sometimes poor quality of data, differences exist between experts on the teratogenic potential of many agents in humans. An additional reason for conflict in expert opinion on human teratogens is the reason for which the assessment was made. If one wishes to counsel a pregnant woman already exposed to an agent as to its teratogenic potential, then it is appropriate to ignore the potential therapeutic benefit of the agent and use only the information on birth defects available on it (10). If, on the other hand, one wishes to prescribe a medication for a condition during pregnancy, it is appropriate to use an assessment that balances the therapeutic benefit to the teratogenic risk. The FDA pregnancy categories (11) are an attempt at such an assessment (Table 2).

It has been reported that one in five women use FDA class C, D, or X drugs at least once during pregnancy (12). As the FDA classification system is extensively used, it is important to recognize its limitations. It is not a teratogenic risk classification. It is a fetal risk classification, which includes both teratogenic risk and the risk of fetal harm by the drug later in pregnancy. It also does not include information on the point in

Table 1 Criteria for Recognizing a Human Teratogenic Agent (9)

1. An abrupt increase in the frequency for a particular defect or group of defects
2. Coincidence of this increase with a known environmental change, such as widespread use of a new drug or sudden exposure to a chemical or a source of radiation
3. Known exposure to the environmental change early in pregnancies yielding the characteristically defective infants
4. Absence of other factors common to all yielding infants with the characteristic defect or defects

Table 2 FDA Pregnancy Categories for Drugs (11)

- Category A: Controlled studies in women fail to demonstrate a risk to the fetus in the first trimester; there is no evidence of a risk in later trimesters, and the possibility of fetal harm appears remote
- Category B: Either animal reproductive studies have not demonstrated a fetal risk, but there are no controlled studies in pregnant women, or animal reproductive studies have shown an adverse effect, other than a decrease in fertility, which was not confirmed in controlled studies in women in the first trimester and there is no evidence of a risk in later trimesters
- Category C: Either studies in animals have revealed adverse effects on the fetus, teratogenic or embryocidal or other, and there are no controlled studies in women, or studies in women or studies in women and animals are not available. Drugs of this class should be given only if the potential benefit justifies the potential risk to the fetus
- Category D: There is positive evidence of human fetal risk, but the benefits from use in pregnant women may be acceptable despite the risk as when the drug is needed in a life-threatening situation or for a serious disease for which safer drugs cannot be used or are ineffective
- Category X: Studies in animals or human beings have demonstrated fetal abnormalities or there is evidence of fetal risk based on human experience or both, and the risk of the use of the drug in pregnant women clearly outweighs any possible benefit. The drug is contraindicated in women who are or may become pregnant

pregnancy when the risk occurs or if there is a dose threshold above which the harm occurs.

An example of the problems of the system can be seen by looking at vitamin A. Vitamin A is an essential fat-soluble nutrient and a known human teratogen. Its U.S. recommended daily allowance (RDA) for pregnancy is 8000 IU/day. Yet when taken in supplements during pregnancy of more than 10,000 IU/day, it is teratogenic (13). According to the FDA classification system, it should be category D or X. Vitamin A in large doses or severe deficiency is harmful to the fetus and this information is not conveyed by the FDA's simple classification system. Recognizing this problem, Braggs, Freeman, and Yaffe (14) in their compendium have modified the FDA risk classes. In the case of vitamin A, they classify it as "A*" with the "*" footnote indicating category X if used in doses above the U.S. RDA.

There are several excellent compendiums of data on teratogenic risk (14–16) to which the reader is referred for details on specific agents. The most common human teratogens used today are listed in Table 3. These agents should be avoided in women who are pregnant or potentially pregnant. The most common agents that have teratogenic potential but whose therapeutic benefit outweighs their risk are listed in Table 4. When assessing maternal drug therapy in pregnancy, the first consideration is whether the drug is necessary for maternal survival or well-being. Once it is established that this is the case, the most effective agent with the least toxicity and the lowest teratogenic potential should be used in the appropriate dose. Vital therapy should not be withheld from a pregnant woman because of teratogenic risk.

RADIATION AS A TERATOGEN

Unlike drugs, radiation always acts directly on the conceptus to produce birth defects or pregnancy loss. For this reason, it is easier to extrapolate from animal experiments to the human condition for radiation defects. Ionizing radiation produces gross congenital malformations, intrauterine growth retardation, and embryonic death. All of radiation's effects have a dose-response relationship and a threshold of exposure below which there is no difference between irradiated and non-irradiated populations. Only ionizing radiation has a clearly established teratogenic potential. Ionizing radiation dosage is reported in either Rads (rad) or Grays (Gy). One rad equals 0.01 Gy. To avoid confusion, all doses will be reported in rads.

Growth retardation and central nervous system effects including microcephaly, mental retardation, and eye malformations are the most prominent manifestations of intrauterine radiation exposure in humans. Severe mental retardation has not been observed in patients who received less than 50 rads in utero, and there has been no report of radiation-induced limb or other gross anomalies in humans where growth retardation or central nervous system anomalies were not also present (17). Mental retardation has never been seen with radiation exposure prior to 10 menstrual weeks of gestation in humans (2), in spite of the fact that major organ differentiation occurs from 5 to 12 menstrual weeks of gestation. Radiation exposure prior to 10 menstrual weeks results in a high rate of loss and therefore a wide range of malformations are not seen (2,17) although theoretically possible (18).

The gestational ages of 10 to 17 menstrual weeks represent the time when the maximum number of infants with mental retardation and central nervous system or eye defects are produced (2). At 18 menstrual weeks, or greater, few cases of mental retardation are seen (2); however, growth retardation continues to be produced. In humans, although malformations are not seen at doses of less than 50 rads, some disturbances of growth can occur with as little as 25 rads (17). However, at exposures in the range of 20 to 5000 mrad, which is the range of most diagnostic radiology studies, there is an extremely low risk of malformations when compared with the spontaneous rate for humans (17). The association of prenatal radiation exposure and childhood leukemia or other cancers remains to be determined (3–6). However, an increased incidence, 1.5 to 2.4 over the background rate, as a result of in utero exposure to radiation at the dosage ranging from

1 to 4 rads, has been reported (19,20). Since X-ray studies with 5 rads or less exposure to the conceptus carry a very low risk, and if medically indicated, it should be performed with the patient's informed consent (18); fetal dosages for some commonly used radiologic procedures are available through the American College of Obstetricians and Gynecologists Committee Opinion number 299 (7).

Special mention should be made of radioiodine during pregnancy. Iodine-131, if given in millicurie doses, can damage or ablate the developing fetal thyroid resulting in either congenital hypothyroidism or hypothyroidism of late onset (17). This can occur after the onset of the iodine-concentrating ability of the fetal thyroid at around menstrual weeks 10 to 12 of gestation (7). Radioiodine is therefore contraindicated in pregnancy.

45 Fetal programming

Katherine E. Pelch, Jana L. Allison, and Susan C. Nagel

INTRODUCTION

The prenatal period requires vigilance to insure a safe environment for the fetus to grow and develop appropriately. Great lengths are taken during prenatal care to avoid exposures known to have teratogenic potential. Fetal programming is the theory that environmental events in utero during sensitive windows of development can have permanent and long-lasting effects. The fetus has the capacity for developmental plasticity. That is, one genotype can lead to different phenotypes depending on environmental factors (1). In other words, the environment interacts with genes in the developing organism to permanently program gene expression in adulthood. Changes in the fetal environment can program childhood and adult response pathways. Therefore, the developmental period represents a critical opportunity for irreversible effects from the fetal environment, whether these are from pharmaceuticals, nutrition, microorganisms, the maternal hormonal milieu, and/or environmental chemicals.

There is a strong precedence for the importance of the perinatal environment. Clinicians are often among the first to recognize the deleterious effects of teratogenic pharmaceuticals. To that effect, a five-tier classification system designed to rate the safety of medications during pregnancy and lactation has greatly improved pharmaceutical counseling during the prenatal and perinatal periods. However, while many effects resulting in obvious birth defects have been documented, such as limb defects during the era of thalidomide use, the potential for pharmaceuticals to alter the fetal hormonal environment and alter adult disease susceptibility is a relatively new area of study. The long-term consequences of these types of effects are difficult to identify and are largely unknown. In addition to pharmaceuticals, maternal nutrition is known to affect fetal development. A physician, DJ Barker, was among the first to put forth the *Developmental Origins of Adult Health and Disease* hypothesis, highlighting the potential for maternal nutrition to impact the offspring's risk for coronary heart disease (CHD) and type II diabetes (1). Although not the focus of this chapter, an extensive body of literature has used animal models of development to confirm cause and effect relationships initially found in epidemiologic studies supporting the *Developmental Origins* hypothesis.

Altered fetal programming may manifest as physical, developmental, or neuropsychiatric abnormalities that often have long latencies and may not become evident until childhood or even adulthood. It is difficult to pinpoint a specific exposure during pregnancy responsible for a certain behavioral pattern or health condition that presents years after the exposure, especially when considering the vast number of potential variables, both physical and psychologic (i.e., emotional nurturing). However, a number of epidemiologic studies have found associations with altered fetal environ-

ments. An area of great interest within fetal programming is the molecular changes within the fetus in response to maternal stress, medications, and exogenous hormone exposure.

We know that pharmaceuticals can program fetal development and cause effects that can be seen at birth. In addition, there is a large and growing body of literature demonstrating that the fetal environment can program the fetus and result in long-latency effects associated with increased risk of adult disease. The developmental origins of adult disease hypothesis evolved to explain this type of programming. In this chapter, we will focus on the long-term consequences of changes within the uterine environment during pregnancy, including nutritional, hormonal, pharmaceutical, and other environmental factors.

BIRTH WEIGHT AND ADULT DISEASE RISK

It is known that maternal nutrition is important for healthy fetal development; however, only recently has a link between maternal and fetal nutrition been made with adult disease (Box 1). The developing fetus is dependent on its mother to receive the proper nutrients required for normal growth and development. Low birth weight has historically been associated with an increased risk of death from CHD. Barker et al. first identified this association in a large population of men born in Hertfordshire, England, in 1911 to 1930 (3). As a baby's weight at birth or year 1 decreased, the risk of death from ischemic heart disease rose. People who were the lightest at birth (≤ 5.5 pounds) and also lightest at 1 year of age (≤ 18 pounds) had the highest standardized mortality ratio (SMR = 200; 95% CI 114–384) (3). Furthermore, Barker et al. also reported that systolic blood pressure, a risk factor for cardiovascular disease, was inversely related to birth weight in 10- and 36-year-olds born and residing in Great Britain (3).

The initial finding that birth weight was associated with CHD in adulthood led Barker to propose the *Developmental Origins of Adult Health and Disease* hypothesis, suggesting that changes that occurred during development that caused a baby to be born small may also impact adult disease risk. For example, low-birth weight babies are known to have increased blood pressure in adulthood (4,5). It has been suggested that decreased blood flow to the kidney during key developmental periods may lead to decreased cell numbers in the glomeruli. Each glomerulus is therefore subjected to increased blood flow, and although blood pressure can initially be maintained, hyperfiltration eventually leads to glomerulosclerosis. This, in addition to the normal loss of glomeruli that occurs with aging, results in a feed-forward loop of increasing blood pressure and glomerular loss (6). Low birth weight is also associated with impaired glucose tolerance (5). In a similar mechanism, an undernourished fetus directs glucose to the developing brain at the expense of the muscles thereby resulting in less muscle mass at birth. As muscle is the primary

location of insulin action, decreased muscle composition in adulthood results in lifelong insulin resistance (7). Another possibility is that there are fewer β -cells in the pancreas of low-birth weight babies.

Low birth weight has also been associated with diseases of the metabolic syndrome in adulthood. Curhan et al. found that low birth weight was associated with an increased risk of hypertension and diabetes in a longitudinal study of 51,529 U.S. males born from 1911 to 1946. Compared with men born with average size (7.0–8.4lb), men born weighing less than 5.5 lb were 26% more likely to have hypertension and 75% more likely to have diabetes (8). Curhan et al. also examined data from the Nurses' Health Studies I and II and found that low birth weight was associated with hypertension in women (8). Additionally, in a study of the Pima Indian population in Arizona, McCance et al. found that low birth weight was strongly associated with increased risk of diabetes (9). Hales et al. also found increased risk of diabetes or insulin resistance with decreasing birth weight in the Hertfordshire studies discussed above (5).

Barker further refined his *Developmental Origins* hypothesis with the introduction of the concept of the *thrifty fetus*. He hypothesized that the fetal environment could provide a “weather forecast” of the nutritional status outside of the womb. His *thrifty phenotype* hypothesis suggests that declines in nutritional status while in the womb can program a fetus to be “thrifty” and to store and ration energy accordingly (10). Problems arise, however, when individuals programmed in utero to be “thrifty” are introduced to an environment of plenty during early adolescence and adulthood. Being “thrifty” in development allows a fetus to conserve energy for important tissues like the brain at the expense of other tissues such as muscle and liver. Barker further suggests that the tissues and organs that were sacrificed during development have a diminished ability to properly respond to a “world of plenty” in adulthood. This hypothesis suggests that catch-up growth creates problems for those who were “thrifty” during development.

As an example of the *thrifty phenotype*, Barker and colleagues have extensively studied the case of people who were in utero during the Dutch Famine, which occurred from October 1944 to May 7, 1945, as a result of the German occupation in the West Netherlands during World War II. This discrete famine has allowed researchers to directly study

the effects of maternal malnutrition on adult disease risk. During the famine, daily caloric intake fell to 300 to 800 calories/day. Fortunately, recovery was swift and the caloric intake rebounded to pre-famine levels by June 1945. Because of the relatively short length of the famine, researchers have been able to determine whether adult-onset diseases are linked to nutritional insufficiency during very specific times of development. Ravelli et al. examined obesity among 19-year-old military draftees who were exposed to the famine compared with those born just before or just after the famine or born during the same time but in unaffected locations. They found that men exposed to the famine during the first two trimesters of pregnancy had a significantly higher prevalence of obesity compared with men born in cities unaffected by the famine. Conversely, men exposed to famine during the third trimester of gestation through the first 3 to 5 months of postnatal life had a decreased prevalence of obesity compared with men born outside of the region of famine (11).

Another series of studies examined 297 people exposed to the Dutch famine during gestation and 444 born just before or just after the famine. Children who were exposed to the famine during mid or late gestation were lighter, shorter, and thinner with smaller heads and placentas than those unexposed and had reduced glucose tolerance following a 2-hour oral glucose test (12,13). Conversely, those exposed to famine in early gestation were heavier and longer at birth than those unexposed (12). They also had a more atherogenic lipid profile, higher low-density lipoprotein to high-density lipoprotein ratio, higher body mass index (BMI), and a higher prevalence of CHD (12,14,15). Since high blood pressure is related to low birth weight, it was expected that it would also be related to famine exposure, particularly late exposure that tended to produce low-birth weight babies. Researchers found, however, that while increased blood pressure was related to low birth weight, it was overall independent of famine exposure (12). They were further able to elucidate that increased systolic blood pressure was inversely related to the protein/carbohydrate ratio in the third trimester regardless of famine exposure (16).

The Dutch Famine occurred for a short, discrete period of time and was followed by a quick return to nutritional sufficiency. By contrast, the famine that was incurred during the Leningrad Siege in what is presently known as St. Petersburg, Russia, from September 1941 to January 1944 lasted much longer and those exposed remained nutritionally deprived throughout much of their early adolescence. In examining those who were exposed in utero (born January 1, 1941–June 30, 1941; $n = 169$) or during infancy (born November 1, 1941–June 30, 1942; $n = 192$) or those born during the same period but outside of the area of the siege, Stanner et al. found very little differences in adult disease risk factors; there was a correlation with BMI and systolic and diastolic blood pressure in females in both exposure groups and von Willebrand factor was decreased in the infant group compared with the in utero group (17). Overall, the authors concluded that there was no effect on glucose concentration or insulin-like molecules or risk for hypertensive or cardiovascular disease with exposure to the Leningrad siege famine (17). The fact that there were very little differences found in the study of those exposed to the Leningrad Siege yet there were

extensive differences found in the study of the Dutch Famine may serve to further highlight Barker's thrifty phenotype hypothesis that catch-up or compensatory growth further attenuates the low-birth weight baby's adult disease risk.

As discussed above and demonstrated in the comparison of the two famine studies, problems arise when the postnatal environment differs from the prenatal in utero environment and catch-up growth occurs. For example, in a study of 3641 men born in Helsinki from 1924 to 1933 for which there were serial measurements of height and weight from 6 to 16 years of age, Eriksson et al. found that men who were born with the lowest ponderal index but that subsequently had the highest BMI at age 11 were the most likely to have died from CHD (18). Forsen et al. reported on the corresponding cohort of 3447 women born in Helsinki during the same time period (19). In contrast to the data on the men, Forsen et al. reported that the risk of CHD was not associated with childhood BMI in women. Instead, in women, an increased risk was related to length at birth and increased placental weight. Women who were shortest at birth but tallest at age 7 (i.e., had experienced "catch-up growth") had the highest risk of CHD. Low birth weight followed by catch-up growth has also been shown to be a risk factor for adult-onset type II diabetes and hypertension (20). Along with others, these studies indicate not only the importance of catch-up growth, but also the important differences between how the sexes develop, namely, that females experience slower prenatal growth than males (21,22). Furthermore, recent work has shown sex-specific alterations in DNA methylation (epigenetic) patterns of genes involved in metabolism in people exposed to the Dutch Famine (23).

While the increase risk of adult disease in association to low birth weight continues to be a major concern in both developing and developed countries, an equally important association with the effects of being born large for gestational age must also be studied, especially in light of the growing obesity epidemic. Large for gestational age is typically defined as birth weight greater than the 90th percentile for gestational age and is often associated with maternal obesity and/or diabetes (24). When excess maternal glucose crosses the placenta, the fetus becomes hyperglycemic and then experiences hyperinsulinemia. As insulin is an important growth factor for the developing fetus, aberrant circulating levels negatively affect adipose, muscle, and cardiac tissues resulting in a large or macrosomic baby (24). Large babies and those born to diabetic mothers are more likely to experience complications during delivery and, as adolescents, are more likely to be obese and to develop type II diabetes (8,9,24–27).

Although birth weight has historically been used as a predictor in the developmental origins of adult health and disease, several studies indicate that it might not fully explain the complex interactions that have occurred to produce a baby of any given size. The utilization of additional markers, such as maternal birth weight, third-trimester maternal weight and weight gain, maternal arm fat area, maternal height, maternal energy intake, socioeconomic status, ponderal index, birth length, placental weight, and postnatal growth rate, may help to further understand how the perinatal environment programs adult disease risks. To this end, Kuzawa and Adair have developed a novel model to address

the importance of fetal growth potential (genetics) versus fetal nutrient supply by relating maternal height to the potential fetal growth demand and third-trimester maternal arm fat area to the potential maternal supply. They found that male offspring born to tall mothers with low arm fat (lowest energy reserves) had the highest risk of cardiovascular disease as measured by lipid levels at age 14 (28). In female offspring, there was no difference in lipid levels, further supporting the idea that fetal programming of CHD risk from nutrition differs between the sexes. As we move forward in our examination of how the maternal and early postnatal nutritional environment affects adult disease risk, we must continually allow for new variables that help clarify the environment in which the fetus is developing. Furthermore, as clinicians, it is important to understand all potential ramifications of counseling new mothers regarding proper nutrition, including effects that may not be seen until their children reach adulthood.

PHARMACEUTICAL TERATOGENS AND BIRTH DEFECTS

Teratogens cause fetal programming that can result in severe birth defects. Throughout history, severe malformations caused by teratogens have been documented. One of the most well-known cases is thalidomide, which was initially used as a sedative and antiemetic and resulted in 10,000 to 20,000 victims worldwide who were born with missing or severely malformed limbs. While thalidomide has both antiangiogenic and anti-inflammatory properties, it has recently been demonstrated that it is the antiangiogenic nature of the drug that prevents the development of newly forming blood vessels necessary to support limb development (29). That is, a chemical exposure permanently altered the course of development and resulted in unformed limbs in those exposed.

Another suspected teratogen, isotretinoin (trade name Accutane), is a pharmaceutical prescribed for the systemic treatment of acne and is a derivative of retinoic acid. Retinoic acid, more generally known as vitamin A, is essential during development. A concentration gradient along the anterior-posterior axis regulates the expression of homeobox genes that subsequently direct the correct timing of developmental events within a growing organ system. The timing and concentration of retinoic acid is exquisitely regulated and involved in the proper development of bone, vision, brain, face, heart, and spinal cord. Because of the molecular similarities with retinoic acid, isotretinoin exposure alters the delicate balance of retinoic acid in the fetus and can interfere with the normal patterns of development causing severe malformations. Today doctors must extensively counsel women prescribed isotretinoin on the risks of severe fetal malformations and the need to use two methods of contraception. Unfortunately, despite their best efforts, more than 2000 women have become pregnant while on isotretinoin treatment (30).

LONG-LATENCY EFFECTS FROM NON-TERATOGENIC PHARMACEUTICALS

Selective Serotonin Reuptake Inhibitor Use During Pregnancy

Treating depression in pregnancy is a difficult decision for patients and physicians; both treatment and lack of treatment are associated with increased fetal risks. Untreated maternal

depression negatively affects secondary to neonates increased maternal tobacco use, substance abuse, inadequate prenatal care, and poor maternal–fetal bonding postnatally. Previous data also suggest an increased risk of preterm labor and fetal growth restriction in fetuses born to mothers with untreated depression. Furthermore, maternal stress and mood disorders can permanently program the fetal adaptive stress response mediated by the hypothalamic–pituitary–adrenal (HPA) axis. Exposure to stress results in an increase in corticosterone levels in humans. In animal models, exposure of fetuses to stress in the prenatal and early postnatal periods resulted in exaggerated cortisol production in response to mild stressors in adulthood (31). Maternal stress and poor mothering behaviors postnatally have also been shown to alter fetal and infant glucocorticoid metabolism through epigenetic mechanisms involving alterations of DNA methylation (32–34). Maternal stress increases cortisol within the fetal HPA axis, resulting in shorter gestations, prematurity, lower birth weights, increased congenital malformations, smaller head circumferences, and depressed neonatal neurologic functioning (35). Importantly, infant and adolescent maltreatment are associated with altered cortisol levels and impaired response to psychologic stressors (36). Specifically, maternal stress and malnutrition have been linked to increased incidence of schizophrenia in offspring (37). The decision not to treat or stop treatment during pregnancy may also increase the risk of postpartum depression (38).

On the other hand, fetal exposure to selective serotonin reuptake inhibitors (SSRIs) also carries certain risks. Certain antidepressants are linked with increased risk of congenital anomalies, such as cardiac defects, omphaloceles, and other midline defects as well as persistent pulmonary hypertension. However, the absolute risk of these conditions secondary to SSRIs (the most commonly prescribed class of antidepressants during pregnancy) is very low (38,39). Although overall risk of anomalies are low, transient side effects as a result of serotonin withdrawal at the time of delivery, such as agitation, altered muscle tone, breathing, and suction problems, are commonly reported (40). These effects typically resolve spontaneously within 2 weeks and are conventionally thought to pose less severe long-term consequences to the fetus than those associated with uncontrolled maternal depression. However, subclinical effects of perinatal exposure to SSRIs on fetal neurodevelopment may be subtle and remain undiagnosed until adolescence or early adulthood. More recently, an association with fetal SSRI and autism has been suggested, as increased serotonin causes dysfunction of the amygdala, which plays a role in emotion perception, and suppressed oxytocin production, a hormone proposed to promote “pro-social” behavior (41). Furthermore, SSRIs enter placental circulation and therefore increase fetal serotonin levels, an effect that may program the fetal HPA axis to function properly only in the presence of elevated serotonin, a state removed at the time of delivery.

Progestin Use During Pregnancy

Progesterone is a necessary component to maintain a healthy pregnancy. From the earliest stages of pregnancy, progesterone assists in implantation and supports pregnancy by formation of the corpus luteum. While endogenous progesterone is

essential, it is still unclear what long-term effects may occur from the use of exogenous progesterone.

Progestin is a component of oral contraceptive pills (OCP) and limited exposure during the periconceptual period occurs with failure of oral contraception. Continued use of OCPs until detection of pregnancy occurs in 2% to 5% of pregnancies and can expose fetuses to exogenous hormones during critical windows of fetal development (42). In addition, emergency contraception exposes fetuses to even higher doses of exogenous hormones and is not 100% effective at preventing implantation. Prior to the advent of modern pregnancy tests that detect human chorionic gonadotropin in urine, the major indication for progestins in pregnancy occurred from progestin administration for 3 to 5 days to induce withdrawal menstruation. Today, the major indications for progestin therapy are to prevent preterm birth and treat recurrent pregnancy loss. Progesterone supplementation is also utilized in assisted reproduction protocols to promote endometrial development favorable for implantation of a transferred embryo.

Several studies have assessed the risk of hypospadias following progestin exposure, the results of which seem to be inconclusive (43). One complication is that many studies examine boys born 20 or more years ago, when different progestins were indicated during pregnancy than those in current use. However, a more recent case-control study by Carmichael et al. of children born from October 1997 to December 2000 found a 3.7-fold increased risk of second- and third-degree hypospadias when women took any progestin to help become pregnant or to prevent pregnancy complications or loss for any length of time, but not from perinatal OCP exposure (44). Furthermore, in a meta-analysis of 14 articles, Raman-Wilms et al. found no increased risk of urogenital malformations with hormonal exposure during the first trimester. In this case, exposure was from OCP, hormonal pregnancy tests, as well as treatment for threatened abortion (45).

To date, 17-hydroxyprogesterone is the formulation of greatest efficacy in preventing preterm deliveries in women with a previous spontaneous preterm birth. In a retrospective cohort study by Waters et al., women receiving weekly injections of 17-hydroxyprogesterone caproate were 3.3 times more likely to develop gestational diabetes, controlling for maternal age, BMI, and maternal race (46). Progesterone may increase insulin resistance by affecting glucose transport at the glucose transporter type 4 (GLUT-4) receptor (46). Gestational diabetes can lead to insulin resistance in utero and permanently modify expression of genes responsible for glucose transport and beta cell development, predisposing fetuses to type II diabetes mellitus in adulthood (47). As use of progesterone to prevent preterm birth continues to gain momentum, the postnatal effects will continue to be elucidated as exposed fetuses reach adolescence and adulthood.

Glucocorticoid Use During Pregnancy

At proper concentrations, glucocorticoids are essential for fetal growth and development. Typical fetal cortisol levels are much lower than maternal levels due to an enzyme within the placenta, 11-beta-hydroxysteroid dehydrogenase type 2 (11 β -HSD2), which catalyzes rapid metabolism of corticosteroids into inactive metabolites (48). Exogenous steroid administration to preterm infants is frequently utilized to

promote lung maturity and decrease complications of preterm delivery including necrotizing enterocolitis, intraventricular hemorrhage, and pulmonary hypoplasia. The two steroids most commonly used, dexamethasone and betamethasone, are utilized because they are poorly metabolized by 11 β -HSD2 and easily diffuse through the placenta, thus enhancing the protective benefits by maximizing exposure (2). However, prolonged fetal exposure to exogenous steroids has been associated with an increased incidence of growth restriction, elevated cortisol levels, and reduced placental 11 β -HSD2 activity (49). These effects are exacerbated by placental insufficiency, which can be seen with maternal hypertension and diabetes, or with modification of the 11 β -HSD2 receptor (2). Conditions that typically occur during preterm labor or preterm premature rupture of membranes, such as increased progesterone, estrogen, nitric oxide, prostaglandins, and inflammatory cytokines, can temporarily reduce activity of placental 11 β -HSD2 activity, thereby increasing the susceptibility to negative side effects to the population at greatest risk (2).

While the benefits to the developing lung are obvious, epidemiologic and animal model data suggest that there are negative side effects, such as altered brain development, particularly in the HPA, following multiple steroid treatments and may be worse in dexamethasone- than betamethasone-treated individuals (50,51). Neuropsychiatric disorders are also prevalent in exposed individuals, including memory impairment, increased emotionality, unsociability, avoidance, and behavioral problems (52,53). Furthermore, Drake et al. recently reported that the effects of in utero exposure of rats to dexamethasone on low birth weight and glucose dyshomeostasis are also transmitted to second-generation offspring that are not directly exposed (54). The safety of exogenous steroids given postnatally for use in respiratory distress syndrome and bronchopulmonary dysplasia has also been questioned. Meta-analyses suggest that postnatal steroid use may increase the risk of cerebral palsy by 63% and increases neurologic impairment up to 40% (51). An important question is whether fetal growth restriction is an effect of glucocorticoid exposure in utero or whether it is the primary cause in warranting steroid administration. This question will be difficult to answer unequivocally.

In laboratory rats, developmental exposure to betamethasone led to altered partner preference, sexual behavior, and reduced testosterone in adulthood (55). The authors suggest that “prenatal treatment with betamethasone, by increasing maternal corticosteroid level, may have diminished testosterone peak in male pups, a peak crucial to brain sexual differentiation.”

Diethylstilbestrol

Because teratogen exposure often results in specific malformations that can be identified at birth, a cause and effect relationship between exposure and birth defect can often be established. However, linking exposure with fetal programming that results in long-latency effects is more challenging. One of the best-known examples is the case of diethylstilbestrol (DES) daughters. From 1940 to 1971, millions of women were prescribed the synthetic estrogen DES in the mistaken belief that it would prevent spontaneous abortion and promote a healthy pregnancy. The negative effects of developmental DES exposure were not known until 1971 when the physician AL Herbst published a case report of eight young girls with vaginal clear cell adenocarcinoma, a rare type of cancer that previously had only afflicted much older women. Herbst found that seven of the eight presenting cases had been exposed to DES during the first trimester (56) and later confirmed this on a larger scale (Fig. 1). Additionally, women exposed in utero to DES had increased incidence of various reproductive abnormalities including T-shaped uteri, transverse vaginal ridges, and cervical collars (58–62). Today, it is known that both men and women exposed to DES in utero have increased risk of adult-onset diseases, several of which are discussed below. Furthermore, it appears that the risks of exposure to DES did not stop with those that were exposed in utero, but extend to a third generation providing evidence for transgenerational effects (63–67).

The phenotype seen in women from fetal programming by DES has been reproduced in laboratory mice developmentally exposed to DES (68,69). In mice, the T-shaped uterus appeared to be caused by posterior shift in the expression of homeobox A genes whose sequential expression are necessary for proper tissue development (70). When the discovery that

Figure 1 Market sales of 25mg DES versus cases of vaginal clear cell adenocarcinoma by year of diagnosis. Source: From Ref. 57 and Market share Litigation exhibit.

developmental exposure to an estrogen pharmaceutical created long-latency developmental effects existed, it opened the door to the exploration of fetal programming. Additional sources range from natural variation in endogenous fetal estrogens to exogenous exposure to chemicals in the environment with hormonal activity, termed endocrine disruptors, among a variety of other pharmaceuticals that are just beginning to be scrutinized for potential fetal programming.

ENDOGENOUS AND EXOGENOUS FETAL ESTROGEN AND ADULT DISEASE

Altered fetal serum estrogen has been associated with fetal programming and altered risk of adult disease (Table 1). It is known that adult estrogen exposure is associated with endometriosis and breast cancer. Conditions associated with *increased* fetal exposure to estrogens are also associated with an increased risk of endometriosis and breast cancer in adulthood. Daughters whose mothers took the synthetic estrogen DES during pregnancy have an 80% increased risk of endometriosis and up to 300% increased risk of breast cancer (58,71). Dizygotic twins, who have two placentas, circulate 60% to 80% higher levels of estradiol than singletons (75). Dizygotic twins subsequently have approximately 70% increased risk of endometriosis and 50% increased risk of breast cancer in adulthood (58,72). Monozygotic twins do not have an increased risk of breast cancer, suggesting that it is not being a twin that raises the risk but having two placentas (72). In addition, maternal estrogen concentrations are positively associated with maternal age and offspring birth weight, and breast cancer risk is also positively associated with maternal age and birth weight (reviewed in 72). High ponderal index at birth is associated with increased circulating estradiol in adulthood (76).

Conditions associated with *decreased* fetal exposure to estrogens are associated with reduced risk of endometriosis and breast cancer in adulthood. Smoking inhibits the estrogen-synthesizing enzyme aromatase and is associated with reduced estrogen levels (77). For example, in adult women smokers, there is a 20-fold reduction in the incidence of the estrogen-dependent disease endometriosis (73,74). Importantly, placental aromatase activity is reported to be reduced in smokers (78). Daughters born to women who smoked during pregnancy have over a fourfold reduced risk of endometriosis and have a threefold reduced risk of breast cancer (73,74). Additionally, maternal estrogens are lower in pre-eclamptic patients versus controls (79,80). Daughters born

to pre-eclamptic mothers have a twofold decreased risk of breast cancer in adulthood (72). No data were found on the risk of endometriosis. Taken together, the fetus appears to be sensitive to permanent programming due to an altered fetal hormonal environment.

ENDOCRINE-DISRUPTING CHEMICALS

While women no longer intentionally take synthetic estrogens during pregnancy, pregnant women and their fetuses are exposed to a wide variety of environmental chemicals that may alter normal development. Many of these chemicals can surreptitiously modulate the endocrine system and have been termed endocrine disruptors or endocrine-disrupting chemicals (EDCs). Hundreds of chemicals, both natural and manmade, have been described with the ability to pirate the body's own endocrine system causing altered hormone signaling. Like teratogens, endocrine disruptors can program the fetus and result in permanently altered phenotypes (81). However, unlike teratogens, EDCs can affect both adults and developing organisms. Whereas the effects of endocrine disruptors in adulthood tend to be reversible, the effects on the developing organism tend to be permanent. For this reason, a considerable amount of research has focused on this sensitive period, where exposure can result in permanent fetal programming.

Teratogens cause severe fetal programming that results in malformations present at birth, but there are probably other persistent changes that are subtler and therefore not attributed to the exposure. Teratogens and EDCs probably represent a continuum of effects from more severe effects often with short latency to more subtle effects often with long latency. Severity can be related not only to higher exposure to teratogens but also to different mechanisms of action. Unfortunately, effects seen at high doses cannot necessarily predict those seen at low doses. The effects of endocrine disruptors most often exhibit a non-monotonic dose–response where qualitatively and/or quantitatively different effects have been described at low doses versus high doses (82,83). For example, in mice developmental exposure to low doses of DES increases the adult estrogen responsiveness in the uterus while exposure to high doses decreases the responsiveness (84). This adds to the difficulty in establishing cause and effect relationships between chemical exposure and adult disease.

To date, there has been a large amount of research in the laboratory demonstrating developmental programming by EDCs. As illustrated above, conditions associated with altered hormonal environments during human pregnancies are

Table 1 Altered Fetal Estrogen and Adult Disease

Fetal or maternal condition	Fetal estrogen	Breast cancer	Endometriosis

associated with altered disease risk in adulthood. While long-latency effects from hormonal chemicals are difficult to detect, humans have been shown to be sensitive to this type of fetal programming (85). Because of the prevalence of EDCs in our environment and the potential for EDCs to cause developmental programming in humans, the Endocrine Society recently released a position statement on endocrine disruptors (86): “The evidence for adverse reproductive outcomes (infertility, cancers, malformations) from exposure to endocrine disrupting chemicals is strong, and there is mounting evidence for effects on other endocrine systems, including thyroid, neuroendocrine, obesity and metabolism, and insulin and glucose homeostasis.” They further suggest partnering of scientific societies to further research the effects in humans. Similar statements have been adopted by the American Medical Association, American Chemical Society, and others.

The U.S. Environmental Protection Agency (EPA) Endocrine Disruptor Screening and Testing Program was established in 1998 in response to the Food Quality Protection Act and was charged with the goal of developing screening and testing methods for endocrine-active compounds. Over 10 years later, the final selection of chemicals to be tested to validate screening and testing methods was chosen (87). Recently, the Endocrine Disruptor Prevention Act of 2009 was introduced to strengthen regulation of EDCs.

MECHANISMS OF EDCS

The U.S. EPA defines an EDC as “an exogenous agent that interferes with synthesis, secretion, transport, metabolism, binding action, or elimination of natural blood-borne hormones that are present in the body and are responsible for homeostasis, reproduction, and developmental process.” A detailed discussion of the mechanisms of EDC action is beyond the scope of this chapter but has been reviewed elsewhere (81,86). Summarized below are potential consequences resulting from developmental disruption of normal estrogen, androgen or thyroid hormone signaling by EDCs in adulthood.

Estrogens

To date, the largest group of environmental chemicals with hormonal activity interferes with normal estrogen signaling. Those chemicals that bind directly to the estrogen receptor are termed xenoestrogens. They can have estrogenic, antiestrogenic, or mixed receptor activity. While hundreds of xenoestrogens have been described, a few selected ones are described below.

Bisphenol A is an estrogen receptor ligand and selective estrogen receptor modulator (88,89). It has been shown to disrupt the endocrine system in >100 reports in different animal systems (82). Bisphenol A is the monomer that is polymerized to form polycarbonate plastic (hard, clear plastic) and is one of the top 50 chemicals in worldwide production, with annual production of >6 billion pounds (90). It is released from polycarbonate products, such as water and baby bottles (91,92), the resin lining of metal food cans (93–95), some dental sealants (96), eyeglasses, CD cases, and polycarbonate laboratory animal cages and water bottles (97,98). Bisphenol A was shown to comprise 84% of the estrogenic activity in landfill leachate (99).

Bisphenol A is an almost ubiquitous chemical in our environment and in people (100). Calafat recently reported that >92% of Americans have detectable levels of bisphenol A

in urine (101). Importantly, children had twice the level as adults (4.5 vs. 2.5 $\mu\text{g/L}$) and women had higher levels than men. It was recently estimated that infants drinking out of polycarbonate bottles would receive a daily exposure of up to 2 $\mu\text{g/kg}$ (102). Of particular concern, bisphenol A alters normal development at this exact dose (and lower) in animal models (82,98,103–115).

Ethinyl estradiol is an orally active form of estradiol, and it is a component of OCPs. While ethinyl estradiol is not considered a teratogen, evidence from laboratory studies suggest that it is an endocrine disruptor. Millions of women use OCP, and approximately 2% to 5% will conceive while taking them due to noncompliance (116). Some of these women deliver infants exposed to 0.2 to 0.5 $\mu\text{g/kg}$ of this potent estrogen during the critical window of sexual differentiation in the first trimester of pregnancy. This dose has been shown to alter mouse development (105,117). Additionally, ethinyl estradiol has been measured in waste water influent and effluent and may be a source of human exposure (118).

Genistein is a naturally occurring phytoestrogen and the predominant soy isoflavone. Adults consuming soy-based foods, particularly vegetarians, circulate 50 to 200 ng/mL total isoflavones. Infants fed soy-based infant formula circulate approximately 700 ng/mL genistein (119). While soy-based foods have been promoted as having beneficial effects in adults, there is increasing evidence that developmental exposure during differentiation of the uterus may be detrimental (120–123).

Importantly, xenoestrogens are found in the human fetus. Pregnant women and their fetuses tend to have higher levels of bisphenol A (124–126), and bisphenol A has been found in human maternal and fetal serum at 0.2 to 10 ng/mL (125–127). Olea and colleagues recently measured total xenoestrogen bioactivity in human placentas. By separating endogenous from xenoestrogens, it was estimated that 16% of the total activity was due to xenoestrogens (128). There is a considerable amount of literature relating to EDCs: on mechanisms of action, controlled laboratory studies, and human health trends. Taken together, these strongly support fetal programming by these chemicals. Outlined below are many of these trends with supporting associations with EDCs.

Puberty

A trend toward earlier onset of puberty has recently been described, and EDCs, particularly early exposure to xenoestrogens, are thought to be a major contributing factor (129–133). Earlier puberty (defined as development of secondary sexual characteristics before 8 years of age) is a risk factor for breast and testicular cancer, polycystic ovarian syndrome, and metabolic disorders (133). Thigpen et al. found that rodent chow containing various low doses of genistein and another soy isoflavone, daidzein, advanced vaginal opening in Wistar rats and CD-1 mice (134). Other xenoestrogens including DES and bisphenol A and various other EDCs have also been shown to advance puberty in rodents at very low doses (25 ng –200 $\mu\text{g/kg/day}$) (104,105,135–138). In humans, early pubertal onset has been associated with neonatal exposure to the polybrominated biphenyl FireMaster, which was accidentally introduced into the Michigan food supply in 1973 when

it was confused with the nutritional supplement Nutri-Master (139,140). Furthermore, precocious thelarche before age 2 has been associated with elevated serum levels of phthalate esters in Puerto Rico. One phthalate in particular, di-(2-ethylhexyl) phthalate, was detected in patients at levels 6.4-fold higher than controls (141). Importantly, a trend toward altered timing of pubertal onset may affect later disease risk (i.e., increased cumulative estrogen exposure increases breast cancer risk), and also how clinicians medically and pharmacologically treat children with precocious or delayed puberty.

Fertility

The rates of infertility and recurrent pregnancy loss have increased over the last 50 years. While delayed childbearing in women is a clear and strong factor in decreased fertility, it has been postulated that developmental xenoestrogen exposure may also play a role (142). McLachlan and colleagues reported reduced fertility in mice following developmental DES exposure (68). Jefferson and Newbold recently showed that developmental 500 µg/kg genistein exposure resulted in impaired fertility in female mice in adulthood (121). This dose of genistein is an order of magnitude lower than that consumed by infants fed exclusively soy infant formula (143).

Breast Cancer

Breast cancer is the second most fatal cancer for women and one out of eight women will be diagnosed in their lifetimes (144). While interpreting the trends in breast cancer incidence is complicated by many factors (145), it appears that incidence has increased in the second half of the twentieth century (146,147). For example, in Hong Kong age-adjusted risk increased two- to threefold for women born in 1960 compared with 1900 (Fig. 2 (147)). Ravdin et al. recently reported a decline in breast cancer incidence in the United

States starting around 2002, but it is still unclear what factors have primarily accounted for the change (146,148).

In humans, exposure to steroidal estrogens is associated with increased breast cancer risk, and xenoestrogen exposure has been associated with increased breast cancer risk in adulthood. As discussed above, increased fetal estrogen exposure, endogenous or exogenous, is associated with increased adult breast cancer risk, while decreased exposure is associated with reduced risk. Developmental DES exposure has clearly been associated with increased breast cancer risk (71). While it is difficult to study unknown exposures with long-latency diseases 40 to 70 years later, developmental xenoestrogen exposure has been associated with altered mammary gland development and cancer risk in laboratory animals (107,149–161).

Male Reproductive Tract

There is some evidence that reproductive tract abnormalities in boys are influenced by developmental estrogen exposure. Cryptorchidism, hypospadias, and testicular cancer incidence are higher in first-born boys. Since maternal estrogens are higher in first pregnancies, these data are compatible with the hypotheses linking excessive pregnancy-estrogen exposure to conditions more common among first-born individuals (162). Additionally, cryptorchidism and testicular cancer increase in boys born to older mothers (163). However, unlike breast cancer and endometriosis, cryptorchidism does not appear to be related to maternal smoking (164).

Vegetarians tend to consume greater quantities of soy-based products than their omnivorous counterparts. Thus, vegetarians are exposed to increased levels of phytoestrogens, chemicals in plants that mimic estrogens. A prospective cohort study in the United Kingdom that sampled 7928 males born in 1991 and 1992 found an odds ratio for hypospadias of 4.99 for boys who were born to vegetarian mothers (165). An increased incidence of hypospadias has also been reported in DES grandsons (63–66).

Figure 2 Relative risk estimates of incidence of breast cancer by birth cohort. Based on full age-period-cohort model with period constraints. Bars around the point estimate indicate the 95% confidence intervals. Source: From Ref. 147.

Metabolic Programming

Newbold and colleagues have also shown that developmental exposure to DES at a dose of 1 µg/kg/day but not at higher doses (10–100 µg/kg/day) can cause obesity in adulthood in mice (reviewed in (166)). At 2 months of age, prior to a difference in size between DES-treated and control mice, the DES mice had elevated levels of leptin, adiponectin, IL-6, and triglycerides. By 6 months of age, densitometry studies indicated that the DES-exposed mice had increased abdominal fat, which was not likely caused by a slightly increased food intake and/or decreased activity. Furthermore, Newbold et al. have also shown that DES-exposed animals have a high level of islet cell hyperplasia, indicating that they may have problems with glucose homeostasis (reviewed in (166)).

Androgens

There are several environmental chemicals that interfere with androgen action. Chemicals that bind to the androgen receptor and prevent androgen action are known as androgen receptor antagonists, including DDE (a metabolite of the pesticide DDT), vinclozolin, a fungicide, and several phthalates. Phthalates are esters of phthalic acid and are used in hundreds of products, including plasticizers, PVC resins, and cosmetic and personal care products such as shampoos and soaps. As of 2004, manufacturers produced about 800 million pounds of phthalates each year. They contribute 10% to 60% of plastic products by weight (167).

The incidence of male reproductive tract disorders, including cryptorchidism, hypospadias, testicular cancer, and low sperm count, has increased over the last 30 to 50 years (168–174). It has been postulated that these disorders comprise a testicular dysgenesis syndrome (TDS) and may have a common etiology of deficient androgen production or action during development of the testes in fetal life (175).

Normal sexual differentiation of the male reproductive tract is androgen dependent. Exposure to antiandrogens during sexual differentiation produces malformations of the reproductive tract in humans and rodents. For example, the fungicide vinclozolin is an antiandrogen. Developmental exposure to vinclozolin during sexual differentiation in rats resulted in reduced anogenital distance, retained nipples, cleft phallus with hypospadias, cryptorchidism, a vaginal pouch, epididymal granulomas, and small-to-absent sex accessory glands (176).

Anogenital Distance (AGD)

AGD is a marker for sexual differentiation. In humans, AGD is measured from the anus to the base of the scrotum in males

and from the anus to the genitals in females and is about twice as long in males as in females (177). AGD is androgen dependent and developmental exposure to antiandrogens reduces AGD. Many laboratory studies have shown that developmental exposure to EDCs with antiandrogenic activity, such as di-*n*-butyl phthalate, bis(2-ethylhexyl)phthalate, linuron, procymidone, and DDE (a metabolite of the pesticide DDT) can reduce AGD (176).

Phthalates have been shown to have estrogenic activity and antiandrogenic activity, and to alter androgen production. Importantly, Swan et al. prospectively examined the relationship between developmental phthalate exposure and age-adjusted AGD (anogenital index) in infant boys (178). AGI was inversely related to four phthalate metabolites in maternal circulation during pregnancy (Table 2). Boys with the highest developmental exposure were 10 times more likely to have a shorter AGD than boys with the lowest prenatal exposure (178).

Testicular Cancer

Testicular cancer incidence is associated with higher serum levels of EDCs in adulthood (179) and maternal levels of EDCs (180,181). Over the past 50+ years, the incidence of testicular cancer has risen at an alarming rate. In a number of studies from around the world, it is estimated that between approximately 1982 and 2005, incidence of testicular cancer rose 2.4% per year in Spain (182), 2.6% per year in Australia (183), 2.3% to 3.4% per year in the Nordic countries, and by 5% in Poland and Germany (184). For men in six European countries born after 1945, the risk of testicular cancer increased in all six countries. Relative risks for those born around 1965 were 3.9 in Sweden and 11.4 in East Germany (185).

Cryptorchidism

The incidence of cryptorchidism doubled in the United States between 1968 and 1993 and has been associated with developmental exposure to several EDCs (168). During a period of peak use of the pesticide DDT in the United States between 1959 and 1967, babies born to mothers with the highest serum DDT levels had nearly a twofold increased risk of cryptorchidism when compared with those whose mothers had lowest serum DDT levels (186).

Similarly, the concentration of 21 persistent and non-persistent EDCs in the breast milk of Finnish and Danish mothers between 1997 and 2001, as measured in a series of case reports from a prospective birth cohort, was associated with an increased risk of cryptorchidism (187–189). A combined statistical analysis for the eight most prevalent persistent EDCs (*p,p'*-DDE, *p,p'*-DDT, β-HCH, HCB,

Table 2 Mean (Median) Phthalate Monoester Metabolite Levels by Anogenital Index Category

Monoester metabolite	AGI category [mean (median; ng/mL)]		
	Long ^a (n = 17)	Intermediate ^b (n = 43)	Short ^c (n = 25)
MBP	13.1 (11.5)	22.2 (13.1)	38.7 (24.5)
MBzP	10.6 (6.6)	15.1 (7.7)	25.8 (16.1)

MiBP	2.3 (1.5)	3.3 (2.1)	7.7 (4.8)

^aLong, AGI ≥75th percentile of expected AGI. ^bIntermediate, 25th percentile ≤ AGI <75th percentile of expected AGI. ^cShort, AGI <25th percentile of expected AGI. *Abbreviations:* MBP, mono-butyl phthalate; MBzP, mono-benzyl phthalate; MEP, mono-ethyl phthalate; MiBP, mono-isobutyl phthalate. *Source:* From Ref. 178.

α -endosulfan, cis-HE, oxychlorodane, and dieldrin) revealed higher concentrations in the breast milk of case mothers. This indicates that a mixture of low concentrations of EDCs may be more important when assessing the risk of cryptorchidism than the concentration of any single chemical (187). The concentration of the sum of seven polybrominated diphenyl ethers, which are commonly found in flame-retardants, was also significantly higher in the breast milk of mothers of cryptorchid boys compared with controls (188). Additionally, phthalate levels in the mothers' breast milk were associated with altered levels of hormones related to Leydig cell function, which might have led to decreased virilization in this cohort (189).

Hypospadias

In 1997, the CDC reported a doubling of hypospadias in the United States from 1968 to 1993 (169). European countries also reported increases in hypospadias but increases were not seen in less affluent countries (168). Exposure to industrial and agricultural EDCs during development is associated with increased risk of hypospadias as demonstrated by Dolk et al. (190) and Carbone et al. (191).

Phthalate exposure during sexual differentiation has been shown to lead to TDS in laboratory animals (192). One hypothesis for the increased incidence of male reproductive tract disorders in humans is developmental exposure to EDCs that can alter androgen signaling. Wilson et al. reviewed different groups of EDCs that converge on androgen signaling. While the exact mechanisms of these EDCs differed, the end result was a reduction in testosterone signaling through androgen receptor (193).

Sperm Count

Sperm counts have declined over the past 60 years. In a meta-analysis, Swan et al. found a twofold reduction in sperm counts from 1938 to 1990 (172). Since Swan et al. have confirmed their initial findings and expanded the scope of years examined, the number of studies examined, and further analyzed confounders and statistical methods used for approximating the decline (171,173), adult and developmental exposure to environment chemicals has been linked to lower sperm counts. Swan et al. compared semen characteristics, including sperm concentration, from samples collected at four centers in the United States (Columbia, Missouri; New York, New York; Minneapolis, Minnesota; and Los Angeles, California). All samples were collected and analyzed following very strict protocols, and it was found that the men from Missouri had the lowest sperm concentrations, which in turn was associated with higher urinary concentrations of five pesticides, including alachlor and atrazine, which are commonly used herbicides (170,194). The data suggest that residence in a rural community with high pesticide exposure may affect sperm concentrations.

Developmental exposure to anabolic steroids or xenobiotics in beef has been linked to low sperm count in adulthood. Fertile men whose mothers consumed seven or more beef meals per week during pregnancy had 24% lower sperm count, were more likely to have a history of infertility, and there was a threefold increase in the proportion of these men with less than 20 million sperm per mL (195).

THYROID HORMONE

Unlike xenoestrogens and environmental antiandrogens that bind directly to the estrogen and androgen receptor, EDCs that disrupt thyroid function do so without binding to the thyroid receptor. Howdeshell extensively reviewed EDCs for their potential to interfere with thyroid hormone signaling and found over 150 chemicals with the ability to disrupt thyroid hormone action (196). EDCs have been shown to disrupt nearly every step in the synthesis and metabolism of thyroid hormone (196). For example, EDCs have been shown to alter thyroid hormone synthesis, uptake of iodine by the thyroid gland, and binding to specific thyroid-binding proteins in blood.

Polychlorinated biphenyls (PCBs) are a group of chemicals used in a variety of manufacturing applications, for example, in coolants, transformers, plasticizers, oils, adhesives, and so on. PCBs are persistent organic pollutants that are highly toxic, similar in action to dioxin, and used widely until their ban in 1976 in the United States. In addition to acute toxicity, PCBs are endocrine disruptors and interfere with normal hormone action, particularly estrogen and thyroid hormone signaling.

Adequate thyroid hormone during development is essential and inadequate levels are associated with cognitive deficits in children born to pregnant women with hypothyroidism (197). PCBs have been shown in the laboratory to interfere with multiple steps in thyroid hormone physiology (reviewed in (196)). Many studies of prenatal exposure to PCBs have been undertaken in various parts of the world and have shown negative effects on neurodevelopment (198–208). For example, Jacobson et al. examined infants in the Lake Michigan area selected based on their mothers' fish consumption. Because PCBs are persistent and lipophilic, they bioaccumulate in the food chain and have been found in high concentrations in fish and fish eaters. Infants with high levels of PCBs showed impaired visual memory (204). In 4-year-olds, prenatal PCB exposure was associated with lower scores in verbal and numerical memory (203), visual discrimination processing, and impaired short-term memory scanning (209). In 11-year-olds, prenatal PCB exposure was correlated with lower full-scale and verbal IQ scores. On average, IQ scores were 6.2 points lower in the highest exposure group than their lesser-exposed peers (202). It was also estimated that PCB-exposed children were up to 7.2 months behind in word comprehension (202). Since PCBs were banned in 1979, human exposure to these persistent chemicals has slowly declined. However, PCBs are very persistent chemicals and cognitive dysfunction is still reported, suggesting that environmentally relevant doses of endocrine-disrupting chemicals may alter human neurodevelopment (210).

SUMMARY

There is a great need for research to define the mechanisms of fetal programming. These mechanisms involve epigenetic changes, that is, the effects do not result from DNA mutations. Intense research centers on elucidating the mechanisms responsible for fetal programming and the epigenetic alterations regulating gene expression and adult disease. Epigenetic mechanisms include DNA and histone methylation, and histone acetylation (211,212). These marks can retain fetal programming information into adult life.

While high-dose/pharmacologic exposures have been associated with birth defects and severe long-latency effects (DES), it is likely that current human exposure to other pharmaceuticals and industrial chemicals may program the fetus and result in more subtle alterations in adult phenotype. Establishing cause and effect relationships between exposures and these subtle effects is much more difficult. Despite the difficulty in demonstrating such cause and effect relationships with subtle long-latency effects, these associations have been found in controlled experiments in human and laboratory animal studies and it is clear that subtle fetal programming occurs in people and alters adult disease risk. It is likely that only the tip of the iceberg has been described to date, and it is largely unknown the extent that the fetal environment programs lifelong phenotypes. Given this backdrop, every effort should be made to use the precautionary principle in counseling pregnant women about pharmaceutical use and minimizing exposure to environmental chemicals, such as indoor pesticides and painting while pregnant. Maternal risk of withholding medication must be considered, but when potential fetal risks outweigh maternal benefit, the precautionary principle should be employed.

46 Assessment of fetal genetic disorders

Teresa Martino, J. Pratt Rossiter, and Karin J. Blakemore

INTRODUCTION

Since the first clinical use of fetal sex determination by amniocentesis in 1967, there has been a virtual explosion in both the availability and the application of prenatal diagnosis in the management of pregnancy. The rapid expansion of this field has been a result of numerous advances. The quality of ultrasonography has vastly improved, allowing detection of both gross and increasingly more subtle congenital anomalies and providing accurate guidance for diagnostic procedures including amniocentesis, chorionic villus sampling (CVS), fetal blood sampling, and fetal biopsy. The safety of these invasive methods improved due to higher resolution ultrasonography as well as progress in the development of the techniques themselves. Simultaneously, the “revolution” in molecular genetics has resulted in the identification of the genes and mutations responsible for many inherited disorders. This knowledge can, in many cases, be applied directly to prenatal diagnosis for pregnancies at risk for specific genetic diseases. All of these factors have contributed to the need for maternal–fetal medicine specialists to become experts in the field of prenatal diagnosis.

This chapter reviews the most common indications for prenatal diagnosis and the invasive methods currently used. The status of preimplantation diagnosis and of prenatal diagnosis using fetal cells or fetal DNA isolated from the maternal circulation is reviewed.

INDICATIONS FOR PRENATAL DIAGNOSIS

The most common reasons for referral for genetic counseling and prenatal diagnosis are summarized in Table 1. Currently, invasive prenatal testing is offered when the likelihood of detecting an abnormality exceeds the statistical risk of pregnancy loss related to the diagnostic procedure. Ethical issues regarding the somewhat arbitrary determination of when to offer prenatal diagnosis were recently considered and universal access to genetic diagnosis proposed (1); however, this practice is presently far from being adopted.

Maternal Age

The relationship between advancing maternal age and increasing incidence of chromosomal abnormalities due to meiotic nondisjunction is well established (2). The steadily rising risk with maternal age applies not only to trisomy 21 (Down syndrome), but to any trisomy or monosomy. The chance for a 35-year-old woman to have a live-born infant with a chromosomal abnormality is 1 in 192 (3). This risk approximates the stated 1 in 200 risk of procedure-related loss with second-trimester amniocentesis; thus, women are offered prenatal diagnosis for chromosome abnormalities when they will be 35 years of age or older at the time of delivery. Many chromosomally abnormal fetuses are lost during the course of pregnancy; therefore, the likelihood of having an aneuploid

fetus at the time of amniocentesis (usually 16–20 weeks of gestation) is greater than the risk at term (4). For example, women who will be 33 years old at the time of delivery have a risk of 1 in 200 of having a chromosomally abnormal fetus at the time of amniocentesis (4). For this reason, some practitioners advocate offering prenatal diagnosis to women who are 33 years of age or older, but no consensus has yet been reached.

Chromosomal Abnormalities

Couples with a previous trisomic child are thought to have approximately a 1% risk of recurrence (5) and are thus offered prenatal diagnosis. Siblings and second-degree relatives to an individual with Down syndrome may have a slightly increased risk for having a similarly affected child (6), though most studies have not demonstrated an increased incidence of Down syndrome in second- or third-degree relatives (7,8). Many people with an affected relative have a high degree of anxiety, which may justify prenatal testing.

Translocations and other chromosomal structural rearrangements can predispose to chromosomally abnormal progeny (see chapter 43 for a description of translocations). Couples in whom one partner carries a balanced reciprocal translocation are at high risk for recurrent pregnancy loss. At the time of prenatal diagnosis, approximately 10% to 12% of progeny have an unbalanced chromosome complement (9,10), while this risk declines to 6% of live-born offspring because of spontaneous abortion (11). Progeny of Robertsonian translocation carriers are at risk for trisomy or monosomy of the involved chromosomes, with the risk dependent on the specific chromosomes participating in the translocation (9,10). An extreme example is that of a Robertsonian 21/21 translocation carrier, whose progeny would all be predicted to be either trisomic (Down syndrome) or monosomic (lethal) for chromosome 21. Couples with a history of multiple pregnancy losses should be offered karyotypes to determine whether one member is a translocation carrier. Individuals known to be translocation carriers should be offered prenatal cytogenetic testing, as the fetal karyotype result may be normal, balanced, or unbalanced, with the proportion of each karyotype result varying, dependent on the specific translocation (10).

Multiple-Marker Screening in the Second Trimester

The history of multiple-marker screening began in 1972 when Brock and Sutcliffe described the association of fetal anencephaly and spina bifida with elevations in maternal serum alpha-fetoprotein (MSAFP) levels (12). Subsequently, studies in the United States (13) and the United Kingdom (14) proposed the establishment of screening programs to detect pregnancies complicated by fetal open neural tube defects. During the 1980s, such screening programs became widespread in the United States, where the incidence of neural tube

Table 1 Indications for Prenatal Diagnosis

- Maternal age 33 or more at delivery
- Family history of chromosomal abnormality
- Parental translocation carrier
- Abnormal MSAFP or multiple-marker screening
- Family history of neural tube defect
- Single-gene disorder—family history or carrier detected by population screening
- Congenital malformation detected by ultrasonography
- Maternal desire

Abbreviation: MSAFP, maternal serum alpha-fetoprotein.

defects is 1 to 2 per 1000 live births (15). Elevated MSAFP values are associated not only with open neural tube defects, but also with other fetal abnormalities involving a break in skin integrity such as ventral wall defects (omphalocele, gastroschisis), teratoma, bladder exstrophy, or aplasia cutis. Numerous other fetal and placental abnormalities have been reported in association with elevated MSAFP levels (16,17). In addition, elevations in MSAFP unexplained by sonographic findings are associated with an increased risk of pregnancy complications, fetal growth restriction, and fetal death (17,18). The American College of Obstetricians and Gynecologists has proposed an algorithm for the evaluation of pregnancies with elevated MSAFP levels including ultrasonography, amniocentesis for amniotic fluid AFP, and acetylcholinesterase if the amniotic fluid AFP is elevated (15). Since MSAFP screening became the standard of care in the United States, elevated MSAFP has become a common indication for referral for prenatal diagnosis.

The clinical utility of MSAFP screening expanded substantially when an association was found between low MSAFP values and fetal chromosomal abnormalities (19,20). Using a combination of maternal age and MSAFP to identify pregnancies at high risk, approximately 20% of Down syndrome pregnancies in women younger than 35 years were detected in prospective trials (21,22). Subsequently, Down syndrome pregnancies were found to be associated with elevated maternal serum concentrations of human chorionic gonadotropin (hCG) (23) and decreased unconjugated estriol (uE_3) (24) as compared with normal controls. In a large prospective trial using maternal age in combination with maternal serum levels of AFP, hCG, and uE_3 to assign a risk of fetal Down syndrome of $>1:190$, 58% of Down syndrome pregnancies were identified, and 38 amniocenteses were performed for each confirmed case of Down syndrome (25). This trial included women ranging in age from 16 to 41 years. Since this publication in 1992, multiple-marker or “triple” screening came into more widespread use. Further applications of the triple screen have followed, with the recognition of a characteristic pattern of low values for AFP, hCG, and uE_3 in association with trisomy 18 (26,27), and a pattern similar to that for an increased risk for Down syndrome (low AFP, low uE_3 , high hCG) in association with Turner syndrome (45,X) (28,29). A newer maternal serum marker, dimeric inhibin-A, also measured in the second trimester, is approximately 2.06 times the median value in fetuses affected with Down syndrome (30). The detection rate for Down syndrome with the addition of inhibin-A is approximately 80%. Serum screening in the second trimester with the inclusion of

inhibin-A may be called the “quadruple screen.” It is important to note that inhibin-A is not used in the calculation of trisomy 18.

Multiple-marker screening allows the detection of pregnancies that would otherwise not be considered at increased risk for either neural tube defects or chromosomal aneuploidy. Older women may opt for multiple-marker screening to readjust their age-related risk of fetal Down syndrome and trisomies 18 and 13. A recent guideline from the American College of Obstetricians and Gynecologists suggests that all women be offered aneuploidy screening before 20 weeks of gestation, regardless of maternal age (31).

One of the main disadvantages of multiple-marker screening was its timing in the second trimester. An abnormal screen, typically obtained at 16–18 weeks of gestation, sets into motion a series of events including repeat screening in some cases (if AFP is high, *not* for increased risk of aneuploidy), ultrasonography to confirm dating, genetic counseling, and the offer to have amniocentesis for chromosomal analysis and amniotic fluid AFP measurement. At the completion of this evaluation, most patients are beyond 18 weeks and many are beyond 20 weeks of gestation. By this time, many pregnant women have begun to feel fetal movement and are readily recognized as pregnant by casual observers. In addition, the options for termination are induction methods (prostaglandin and/or urea instillation, prostaglandin suppositories) or dilatation and evacuation at an advanced gestational age. Either method is associated with significantly greater morbidity than first-trimester dilatation and curettage, as well as increased medical costs. For these reasons, the ability to perform screening in the first trimester provides a significant benefit over second-trimester screening.

Multiple-Marker Screening in the First Trimester

Multiple biochemical marker screening may also be offered in the first trimester. Investigations into the first-trimester biochemical maternal serum marker screening began in the 1980s. Two useful markers emerged, free beta human chorionic gonadotropin ($f\beta hCG$) and pregnancy-associated plasma protein A (PAPP-A). While maximum detection rates for each of these markers are at 14 completed weeks for $f\beta hCG$ and 9 completed weeks for PAPP-A (32,33), used together (along with maternal age) at 11 to 13 weeks of gestation yields a detection rate for Down syndrome of approximately 67% with a false positive rate set at 5%. Better detection rates are obtained by incorporating a sonographically acquired measurement of the sonolucent area just under the skin line on the posterior fetal neck, the nuchal translucency (NT). Using *only* first-trimester NT screening and maternal age (without biochemistry) has yielded a Down syndrome detection rate of 73% at the same 5% false positive rate. Today, first-trimester “combined” screening employs maternal age, maternal serum analytes, and an NT, with or without the presence or absence of the fetal nasal bone to arrive at an individual’s risk for fetal Down syndrome. In one large prospective study, in women ≥ 35 years old, the detection rate was 89.8% for fetuses with trisomy 21 with a false positive rate of 15.25%, while 100% of fetuses with trisomy 18 were detected (34). For those women < 35 years old, first-trimester “combined” screening had a detection rate for trisomy 21 of

60% with a false positive rate of 5%. In pregnancies complicated by fetal trisomies 13 and 18, free β hCG and PAPP-A are decreased, while those pregnancies complicated by fetal sex chromosome abnormalities demonstrate a normal free β hCG and PAPP-A is low (35–37).

Measurements of the NT may be taken from 10 to 14 weeks of gestation. In a prospective screening study of 1273 women mostly of advanced maternal age, Nicolaides et al., observed an NT of ≥ 3 mm in 86% of the trisomic and 4% to 5% of the normal fetuses. An NT of ≥ 3 mm was associated with a 12-fold increase in fetal aneuploidy and was independent of maternal age (38). This study was confirmed by Chitty et al. in a group of patients who were not considered at risk for fetal aneuploidy (39). As the gestational age increases, so does the NT. Gestational age-specific multiples of the median have been derived and are used commonly.

There are several other terms in use today that describe various combinations of first-trimester screening with second-trimester aneuploidy screening, including “integrated” screening and “sequential” screening. The “combined” first-trimester screen includes an NT, PAPP-A, and a β hCG. “Integrated” and “sequential” screenings both combine elements of first- and second-trimester screening and differ when the first-trimester screening results are reported. In an “integrated” test, an NT is obtained along with a PAPP-A plus a quadruple screen. The results are provided to the patient after all tests are completed. In a “stepwise sequential” test, the combined first-trimester screen is used plus a quadruple screen with results given after each test. In a “contingent sequential” test, the combined first-trimester screen is performed, and only those with a risk between 1:30 and 1:1500 have a quadruple screen (40). Not all centers offer, and not all women opt for “combined” first-trimester screening.

Family History of Single-Gene Disorders

A family history of a single-gene disorder is another common indication for referral for prenatal genetic counseling. Fetal risk assessment is dependent on many factors, such as the distance of the relationship between the affected family member and the individual seeking counseling, as well as the frequency of the disease gene in the population. Couples with a previously affected child may be obviously at higher risk for recurrence, while the risk declines with increased distance from the affected relative ($1^{\circ} > 2^{\circ} > 3^{\circ}$). For example, parents of a child with an autosomal recessive disorder have a 25% risk of recurrence with each pregnancy. By contrast, the offspring to the siblings of an affected individual have a risk calculated as follows: the risk of the unaffected sibling being a carrier (2/3), times the risk that the partner is a carrier (the population carrier frequency if the family history is negative), times the risk of having an affected offspring given that both parents are carriers (1/4). Thus, for cystic fibrosis, with a carrier frequency of 1 in 25 Caucasian Americans, the risk for an unaffected sibling of an affected individual to have an offspring with cystic fibrosis is $2/3 \times 1/25 \times 1/4 = 1/150$. Carrier testing of the sibling, when available, may refine these odds.

Carrier screening is currently widely available for some recessive conditions, including sickle cell anemia and Tay-Sachs disease. Carrier screening has become available for other relatively common genetic conditions, creating another group

of candidates for prenatal diagnosis. In 2001, the American College of Obstetricians and Gynecologists and the American College of Medical Genetics issued guidelines that recommended cystic fibrosis carrier screening be offered to Caucasian couples who are planning a pregnancy or seeking prenatal care, and be made available to patients, regardless of ethnic background (2001 guideline). Cystic fibrosis is more common in Caucasians and in Ashkenazi Jews than in other populations, and the screening test detects a higher percentage of carriers in this population than in other groups. Due to the fact that defining a single ethnicity in many people in the United States is becoming more difficult, the guidelines for carrier screening from the American College of Obstetricians and Gynecologists were updated in 2005 and state that it is reasonable to offer cystic fibrosis carrier screening to all pregnant patients, provided that women are aware of their a priori carrier risk and the test limitations (41).

Sonographic Findings

As the resolution and therefore the sensitivity of ultrasonography improve, an increasing number of referrals for prenatal diagnosis are generated because of sonographic fetal abnormalities. Some of the more frequent findings include fetal heart defects, ventral wall defects, central nervous system abnormalities, gastrointestinal anomalies, renal anomalies, choroid plexus cysts, and nuchal fold thickening. These may be found in isolation, in conjunction with chromosomal abnormalities or as part of a genetic syndrome. As technical skills in ultrasonography as well as the resolution of the images improve, fetal abnormalities will be more frequently identified. As a result, our understanding of developmental abnormalities and what may represent normal variation will expand and thereby modify the genetic counseling engendered and what is offered in terms of prenatal diagnosis.

Not only have the indications for referral for prenatal diagnosis have expanded over the last four decades, but also the methods available to prenatally detect genetic disorders have also expanded. In addition to amniocentesis, invasive diagnostic methods currently include CVS, fetal blood sampling, and fetal biopsy for specific indications. Samples obtained by these techniques are used for cytogenetic analysis (karyotype, fluorescence in situ hybridization (FISH), array comparative genomic hybridization), molecular DNA diagnosis, and/or biochemical evaluation, dependent on the specific disorder being investigated. Each invasive procedure has risks and benefits to be considered when offering diagnostic testing.

INVASIVE PRENATAL DIAGNOSTIC METHODS

Midtrimester Amniocentesis

The use of amniocentesis to prenatally detect chromosomal abnormalities was first reported in 1967 (42). Since that time, amniocentesis has become a widely accepted method for prenatal diagnosis of chromosomal abnormalities, inherited diseases, and some congenital infections. Despite about experience of three decades with midtrimester amniocentesis, determination of the risk of procedure-related pregnancy loss has been difficult. Risk estimates have ranged from 0.5% to 1% in large, prospective, multicenter trials (43–45). Total loss rates following invasive procedures are more readily accessible,

encompassing the “background” fetal loss rate plus the procedure-related loss rate. A systematic review by Mujezovic et al. showed a pooled pregnancy loss within 14 days after amniocentesis of 0.6% and rising to 0.9% before 24 weeks of gestation. The total pregnancy loss rate was 1.9% (46).

While fetal loss resulting from amniocentesis is considered the most serious risk of the procedure, other fetal and maternal risks must also be considered. Fetal-needle puncture resulting in scars at birth has been reported (47), but is quite rare. Amniocentesis performed under continuous ultrasound guidance allows sampling of fluid while avoiding fetal parts, thus minimizing the risk of such an injury. Two large prospective trials found an association between midtrimester amniocentesis and neonatal respiratory difficulty (43,44), while a study from the National Institute of Child Health and Human Development (NICHD) of the U.S. National Institutes of Health (43) did not corroborate this finding. An increased incidence of orthopedic postural deformities in association with amniocentesis was reported in the initial United Kingdom Medical Research Council (MRC) study (44), but was not found in two other large trials (42,45).

Other complications from midtrimester amniocentesis include chorioamnionitis, leakage of amniotic fluid, and vaginal bleeding. The incidence of chorioamnionitis is <1 per 1000 procedures (48). Amniotic fluid leakage occurs in 1% to 2% of patients (42,44), but is usually self-limited, with re-accumulation of fluid and a normal pregnancy outcome in most cases (49). The incidence of vaginal bleeding after second-trimester amniocentesis is also approximately 1% and is positively correlated with the number of needle insertions required (42).

An advantage of midtrimester amniocentesis over CVS is the ability to measure amniotic fluid levels of AFP, a sensitive marker for open neural tube defects and ventral wall defects. Normal values for amniotic fluid AFP levels in the first trimester have not been clearly established. Detection of acetylcholinesterase in the amniotic fluid is a useful adjunct to amniotic fluid AFP. Today, high-resolution ultrasound imaging with a qualified sonographer is more sensitive than MSAFP, which has an 80% sensitivity. High-resolution sonographic visualization approaches the sensitivity of amniotic fluid AFP to detect open neural tube defects. In practice, ultrasound imaging may detect some closed neural tube defects missed by AFP testing. In a study evaluating neural tube defect detection, standard ultrasound improved the sensitivity of MSAFP by correcting the errors in gestational age (50). In this study, moreover, ultrasound detection of neural tube defects was 100% (50).

Chorionic Villus Sampling

Due to the desire for prenatal diagnosis in time to allow safer termination options, increased patient privacy, and decreased emotional stress, earlier diagnostic measures were being sought. The technique of CVS entered the realm of clinical practice in the 1980s. Early attempts to obtain trophoblastic tissue had been described in the 1960s and 1970s, which were fraught with high failure and complication rates (51,52). The ability to perform ultrasound guidance (53) and the development of a thin, malleable catheter for transcervical sampling (54) led to a resurgence of the technique and the

naissance of first-trimester genetic diagnosis. Since the publication of these groundbreaking articles, numerous investigations, including large prospective trials to determine the risks and benefits of CVS, have been undertaken.

CVS is usually performed between 10 and 14 weeks of gestation, but can be performed transabdominally in the first trimester as well as throughout later gestation. Cytogenetic, molecular DNA analysis, and/or biochemical methods can be applied to villus tissue. These assays can detect chromosomal abnormalities, specific gene defects or linkage to at-risk loci, and/or evidence of enzymatic activity abnormalities in pregnancies at known risk for particular inherited conditions. In all of these respects, CVS generally provides the same type of information available through amniocentesis. There are several instances in which these two procedures are not equivalent in their ability to provide diagnostic information. For example, CVS is not useful in detecting a fetus with an open neural tube or ventral wall defect. Admittedly, the sonogram performed at the time of CVS might identify such a fetus; no information regarding AFP level or the presence of acetylcholinesterase, however, can be obtained through CVS. In fragile X testing, the methylation status may not yet be established in chorionic villi at the time of sampling, and an amniotic fluid sample may be needed if ambiguous results are obtained from villus tissue. On the other hand, some assays can be performed using chorionic villi but not amniocytes. The prenatal diagnosis of forms of osteogenesis imperfecta that are based on collagen studies cannot be completed on amniotic fluid samples (55). Thus, in contemplating the preferred method for prenatal diagnosis in a given pregnancy, both the couples' wishes and the ideal means to obtain the desired information must be considered.

The same issues that faced early laboratory investigations of cultured second-trimester amniocytes were confronted by early investigators of chorionic villus cells, including maternal contamination and chromosomal mosaicism. Maternal contamination from decidual cells poses a threat to long-term chorionic villus cell cultures. Careful dissection of the villi using a microscope with 40× magnification will minimize this risk.

Chromosomal mosaicism refers to two (or more) cell lines in the same tissue, organ, or individual. An example would be a villus sample with both a normal (e.g., 46,XX) cell line and a trisomic (47,XX,+21) cell line. Because the placenta arises from different late progenitor cells than the embryo, mitotic errors that result in chromosomal nondisjunction can be limited to cells destined to become chorionic villi (56). This circumstance is identified as mosaicism by the laboratory at the time of CVS and is found in about 1% of chorionic villus samples (55). By contrast, mosaicism is seen in 0.25% of midtrimester amniotic fluid samples (57).

Frequently, when mosaicism is found by CVS, the fetus is chromosomally normal (58). If, however, a mitotic error occurred in a very early progenitor cell, both the villus and the embryonic descendants of this progenitor could contain the abnormality. In such a case, a chromosomal abnormality would often be revealed both at CVS and at follow-up amniocentesis. More often, follow-up amniocentesis in the midtrimester usually has normal cytogenetic results (59), with normal fetal outcomes. Though a normal karyotype on

amniocytes provides presumptive evidence for a chromosomally normal fetus, it is not a guarantee, as mosaicism can be limited to only some fetal tissues.

As for any prenatal diagnostic method, patients are concerned about the risk of procedure-related pregnancy loss. Initial studies to assess the safety of first-trimester CVS were descriptions of clinical experience, which described total fetal loss rates from 2% to 7% (60,61) and were unable to address the procedure-related loss rate. A large proportion of the total loss rate represents the naturally occurring spontaneous abortions characteristic of an earlier gestational age. In addition, chromosomally abnormal fetuses are viable in greater proportions at 10 to 12 weeks than at 16 to 20 weeks, the time of midtrimester amniocentesis. These and other issues were subsequently addressed in several multicenter trials of CVS.

Similar rates of pregnancy loss were found between CVS and midtrimester amniocentesis in a large randomized Canadian trial (62), in which the observed difference in loss rates between eligible women with a sonographically viable fetus at 9 to 12 weeks in the CVS and midtrimester amniocentesis groups was 0.6%, which was not statistically significant.

The MRC European trial of CVS (63) was less optimistic about the safety of the procedure. This multicenter, prospective study compared pregnancy outcomes after randomization with either first-trimester CVS or midtrimester amniocentesis. The study concluded that CVS "reduces the chances of a successful pregnancy outcome by 4.6% in comparison with second-trimester amniocentesis." One explanation for the increased loss rate in the MRC trial may be related to operator experience; the European study included a larger number of centers, with individual centers contributing fewer patients.

A prospective, nonrandomized trial conducted by the NICHD Collaborative Group (46) also compared pregnancy outcomes in patients undergoing first-trimester transcervical CVS with a group of patients undergoing midtrimester amniocentesis. This study showed total loss rates of desired pregnancies of 7.2% in the CVS group and 5.7% in the amniocentesis group. These rates included elective terminations for chromosomal and sonographic abnormalities, as well as spontaneous losses. After correction for differences in gestational age and maternal age between the two groups, the total excess loss rate in the CVS group was 0.8% when compared with the amniocentesis group. While this difference was not statistically significant, some centers currently quote a slightly higher procedure-related loss rate for CVS than for second-trimester amniocentesis. Many patients, nonetheless, would consider the benefits of early diagnosis in choosing to have CVS including the greater safety of pregnancy termination at an earlier gestational age. The systematic literature review cited earlier estimates a total pregnancy loss rate of 0.7% within 14 days, 1.3% before 24 weeks of gestation, and an overall pregnancy loss rate of 2% with CVS (46).

In addition to the pregnancy loss rate, the question of an increased risk of fetal limb abnormalities in association with CVS has undergone scrutiny. Firth and coworkers (46) reported an unusually high incidence of oromandibular-limb hypogenesis syndromes in pregnancies undergoing CVS at 56

to 66 days of gestation (8–9 weeks). None of the three large trials (61–63), in which CVS was usually performed at 10 to 12 weeks of gestation, found such an association. This led Firth et al. to hypothesize that an earlier gestational age at the time of CVS may predispose to limb reduction defects (64).

Subsequently, Burton and colleagues (65) reported their experience in which four transverse limb reduction defects were identified during follow-up after CVS in 436 pregnancies, an incidence far greater than the reported incidence of limb malformations of 1 in 1500 to 2000 live births (66). The procedures were performed at 9.6 to 11.3 weeks of gestation, thus the limb abnormalities cannot be explained by early timing of the CVS. This report has prompted speculation regarding the technique used in the single center involved, particularly since their spontaneous loss rate was considerably higher than that of other centers (67). A survey conducted in Taiwan (68) also found an association between CVS and limb defects, with a 100-fold increased incidence of severe limb defects after CVS exposure as compared with the general population. However, in this series, 87% of the cases involving limb defects in which the timing of CVS was known were performed prior to 63 days (9 weeks) of gestation. In an effort to objectively evaluate the potential etiologic role of CVS in the development of limb reduction defects she first described, Firth and colleagues reported a series of 75 infants who were exposed to CVS in utero and had limb reduction defects at birth (69). The authors found a strong correlation between increasing severity of the defects and earlier gestational age at the time of CVS, with the most severe defects following CVS at 9 weeks of gestation or less. These studies and others support postponement of CVS until 9 completed weeks of gestation to minimize the risk of fetal injury.

Operator experience may explain the lack of an association with fetal limb defects reported by the majority of U.S. centers. A publication by the World Health Organization reported an incidence of approximately 6 limb reduction defects per 10,000 CVS cases (70), which is consistent with the background rate of this congenital anomaly (65). At this time, most centers feel that patients should be informed of the possible association, made aware of their options, and allowed to select a method of prenatal diagnosis most consistent with their medical and psychosocial needs.

Chorionic villus tissue may be obtained by one of three approaches: transcervical, transabdominal (71,72), or transvaginal (73). The transcervical method is currently the most widely used, although some claim that transabdominal sampling has a lower risk of infection and is easier to perform due to the technique's similarity with amniocentesis. Several prospective randomized trials compared transabdominal and transcervical methods. Two of these studies, a collaborative one through the NICHD (74) and a single-center study by Brambati and colleagues (75), found no difference in the success of sampling, fetal loss, delivery, or neonatal outcome between groups. A third randomized trial (76) showed a significantly greater total fetal loss rate after transcervical CVS (10.9%) when compared with transabdominal CVS (6.3%) and midtrimester amniocentesis (6.4%). The reasons for the differences in fetal loss rates are unclear. In all the three studies, an increased incidence of minor symptoms were found in the groups undergoing transcervical CVS.

Common symptoms following CVS include cramping, spotting, and vaginal bleeding. Minor cramping is reported by 16% to 22% of women after transabdominal or transcervical CVS (74,78); 19% to 32% reported spotting after transcervical procedures, versus 4% after transabdominal CVS (74,78); vaginal bleeding as heavy as a menstrual period was reported by up to 6% to 7% of patients after transcervical CVS and only 1% to 2% of women undergoing transabdominal CVS (63,74). Amniotic fluid leakage is uncommon after CVS, occurring transiently in 1.1% and for several weeks in 0.7% of cases in the initial NICHD study (78), and less frequently in other reports. Of those women who continued to leak fluid, 20% (3 of 14 patients) went on to lose the pregnancy.

A significant concern is the risk of infection. For this reason, transcervical CVS is contraindicated in the presence of a genital tract infection, including active herpes genitalis. Case reports of septic abortion and septic shock following CVS have been published (77,79); however, this complication was not reported in any of the large CVS trials.

Fetal Blood Sampling

Though amniocentesis or CVS is usually sufficient for prenatal diagnosis, fetal blood sampling can provide rapid and accurate analysis for a multitude of disorders (Table 2). For prenatal cytogenetic analysis, amniocentesis and CVS are the most widely used methods. However, patients occasionally present at late gestational ages with compelling indications for rapid fetal karyotype, such as severe intrauterine growth retardation, oligohydramnios, hydrops fetalis, or major fetal anomalies. Though CVS or amniocentesis may provide diagnostic information, the quality of a rapid cytogenetic analysis from direct preparations of villus tissue may be poor, and the time required for culture of amniocytes or villi may significantly alter obstetric management. Under such circumstances, fetal blood sampling to obtain a fetal lymphocyte karyotype, which is usually available in 2 to 3 days, may be indicated. A clinical example would be a patient in the mid-third trimester of pregnancy presenting with preterm labor, severe fetal growth retardation, and a fetal cardiac defect detected by ultrasound. A rapid diagnosis of trisomy 18 would allow that patient to undergo counseling and afford her the option of foregoing tocolysis, antepartum surveillance, cesarean section for fetal

indications, and neonatal intervention after birth. Patients may also be offered fetal blood sampling to provide rapid diagnosis at the time limits of legal pregnancy termination.

An ever-increasing number of inherited conditions can be diagnosed through molecular, cytogenetic, and biochemical techniques, as the gene alterations, chromosomal locations (for linkage analysis), and/or enzymatic derangements relevant to specific disorders are identified. As a result, fetal blood has become infrequently required for the prenatal diagnosis of coagulopathies, hemoglobinopathies, and other heritable diseases. Historically, some of the first applications of prenatal diagnosis were to detect hemoglobinopathies. This was done initially using fetoscopically obtained fetal blood, a procedure associated with higher rates of morbidity and fetal mortality (80,81). Later, knowledge of specific gene defects and advancements in molecular technology allowed diagnosis using DNA extracted from amniocytes (82), and subsequently chorionic villi, methods that are now applied for the detection of numerous inherited conditions.

Other specific applications of fetal blood sampling for diagnostic and treatment purposes are considered throughout this text. Examples include fetal evaluation for viral infections, erythroblastosis fetalis, alloimmune thrombocytopenia, and assessment of fetal acid–base status. Fetal blood sampling may be performed either by cordocentesis or fetal intrahepatic vein sampling (83). The techniques and complications of fetal blood sampling are discussed at length in chapter 53 and therefore will not be considered here.

NONINVASIVE METHODS FOR PRENATAL DIAGNOSIS Preimplantation Genetic Screening and Diagnosis

Preimplantation genetic techniques have transformed our existing ideas of ascertaining genetic abnormalities in offspring. Preimplantation genetic screening (PGS) refers to the technique used to assess for the possible existence of embryonic aneuploidy. Preimplantation genetic diagnosis (PGD) refers to the technique used to rule out specific genetic conditions, by analyzing the embryonic DNA. Development of the polymerase chain reaction (PCR) (84) revolutionized molecular genetics. PCR permits millions of copies of a targeted DNA segment to be amplified from a small DNA sample in a matter of hours. This technology has been combined with in vitro fertilization in an effort to provide earlier information by PGD. For couples at risk for an inherited disorder, results obtained from amniocytes or chorionic villi may present them with a difficult decision of whether or not to continue the pregnancy. Many women would prefer to completely avoid carrying affected fetuses (85), and some would prefer a technology that allows testing of embryos prior to implantation. The technology for PGD is quite expensive, however, a factor that must be considered at a time when resources available for health care are being allocated.

The technology involved in preimplantation diagnosis includes in vitro fertilization, embryo or polar body biopsy, PCR amplification of the DNA sequences of interest, and molecular genetic techniques using the amplified DNA to determine the presence or absence of a specific allele(s) in the embryo. Only those embryos with genetic material predictive of an unaffected fetus are implanted, thus avoiding the need for pregnancy termination.

Table 2 Indications for Fetal Blood Sampling

Chromosomal
Karyotype
Mosaicism
Intrauterine infection
Toxoplasmosis
Rubella
Varicella
Cytomegalovirus
Human parvovirus B19
Red cell isoimmunization
Platelet isoimmunization
Fetal hematologic indices
Hemoglobinopathies
Immunodeficiency syndromes
Assessment of fetal acid–base status

Methods to obtain the cell(s) required for analysis include biopsy of one to several cells of the 2- to 3-day embryo, biopsy of the trophectoderm of the 5- to 6-day blastocyst, and polar body biopsy (removal of the nonfunctioning haploid product of meiosis I) (86). Each of these methods has benefits and drawbacks, including the degree of technical difficulty, variations in pregnancy rates, and errors in diagnosis due to the hazards of single-cell analysis. An analysis of various embryo biopsy techniques concluded that biopsy of a quarter of the embryo on day 3 after fertilization (approximately the 12-cell stage) may be the "most feasible" for PGS (87). Preimplantation diagnosis from polar body biopsy is in use for PGD or PGS. This technique has been performed for aneuploidy screening, X-linked disorders, and maternal translocations. It may also be used in autosomal recessive conditions where both parents are carriers of a particular condition, and an oocyte spared of the mutant gene is used for fertilization. When polar body biopsy is used, the paternal genetic component cannot be evaluated.

Of central importance is the accuracy of diagnosis. When basing a diagnosis on DNA amplified from a single cell, problems such as contamination, PCR failure, and PCR error are of paramount importance. Navidi and Arnheim (88) considered these sources of error mathematically and suggested that blastomere analysis may be preferable in this regard to polar body analysis, while a combination of the two results in a significantly lower risk of misdiagnosis.

The clinical use of preimplantation diagnosis was first described in 1990 by Handyside and colleagues (89) for sex selection in pregnancies at risk for X-linked diseases. Since that time, this technology has been applied for the specific diagnosis of many disorders, including cystic fibrosis (90), Duchenne muscular dystrophy (91), and alloimmune thrombocytopenia (92). It is also being used to evaluate or screen for aneuploidy employing FISH, in the form of chromosome-specific probes to rapidly determine the copy number of a certain chromosome. As has been done with X- and Y-chromosome-specific probes for sex determination (93), PGS utilizes probes for the chromosomes most commonly involved in aneuploidy (X, Y, 18, 13, and 21) (94).

PGS is offered at a number of infertility centers in the United States. Misdiagnosis rates for PGS by single-cell blastomere vary with reporting centers. Cytogenetic FISH analysis appears to offer a positive predictive value of 83% and a negative predictive value of 81% when evaluating a single blastomere in conjunction with PGS (95). Laboratory error with FISH and early embryonic mosaicism are primarily responsible for the inaccuracies associated with cytogenetic preimplantation testing (96). It is recommended that a confirmatory diagnosis be performed when PGS indicates a normal karyotype, or normal DNA results in the case of a single-gene disorder by PGD, in the form of an amniocentesis or a CVS, due to the risk of misdiagnosis.

As PGS is becoming readily available to women who seek diagnostic testing before the time of implantation, it will be important to determine risks, benefits, and pregnancy rates using the procedure. This is particularly true for cytogenetic PGS. Although cytogenetic PGS has been shown to lower the rate of spontaneous miscarriage in women who are >35 years of age (96,97), studies demonstrating accuracy in diagnosing

fetal aneuploidy have yielded controversial results. The number of candidate embryos eligible for transfer after PGS for aneuploidy, furthermore, is diminished. Studies examining the loss and nonuse of cytogenetically normal embryos following PGS will need to be conducted.

Fetal Cells, DNA, and RNA in the Maternal Circulation

The same molecular techniques (PCR, FISH) that have allowed the development of PGS have also played a major role in efforts to provide prenatal diagnosis based on the analysis of fetal cells obtained from maternal peripheral blood. If this type of noninvasive testing were developed to the point of cost-effective and accurate diagnostic clinical application, the risks associated with invasive prenatal diagnostic techniques (amniocentesis, CVS) could be avoided. Thus far, its potential has been evaluated more in terms of a screening test.

Earlier studies suggested that fetal cells exist in the maternal circulation (98,99), and work based on PCR technology has confirmed this (100). Requirements to achieve a diagnosis based on fetal cells isolated from maternal blood would include a sensitive and specific method to identify fetal cells, a process to enrich for the infrequent fetal cells, and techniques to analyze the fetal genetic material for prenatal diagnosis. Each of these aspects is currently in the process of development, and a variety of methods have been attempted with varying success.

In order to identify fetal cells, monoclonal antibodies against various fetal cell antigens have been developed. These include antibodies to trophoblasts (101,102), fetal erythrocyte cell surface antigens (103–105), and paternally derived human leukocyte antigens (106,107). To enrich for fetal cells, the monoclonal antibodies have been fluorescently tagged and used in combination with flow cytometry, a method to sort individual cells based on their specific physical and chemical properties. Characteristics selected for include cell size, cell granularity, and the presence of a fluorescent tag (104,105). By report, multiparameter flow cytometry applied to first-trimester maternal peripheral blood enriches from one fetal nucleated erythrocyte in approximately 10^7 to 10^8 maternal cells to approximately 4 fetal cells per 1000 maternal cells (104). The proportion of fetal cells after sorting second-trimester samples was approximately 20 fetal cells per 1000 maternal cells in this study, though other investigators have not described such high yields of fetal cells (108,109). In addition to fluorescence-activated flow cytometry, isolation methods under investigation include immunospecific magnetic-activated cell sorting (110), immunomagnetic beads (111), avidin–biotin columns (112), and discontinuous density-gradient centrifugation (113). The various methods were reviewed and their advantages and disadvantages were analyzed by Holzgreve and colleagues (114).

Techniques for genetic analysis that have been applied to fetal cells isolated from the maternal circulation include PCR and in situ hybridization. PCR has been used to detect Y-chromosome-specific DNA sequences to identify male fetuses in both unsorted (115) and sorted (104,105) maternal peripheral blood. More recently, this technology has been applied to determine fetal rhesus antigen status (116,117). FISH to detect fetal aneuploidies has also been described using fetal cells derived from the maternal circulation (104,118,119).

The ongoing research using fetal nucleated RBC is of critical importance. In a recent publication from Huang et al., a microfluidic device was used to isolate nucleated RBCs from pregnant women and showed a 10- to 20-fold enrichment of nucleated RBCs over other methods described (120).

In recent years, there has been a greater focus on using cell-free fetal DNA or RNA within the maternal plasma or serum for use in prenatal DNA diagnosis. In 1997, Lo et al. demonstrated that cell-free fetal DNA circulates within the plasma and serum of pregnant women (121). Fetal DNA can be detected within the maternal circulation as early as 7 weeks of gestation (122). In 2009, Tobias et al. reported a method of specific magnetic bead-based capture of free fetal DNA from maternal plasma. The team developed a magnetic capture hybridization technique using specific hybridization primers for the extraction of fetal DNA from maternal plasma, which is almost twice as efficient as older methods (123). Both forms of nucleic acids may prove useful for accurate fetal gender determination and fetal RhD blood typing. Their utility for screening and/or detection of fetal aneuploidy remains under active investigation.

48 First-trimester screening for aneuploidy

Mark I. Evans and Howard S. Cuckle

INTRODUCTION

Advanced maternal age was the be all and end all of prenatal risk assessment for aneuploidy for nearly half a century (1–3). In virtually all countries, women above a given age cutoff were regarded as being at high enough risk of aneuploidy to warrant the costs and hazards of performing an invasive, diagnostic procedure. Over the past three decades, attempts have been made to refine the assessment of an individual woman's risk using biochemical and ultrasound markers within pregnancy. These have markedly improved the sensitivity (proportion of aneuploidy pregnancies at high risk, or detection rate) and specificity (proportion of unaffected pregnancies not at high risk) (3). Using a cutoff maternal age of 35, a 30% to 40% sensitivity and 90% to 95% specificity (or 5–10% false-positive rate) were the best available statistics throughout the 1970s and early 1980s (4).

Over the past 25 years, there have been multiple iterations of approaches that have improved the statistics of screening (2,3). Incorporation of these approaches has been haphazard with huge variability around the world and even within countries. Much has been written over the years describing the state of the art at given times and will not be repeated in extensive detail here for previous eras.

In 1984, Merkatz et al. published the association of low maternal serum alpha-fetoprotein (AFP) with an increased risk of aneuploidy in general (4), and Cuckle et al. confirmed that this holds for Down syndrome (5). In subsequent years, there was also an eventual understanding that the extent of AFP reduction differed according to the type of aneuploidy. For example, trisomy 18 has much lower values on average than Down syndrome (6).

Since AFP was already widely being used to screen for neural tube defects, at 16 to 18 weeks of gestation, it was relatively simple to include aneuploidy. This was done by the calculation of a likelihood ratio (LR) (proportion of aneuploidy pregnancies divided by proportion of unaffected pregnancies with the given AFP level) and using this to increase or decrease the maternal age-specific risk. The LR was derived from a Gaussian model of the AFP distributions in aneuploidy and unaffected pregnancies. The detailed practical mechanics of biochemical screening, such as adjustments for gestational age, race, diabetic status, multiple gestation status, and maternal weight have been published previously and will not be repeated here (2,3).

Maternal serum AFP screening for aneuploidy was widely adopted and had the potential to increase the detection rate, but it was inefficient. The optimal use of a biochemical or ultrasound marker is to screen all women regardless of age and to define high risk purely on the basis of the screening result. However, many clinicians did not consider a low-risk AFP result in an older woman as sufficient grounds for not offering

invasive testing. While the use of maternal serum AFP was a notable improvement over “how old are you,” it left much to be desired.

The situation changed in the late 1980s when the first highly discriminatory biochemical marker was discovered, namely human chorionic gonadotropin (hCG). The molecule is a hetero-dimer consisting of α and β subunits, which is not only present in maternal serum predominantly as the biologically active intact dimer, but also exists to a much lesser degree as both the free- α and free- β subunits. Most modern hCG assays are actually nonspecific and measure both the intact dimer and the free- β subunit. However, since the intact dimer is present in the maternal serum in a 200-fold molar excess relative to the free- β subunit, these assays primarily reflect the intact hCG concentration (3). Unfortunately, inconsistency in the terminology used to describe hCG assays has created confusion (sometimes deliberately) when comparing first-trimester screening studies. Intact hCG assays are often termed “total β ” or simply “ β hCG” assays, and some researchers have also described free β -hCG as β hCG (7).

Both intact (or total) hCG and free β -hCG are established markers of both Down syndrome and trisomy 18, being increased on average in the former and decreased in the latter type of aneuploidy (8,9).

MULTIPLE BIOCHEMICAL MARKERS

The discovery that hCG was a marker was quickly followed by another second-trimester marker, unconjugated estriol (uE_3), and later dimeric inhibin A (3,10). This gave the impetus in the 1990s, for the combination of multiple second-trimester maternal serum markers (3,10). As with AFP alone, an LR was calculated and used to modify the maternal age-specific risk. In this case, it was derived from a multivariate Gaussian model of the marker distributions taking into account the various correlations between markers.

Down syndrome detection rates increased to approximately 60% to 70% for a 5% false-positive rate (11–13). Table 1 shows the predicted detection rate for a fixed 1%, 3%, and 5% false positive using the principal combinations found in clinical practice (15).

While the switch over from AFP alone to two (*double test*), three (*triple test*), or four (*quadruple test*) marker combinations has gradually taken place in most countries, there have been continual disputes over the best combinations. There was essentially universal agreement that among the single markers in the second trimester, hCG, free β -hCG, and inhibin have the greatest discriminatory power. While uE_3 has similar discriminatory power to AFP, since the latter is already used for neural tube defect screening, it is always included as the second marker. There have been disputes over whether to include uE_3 as a third parameter. Some have claimed that the

Table 1 Biochemical Marker Combinations (Second Trimester): Predicted^a Detection Rate for a Given False-Positive Rate

Marker combination	False-positive rate		
	1%	3%	5%
AFP and free β -hCG	37%	53%	61%
AFP, free β -hCG, and uE ₃	42%	57%	65%
AFP, free β -hCG, uE ₃ , and inhibin	50%	64%	71%
AFP and intact hCG	33%	48%	56%
AFP, intact hCG, and uE ₃	39%	53%	60%
AFP, intact hCG, uE ₃ , and inhibin	46%	60%	67%

^aModeling with parameters in (14).

predicted marginal increase in detection rate cannot be achieved in practice. However, much of the prospective series literature did show the predicted benefit. Moreover, uE₃ is of value in the detection of trisomy 18, Smith–Lemli–Opitz syndrome, and placental sulfatase deficiency, where uE₃ levels are extremely low. Incidentally, levels are also slightly lowered in spina bifida and more so in anencephaly, but the changes are much less than that for AFP (16).

Like hCG, free β -hCG, and AFP, the levels of uE₃ and inhibin are altered on average in trisomy 18. For some of these markers, the direction of change is the same for both types of aneuploidy. Consequently, although the birth prevalence of trisomy 18 is 10-fold lower than Down syndrome, it is a relatively frequent incidental diagnosis in women having invasive testing following second-trimester screening. But in order to achieve a high detection for this disorder, it is necessary to calculate a separate risk specifically (8).

Despite overwhelming evidence by the early 1990s, and recommendations of national organizations such as the American College of Obstetricians and Gynecologists, that the multiple biochemical marker combinations discussed so far be offered, even by the millennium, still nearly 20% of patients in the United States who had screening were having AFP alone (3). Such slow uptake by practicing obstetricians is worrisome precedent for the incorporation of future test combinations.

Another long promising but yet fulfilled marker was the search for fetal cells in maternal circulation. Studies throughout the 1990s and early 2000s suggested that isolation and analysis of fetal cells might, in fact, become practical and useful as a screening test (17,18). Much of the 1980s and 1990s focused on ways to improve the efficacy of detection methods primarily centered on the need to increase the enrichment of fetal cells from the maternal blood circulation whose prevalence has been estimated to be approximately 1 in 10,000,000 cells with no clear likelihood of success (19). After the failure of the first lines of methodology in detecting fetal cells, modified approaches have emerged that are being evaluated for more precise identification and isolation of fetal cells.

A more recent line of research has been the detection of fetal cell-free DNA and RNA in the maternal circulation initially suggested by Lo et al. (20). There have been three generations, to date, of technologic approaches in this area. First, the concentration of these materials in maternal blood is approximately doubled in aneuploidy, and it was thought that

quantitative differences could be used as an additional marker. However, fetal DNA only makes up a small proportion of free DNA in maternal circulation such that the actual difference between a trisomic fetal contribution to overall maternal DNA levels is only a few percent. Second, Lo et al. proposed that using a placental-specific RNA such as PLAC-4 would allow a real 2:1 discrimination. His data suggested a 90% sensitivity for a 96% specificity. The methods were licensed to Sequenom whose unpublished investor presentations claimed 100% sensitivity for 99% sensitivity. Unfortunately these data were falsified, and the investigator has pleaded guilty to fraud charges setting back the approach immeasurably. Furthermore, RNA is very labile requiring stabilization within hours rendering problematic the use of the technique for mass screening. Third, the advent of the next-generation massive sequencing methods does have real scientific merit. There is significant potential for its use (21–26).

Amplification and molecular analysis of this circulating fetal product is already being used clinically for fetal gender and RhD determination. Other Mendelian diagnoses may probably follow in short order. It might eventually be used as a noninvasive method of prenatal diagnosis for aneuploidy, but much more research is still needed before this goal can be achieved in any reliable fashion. While the diagnosis of Mendelian disorders may be possible by fetal cells or cell-free DNA, it is very likely that aneuploidy detection will be seen as a screening test to modify risk as a predicate for invasive diagnostic procedures (26).

COMBINATION OF BIOCHEMICAL WITH ULTRASOUND MARKERS

Considerable work in the mid-1990s focused on the development of ultrasound markers to be used to modify the risk of aneuploidy. As early as 1985, Benacerraf et al. observed an increased nuchal skinfold during the second-trimester genetic ultrasound examination among aneuploid fetuses, but it was rarely used in routine screening (27). Nevertheless, in 1992, Nicolaides et al. reported on a related, but more discriminatory marker, nuchal translucency (NT) determined in the first trimester, which did enter routine practice, and results have now been reported on well over a million pregnancies scanned at 11 to 13 weeks of pregnancy (28). The literature on this development has been reviewed extensively elsewhere and will not be repeated here except to state that quality control of NT measurements is inferior to biochemical methods. Undermeasurement of NT continues to be prevalent and lowers detection rates considerably (29,30). Instead, we concentrate on combinations between ultrasound NT and biochemical markers (*combined test*), which can be shown to yield a much higher detection rate than NT alone.

The most widely studied first-trimester biochemical markers are pregnancy-associated plasma protein (PAPP)-A and free β -hCG. The discriminatory power of PAPP-A decreases with gestation, as does NT, while that of free β -hCG increases with gestation. First-trimester multiple-marker Down syndrome screening using a combination of the biochemical and ultrasound markers has been offered clinically for nearly 15 years (3). Most centers perform the NT scan at 11½ to 12½ weeks since the NT is easier to visualize than at earlier and some fetal structural abnormalities can be seen, while by

Table 2 Nuchal Translucency with or Without Biochemical Marker Combinations (First Trimester): Predicted^a Detection Rate for a Given False-Positive Rate

Serum (weeks)	Intact hCG	Free β-hCG
9	80%	84%
10	78%	83%
11	75%	81%
12	77%	80%

^aModeling with parameters in (7).

13 weeks the discriminatory power is reduced. To maximize the effectiveness of the biochemical markers and to ensure that the risk is calculated and immediately available at the same time, the woman attends for the ultrasound examination, while the blood sample may be drawn 1 to 2 weeks before the scheduled scan date, ideally at 10 weeks of gestation (14,31,32).

Table 2 shows the predicted detection rate for a fixed 1%, 3%, and 5% false positive using the marker combinations at different gestations and for comparison the results for NT alone. As before, the predictions are based on statistical modeling using published marker parameters derived by meta-analysis (14). The addition of biochemical markers leads to a substantial increase in the detection rate, which is considerably higher than that for the second-trimester combinations. PAPP-A levels are also altered on average in trisomy 18. Since for all the first-trimester markers the direction of change is the same for Down syndrome and trisomy 18, unlike in the second trimester, there is little value in a separate risk calculation.

First-trimester screening not only has a yield greater than that of the second-trimester screening protocols, but also offers significant advantages including, earlier reassurance for the vast majority of patients and greater privacy and safety for patients who may decide to terminate an affected fetus (32). There is no disagreement over the utility of combining first-trimester biochemical markers and NT, but there remains controversy over the use of free β-hCG rather than intact (or total) hCG in the combination in the United States but not the rest of the world. The medical and economic implications of this choice in the United States are

enormous, and we therefore dwell on this otherwise relatively minor point.

Most retrospective reports on biochemistry indicated that while free β-hCG was a very effective marker for Down syndrome in the first trimester, intact hCG was not (3,7). Indeed, the discriminatory power of intact hCG is extremely low at 10 weeks and does not even reach that of the weakest second-trimester markers until 12 weeks (10). Consequently, the vast majority of prospective first-trimester screening studies have used free β-hCG in combination with PAPP-A, and NT. The Serum, Urine, and Ultrasound Screening Study tested both hCG isoforms and suggested that free β-hCG is a more discriminatory first-trimester marker than intact hCG, but there may be little difference in the overall screening performance when included in a multiple marker protocol (10). Although often described as a prospective study with results on more than 47,000 pregnancies, the biochemical results are actually based on retrospective analysis of less than 500 samples. Furthermore, we believe that a statistical correction to the analysis would have demonstrated the advantage of free β-hCG even when combined with other markers (7). Nevertheless, the study has created some uncertainty and opened a debate in the United States about which isoform of hCG to use in first-trimester screening.

This prompted us to address the issue using a meta-analysis based on a considerable body of available evidence to predict the consequence of adding either free β-hCG or intact hCG to a PAPP-A and NT protocol; the methodology was described extensively in the paper (7). At a fixed 5% false-positive rate, when the blood sample was drawn at 9, 10, 11, and 12 weeks, adding free β-hCG reduced the false-negative rate by 26%, 29%, 33%, and 35%, respectively, compared with reductions of 0%, 5%, 12%, and 21%, respectively, adding intact hCG. Averaging across weeks, the reductions were 31% and 9%, a statistically significant difference ($p = 0.01$). Similarly, at a fixed 90% detection rate, adding free β-hCG reduced the false-positive rate by 41%, 45%, 48%, and 52% compared with 2%, 8%, 20%, and 37% for intact hCG, averages of 47% and 17% ($p = 0.01$). Overall multivariate detection rates averaged a 3% to 6% improvement using free β as opposed to total hCG, and maximal detection was achieved by blood drawn at 9 to 10 weeks with NT at 11 to 12 weeks (Table 3) (7).

Canick et al. (33) carried out a secondary analysis of data from the First and Second Trimester Evaluation of Risk (FASTER) trial (34) and found that while the sensitivity of free β-hCG was notably higher than that for total hCG, there was only a 1% detection rate difference in combination with PAPP-A and NT and it was not statistically significant. The authors concluded that the choice of the third marker was not critical. The analysis was not based on the entire 38,000 patients in the trial, but only on statistical modeling with total hCG and free β-hCG parameters derived by retrospectively assaying stored serum samples from 79 Down syndrome and 395 unaffected pregnancies (31).

Canick’s conclusions regarding screening policy are unwarranted for three reasons. First, the standard deviation of free β-hCG was much wider than generally found elsewhere, possibly due the specific reagents used to retrospectively assay the samples. The standard deviation among unaffected pregnancies, compared with values from all the

recent large published prospective first-trimester series, and that from our own experience is shown in Table 4. This will inevitably have led to the underestimation of effectiveness for free β -hCG. Moreover, the retrospective testing was done over a short time period, reducing the standard deviation compared with routine practice. Hence, the discrepancy with routine practice is even greater. Second, decisions regarding screening policy need to take account of the totality of available evidence. Modeling with parameters derived by meta-analysis from series including several hundred Down syndrome pregnancies indicates a 2% detection advantage for free β -hCG (7,14). The failure of a relatively small study to find a statistically significant effect is insufficient grounds for changing policy. Third, at the high detection rates achievable by first-trimester marker combinations, a 2% increment in detection is not small. Each marginal increase in detection is achieved by a large increase in the false-positive rate. Had the current study estimated the false-positive rate for a fixed 90% detection rate, as we have done above, this would have been apparent. Therefore, on the basis of all available evidence, there is no good reason for health planners to consider substituting intact hCG for free β -hCG in first-trimester protocols.

SEQUENTIAL SCREENING METHODS

In the last few years, considerable discussion of screening policy has been focused on carrying out screening in both the first and second trimesters, in sequence. In general, this achieves a higher yield than screening within trimester.

Three types of sequential policy have received attention. The first to be proposed was a form of nondisclosure sequential screening using first-trimester PAPP-A and NT together with

second-trimester AFP, uE_3 , free β -hCG or intact hCG, and inhibin (*integrated test*). Risks are not used clinically until all markers have been tested. The proponents of such “integrated” screening argue that higher sensitivities can be achieved and therefore justify the nondisclosure. However, many clinicians in the United States and elsewhere feel that it is simply not acceptable under local culture and ethical beliefs to withhold potentially serious screening results for a month when the odds of substantial change are minimal. Such an approach also has the substantial disadvantage that there is no early diagnosis or reassurance. Also there may be practical difficulties such as a considerable proportion of patients who do not present for the second half of the screening evaluation. There are also profound ethical concerns over nondisclosure of potentially considerably increased risks that could be addressed in the first trimester with its considerable advantages of privacy for the patient in difficult reproductive decisions.

A second approach (*step-wise test*) begins with first-trimester PAPP-A, free β -hCG or intact hCG, and NT; those with low risk have second-trimester AFP, uE_3 , free β -hCG or intact hCG, and inhibin; their risk is estimated from all seven markers. It is important to use a high first-trimester cutoff than with nonsequential screening, otherwise the overall false-positive rate will be too high. And it is essential to use all seven markers together when calculating the final risk. It is invalid to ignore the first-trimester markers at this stage although many practitioners are doing so because they do not have access to the appropriate risk calculation software. This policy restores some first-trimester diagnosis.

A third policy, more efficient than the other types, is called the *contingent test*. This begins with first-trimester PAPP-A, free β -hCG or intact hCG, and NT. Women with very high risk are offered immediate invasive prenatal diagnosis and only those with borderline risks are offered second-trimester AFP, uE_3 , free β -hCG or intact hCG, and inhibin; their risk is estimated from all seven markers. The borderline is chosen so that a large proportion of women have early assurance. This group has such a low risk that it is very unlikely that further markers will lead to a final high-risk result.

Table 5 shows the predicted detection rate for a fixed 1%, 3%, and 5% false positive for different sequential policies, as before based on statistical modeling using published marker parameters derived by meta-analysis. In the current predictions, the first-trimester very high cutoff for step-wise and contingent is set to obtain an early detection rate of 70%, and the very low cutoff for contingent screening is set so that 85%

of women have early assurance. The prediction is that the contingent test is extremely efficient, achieving comparable detection rates with the other types of sequential screening but requiring second-trimester tests on just a small proportion of women. The tabulated combinations use free β -hCG, but similar analyses with intact (or total) hCG, tested in the late first trimester and/or the second trimester, reach the same conclusion.

Sequential screening can also be carried out within trimester. One contingent approach suggested by Nicolaides et al. has the potential to further increase detection while completing all screening within the first trimester (35). It is proposed that women with borderline risk based on PAPP-A, free β -hCG, and NT are offered a more specialist scan to determine, among other things nasal bone, and reassess the risk. Nasal bone hypoplasia is a very powerful marker of aneuploidy but requires appropriate training not generally available. Another approach might be to measure additional biochemical markers in a very early serum sample at about 8 weeks of gestation in addition to the 10-week sample; one possible very early marker is ADAM12 (36).

SECOND-TRIMESTER REVISITED

Despite the clear advantages of beginning the screening process in the first trimester, some women do not present until later in pregnancy. If biochemical screening alone, even with the *quadruple test*, is regarded as inadequate, there is the option of combining information on the serum markers and ultrasound results to improve detection. The results of the genetic sonogram can be used to modify the risk from the biochemical markers. Provided an algorithm is used that uses a separate LR for the presence *and absence* of each soft marker, the detection rate can be increased by 5% to 10% (37). Moreover, there are new second-trimester ultrasound markers such as prenasal translucency, which are even more discriminatory than the traditional soft markers and can by themselves increase detection by about 15% (38).

CONCLUSIONS

Over the past 35 years, there has been a steady evolution of biochemical and also biophysical parameters used to adjust the risk that a woman is carrying a fetus with aneuploidy. At every step, there has been controversy as to the best methods to employ in this endeavor. We have laid out many of the proposals, and our conclusions are that as of 2011:

1. A combined test in the first trimester can yield a very high detection rate for an acceptable false-positive rate.
2. Second-trimester multiple marker biochemical screening yields a much lower detection rate and imposes a considerable emotional burden in requiring women to be very visibly pregnant, feel the baby moving, and have to undergo second-trimester termination methods if an abnormality is found and the women choose to end the pregnancy.
3. Sequential screening in both trimesters yields even higher detection rates, and the most efficient methods is the contingent test. Centers with appropriate training and experience of newer ultrasound markers such as nasal bone hypoplasia

could consider carrying out the contingent test within the first trimester.

Although comprehensive national data are not available, there is a continuing shift toward the first trimester. Only the exact components and timing remain to be determined.

49 Second-trimester screening for fetal abnormalities

Jolene C. Muscat and Anthony M. Vintzileos

INTRODUCTION

Screening tests to identify women at risk for fetal aneuploidy and fetal structural abnormalities are routinely offered to all women during pregnancy. A number of screening strategies are currently available, which utilize both biochemical analysis and ultrasonography to achieve high detection rates and determine whether further diagnostic testing is needed. Recently, first-trimester screening for fetal abnormalities has been utilized with increasing frequency as it offers women the opportunity of earlier testing and subsequent option for earlier diagnosis. Despite this change in practice, second-trimester biochemical and ultrasound screening remains a valuable resource in modern obstetric care as complementary to first-trimester screening or as the only screening in women who present for prenatal care after the first trimester of pregnancy.

SECOND-TRIMESTER SERUM MARKER SCREENING

Most second-trimester serum marker screening is now performed in conjunction with first trimester–combined screening protocols that utilize either an integrated, stepwise, or contingent approach. Currently, second-trimester maternal serum screening alone is available as a triple, quadruple, or penta-marker testing modality. Whether integrated with first-trimester serum marker testing or used in isolation for women who defer first-trimester screening or do not seek prenatal care until after 13 weeks of gestation, second-trimester serum marker screening remains a valuable tool in prenatal management.

Maternal Serum Alpha-Fetoprotein

Maternal serum alpha-fetoprotein (MSAFP) was the first maternal serum analyte utilized to detect fetal abnormalities, specifically, open neural tube and abdominal wall defects in cases of elevated MSAFP. In the mid-1980s, an association between a low MSAFP level and increased risk for Down syndrome was reported (1). MSAFP, along with other maternal serum analytes, was then incorporated into various screening protocols designed to modify maternal age–related risks for fetal aneuploidy.

Elevated MSAFP

Alpha-fetoprotein (AFP) is a normal fetal protein found in high concentrations in the fetal serum. It is present in amniotic fluid in normal pregnancies, presumably reaching the fluid through excretion in the fetal urine. From the amniotic fluid, AFP diffuses across the fetal membranes and can be detected in the maternal serum beginning at approximately 12 weeks of gestation (2). In cases of fetal anencephaly or open spina bifida, increased levels of AFP reach the amniotic fluid secondary to the concentration gradient from fetal serum to amniotic fluid. This increased AFP concentration can then be detected in the maternal serum. Ventral wall defects

(i.e., omphalocele or gastroschisis) can also result in similar elevations in MSAFP through this same mechanism. Other causes of elevated MSAFP are listed in Table 1.

MSAFP screening provides an effective means for selecting patients who are at increased risk for neural tube defects and other fetal disorders and identifies patients who warrant further evaluation with diagnostic ultrasound and/or amniocentesis. Additionally, elevated MSAFP in a patient with a normal fetal anatomic survey has been associated with adverse pregnancy outcomes (3). As a matter of fact, the most frequent pathologic reason for elevated MSAFP is placental disease. Although there is no consensus regarding the management of this patient population, women in this high-risk group for obstetric complications should be followed closely for the duration of the pregnancy for stillbirth, prematurity, intrauterine growth restriction, and neonatal death. In the presence of placenta previa and elevated MSAFP, placenta accreta should be ruled out, especially in patients with previous cesarean delivery.

Low MSAFP

The association between low MSAFP and fetal chromosomal abnormalities is well described in the literature and will be discussed in further detail later in this chapter. As with elevated MSAFP levels, a low MSAFP level is associated with a variety of fetal and maternal conditions (Table 2).

Ultrasound can be used in the initial evaluation of a patient with low MSAFP. The most common explanation for a low value is incorrect pregnancy dating and a gestational age less advanced than expected. Ultrasound will also identify missed abortion or molar pregnancy as a potential cause of low MSAFP. If ultrasound reveals a viable fetus at the anticipated gestational age, targeted genetic ultrasound for evaluation of Down syndrome should be performed. Patients should be counseled regarding the availability of amniocentesis as a diagnostic procedure. Low MSAFP in a patient with normal ultrasound and amniocentesis has not consistently been associated with adverse pregnancy outcomes and at this time warrants no further investigation.

Serum Screening for Trisomy 21

An association between low MSAFP levels and fetal chromosomal abnormalities was first described by Merkatz and colleagues in 1984 (1). The initial studies focused primarily on Down syndrome detection; however, further studies have shown an association with other chromosomal abnormalities. Combined maternal serum marker panels were subsequently developed to calculate a risk for Down syndrome in the fetus for a given pregnancy. Historically, maternal age 35 years or older at the time of delivery was used to identify women at the highest risk of having a child with Down syndrome, and only these women were offered genetic counseling and amniocentesis

Down syndrome and other aneuploidy

or chorionic villus sampling. With the introduction of biochemical serum screening for Down syndrome, the American College of Obstetricians and Gynecologists now recommends that all women should be offered invasive diagnostic testing or aneuploidy screening before 20 weeks of gestation, regardless of maternal age (4).

Triple-marker screening utilizing AFP, hCG, and unconjugated estriol was the first combined marker panel used to screen patients for trisomy 21. In the general population, triple-marker screening identifies approximately 60% to 70% of pregnancies affected by trisomy 21 with a 5% screen-positive rate (5). The quadruple screen was later developed when inhibin A was added to the triple-screen panel (6,7). Penta-screen testing is now available with the addition of invasive trophoblast antigen testing (8–10). These expanded panels increase trisomy 21 detection rate at the same 5% screen-positive rate (11) (Table 3).

Maternal serum screening for trisomy 21 can be performed anytime between 15 and 22 weeks, but is most accurate when performed between 16 and 18 weeks. Serum analyte levels can vary with gestational age, maternal weight, diabetic status, race, and number of fetuses; therefore, these variables are incorporated into an individual's risk score calculation. Because the maternal age-related risk of trisomy 21 is the basis of any serum screening protocol, both the detection rate and the screen-positive rate increase with maternal age. Different laboratories have established their own reference values and screen-positive cutoffs that reflect an individual woman's reported risk. Based on this modified risk, a woman may opt to pursue invasive diagnostic procedure such as amniocentesis or further modify her risk with genetic ultrasound, which will be detailed later in this chapter.

Serum Screening for Trisomy 18 and Other Fetal Aneuploidy

In counseling patients, it is important to emphasize that multiple maternal serum screening protocols were developed

Table 3 Sensitivity and Specificity of Prenatal Screening Tests for Down Syndrome

Markers	Detection rate (%)	False-positive rate (%)

primarily to detect trisomy 21, and the patterns of serum markers observed in pregnancies affected by trisomy 18 and other fetal chromosomal abnormalities are different. In trisomy 18, MSAFP and unconjugated estriol are low; however, in contrast to Down syndrome, hCG value is low as well. Although these results are well correlated with trisomy 18, a positive second-trimester serum screen has poor sensitivity and poor prediction for trisomy 18 (12). By contrast, genetic ultrasound to evaluate for characteristic sonographic findings associated with this diagnosis is highly sensitive in identifying fetuses with the disorder (13,14). Ultrasound evaluation of fetuses with trisomy 18 will be discussed later in this chapter. Trisomy 13 is usually associated with normal levels of all three maternal serum markers, except in cases where open fetal defects are present. In fetal triploidy, all three biochemical markers are low. Table 4 summarizes the changes in serum marker levels in various fetal chromosomal abnormalities.

SECOND-TRIMESTER FETAL ANATOMY SURVEY

The American Institute of Ultrasound in Medicine first published guidelines for the performance of obstetric ultrasound in 1994 (15). These guidelines were updated in 2007 to reflect the minimum criteria for a completion of a fetal ultrasound examination (16). A standard obstetric sonogram in the second or third trimester includes an evaluation of fetal presentation, amniotic fluid volume, cardiac activity, placental position, fetal biometry, and fetal number, plus an anatomic survey. Fetal anatomy may be adequately assessed by ultrasound after approximately 18 weeks of gestational age. Minimum requirements in the standard examination of fetal anatomy include evaluating the cerebellum, choroid plexus, cisterna magna, lateral cerebral ventricles, midline falx, cavum septum pellucidum, upper lip, nuchal fold, four-chamber view of the fetal heart, outflow tracts (if technically feasible), stomach (presence, size, and situs), kidneys, bladder, umbilical

cord insertion site into the fetal abdomen, umbilical cord vessel number, cervical, thoracic, lumbar, and sacral spine, extremities, and genitalia (as medically indicated in low-risk pregnancies and in the evaluation of multiple gestations) (Table 5). The placental location, appearance, and relationship to the internal cervical os should be recorded and the umbilical cord should be visualized. The maternal cervix and adnexa should be examined.

A more detailed fetal anatomic examination may be necessary if an abnormality or suspected abnormality is found on the standard examination. Multiple gestations require the documentation of additional information including chorionicity, amnionity, comparison of fetal sizes, estimation of amniotic fluid volume on each side of the membrane, and fetal genitalia.

Fetal anatomy may be adequately assessed after 18 weeks of gestation and is ideally performed before 20 weeks to optimize assessment of anatomy while at the same time allowing time for invasive testing if necessary or desired. Factors that may limit sonographic examination include equipment quality, sonographer experience, length of time spent on examination, fetal size, position, movement, fluid abnormalities, maternal abdominal scar, and increased maternal abdominal wall thickness.

Performing a complete fetal anatomy survey should be approached in a systematic way. The examination should ideally begin with imaging of the fetal head and proceed caudally. The entire uterus should be scanned in both a transverse and longitudinal direction to determine fetal situs, fetal position, amniotic fluid volume, and placental location. The fetal anatomy is then examined in a stepwise fashion. To begin, the fetal head, face, and neck are evaluated. The calvarium should be well mineralized and elliptical. The head shape may be flattened (dolichocephaly/increased anteroposterior distance) or rounded (brachycephaly/shortened

Figure 1 Axial view through fetal head at level of thalami and cavum septum pellucidum. The calipers show measurement of the biparietal diameter.

anteroposterior distance) as a normal variant or may suggest fetal aneuploidy (trisomy 21 or 18 associated with brachycephaly). A lemon-shaped head may be suggestive of a neural tube defect. The cranial sutures appear as hypoechoic areas between cranial bones and visualization excludes premature closure, craniosynostosis syndromes, and some skeletal dysplasias. The biparietal diameter is measured at the level of the thalami and cavum septum pellucidum (Fig. 1). The cerebellar hemispheres should not be visible in this transthalamic axial plane. The measurement is taken from the outer edge of the proximal skull to the inner edge of the distal skull. Head circumference is measured at the same level as the biparietal diameter, around the outer perimeter of the calvarium. The cavum septum pellucidum, midline falx, third ventricle, and frontal horns of the lateral ventricles can also be visualized in this view. The presence of a normal cavum suggests proper midline brain formation and makes diagnosis of holoprosencephaly or agenesis of the corpus collusum less likely. Next, a transventricular view should be obtained just superior to the transthalamic view (Figs. 2 and 3). This allows visualization of the lateral ventricles and bilateral choroid plexuses. The ventricle is measured through the atrium in an axial plane and is normally less than 10mm, and the choroid plexuses should fill the entire width of the lateral ventricles. The posterior fossa is then evaluated. This begins with obtaining a transcerebellar view to properly visualize the cerebellum, cerebellar vermis, cisterna magna, and nuchal fold (Fig. 4). Transcerebellar diameter provides a useful and accurate estimation of gestational age and is relatively spared in growth restriction (17,18). Thorough evaluation of the structures in the posterior fossa is crucial to exclude spina bifida, Dandy-Walker malformation or variant, occipital encephalocele, and cerebellar agenesis or hypoplasia. The nuchal fold can be measured in this transcerebellar view, with 5 to 6mm being the upper limit of normal. It is important to note that if fetal intracranial structures cannot be adequately visualized secondary to fetal positioning, transvaginal ultrasound may be utilized to complete this portion of the fetal anatomy survey.

After the fetal head is evaluated, the fetal facial structures are examined. A range of genetic syndromes and disorders are associated with characteristic facial features, and thorough

Figure 2 Transventricular view of the fetal head showing the far lateral ventricle. Note the choroid plexus filling the width of the ventricle (white arrow).

Figure 3 Transventricular view of the fetal head with calipers showing measurement of the atria of the lateral ventricle.

evaluation of the fetal face can aid in supporting or excluding their diagnosis. Obtaining a combination of coronal, sagittal, and axial views is necessary to complete the facial evaluation. To begin, a fetal profile should be obtained in the sagittal plane (Fig. 5). This allows for proper visualization of the frontal bone, nasal bone, and fetal chin. Absent or shortened nasal bone may indicate fetal aneuploidy and will be discussed later in this chapter. Micrognathia has also been associated with a variety of genetic syndromes and disorders, making characterization of the fetal chin important. The fetal nose and lips should be imaged in coronal plane and the anterior palate should be visualized to exclude cleft lip and palate.

Next, the fetal spine should be imaged and fetal skeletal survey should be performed. It is important to note that any intracranial abnormality noted in the fetal anatomy survey may be the first indication of neural tube abnormality, and the presence of any such finding warrants comprehensive review. Again, a combination of coronal, sagittal, and axial views is necessary for evaluation. The skin overlying the fetal spine should be visualized and intact to exclude open spina bifida and any mass or tumor (Fig. 6). The ossification centers

Figure 5 Sagittal profile of the second-trimester fetus. Note the presence of the nasal bone (white arrow).

of each vertebral segment should align in a symmetrical fashion to exclude hemivertebrae and neural tube defect. Notation of the spinal curvature should be made. Overall evaluation of fetal bony structures may be completed at this time, with the evaluation of fetal ribs, clavicles, and extremities. Normal echogenicity and appearance aid in the exclusion of skeletal dysplasia. Documentation of fetal extremities as present or absent is the minimum requirement included in the guidelines for routine obstetric ultrasound examination; however, more complete evaluation may provide important diagnostic information. Movement and tone should be normal. Any absence, fracture, contracture, bowing, or hypomineralization of the bones should be considered abnormal. The length of each long bone (femur, humerus, radius, ulna, tibia, and fibula) should be measured and standard nomograms are available for comparison. The hands and feet should be examined. The hands should be noted to open freely and all five fingers should extend fully, as persistently clenched hands with overlapping digits is sonographic finding often associated with trisomy 18. The middle phalanx of the fifth digit may be imaged as its absence has been

Figure 6 Normal sagittal view of the fetal spine. The skin overlying the vertebral processes is well visualized and intact.

Figure 8 Fetal foot showing plantar surface at right angle with long bones of the lower extremity.

Figure 7 Fetal hand showing echogenic phalanges of four fingers, including the fifth digit (white arrow).

Figure 9 Apical four-chamber view of the fetal heart. Abbreviations: RA, right atrium; RV, right ventricle; LA, left atrium; LV, left ventricle.

associated with trisomy 21 (Fig. 7). Fetal toes should be visualized and the foot length can be measured. Sagittal views of the feet should be obtained so that the plantar surface is at a right angle to the lower extremity (Fig. 8). This allows exclusion of “rocker-bottom” appearance, which also has been associated with various genetic disorders.

The fetal thorax and visceral contents are imaged next. The diaphragm is examined for evidence of diaphragmatic hernia. Fetal lung echogenicity should be homogeneous to exclude mass or tumor such as cystic adenomatoid malformation. Any pleural effusion or evidence of pulmonary hypoplasia is considered abnormal. Fetal cardiac examination should then follow. American Institute of Ultrasound in Medicine practice guidelines for basic cardiac examination include a four-chamber view of the fetal heart and, if technically feasible, views of both outflow tracts. However, a more comprehensive cardiac evaluation may be needed to exclude some fetal cardiac abnormalities. To begin, cardiac rate and rhythm should be documented. Cardiac size should be measured and is expected to be approximately one-third of the fetal thorax. The cardiac apex should point to the left at an angle of 45 ± 20 degrees relative to the midline. Normal situs should be established

with fetal liver on the right and stomach on the left. A four-chamber apical view should be obtained with all chambers being approximately equal in size (Fig. 9). There should be no pericardial fluid or collection. An intact intraventricular and intra-atrial septum excludes the presence of ventricular septal defect and atrial septal defect respectively. The outflow tracts, aortic arch, ductal arch, and inferior and superior vena cava should be identified. An echogenic intracardiac focus (EIF), most commonly seen in the left ventricle, can occur in up to 5% of normal pregnancies (19). It is typically caused by a specular reflection secondary to mineralization within the papillary muscles (20,21). Because it is seen in approximately 13% to 18% of pregnancies complicated by Down syndrome, presence of an EIF has traditionally been utilized by some investigators as a sonographic marker to modify a woman’s a priori risk of fetal aneuploidy (22–24). However, more recent literature suggests that when an EIF is seen as an isolated finding in an otherwise normal fetal anatomy survey, it is more likely to be a normal variant (25,26). This will be further discussed later in the chapter.

Abdominal circumference should be determined at the skin line on a transverse view at the level of the junction of the

Figure 10 Appropriate plane for the measurement of abdominal circumference. Abbreviations: UV, umbilical vein; SP, spine; ST, stomach.

umbilical vein, portal sinus, and fetal stomach (Fig. 10). The umbilical vein should curve away from the fetal stomach; otherwise, persistence of the right umbilical vein is suspected. The abdominal circumference is the most sensitive fetal growth parameter and is used in conjunction with other fetal biometric measurements to determine an overall estimated fetal weight. Abdominal viscera identifiable on ultrasound include the liver, spleen, gallbladder, stomach, and bowel. The liver occupies most of the upper abdomen and should be located on the right. The gallbladder appears as a tear-shaped organ in the right upper quadrant at the inferior edge of the liver. The fetal stomach should be located on the fetal left below the level of the diaphragm. An absent or small stomach that remains unchanged throughout the course of sonographic evaluation may suggest esophageal atresia, tracheoesophageal fistula, or a diaphragmatic hernia. The appearance of the fetal bowel varies with gestational age. If fetal anatomy survey is performed in the second trimester, the bowel should appear uniformly echogenic and fill the majority of the fetal abdomen. Hyperechoic bowel is associated with aneuploidy, infection, ischemia, intrauterine bleeding, and other bowel abnormalities. In the third trimester, more prominent loops of hypoechoic large bowel may be seen. More dilated loops of bowel may reflect atresia or obstruction. The umbilical cord should be identified at its insertion site into the fetal abdomen. As the umbilical vein enters the abdomen, it should course superiorly where it enters the liver to communicate with the portal vein. The umbilical vein then continues into the ductus venosus and then inferior vena cava and right atrium. The ventral abdominal wall adjacent to the umbilical cord insertion should be visualized and intact to exclude ventral wall defects including omphalocele and gastroschisis.

The genitourinary tract should next be examined for evidence of fetal anomaly. The kidneys should be identified bilaterally and appear as hypoechoic paraspinal structures. Identification of the anechoic urine-containing renal pelvis assists in their visualization (Fig. 11). Abnormal findings include enlargement or absence of the kidneys, renal masses or cysts within the parenchyma, hyperechogenicity, and dilation of the renal pelvis, calices, or ureter. When the kidneys cannot be easily identified, color or power Doppler imaging of the

Figure 11 Transverse view through fetal abdomen at the level of fetal kidneys that appear as hypoechoic paraspinal structures. The white arrows indicate the central anechoic renal pelvis.

renal arteries can be utilized to confirm congenital absence of one or both kidneys or presence of a pelvic kidney. The bladder is an anechoic urine-filled structure located in the anterior midline of the fetal pelvis. The bladder may empty and fill during the course of the fetal anatomy survey and care should be taken to exclude bladder exstrophy or evidence of lower obstructive uropathy. The two umbilical arteries should be identified as they course around the fetal bladder to confirm the presence of a three-vessel cord. Attempt at fetal gender assignment should be made in order to exclude ambiguous genitalia. Female gender is confirmed by the identification of the labia, which may appear as three parallel linear echoes. Male gender is assigned if both the penis and scrotum are seen.

SECOND-TRIMESTER GENETIC ULTRASOUND

The genetic ultrasound is a targeted examination for fetal aneuploidy, specifically trisomy 21. The goal of genetic ultrasound is to further modify the a priori age or serum screening risk for trisomy 21 and thus improve the selection of pregnant women who may be candidates for invasive prenatal diagnosis. First characterized in the 1990s, the combination of second-trimester serum screening with identification of ultrasound markers on genetic ultrasound improved the detection rate of fetuses affected with Down syndrome (27). At the same time, it identified patients at decreased risk of carrying a pregnancy complicated by Down syndrome if the genetic sonogram was normal (28,29). With the increased use of first-trimester screening, the prevalence of fetal Down syndrome in the second trimester has decreased (30). For this reason, interpretation of second-trimester sonographic markers of Down syndrome must be interpreted in the context of first, second, and/or integrated screening results in order to achieve the most accurate risk assessment of a potentially affected fetus.

Approximately 25% of fetuses with Down syndrome have major characteristic structural abnormalities that can be identified on second-trimester ultrasound (31). For the majority of Down syndrome fetuses, no major fetal malformation will be present on sonographic evaluation. Over the past 20 years, numerous sonographic markers have been associated

Table 6 Sonographic Aneuploidy Markers of the Genetic Sonogram

with fetal Down syndrome, which, when present, convey an increased risk for fetal aneuploidy. As with any screening modality, a useful sonographic marker Down syndrome screening should be present in a high proportion of Down syndrome pregnancies, not commonly seen in normal fetuses and amenable to imaging during a standard sonographic examination. The marker should be easily seen at a gestational age that does not preclude subsequent diagnostic testing by amniocentesis and option for pregnancy termination.

At the time of genetic ultrasound, thorough investigation for abnormal fetal biometry, fetal structural anomalies, and markers for fetal aneuploidy is performed. In this way, second-trimester ultrasound can be combined with serum biochemistry to determine which women would most benefit from amniocentesis. Additionally, a normal sonogram may be an indication to defer amniocentesis, even when a woman is at increased risk for aneuploidy based on serum screening (32). Conversely, abnormal findings on a genetic sonogram may prompt invasive testing even when a woman has normal serum biochemistry. Markers of aneuploidy include increased nuchal fold thickness, absent or hypoplastic nasal bone, shortened long bones, pyelectasis, hyperechoic bowel, EIF, choroid plexus cysts, short ear length, wide iliac angle, sandal gap toes, hypoplastic midphalanx of the fifth digit, and clinodactyly (Table 6).

When considered in isolation, each marker, except thickened nuchal fold or absent nasal bone, has a low to moderate sensitivity for trisomy 21 and may not necessarily increase the risk of aneuploidy, especially in low-risk patients (maternal age <35 with normal serum analyte screening) (31). The risk of fetal aneuploidy increases when two or more sonographic markers are seen in low-risk patients or when isolated markers are seen in high-risk patients.

An increased nuchal fold (>5–6mm) is a highly specific marker for Down syndrome. Approximately 40% to 50% of second-trimester fetuses with Down syndrome have a thickened nuchal fold with a false-positive rate of 0.1% (33–35). To obtain this measurement, the fetal head is imaged in a transverse plane similar to that for measuring the biparietal diameter (Fig. 4). The thalami and the upper portion of the cerebellum should be in the plane of the image. The measurement is then made from the outside of the occipital bone to the distal surface of the skin edge.

The fetal nasal bone has been demonstrated to be hypoplastic or absent in up to 60% of Down syndrome

Figure 12 Sagittal profile of second-trimester fetus with absent nasal bone as indicated by circle.

pregnancies imaged in the second trimester and only about 1% to 2% of unaffected pregnancies (Fig. 12) (36,37). Initially observed at the time of first-trimester evaluation of nuchal translucency, hypoplastic or absent nasal bone ossification is being used with increased frequency as a second-trimester screen for Down syndrome (37–42). Numerous studies have been performed to determine the optimal definition of nasal bone hypoplasia as an ultrasonographic marker for aneuploidy in the second trimester. In one series, expressing multiples of the median (MoM) for the nasal bone length at each gestational age was the most efficient definition of nasal bone hypoplasia (43). Nasal bone smaller than 0.75 MoM had a sensitivity and specificity of 49% and 92% respectively. Another series showed the positive likelihood ratio for fetal trisomy 21 increased from 17.1 with a nasal bone length of 0.7 MoM or less to 74.1 with a nasal bone length of 0.5 MoM or less (44). In the hands of experienced operators, nasal bone evaluation may be the best single ultrasound marker for second-trimester risk assessment. It is important to keep in mind that there is variability in the prevalence of this finding depending upon ethnicity, and this should be incorporated in to patient counseling if this finding is present on ultrasound evaluation. In general, absent nasal bone in the second trimester is seen in approximately one-third of Down syndrome fetuses (40).

Down syndrome fetuses may have a shorter humerus and femur length than expected based on biparietal diameter measurement. An observed-to-expected ratio of ≤ 0.90 or a biparietal diameter-to-femur ratio of >1.5 has a reported likelihood ratio of 1.5 to 2.7 when present as an isolated finding (45,46). A short humerus is more strongly associated with Down syndrome (sensitivity of 50%, false-positive rate of 5%) when compared with shortened femur length (sensitivity 40–50%, false-positive rate of 7%) (47–49). As with nasal bone ossification, there is variability in these long bone lengths between different ethnic groups, making these markers difficult to use as isolated findings or in a low-risk population.

Fetal pyelectasis, defined as a renal pelvis anterior–posterior diameter at least 4 mm, is present with increased frequency in Down syndrome fetuses as compared with second-trimester euploid fetuses (Fig. 13) (50). As an isolated marker, the likelihood ratio ranges from 1.5 to 1.9; however, the sensitivity

Figure 13 Transverse view at the level of fetal kidneys with calipers showing bilateral renal pyelectasis.

Figure 14 Fetal abdomen with increased echogenicity of the fetal bowel as indicated by white arrow.

for this marker is low (17–25%) with a false-positive rate of 2% to 3%, making this marker difficult to use as an isolated finding or in a low-risk population (49–51).

Increased echogenicity of the fetal bowel, defined as fetal bowel at least as echogenic or brighter than the surrounding bone, is a subjective marker for Down syndrome and is dependent on the machine and the operator performing the ultrasound (Fig. 14). Sensitivity of this marker ranges anywhere from 3% to 27% with a low false-positive rate of <1% (35,49,52–54). The finding of hyperechoic bowel can also be seen with fetal cystic fibrosis, cytomegalovirus infection, swallowed bloody amniotic fluid, and severe intrauterine growth restriction. This differential diagnosis list must be kept in mind when counseling patients regarding this finding.

EIFs occur in up to 5% of normal pregnancies and in approximately 16% to 18% of Down syndrome gestations (Figs. 15 and 16) (19). The risk does not seem to vary if the isolated focus is in the right or left ventricle; however, the presence of bilateral or multiple unilateral EIFs, especially in the right ventricle, may increase the risk for Down syndrome (55–57). Because an EIF is one of the most common sonographic markers of aneuploidy to be seen among normal fetuses, much recent

Figure 15 Apical four-chamber view of fetal heart showing single echogenic focus in the left ventricle (white arrow).

Figure 16 Apical four-chamber view of fetal heart showing multiple echogenic foci [two in the left ventricle (white arrows) and one in the right ventricle (yellow arrow)].

literature has focused on its clinical utility as a screen for Down syndrome. Recent literature has shown EIF as an isolated finding, and no additional maternal risk factor probably does not increase the risk of fetal aneuploidy and does not require invasive testing (25,26,58).

Like the EIF, the presence of a choroid plexus cyst is a sonographic finding, which can also be seen in euploid fetuses (Fig. 17). Again, there has been debate in the literature regarding an association between isolated choroid plexus cyst in a low-risk woman and fetal aneuploidy, with most researchers identifying this finding as a benign variant when noted in isolation (26,59).

Other minor sonographic markers associated with Down syndrome include short ears, altered foot-to-femur ratio, widened iliac wing angle, sandal gap between the first and second toes, hypoplastic fifth middle phalanx of the hand, and clinodactyly. These markers are inconsistently used because of variable operator experience and possibly high false-positive rates.

Different methods have been proposed to interpret the presence or absence of sonographic markers identified at

Figure 17 A single sonolucent choroid plexus cyst in the far lateral ventricle (white arrow).

the time of genetic sonogram (60). These include summing up the scores of individual markers to obtain a “Sonographic Scoring Index” (49), multiplying the likelihood ratios of individual markers (61), calculating a negative likelihood ratio in the absence of any sonographic markers (32), and using multivariate analysis to identify independent sonographic predictors (62,63). A standardized methodology in applying soft markers as a screening test for Down syndrome will aid in patient counseling regarding the findings. Additionally, the development of uniform and reproducible sonographic and measurement standards will further enhance the clinical utility of the genetic sonogram. Regardless of its interpretation, the genetic sonogram plays a useful role in identifying fetuses at risk for Down syndrome or reducing the risk for Down syndrome, if normal, in high-risk women who wish to avoid amniocentesis. The reported detection rates of Down syndrome after genetic sonography when combining multiple ultrasound markers range from 50% to 90% (64–66). It is important to combine the genetic sonogram with first- and/or second-trimester maternal serum screening, as these results establish a woman’s baseline or a priori risk. Additionally, combining maternal serum screening with second-trimester fetal ultrasound evaluation is more effective than either modality alone at identifying fetuses at risk for aneuploidy (67,68).

Finally, obstetricians must keep in mind that although ultrasound is a low-risk and non-invasive screening tool for the evaluation of the fetus and intrauterine environment, it is not always a benign process. Pregnant women referred for targeted ultrasound because of the finding of a marker have high anxiety, with reported anxiety levels higher than women referred for ultrasound evaluation based on advanced maternal age alone and comparable with women with abnormal maternal serum screening (69,70). This further supports the need for standardization in the approach to performing and interpreting sonographic aneuploidy markers and the patient counseling that accompanies this evaluation.

SECOND-TRIMESTER ULTRASOUND TO DETECT TRISOMY 18 AND 13

After Down syndrome, trisomy 18 is the second most common aneuploidy among live-born fetuses, occurring in

approximately 1 in 8000 live births (71). While most of the literature detailing second-trimester ultrasound has focused on the detection for fetal structural anomalies and sonographic markers for Down syndrome, several ultrasound markers, such as choroid plexus cysts and clenched hands, have been shown to be associated with trisomy 18 (72–77). The vast majority of trisomy 18 fetuses have sonographically detectable abnormalities in the second trimester (78,79). In one series of 8763 women with singleton pregnancy and serum screening significant for increased risk trisomy 18, 15% had an abnormal genetic sonogram, including 1240 of pregnancies with normal fetuses and 50 of those with trisomy 18 (80). If the genetic sonogram was normal, a woman’s risk of having a fetus with trisomy 18 was reduced by approximately 90%. The most commonly identified abnormality was a cardiac defect, followed by skeletal, central nervous system, facial, and abdominal abnormality. Most fetuses (81%) with trisomy 18 had an ultrasound marker present. Specifically, choroid plexus cysts and clenched hands were seen in large percentage of affected fetuses (52% and 36% respectively). These ultrasound markers were almost always seen in conjunction with one or more structural anomalies or other markers.

Trisomy 13 is the third most common of the autosomal trisomies to result in a live-born neonate. Prevalence of this disorder ranges between 1 in 5000 to 1 in 20,000 and it is characterized by multiple severe anomalies resulting in neonatal death (81). Severe craniofacial and midline defects are more common and severe in this trisomy when compared with the abnormalities seen in trisomy 18 or 21 fetuses. As with trisomy 18 fetuses, second-trimester sonographic examination can show many of the anomalies characteristic of trisomy 13. In one series of 28 fetuses with trisomy 13, major structural malformations were seen in 23 cases (82.1%) and minor anomalies were detected in 16 cases (57.1%) (82). Among major anomalies, the most common (64.3%) were central nervous system (ventriculomegaly, holoprosencephaly, posterior fossa cysts) and facial (midline clefts, microphthalmos, protrusio bulbi, hypertelorism). Cardiovascular anomalies were the next most common abnormality detected (53.6%) followed by renal anomalies (42.9%) and polydactyly (7.1%). Ultrasound markers for fetal aneuploidy were also detected (57.1%), but almost always in association with a major structural defect (87.5%).

THREE-DIMENSIONAL SONOGRAPHY

In recent years, the use of three-dimensional (3D) ultrasound has emerged as an important imaging tool for the diagnosis of fetal abnormality. The 3D ultrasound may be utilized to further identify the nature, severity, and location of fetal defects first identified on standard ultrasound evaluation (83). It is a complementary tool that may be used to expand upon the 2D ultrasound examination. Specific applications include improved visualization of fetal facial features in the evaluation of suspected abnormal findings including micrognathia, cleft lip and palate, tumors extending to the face, and markers of trisomy 21 (84–88). The 3D ultrasound has proven useful in the assessment of limb malformation and prenatal diagnosis of skeletal abnormalities, including rib anomalies and abnormal cranial sutures (89–91). It also has been utilized to localize the severity and extent of fetal neural tube defects (92). Other

applications include spatial presentation of blood flow and vasculature and, more recently, the ability to reconstruct a 3D rendered image of the fetal heart (93,94).

FETAL MAGNETIC RESONANCE IMAGING

Fetal magnetic resonance imaging (MRI) has emerged as a useful complementary imaging modality to further elucidate abnormalities noted at the time of fetal ultrasound evaluation. MRI provides superior soft tissue resolution in comparison with ultrasound regardless of fetal position, gestational age, maternal body habitus, oligohydramnios, or skill of operator (95). Brain imaging is the most common application for MRI of the fetus and use of MRI for diagnosing central nervous system abnormalities is widely reported. It has been utilized in cases of unexplained hydrocephalus, suspected agenesis of the corpus callosum, abnormalities of the posterior fossa, and neural tube defects (96,97). MRI has also been utilized in fetal imaging to study lung and chest anatomy, cervical masses, and urogenital abnormalities (98–101). MRI also has been shown to play a role in assessing abnormal placentation, including cases of suspected placenta accreta, increta, and percreta (102–105).

50 Genetic Counseling

Zoltán Papp, Valéria Váradi, and Júlia Hajdú

Classical genetic counseling is aimed to help families with emotional support by disclosing and discussing the causes of certain “genetic” problems, the risks of recurrence, and the possibilities for prevention or other options. In many situations, no reliable figures for recurrence risk were available. The classic options in many cases included contraception, sterilization, adoption, or AID (artificial heterologous insemination by donor) (1–7).

Subsequently, a number of diagnostic techniques, applicable in pregnancy, became available, together with a much better understanding of genetically determined disease at many levels. Now, in many disorders, one can suggest undertaking further pregnancies, with the offer of *prenatal genetic counseling*: the phenotype may be examined (ultrasound, for malformations or growth retardation; cell biochemistry, for metabolic disorders) or the fetal genotype be examined (cytogenetic analysis, for chromosome disorders; DNA, for direct identification of mutant genes). There remain disorders for which no diagnosis is available or for which one can offer no more than “classical genetics,” but it is likely that many disorders at present of unknown cause will soon be understood at the biochemical or gene level, and that many presently “unmapped” genes will be mapped within the next decades (8).

The increased availability of prenatal diagnosis (available in more centers, for more patients, for more disorders) has stimulated the development of screening for genetic disease. Subpopulations at particular risk may be easily identified (e.g., older mothers) or identified only after specific testing (e.g., for thalassemia, hemoglobinopathies, Tay–Sachs disease, and, possibly, cystic fibrosis). The screening process may take place before or during an actual pregnancy; some screening methods, for example, biochemical markers, ultrasound, can be applied only during pregnancy (8).

The goal of genetic counseling is to *prevent birth defects* in cooperation with the couples (9). Without prevention, at least 3% to 4% of all births are associated with major congenital defect, mental retardation, or a genetic disorder.

Clinically significant chromosomal defects occurred in 0.65% of all births before prenatal diagnosis was introduced; an additional 0.2% of infants were born with balanced structural chromosome rearrangements. Congenital malformations, disruptions, and deformations with obvious *structural defects* were found in about 2% to 3% of all births. More than 9000 monogenic disorders and traits have been catalogued (10). Prevalence of monogenic disorders has been estimated to be 3.6 in 1000 live births, consisting of autosomal dominant (1.4 in 1000), autosomal recessive (1.7 in 1000), and X-linked (0.5 in 1000) (8).

The indications for *preconception genetic counseling* should be determined at the first visit and can be considered in a few clear categories:

- advanced maternal age,
- a previous fetus or child with a genetic disorder,
- a parent with a genetic disorder,
 - genetic disorders that pregnancy may aggravate,
 - maternal genetic disorders that may threaten fetal health and survival,
- a history of infertility,
- parental carrier of a genetic trait,
- family history of a genetic disorder,
- consanguinity (11), and
- environmental exposures that threaten fetal health.

Preconception counseling identifies specific risks and attendant options, which include the following:

- decision not to have children (includes consideration of vasectomy or tubal ligation),
- adoption,
- in vitro fertilization (IVF) and other reproductive technologies,
- carrier detection tests,
- presymptomatic diagnosis and predictive genetic testing,
- preimplantation genetic diagnosis (PGD), and
- folic acid supplementation in periconceptional period.

The optimal time to initiate counseling is not during pregnancy. Counsees whose first antenatal visits occur after the second missed menstrual period miss the critical period of organogenesis, and patients referred well after conception have lost almost all their options except selective abortion.

The ideal genetic counseling is composed of (12)

- an appropriately trained professional,
- relevant and objective information,
- assurance of the counselee’s understanding,
- psychological support,
- informed consent,
- assuring autonomous decision-making,
- confidentiality of genetic information,
- considering familial implications, and
- appropriate handling of potential discrimination of testing.

The option of further pregnancies includes the option of prenatal diagnosis, which, in turn, includes the option of pregnancy termination. Many couples, even in high-risk situations, will be lucky and have a healthy child; only a few will go through the trauma of one or several terminations. Couples identified by screening as “high risk” may be at very high risk (25%) in the cases of monogenic traits, at a lower risk (10% ±) if identified through positive

biochemical tests, or at relatively low risk (1% \pm) if identified by maternal age (13).

Decisions on pregnancy testing and termination must be the couple's own; it is the duty of the counselor to support and to inform, but not to persuade. Some couples refuse the idea of interrupting pregnancy, for example, for religious reasons. Unlike some infectious diseases, which may be controlled by immunization, compulsory screening, and therapy, genetic diseases do not endanger society directly. It is families that are affected by them (14–16).

Nevertheless, the indirect effect of genetic disease on society cannot be ignored. Unlike infectious diseases, genetic diseases do not threaten the health of other people, but they do burden society (e.g., the cost of institutional care for handicapped children). The question arises whether anybody has the right to insist on the birth of a child who will suffer from an undoubtedly incurable disease and also severely burden public finances. Some people do insist on continuing such pregnancies, and there is no doubt that the right to make individual decisions must be respected.

Often couples coming for genetic counseling are full of fears and anxiety, oppressed with the memory of one or more ill or dead children. Couples appreciate the opportunity for a counseling session and discussion, and the offer of prenatal diagnosis will be accepted by most of them (17,18).

Counseling sessions may often be strongly psychological in nature (19–24). It is essential to present a clear and full description of the relevant disorder and to answer all questions honestly and promptly. A good and harmonious relationship should develop or be developed between the counselor and the couple. The physician–patient relationship, always important in medicine, here is replaced by a physician/counselor–family relationship, which deepens in the course of counseling. This sort of relationship is necessary for the proper help and management of high-risk couples in this situation. A great deal depends on the character of the individual physician.

GENETIC TESTING

The completion of the Human Genome Project was a phenomenal accomplishment, providing researchers with the reference sequence of the human genome, which has subsequently led to the identification of many genes associated with human disease. Development of new technologies has made it possible to study these genes, search for disease-causing mutations, and develop genetic tests (25). Genetic testing has the potential to offer dramatic benefits, both clinically and psychologically, for patients and their families. The array of benefits begins with the clarification of diagnosis and prognosis, which assists in decision-making about clinical care. Testing for familial mutations makes available predictive, carrier, and prenatal testing, all of which provide risk assessment for family members of an affected patient to assist them in making complex personal, medical, and reproductive decisions. In addition, there are a multitude of genetic tests available to those with no family history of genetic disease that can provide information about potential reproductive or future health risks.

The process of ordering genetic testing can be a complex and often bewildering process for health-care professionals. There are challenges related to test selection, laboratory choice,

standards of practice, and ethical issues. Commonly, genetic counselors receive requests for genetic testing for disorders for which gene identification has only recently been reported in the scientific literature. Often these requests come from primary care providers, but increasingly they come from families who follow the research on a particular genetic disease that has been diagnosed in their family. The immediacy with which peer-reviewed research findings are available on publicly available Internet sites speeds up this process (26).

Historically, the broad categories of genetic tests were (i) cytogenetic tests (chromosome analysis), (ii) molecular tests (DNA analysis), and (iii) biochemical tests (enzyme assays, metabolites, protein analysis). Globally, cytogenetic tests detect changes in chromosome number, structure, and arrangement. Molecular tests look for changes in the DNA sequence, methylation, deletions, and duplications, and biochemical tests detect changes in the gene products, such as changes in levels of enzymes and proteins. Evolving technologies have led to considerable overlap between these categories of genetic tests as there are cytogenetic tests that actually use molecular/DNA methodologies, such as fluorescent in situ hybridization analysis and chromosomal microarray analysis. Genetic tests have different clinical applications, and these will influence the specific technology selected (26).

In genetic testing, it is often important to take into account both the genotype and the associated phenotype. The genotype is defined as the genetic makeup and the phenotype as the observable traits, characteristics, and symptoms. In an “ideal” genetic test, there is one-to-one relationship between the genotype and the phenotype. However, it is possible to have a genetic test that can accurately identify changes in genotype but can be quite limited in its ability to predict phenotype, particularly type and severity of symptoms, age of onset, and disease course. This limitation in predicting outcome can be particularly challenging and requires that genetic counselors use a wide variety of critical thinking, educational, and counseling skills in discussing these testing issues with patients.

Genetic testing is now widely available for diagnostic confirmation, predictive testing, and carrier and fetal risk assessment. Genetic counselors have a crucial role in evaluating the clinical usefulness of these tests as they work with patients and their families to assess the medical and personal benefits, as well as the risks, of undergoing testing. Critical thinking and assessment skills are needed to determine whether genetic testing is clinically indicated and in selecting the type of genetic test and the appropriate laboratory. Genetic counselors must be knowledgeable about test validation procedures and laboratory variability. Through consideration of the clinical utility of the genetic test and client-focused genetic counseling should precede the use of any genetic test. These considerations are particularly important before the utilization of new technologies, which may have a higher likelihood of inconclusive test results, or use of genetic tests whose outcomes directly influence medical interventions (27).

To appropriately select a diagnostic laboratory for their clients, genetic counselors must be aware of the rapidly evolving standards by which clinical laboratories are certified and the increasing involvement and oversight of other

government agencies and interested entities from the private sector. When a genetic counselor is not familiar with a laboratory, the genetic counselor should inquire about the laboratory's accreditation, the additional voluntary professional guidelines the laboratory follows, and the laboratory's participation in proficiency testing, both external and internal. In addition, it is important to determine the laboratory's experience with the particular test being considered and the specific technology utilized, as well as the training and certification of the laboratory and medical directors and other staff. In general, laboratories that voluntarily participate in multiple certification programs and that adhere to guidelines provided by professional organizations provide testing at a higher standard and should be utilized whenever possible.

Genetic counselors play a critical role in ensuring that their patients receive the "ideal genetic test," one that has optimal parameters for them. Genetic counselors should continue to participate actively in research aimed at evaluating the impact of the genetic testing outcomes and work with other stakeholders in defining enhanced oversight of genetic testing and global practice guidelines for the appropriate use of genetic tests (28–34).

QUESTIONS TO BE ANSWERED

Four questions must be answered by the genetic counselor: (i) What is the disease in question (clinical and laboratory diagnosis)? (ii) How severe is it (prognosis and therapeutic possibilities)? What can be done to treat the affected child postnatally? (iii) How is it caused/inherited (risk of recurrence)? (iv) What can be done to avoid or prevent the disease (prenatal diagnosis)? (35).

Diagnosis

Knowledge of the disease in question is a prerequisite of genetic counseling. Confirmation of an exact diagnosis, which is of basic importance, may be difficult. Obtaining old or recent medical records, pedigree analysis, careful history-taking, clinical examination of relatives, special laboratory tests, and other investigations (may be involving referral to other specialist departments) can all be relevant or necessary procedures (36).

The family history and pedigree are the basis for providing clients referred for genetic evaluation and counseling with a diagnosis, risk assessment, education, and psychosocial support. Accuracy, detail, and relevance are paramount. The genetic counseling student must develop a mastery of this fundamental task and employ standardized pedigree symbols and nomenclature that enhance the utility of the information obtained. The family history and pedigree have come a long way since the era of Francis Galton. An accurate and complete family history and pedigree lay the foundation for the highest standards of patient care and genetic counseling. They are tools now clearly viewed as having an essential role in all aspects of health care (37–41).

Disease, whether genetic or nongenetic, may be due to a variety of factors. Genetic disease is particularly likely to be heterogeneous in this respect. For example, a muscular dystrophy may result from a number of mutant genes. Among the common types of muscular dystrophy, we have the facioscapulohumeral form, which is characteristically auto-

somal dominant, and myotonic dystrophy, also autosomal dominant. "Limb-girdle" muscular dystrophy, a diagnosis that probably comprises a number of disorders, is autosomal recessive. Duchenne, Becker, and Emery–Dreifuss muscular dystrophies are all X-linked recessive, with fairly distinct, but overlapping, phenotypes; under some conditions, they can manifest, usually in mild degree, in females also (e.g., symptomatic carriers). Sometimes investigation of a family with "muscular dystrophy" reveals that the primary disease was not in the muscles at all but, for example, a spinal muscular atrophy, originating in the anterior horn cells, or a more generalized disorder, for example, a glycogenosis (42).

A practically identical clinical picture is characteristic of some of the commoner types of mucopolysaccharidoses. However, Hurler, Scheie, and Sanfilippo diseases are of autosomal recessive inheritance, whereas the Hunter disease is X-linked recessive.

It should be noted that there are diseases that do not usually manifest until adulthood (e.g., Huntington disease, facioscapulohumeral muscular dystrophy), and that in connection with certain diseases of recessive (autosomal or X-linked) inheritance, heterozygotes may also show clinical symptoms, for example, axillary and pubic hair may be sparse in heterozygotes for testicular feminization, cutaneous symptoms may be seen by gene carriers for Fabry disease, and nephrolithiasis occurs in heterozygotes for cystinuria.

In some cases, medical documents may be incomplete, or unobtainable; certain tests, which are now considered essential for the diagnosis, may not have been carried out or available at that time. There may be no histologic information, no postmortem report, no roentgenograms, no photographs, no biochemical results. Genetic counseling cannot be based on a diagnosis like "mental retardation," "growth disorder," or "degenerative disease." Sometimes an exact diagnosis, like "achondroplasia," may be clearly misleading. To make a correct diagnosis, with a few exceptions, requires detailed and correct information (42).

Prognosis and Therapy

Without a correct diagnosis, the genetic counselor cannot tell the parents whether there is a high or low risk of recurrence within the family, whether tests can be carried out to detect those persons/couples at high risk of having an affected child, whether prenatal diagnosis is possible (and if so, how, where, and when), whether the disease is in any way treatable, whether the severity is highly variable within a family, whether there are other (as yet undiscussed) serious implications, or whether other "reproductive options" are available.

Although much genetic disease remains untreatable, the counselor must know the possibilities for the disease in question. He/she must be up-to-date and informed about surgical procedures and appliances (e.g., neonatal or prenatal surgery, transplantation, artificial limbs), about medical treatment (e.g., physiotherapy and antibiotic therapy for cystic fibrosis, use of restricted/special diets—for phenylketonuria/galactosemia, use of specific vitamins—pyridoxine for certain epilepsies, hydroxocobalamin for B₁₂ transport disorders), and about what is available within the community (e.g., help from social services, financial help for parents with handicapped children, institutional care). He/she must be able to discuss

Table 1 General Population Risks

Condition	Risk
Fetal loss	
in the first trimester	1/6
in the second and third trimesters	1/30–1/100
Neonatal death	1/100
Malformation detectable at birth	1/33
Mental retardation	1/50
Chronic disease in adulthood	1/5

more remote possibilities, such as “gene therapy,” within a realistic perspective. He/she must be able to talk to the parents in a way, and at a level, that is appropriate to their preexisting knowledge and education, and their degree of anxiety or depth of grief. He/she must be prepared to educate them further. He/she must be understood and supportive (42).

Genetic Risk

This term covers two concepts: the *general population risk* of a disorder/disease and the risk, or recurrence risk, of a disorder/disease in a specific family situation.

Many couples have no idea at all of general population risks. They may imagine that it is extremely unusual to abort spontaneously, bear a baby with a malformation, or have a child with mental retardation. They cannot understand how such things can happen, if they are not in the family already. They do not understand why a particular disaster happened to them, as they had done nothing to deserve or provoke it.

The general population risks for a few commonplace situations are given in Table 1. All genetic counseling has to be given, and understood, against this general “background” risk. For example, a couple may be horrified to be told there is a 1% recurrence risk for a certain malformation; they may perceive that as a very high-risk situation (although 100 to 1 odds in a gambling situation are usually perceived as far from certainty!). It may help couples realize that an additional risk of 1% for a malformation is not so enormous when compared with the starting risk of 3% to 5%; they have only a 33% increase above the general risk level.

In some counseling situations, couples may be at increased risk for one or a number of problems, as compared with general population risks, yet one is not talking of “recurrence risk,” the condition provoking anxiety, and the request for counseling has not yet happened. In these situations, *actual risk* may not be very high, though much above the general population level. For example, a woman of 40 has a risk of bearing a live-born with Down syndrome that is 20-fold the risk she ran when she was only 20. Yet the actual risk is only 1/100. Similar low levels of risk (yet high, compared with general population risks) may be associated for example with exposure to teratogens or radiation; slightly higher levels of risk will be run in cousin marriages.

Very high levels of risk, for a problem that has not yet appeared within the family, will seldom be met with except in connection with specific screening programs, for example, detection of Tay-Sachs heterozygotes in Ashkenazi Jews, of thalassemia carriers in Mediterranean populations; in these situations, when both (prospective) parents are heterozygotes, the risk of an affected child is 25%. In, virtually, all of these

very high-risk situations identified by screening, a prenatal test can be offered: but this would *not* be acceptable to *all* couples.

When a disorder has already appeared within a family, recurrence risks may be *high* ($>1/10$), *intermediate* (1/10–1/100), or *low* ($<1/100$): use of these words, high, intermediate, low, is extremely arbitrary. The counselor’s use of such words may be at variance with the use, or perceptions, of the counseled couple. To the counselor a risk estimate may appear intermediate or low, yet to the counseled couple it is high. Risk figures can be “rewritten” by turning statements around; 1/100 recurrence risk, for a serious malformation may appear formidable to the threatened parents; it is more reassuring to be told there is 99% chance that the baby will be unaffected. Risk figures should be compared with general population risks. The nature of the disorder/problem itself, and the impossibility/possibility of prenatal diagnosis, will affect the way it is perceived (8).

In some situations, recurrence risk is very low. If problems with a previous pregnancy were due to teratogen exposure, and the teratogen can be avoided in further pregnancies, risks may not be much above the general population risk.

Most malformations are multifactorially determined. After a child with an isolated exomphalos, or tracheo-esophageal malformation, recurrence risk may be 1% to 2% only; although this represents a 20- to 40-fold increase over the general population level, it is still not a very daunting risk. After having a child with congenital heart disease, the recurrence risks are usually 2% to 5% (depending on the malformation type); the background rate, for congenital heart disease, is nearly 1% (8/1000).

When dealing with a malformation problem, the counselor must be sure that it is really isolated and not part of a syndrome (that may be monogenic); for example, an occipital encephalocele alone might suggest a recurrence risk, for all types of neural tube defects, of about 2%; if the encephalocele was accompanied by cystic kidneys or polydactyly, the Meckel syndrome would probably be diagnosed, with a recurrence risk of 25%.

In families with monogenic disorders, many relatives will run risks that are intermediate or low. For example, with a heterozygote frequency of 1/25 for cystic fibrosis, risk to the child of a woman whose brother was affected is 1/150, and risk to a child of a man whose brother’s child was affected is 1/200. In families with X-linked recessive disease, some females, with no closely affected relatives (but with many unaffected brothers or maternal uncles), will be at very low risk for being carriers or having affected sons.

The background general population risk is not identical with the risk within a given family (*specific risk*), nor with the risk calculated for a given pregnancy (*actual risk*). For example, the background risk for a healthy person of being heterozygous for cystic fibrosis is 1/25, and the risk of his/her child being affected by the disease is 1/2500. However, the situation will change completely if it is revealed that the couples already have a child suffering from cystic fibrosis. In this case, the specific risk that both members of the couples are heterozygotes is 1/1, and the risk for a further child being affected is 1/4. If the couples undertake a pregnancy, and the pregnancy tests give normal results, the actual risk for an affected child will fall to about nearly zero.

To talk about 100% reliability of a biochemical or molecular prenatal diagnosis is, in practice, nonsense. The counselor

should not use words like “never” or “always.” Instead, expressions like “probably not,” “a very high chance,” and “almost certainly” are preferable and might also avoid legal complications! (42).

To explain the concept of risk, we may use analogies, for example, one coin (heads/tails) may be useful in explaining autosomal dominant inheritance and two coins may explain recessive inheritance.

Discussion of risk situations demands tact. In particular, one should avoid laying “blame” to one member of the couple: this might be difficult in the case of autosomal dominant or X-linked recessive disorders or inherited chromosome rearrangements. It is better, if possible, to spread the “responsibility” to both members of the couple: for example, with an X-linked disorder and an affected male child, the mother gave the mutant gene, but without the paternal Y chromosome all would have been well.

In cases of multifactorial determination, it is important not to accuse anybody, e.g., the physician who prescribed a drug or the factory in which the counselee was exposed to chemicals (and which guaranteed the safety of her work). An unfortunate combination of environmental factors and predisposing genes may be stressed. The counselor should intervene to prevent any further, possibly dangerous, exposure (43,44).

In many cases, the client’s concerns center not on the diagnosis of an affected individual but on assessing future reproductive or personal health risk. The counselor can sometimes make such an assessment by analyzing the pedigree, taking into account the pattern of inheritance and the client’s relationship to individuals with the condition. Mathematical calculations may be needed to incorporate additional information (e.g., carrier frequencies, test sensitivity and specificity, numbers of affected and unaffected individuals, the client’s age) to modify the risk. Questions about carrier status may be resolved with appropriate laboratory tests. When a condition has a multifactorial basis or is genetically heterogeneous, the best risk estimates may come from epidemiologic data on other families with affected individuals. Answering concerns about potentially mutagenic or teratogenic exposures also usually relies on empirical data about the agent in question and on evaluating the timing, duration, and dose of the exposure. In some areas of genetic counseling, such as cancer risk assessment, factors such as reproductive history, hormone use, and lifestyle issues such as smoking, obesity, or alcohol use are also important variables in risk assessment.

Prenatal Diagnosis

In very many counseling situations, the specific recurrence risk is so low that apart from a general screening for malformations, further tests are superfluous. A simple reassurance may disappoint certain couples if they feel that their problem has been oversimplified.

For most couples running a higher than average risk/recurrence risk, one can offer prenatal diagnosis. Cases require individual assessment. The reliability and the safety of the diagnostic procedures should be discussed with the parents. These should be carefully weighed, bearing in mind the nature and severity of the disease/disorder prompting the desire for diagnosis/termination. It should be explained that the test(s) will be for one problem only or a limited range of

disorders, and normal results will not guarantee a child normal in *every* way.

The final decision, to accept or reject the offer of prenatal diagnosis, is for the couple to make. Their decision will reflect their attitude to the disorder in question, and also their feelings regarding termination of pregnancy, should the test show an “affected” fetus. They should *not* be required to give any consent in advance, regarding abortion in this latter eventuality.

The couples decide whether or not to undertake pregnancy and they decide whether or not to accept an offer of prenatal diagnosis. However, prenatal testing is time-consuming, laborious, and expensive; it uses human resources and materials that are, as a result, not available to others; it involves certain risks for the mother and fetus. If a couple are convinced that they would not terminate pregnancy in any event (an “affected” fetus), they will probably also be convinced that the risks, to mother and pregnancy, are not worth taking.

In some autosomal or X-linked recessive situations, prenatal diagnosis is, at present, impossible, even though the genetic risk is high. In this difficult situation, some counseled couples will decide the 25% recurrence risk is too high and will choose termination of an existing pregnancy, sterilization, conception by AID, or divorce and remarriage. Other couples regard the 75% chance of a healthy child a sufficient encouragement to make at least one more attempt to have a healthy child.

Decision-Making of the Couple: Nondirective Counseling

The physician/counselor gives information and the parents, in light of their own individual circumstances and attitudes, make the decision (45–48).

The parental decision will depend on a number of factors: of importance may be their optimistic or pessimistic attitude of mind, their ethical and religious principles, their level of education, and/or their social circumstances. Their previous experiences with the disease in question may also be of decisive importance. Many couples declare that they do not want to undergo another tragedy. This is a most convincing argument.

The personality of the counselor, too, is of great importance: the way in which information is imparted, the content and clarity of such information, the manner in which the couples’ own questions, fears, and problems are discussed and dealt with. Decision-making is extremely difficult and painful for some couples, and decisions will often have lifelong consequences. The counselor should help the couple to the best of his/her ability.

All over the world, genetic counseling is primarily done by biologists, geneticists, and various medical specialists, mainly pediatricians and obstetricians (49). Pregnant women and their partners facing various genetic problems can base their decision on information and advice made available by these professionals’ knowledge and expertise. Counseling can follow two principles: the more widely used nondirective genetic counseling and the so-called directive genetic counseling (50–53). Because the current era is dominated by legal claims against physicians, the nondirective method is more acceptable and more easily defensible, even though in *Ethical Considerations in Prenatal Diagnosis*, in many cases, patients expect and demand a decision-shaping process closely guided

by the physicians. When applying the nondirective method, the genetic counselor is ready to share information in a nondirective manner without committing to any potential alternative. It is very important that having thoroughly described the disease in question, the consultant should also inform the patient about the risk of occurrence and/or recurrence. After that, diagnostic alternatives should be described and offered—if there are any. This has to be done in a fashion so that the patients seeking counseling can understand the basic facts, and it may vary with the given circumstances. The patient's fear and anxiety must not be worsened by giving an opinion expressed in mystical complicated sentences that are incomprehensible to ordinary people. By this point, the couples have already started the decision-making process. The physician leaves it to the patients to use the intensive interactive process to arrive at their final decision (50,53–55).

PREDICTIVE TESTING AND PRESYMPTOMATIC DIAGNOSIS

Predictive (susceptibility) testing (sometimes called “predisposition testing” in the case of mutations with less than 100% penetrancy) identifies healthy individuals who may have inherited a genetic predisposition that puts them at increased risk of developing a multifactorial disease (e.g., Alzheimer disease or cancer), but who may never develop the disease in question (56). *Presymptomatic diagnosis* refers the identification of healthy individuals who may have inherited a gene for a late-onset monogenically inherited disease and, if so, will develop the disorder if they live long enough (e.g., Huntington disease) (57,58). DNA arrays could potentially include mutation probes for a large panel of late-onset disorders and an extended spectrum of mutations and polymorphisms for each one, dramatically complicating an already thorny genetic and social counseling problem (59). Do we have the right to inform the patient about the existence of untreatable disease before symptoms appear? Is it necessary to do so? Are we obliged to do that? Is this individual ill at all? Can or need populations be screened for certain diseases? Indeed, the development of some diseases might be slowed down if changes in lifestyle were implemented. The knowledge, however, that the development of serious disease is inevitable in a later stage of one's life could put a heavy burden on his everyday existence and might even change an individual's personality. Surviving in the knowledge that one is to expect to develop a malignant tumor by the age of 30 to 40 years is difficult (60–62). By the same token, possessing the relevant information might result in more careful diagnostic examinations, which should have a substantial effect on the life expectancy (8).

At the same time, it raises the question of who is entitled to know the information, that is, confidentiality, the individual affected or his relatives. One might think that only the individual affected should, but with the disease in question being a genetic one, are the relatives not affected too? Do they not have the right to know their risk? Is the parent obliged to tell his or her child? Can the child request the performance of a predictive test? (63) Can the parent make a decision on whether the examination should be performed for her minor child? (64). Susceptibility testing and presymptomatic

diagnostics in the absence of therapeutic options should be available if certain conditions are met. It is important that the individual be provided thorough information about the limits of testing, and the information contribute to enhancing the pathography and informing the family because, in many cases, it is impossible to predict the onset and seriousness of a particular disease and its symptoms. Awareness of susceptibility could induce a change in the lifestyle that could prevent or prolong the development of a disease. If a disease is inevitable, the individual will have the chance of planning for his or her short life, as in the case of Huntington disease. Such genetic information can influence plans for marriage and having children (8). The problem is further complicated by the shortcomings of available predictive genetic tests that still carry a factor of serious uncertainty about whether a disease will develop and, if it does, when exactly and to what extent. Given the onus of this information, if there is no medical advantage concerning prevention or treatment, these examinations can best be postponed until adulthood, when the individual is able to make decisions on crucial aspects of his own life. Considering the likely rapid dissemination of predictive tests, there is an urgent need to develop a well-thought-out, detailed legal framework. Prohibition cannot be allowed because it would deprive the individual of rather important information. The proper regulation would eliminate the situation of diametrically opposed interests among the parties and would make them interested in wide-ranging examinations.

TERMINATION OF PREGNANCY BECAUSE OF GENETIC INDICATIONS

Recent advances in technology have enabled the development of a wide range of methods for prenatal diagnosis (65). The demands of modern society are for a healthy “perfect baby” (66). The new techniques are aimed at early diagnosis of the abnormal fetus at a point where parents who wish to do so may terminate the pregnancy. The emphasis is not on the removal of the defective child, but rather on the provision of life for new healthy children, who may otherwise never have been born.

The most challenging moments of genetic counseling arise when a decision has to be made on the disposition of a pregnancy (67). From the consultant's point of view, those situations are the most difficult when the problem is so severe and the diagnosis is so bad that termination on a genetic basis may be proffered. Even in this case, the goal of nondirective counseling is to inform the patient about this option. The woman is about to resolve one of the most difficult situations of her life. The problems of fetal life have often been put in the center of debates, not only in professional circles, but also as a political issue. The rigid attitude of the Roman Catholic Church is well known and stirs a lot of debates even within that faith community. The church turns a deaf ear to the issue of termination and does not accept contraception as a legitimate option (with a few exceptions). Thus, it is difficult to provide the opportunities offered by the achievements of prenatal diagnosis to Catholics. In some liberal circles' view, parents must be assured of having the widest possible sphere of authority. This cannot be readily accepted by a physician or an obstetrician-geneticist.

The weight of the decision depends on the gestational age of the pregnancy and other factors. Decisions on serious conditions detected in the first trimester are made easier (40). Given that most diagnoses are made in the second trimester, a very close relationship has sometimes developed between the fetus and the expectant mother by decision time. She may have seen its face during an ultrasound examination, and she may even know her offspring's sex. Realizing her widening waistline, the people around her may learn about the pregnancy, and this knowledge and having to wait make it even more difficult for her to cope. The necessity to make a decision presents a major state of crisis, the extent of which depends, among other things, on the obstetrical anamnesis. In such a case, the task is to give the relevant facts, help the patient to consider them thoughtfully and calmly, and encourage her to develop positive prospects for the future. It is important to outline the possible short-term and long-term consequences of the decisions, the risk of the defect being recurrent, and the details of its heredity.

If the woman opts to continue her pregnancy, she needs to be briefed on what sort of aid she can rely on from the fields of medicine and social services, as well as family care. Those deciding to terminate the pregnancy must be informed about the procedure to relieve tension and distress. In any case, this should ease the anxiety regarding the operation itself. It must be stressed that if the couple opts to terminate the pregnancy, the procedure must be initiated as early as possible. The methods used for midterm abortions vary from country to country. Third-trimester abortion also has a place in obstetrical practice. It is justified if the fetus will be unable to survive after birth, and the couple requests termination of pregnancy. Parents have a right to make this decision if the continuation of the pregnancy may increase the risk of maternal complications with no effect on fetal outcome (68,69).

Fetal disease or disorder diagnosed in a twin pregnancy may be concordant or discordant. In the former situation both fetuses are affected, and termination may be carried out as for a single pregnancy. In a discordant twin pregnancy, when only one of the fetuses is affected, three outcomes are possible: (i) the couple may decide against any form of termination; (ii) the parents may decide to lose both fetuses, the affected and the healthy one; (iii) partial selective termination, bringing about death of the affected twin while preserving the normal one, may be attempted. The dead fetus develops into a fetus papyraceus, while the other fetus should develop normally (70). Multifetal pregnancy reduction also has become a well-established and integral part of infertility therapy and the attempts to deal with sequel of aggressive infertility management. Now we have very clear and precise data on the risks and benefits as well as an understanding that the risks increase substantially with the starting and finishing number of fetuses in multifetal pregnancies (71). Regardless of the method, the objective is to get the procedure over within the shortest possible time and in the least intrusive way. The patient ought to get back to her home as soon as possible to be able to deal with the tragedy with her loved ones. Access must be made available to post-termination counseling (50,55).

POST-TERMINATION FETOPATHOLOGY AND COUNSELING

Fetopathology is a postmortem specialty concerned with causes and mechanisms of reproductive loss. In late first and early second trimesters, prenatal diagnosis of fetal anatomy by ultrasound became a major factor leading to termination. Even in centers with high rate of accurate prenatal ultrasound, a high percentage of fetuses with correctly diagnosed anomalies have additional defects that are not recognized by ultrasound. At the post-termination autopsy, the fetopathologist must concentrate on small, even minute anatomic details to find these additional defects to refine the pretermination diagnosis. It cannot be emphasized enough that with all terminations and pregnancy losses, the placenta should be submitted to the pathologist and the pathologist has to evaluate it in context with the clinical history and the postmortem findings of the fetus. The precise description of a clinically suspected anomaly and fine details of dysmorphic features and a solid final diagnosis are essential to the correct estimation of the recurrence risk so that the appropriate plan for surveillance in subsequent pregnancies can be instituted. Discussion of postmortem findings at regular fetal pathology/dysmorphology meetings is also recommended for education as part of a multidisciplinary approach. In these ways, fetopathology serves to promote the quality of the care of the individual and public health (72,73).

PREIMPLANTATION DIAGNOSIS

PGD is a technique devised within the last 20 years used primarily to identify genetic disorders or defects in human pre-embryos created by IVF prior to their implantation for gestation (74). PGD is intended to result in the selective destruction of extracorporeal human pre-embryos following genetic diagnosis. PGD is an attractive means of preventing genetic diseases, which, as an alternative to traditional prenatal genetic diagnosis, can avoid the need for termination of the affected fetuses. PGD is also used to detect aneuploidy and to select chromosomally normal pre-embryos for implantation, mostly in women of advanced maternal age undergoing IVF. The purpose of PGD is not simply to inform couples about the genetic nature of their pre-embryos, but the explicit purpose is also to transfer healthy pre-embryos (75). As a matter of general principle, prevention of the birth of a genetically or otherwise diseased or disabled child is plainly a morally legitimate goal. Nevertheless, strong moral objections have been made to the use of PGD to determine conditions that cannot plausibly be called "diseases," such as sex and the absence of desirable physical, mental, or social characteristics. The selection of an embryo's sex via PGD is done for two basic reasons: (i) preventing the transmission of sex-linked genetic disorders and (ii) choosing sex to achieve gender balance in a family with more than one child, to achieve a preferred order in the birth of children by sex, or to provide a parent with a child of the sex he/she prefers to raise. While little extended ethical debate exists regarding the former, sex selection for the purpose of preventing the transmission of sex-linked genetic disease, the latter is the subject of heated ethical disagreement (76). If some services become embroiled in the sex selection and in the detection of conditions having little or nothing to do with health and

disease and some traits unrelated to health in order to satisfy patient demand or be a profitable business, its practitioners will get, and deserve, serious ethical criticism (77).

SUMMARY

Over the last four decades, the portion of the patient population that needs genetic counseling services has steadily expanded. In the early years, genetic counselors met mostly with parents of children with genetic diseases or adults who had relatively uncommon disorders. Now we are counseling patients and families who are at relative risk for cardiovascular, oncologic, neurologic, and other common diseases (8,78).

The principles of genetic counseling are universal, even though the practice of genetic counseling varies nationally and internationally.

Genetic counseling is a dynamic profession, which undergoes rapid change with the discovery of new genetic information and the development of new genetic tests and treatment options.

The role of the genetic counselor is to provide the most complete information available. His/her role is *not* that of an *advocate* for society. The geneticist has continuing obligation to *recontact* patients when new information develops.

The 20th century witnessed revolutionary progress in the science of genetics that coincided with increasing societal demands, and therefore genetic counseling became an integral part of modern medicine and health care (79,80).

52 Assessment of fetal brain abnormalities

Ritsuko K. Pooh

INTRODUCTION

Recent advanced ultrasound imaging technologies such as high-frequency transvaginal scanning and three-dimensional (3D) sonography have been remarkably improved, and introduction of those technologies in clinical practice has contributed to prenatal evaluation of fetal central nervous system (CNS) development and assessment of CNS abnormalities in utero.

Sonographic assessment of the fetal brain in the sagittal and coronal sections requires an approach through anterior/posterior fontanelle and/or the sagittal suture. Transvaginal sonography of the fetal brain opened a new field in medicine, “neurosonography” (1). Transvaginal approach to the normal fetal brain during the second and third trimesters was introduced in the beginning of 1990s. It was the first practical application of 3D CNS assessment by two-dimensional (2D) ultrasound (2). Transvaginal observation of the fetal brain offers sagittal and coronal views of the brain (3–6) through the fontanelles and/or the sagittal suture as ultrasound windows. Serial oblique sections (1) via the same ultrasound window reveal the intracranial morphology in detail. This method has contributed to the prenatal assessment of congenital CNS anomalies and acquired brain damage in utero. Furthermore, the brain circulation demonstrated by transvaginal power Doppler was first reported in 1996 (7,8); brain vascularity and blood supply have become clearly detectable afterward.

Three-dimensional ultrasound is one of the most attractive modality in a field of fetal ultrasound imaging. Automatic scan by dedicated 3D transducer produces motor-driven automatic sweeping and is called as a fan scan. With this method, a shift and/or angle change of the transducer is not required during scanning and scan duration needs only several seconds. After the acquisition of the target organ, multiplanar imaging analysis and tomographic imaging analysis are possible. Combination of both transvaginal sonography and 3D ultrasound (9–19) has been a great diagnostic tool for evaluation of 3D structure of fetal CNS. Recent advanced 3D ultrasound equipments have several useful functions as follows:

- Surface anatomy imaging
- Bony structural imaging of the calvaria and vertebrae (13,14)
- Multiplanar imaging of the intracranial structure
- Tomographic ultrasound imaging of fetal brain in the any cutting section (Fig. 1)
- Thick slice imaging of the intracranial structure
- Simultaneous volume contrast imaging of the same section or vertical section of fetal brain structure
- Volume calculation of target organs such as intracranial cavity, ventricle, choroid plexus, and intracranial lesions (20–25)

- Three-dimensional sono-angiography of the brain circulation (3D power Doppler) (8)

Fetal neuroimaging with advanced 3D technology is an easy, noninvasive, and reproducible method. It produces not only comprehensible images but also objective imaging data. Easy storage/extraction of raw volume data set enables easy off-line analysis and consultation to neurologists and neurosurgeons.

VENTRICULOMEGALY AND HYDROCEPHALUS

“Hydrocephalus” and “ventriculomegaly” are both the terms used to describe dilatation of the lateral ventricles. However, those two should be distinguished from each other. Hydrocephalus signifies dilated lateral ventricles resulted from increased amount of cerebrospinal fluid (CSF) inside the ventricles and increased intracranial pressure, while ventriculomegaly is the dilatation of lateral ventricles without increased intracranial pressure, due to cerebral hypoplasia or CNS anomaly such as agenesis of the corpus callosum (26,27). Of course, ventriculomegaly can sometimes change into hydrocephalic state. In sonographic imaging, those two intracranial conditions can be differentiated by visualization of subarachnoid space and appearance of choroid plexus. In normal condition, subarachnoid space, visualized around both the cerebral hemispheres, is well preserved during pregnancy. Choroid plexus is a soft tissue and is easily affected by intracranial pressure. Obliterated subarachnoid space and dangling choroid plexus are observed in the case of hydrocephalus. By contrast, the subarachnoid space and choroid plexus are well preserved in cases of ventriculomegaly. It is difficult to evaluate subarachnoid space in the axial plane because the subarachnoid space is observed in the parietal side of the hemispheres. It is suggested that the evaluation of enlarged ventricles should be done in the parasagittal and coronal views by transvaginal approach to the fetal brain or 3D multidimensional analysis (Fig. 2). As a screening examination, the measurement of atrial width (AW) is useful with a cutoff value of 10mm (28,29). In normal fetuses, blood flow waveforms of dural sinuses, such as the superior sagittal sinus, vein of Galen, and straight sinus have pulsatile pattern (30). However, in cases with progressive hydrocephalus, normal pulsation disappears and blood flow waveforms become flat pattern (30). Intracranial venous blood flow may be related to increased intracranial pressure.

Variety of Mild Ventriculomegaly with AW 10–15mm

Mild ventriculomegaly is defined as of a width of the atrium of the lateral cerebral ventricles of 10 to 15mm. It has been reported that mild ventriculomegaly with AW 10 to 15mm resolves in 29%, remains stable in 57%, and progresses in 14% of the cases during pregnancy (31). In cases of

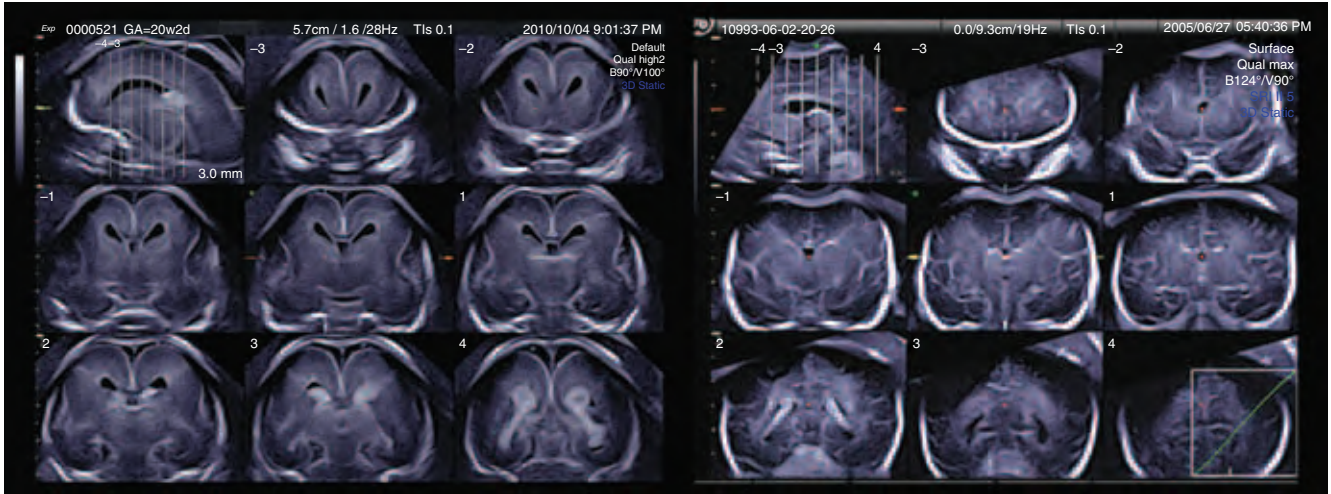

Figure 1 Tomographic ultrasound imaging by three-dimensional transvaginal sonography. Normal brain at 20 weeks (left) and 31 weeks (right) on the coronal cutting sections. Note the changing cortical development between those two different gestational stages.

Figure 2 Hydrocephalus (left) and ventriculomegaly (right). Tomographic ultrasound imaging of X-linked hydrocephalus at 21 weeks (left) and ventriculomegaly at 25 weeks (right). Note the obliterated subarachnoid space in the hydrocephalic case compared with normal subarachnoid space in the ventriculomegaly case.

ventriculomegaly with AW of 10 to 13mm at referral, the ultimate fetal outcome and prognosis depends on associated abnormalities.

Generally, in cases of mild fetal ventriculomegaly with a normal karyotype and an absence of malformations, the outcome appears to be favorable (32). Piliu and his colleagues (33) reviewed 234 cases of borderline ventriculomegaly including an abnormal outcome in 22.8% and concluded that borderline ventriculomegaly carries an increased risk of cerebral maldevelopment, delayed neurologic development, and, possibly, chromosomal aberrations. Isolated mild ventriculomegaly with AW of 10 to 12mm may be normal variation. Signorelli and colleagues (34) described that their data of normal neurodevelopment between 18 months and 10 years after birth in cases of isolated mild ventriculomegaly (AW of 10–12mm) should provide a basis for reassuring counseling. Ouahba and colleagues (35) recently reported the outcome of 167 cases of isolated mild ventriculomegaly and concluded that in addition to associated anomalies, three criteria are often associated with an unfavorable outcome: AW greater than 12mm, progression of the enlargement, and asymmetrical and bilateral ventriculomegaly.

Moderate to Severe Ventriculomegaly and Hydrocephalus with AW>15mm

The term of “hydrocephalus” does not identify a specified disease, but is a generic term that means a group of pathologic conditions due to abnormal circulation of CSF. Treatment method of hydrocephalus should be selected according to age of onset and symptoms. Congenital hydrocephalus is classified into three categories by causes that disturb CSF circulation pathway: simple hydrocephalus, dysgenetic hydrocephalus, and secondary hydrocephalus (15,26).

1. Simple hydrocephalus

Simple hydrocephalus, caused by developmental abnormality that is localized within CSF circulation pathway, includes aqueductal stenosis, atresia of foramen Monro, and maldevelopment of arachnoid granulation.

2. Dysgenetic hydrocephalus

Dysgenetic hydrocephalus indicates hydrocephalus as a result of cerebral developmental disorder in early developmental stage and includes hydranencephaly, holoprosencephaly, porencephaly, schizencephaly, Dandy-Walker malformation, dysraphism, and Chiari malformation.

Figure 3 Encephalocele. Tomographic ultrasound imaging (upper) and MR imaging (lower) in a case of encephalocele at 28 weeks of gestation.

3. Secondary hydrocephalus

Secondary hydrocephalus is a generic term indicating hydrocephalus caused by intracranial pathologic condition, such as brain tumor, intracranial infection, and intracranial hemorrhage.

In cases with progressive hydrocephalus, there may be seven stages of progression: (i) increased fluid collection of lateral ventricles, (ii) increased intracranial pressure, (iii) dangling choroid plexus, (iv) disappearance of subarachnoid space, (v) excessive extension of the dura and superior sagittal sinus, (vi) disappearance of venous pulsation, and finally (vii) enlarged skull (24). In general, both hydrocephalus and ventriculomegaly are still evaluated by the measurement of biparietal diameter and AW in transabdominal axial section.

Although all cases have similar ventricular appearance, the causes of ventriculomegaly vary, such as Chiari type II malformation, aqueductal obstruction, and amniotic band syndrome (ABS). In the case of ABS, amniotic band attached to the scalp resulted in partial cranial bone defect and a small cephalocele, which may have caused Monro obstruction and enlarged ventricles.

From our data of 23 ventriculomegaly cases with AW > 15 mm (27), 9 cases (39.1%) had no other CNS abnormality, but 2 out of those 9 were complicated with chromosomal aberration. Four cases out of seven without any complication had favorable postnatal prognosis after ventricular-peritoneal shunting procedure. Among the rest of 14 cases with other CNS abnormalities, holoprosencephaly was detected in 5 cases and myelomeningocele in 5 cases (27).

NEURAL TUBE DEFECTS

Cranium Bifidum

Cranium bifidum is classified into four types of encephaloschisis (including anencephaly and exencephaly), meningocele, encephalomeningocele, encephalocystocele, and cranium bifidum occultum. Encephalocele occurs in the occipital region in 70% to 80%. Acrania, exencephaly, and anencephaly are not independent anomalies. It is considered that dysraphia (absent cranial vault, acrania) occurs in very early stage and disintegration of the exposed brain (exencephaly) during the fetal period results in anencephaly. Encephalocele (Fig. 3) is often observed in the median section and in the parieto-occipital part. ABS should be differentiated from acrania during early pregnancy, because ABS has completely different pathogenesis from acrania/exencephaly. In cases of ABS, cranial destruction occurs secondary to an amniotic band; similar appearance is often observed.

Spina Bifida

Spina bifida aperta, manifest form of spina bifida, is classified into four types: meningocele, myelomeningocele, myelocystocele, and myeloschisis. In myelomeningocele, the spinal cord and its protective covering (the meninges) protrude from an opening in the spine. In meningocele, the spinal cord develops normally but the meninges protrude from a spinal opening. The most common location of the malformations is the lumbar and sacral areas of the spinal cord. Chiari type II malformation and secondary hydrocephalus/ventriculomegaly are mostly, and scoliosis or kyphosis occasionally, associated with open spina bifida. Surface anatomy of the fetus and appearance of clubfoot, which occasionally manifests early in

Figure 4 Myelomeningocele. Two-dimensional (2D) ultrasound of myelomeningocele (upper left) and myelomeningocele with kyphosis (lower left), 3D ultrasound (middle), and MRI (right). Right upper MRI shows Chiari type II malformation (arrows). Clear visualization of spinal cord protrusion is obtained by 2D ultrasound and MRI. The 3D ultrasound images show the bony structure that helps to determine the level of spina bifida and lower extremity appearance.

mid-gestation as a complication of spinal bifida, are easily demonstrable by using 3D ultrasound. The 3D ultrasound with maximum mode can demonstrate bony structure (Fig. 4) and is helpful to detect the spinal levels of lesion and to predict neurologic prognosis. Although most myelomeningoceles are demonstrated as a protruding swelling, fetal back appears flat in the type of myeloschisis; therefore, open spina bifida may be often overlooked. Because more than 80% of cases of open spina bifida are associated with ventriculomegaly due to Chiari type II malformation, demonstration of ventriculomegaly is usually the first observable sign leading to the detailed examination of spine and the subsequent diagnosis of spinal bifida.

PROSENCEPHALIC DEVELOPMENTAL DISORDER

Holoprosencephaly

Holoprosencephalies are classified into three varieties: alobar, semilobar, and lobar types. Facial abnormalities such as cyclopia, ethmocephaly, cebocephaly, flat nose, cleft lip, and palate are invariably associated with holoprosencephaly and extracerebral abnormalities. Facial abnormalities are often associated with holoprosencephaly.

Agenesis of the Corpus Callosum

Absence of the corpus callosum (AOCC) is divided into complete agenesis, partial agenesis, or hypogenesis. Chromosomal aberration or syndromic diseases may occasionally be related to agenesis of the corpus callosum. Colpocephalic ventriculomegaly with disproportionate enlargement of trigones, occipital horns and temporal horns, and superior elongation of the third ventricle is usually observed. Interhemispheric cyst is often associated with AOCC and some cases are with pericallosal lipoma. Complete AOCC is

demonstrated in the coronal and sagittal sections by sonography and fetal MRI. Typical shape of enlarged ventricles associated with AOCC is colpocephaly with large occipital horns. Typical radiated formation of brain vessels in the sagittal section is demonstrated by color Doppler study. As the corpus callosum is depicted after 17 or 18 weeks of gestation by ultrasound, it is impossible to diagnose agenesis of the corpus callosum prior to this age (36).

POSTERIOR FOSSA ANOMALY

Chiari Malformation

Chiari classified anomalies with cerebellar herniation in the spinal canal into three types by contents of herniated tissue: contents of type I is a lip of cerebellum; type II part of cerebellum, fourth ventricle and medulla oblongata, and pons; and type III large herniation of the posterior fossa. Thereafter, type IV with just cerebellar hypogenesis was added. However, this classification occasionally leads to confusion in neuroimaging diagnosis. Therefore, at present, the classification as below is advocated: type I not associated with myelomeningocele, type II (schematic picture is shown in Fig. 5 upper left) associated with myelomeningocele, type III associated with cephalocele or craniocervical meningocele, and type IV associated with marked cerebellar hypogenesis and posterior fossa shrinking. Chiari malformation occurs according to i) inferior displacement of the medulla and the fourth ventricle into the upper cervical canal, ii) elongation and thinning of the upper medulla and lower pons and persistence of the embryonic flexure of these structures, iii) inferior displacement of the lower cerebellum through the foramen magnum into the upper cervical region, and iv) a variety of bony defects of the foramen magnum, occiput, and upper cervical vertebra (37). Hydrocephalus is caused by

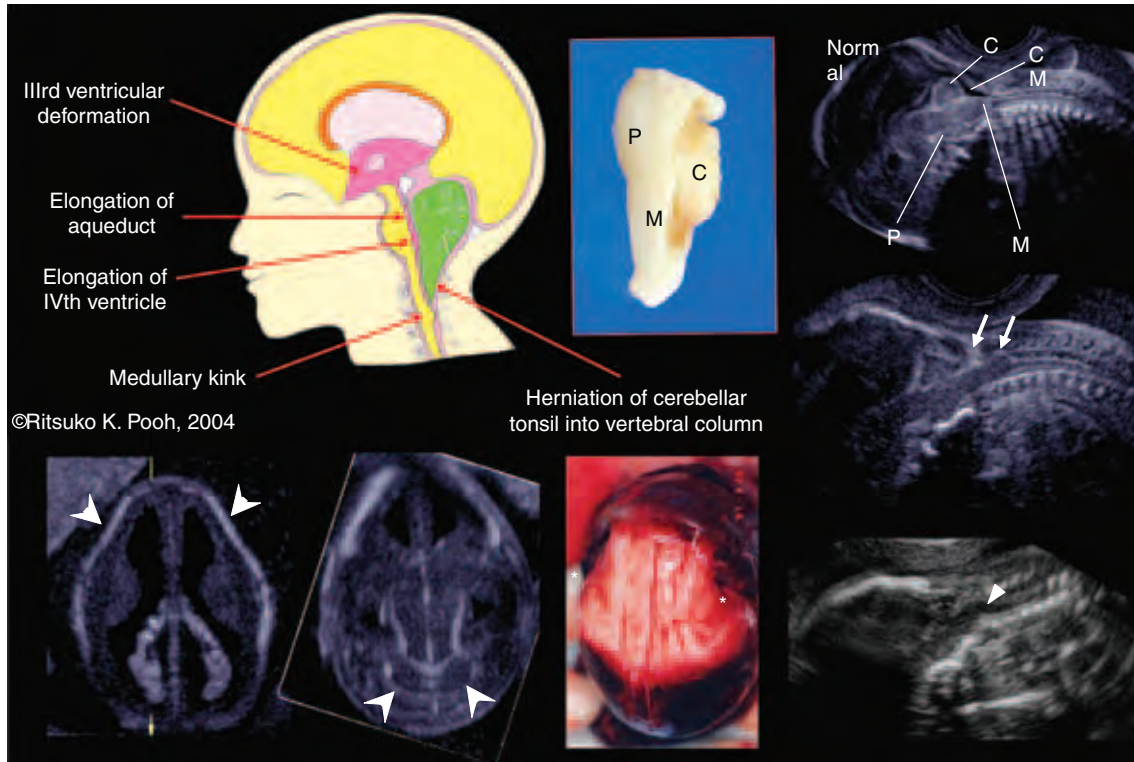

Figure 5 Chiari type II malformation. Schematic picture of Chiari type II malformation (upper left). Elongation and stenosis of the aqueduct and fourth ventricle in the specimen from aborted fetus at 21 weeks (upper middle) are shown. Lower brain images are lemon sign and banana sign from the left. Arrowheads indicate indentations of lemon-shaped skull and banana-shaped cerebellum. Lower middle picture shows the lemon sign on the autopsy of an aborted fetus. Right sagittal ultrasound images show normal cerebrospinal structure, Chiari type II malformation without kink, and Chiari II with medullary kink from above.

obstruction of fourth ventricular outflow or associated aqueductal stenosis. Eighty-eight percent of fetuses with open spina bifida develop ventriculomegaly, by 21 weeks of gestation in the majority of cases (38). As prenatal neuroimaging of Chiari malformation, lemon and banana signs (39) are circumstantial evidences of Chiari malformation, which are easily demonstrated in the early second trimester. Lemon sign indicates deformity of the frontal bone, and banana sign indicates abnormal shape of cerebellum without cisterna magna space (Fig. 5, lower). Herniation of the cerebellar tonsil and medulla oblongata and medullary kink are demonstrable (Fig. 5, right). Small clivus–supraocciput angle is seen in cases of Chiari malformation (40).

DANDY WALKER MALFORMATION, DANDY WALKER VARIANT, MEGACISTERNA MAGNA

During development of the fourth ventricular roof, a delay or total failure of the foramen of Magendie to open occurs, allowing a buildup of CSF and development of the cystic dilation of the fourth ventricle. Despite the subsequent opening of the foramina of Luschka (usually patent in Dandy–Walker malformation), cystic dilatation of the fourth ventricle persists and CSF flow is impaired. At present, the term “Dandy–Walker complex” by Barkovich et al. (41) is used to indicate a spectrum of anomalies of the posterior fossa that are classified by axial CT scans as it follows. Dandy–Walker malformation, Dandy–Walker variant, and megacisterna magna seem to represent a continuum of developmental anomalies of the posterior fossa (41). Figure 6 (upper) shows the differential diagnosis of hypoechoic lesion

of the posterior fossa, and typical sonographic images of Dandy–Walker malformation are shown in the lower part of Figure 6.

- *(Classic) Dandy–Walker malformation:* cystic dilatation of fourth ventricle, enlarged posterior fossa, elevated tentorium, and complete or partial agenesis of the cerebellar vermis.
- *Dandy–Walker variant:* variable hypoplasia of the cerebellar vermis with or without enlargement of the posterior fossa.
- *Megacisterna magna:* enlarged cisterna magna with integrity of both cerebellar vermis and fourth ventricle.

NEURONAL PROLIFERATION DISORDER

Microcephaly

Microcephaly is defined as a head circumference that is more than two standard deviations below the normal mean for age, sex, race, and gestation. Infections such as with rubella, cytomegalovirus, varicella (chicken pox) virus, and toxoplasmosis, radiation, medications, chromosome abnormalities, and genetic diseases may cause microcephaly. Occasionally, microcephaly occurs with late onset during pregnancy (42).

NEURONAL MIGRATION DISORDERS

Neuronal migration disorders are caused by the abnormal migration of neurons in the developing brain and nervous system. Neurons must migrate from the areas where they are born to the areas where they will settle into their proper neural

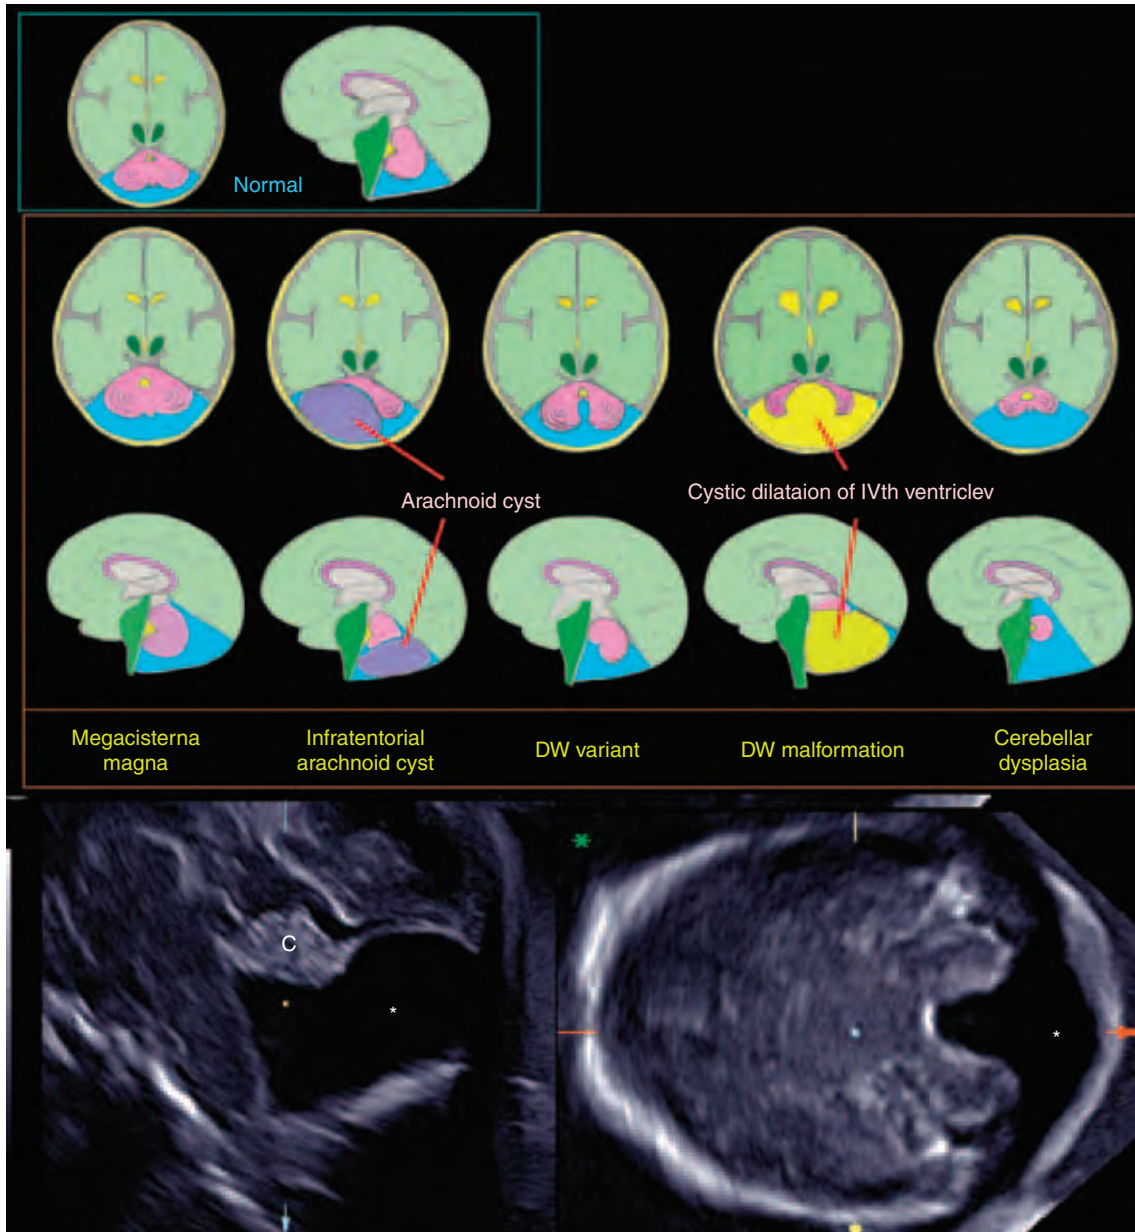

Figure 6 Differential diagnosis of hypoechoic lesion of the posterior fossa (upper) and typical sonographic images of Dandy–Walker malformation (lower). Abbreviation: C, cerebellum. Asterisks indicate cystic dilatation of the fourth ventricle.

circuits. Neuronal migration, which occurs as early as the second month of gestation, is controlled by a complex assortment of chemical guides and signals. When these signals are absent or incorrect, neurons do not end up where they belong. This can result in structurally abnormal or missing areas of the brain in the cerebral hemispheres, cerebellum, brainstem, or hippocampus, including schizencephaly, porencephaly, lissencephaly, agyria, macrogyria, pachygyria, microgyria, micropolygyria, neuronal heterotopias (including band heterotopia), agenesis of the corpus callosum, and agenesis of the cranial nerves. Symptoms vary according to the specific disorder and the degree of brain abnormality and subsequent neurologic losses, but often feature poor muscle tone and motor function, seizures, developmental delays, mental retardation, failure to grow and thrive, difficulties with feeding, swelling in the extremities, and a smaller than normal head. Most infants with a neuronal migration disorder appear

normal, but some disorders have characteristic facial or skull features.

Lissencephaly

Lissencephaly is very rare and characterized by a lack of gyral development and divided into two types.

Lissencephaly type I shows a smooth surface of the brain and cerebral wall is similar to that of an approximately 12-week-old fetus (43). *Isolated lissencephaly* (Fig. 7) or *Miller–Dieker syndrome* is associated with additional craniofacial abnormalities, cardiac anomalies, genital anomalies, sacral dimple, creases, and/or clinodactyly. *Lissencephaly type II* shows cobblestone appearance. *Walker–Warburg syndrome* with macrocephaly, congenital muscular dystrophy, cerebellar malformation, and retinal malformation or *Fukuyama congenital muscular dystrophy* with microcephaly and congenital muscular dystrophy has been proven.

Figure 7 Changing appearance of Sylvian fissure in the anterior coronal section (upper) and abnormal Sylvian fissure in cases of migration disorder (lower). At 20 weeks of gestation, bilateral Sylvian fissures (arrowheads) appear to be indentations (left). With cortical development, Sylvian fissures are formed during the latter half of second trimester (middle) and become as lateral sulci. Sylvian fissure appearance is one of the most reliable ultrasound markers for the assessment of cortical development. Lower MR images show coronal cutting sections of various migration disorders after 30 weeks of gestation: Isolated lissencephaly, cobblestone lissencephaly, and pachygyria from left.

Recently, classification has been made based on associated malformations and etiologies.

- Classic lissencephaly (previously known as type I lissencephaly)
 - Lissencephaly due to LIS1 gene mutation
 - Type I isolated lissencephaly
 - Link to chromosome 17p13.3 and chromosome Xq24-q24
 - Miller–Dieker syndrome link to chromosome 17p13.3
 - Lissencephaly due to doublecortin gene mutation
 - Lissencephaly type I, isolated, without other genetic defects
- Lissencephaly X-linked with AOCC (ARX gene)
- Lissencephaly with cerebellar hypoplasia
 - Norman–Roberts syndrome (mutation of reelin gene)
- Microlissencephaly (lissencephaly and microcephaly)
- Cobblestone lissencephaly (previously known as type II lissencephaly)
 - Walker–Warburg syndrome, HARD(E) syndrome
 - Fukuyama syndrome linked to chromosome 9q31, fukutin (44)
 - Muscle–eye–brain disease

A few reports of prenatal diagnosis of lissencephaly have been published (45–47). It was described that without previous history of an affected child, lissencephaly probably cannot be reliably made until 26 to 28 weeks of gestation (48). However, from recent study in the assessment of Sylvian fissure appearance during pregnancy, there might be a potential of earlier diagnosis of migration disorders (49).

Schizencephaly

Schizencephaly is a disorder characterized by congenital clefts in the cerebral mantle, lined by pia-ependyma, with

communication between the subarachnoid space laterally and the ventricular system medially. Of that 63% is unilateral and 37% bilateral. Frontal region is 44% and frontoparietal is 30% (43). Schizencephaly is associated with ventriculomegaly, microcephaly, polymicrogyria, gray matter heterotopias, dysgenesis of the corpus callosum, absence of the septum pellucidum, and optic nerve hypoplasia.

OTHER CONGENITAL ANOMALIES

Arachnoid Cyst, Interhemispheric Cyst

Congenital or acquired cyst, with prevalence of 1% of intracranial masses in newborns, is lined by arachnoid membranes and filled with fluid collection, which is of the same characteristic as the CSF. The number of cysts is mostly single, but two or more cysts can be occasionally observed. Location of arachnoid cyst is various, and it is said that approximately 50% of cysts occurs from the Sylvian fissure (middle fossa), 20% from the posterior fossa, and 10% to 20% each from the convexity, suprasellar, interhemisphere, and quadrigeminal cistern in the pediatric field. Interhemispheric cysts are commonly associated with agenesis or hypogenesis of the corpus callosum. Callosal agenesis with interhemispheric cyst is classified as two types (50). Type I cysts appear to be an extension or diverticulum of the third or lateral ventricles, whereas type 2 cysts are loculated and do not communicate with the ventricular system. Prenatal neuroimaging examples of interhemispheric cyst, middle fossa arachnoid cyst, and suprasellar arachnoid cyst are shown in Figure 8. As intrauterine spontaneous resolution or changing cyst size is often seen during fetal period, serial scanning is important. Detection in the first trimester was

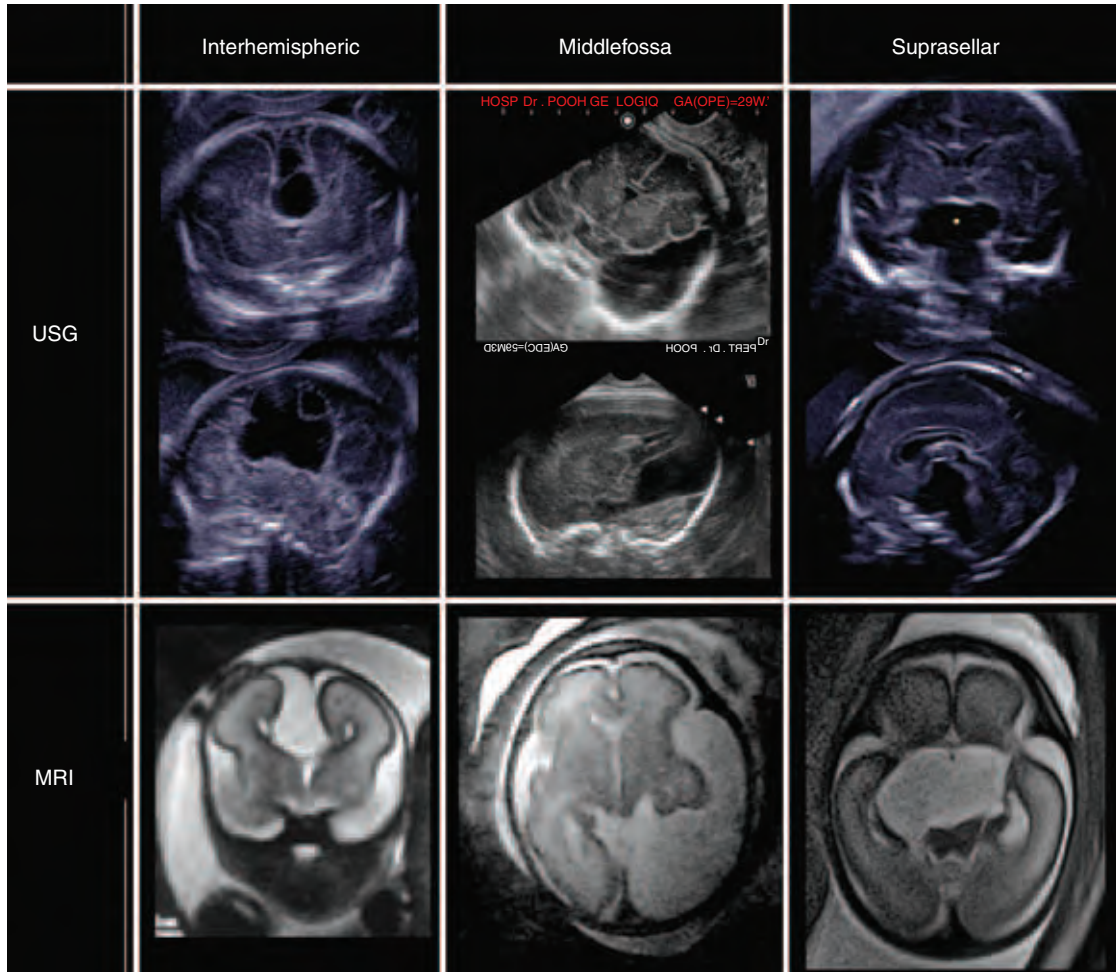

Figure 8 Prenatal neuroimaging of interhemispheric cyst, middle fossa arachnoid cyst, and suprasellar arachnoid cyst. Abbreviations: USG, ultrasonography; MRI, magnetic resonance imaging.

reported (51). Prognosis is generally good. Many are asymptomatic and remain quiescent for years, although others may expand and cause neurologic symptoms by compressing adjacent brain, development of ventriculomegaly, and/or expanding the overlying skull.

Brain Tumors

Brain tumors are divided into *teratomatous*, most are the commonly reported brain tumors, and *nonteratomatous*. Nonteratomatous tumors includes *neuroepithelial tumor*, such as medulloblastoma, astrocytoma, choroid plexus papilloma, choroid plexus carcinoma, ependymoma, ependymoblastoma, and *mesenchymal tumor* such as craniopharyngioma, sarcoma, fibroma, hemangioblastoma, hemangioma, and meningioma, and *others* such as lipoma of the corpus callosum, subependymal giant-cell astrocytoma associated with tuberous sclerosis (often accompanied by cardiac rhabdomyoma) (52). Depending on the site and vascularity, these tumors may lead to macrocrania or local skull swelling, epignathus, secondary hydrocephalus, intracranial hemorrhage, intraventricular hemorrhage, polyhydramnios, and heart failure by high-cardiac output (53) or hydrops. Intracranial masses with solid, cystic, or mixture pattern with or without visualization of hypervascularity can be detected by ultrasound and fetal MRI. Brain tumor should be considered in cases with unexplained intracranial hemorrhage.

Craniosynostosis

Craniosynostosis is the premature closure of cranial suture, which may affect one or more cranial sutures. Simple sagittal synostosis is most common. Various cranial shapes depend on affected suture(s).

Sagittal suture	Scaphocephaly or dolichocephaly
Bilateral coronal suture	Brachycephaly
Unilateral coronal suture	Anterior plagiocephaly
Metopic suture	Trigonocephaly
Lambdoid suture	Acrocephaly
Unilateral lambdoid suture	Posterior plagiocephaly
Coronal/lambdoid/metopic or squamous/sagittal suture	Cloverleaf skull
Total cranial sutures	Oxycephaly

Craniosynostosis due to specific syndromes (syndromic craniosynostosis) is usually associated with additional specific features and therefore correct differentiation between these conditions is possible. Examples include *Crouzon syndrome* (acrocephaly, synostosis of coronal, sagittal and lambdoid sutures and ocular proptosis, maxillary hypoplasia), *Apert syndrome* (brachycephaly, irregular synostosis, especially coronal suture and midfacial hypoplasia, syndactyly, broad distal phalanx of thumb, and big toe), *Pfeiffer syndrome* (brachycephaly, synostosis of coronal and/or sagittal sutures

Figure 9 Three-dimensional B-flow detection, color Doppler image, and MRI of vein of Galen aneurysmal malformation.

and hypertelorism, broad thumbs and toes, and partial syndactyly), and *Antley–Bixler syndrome* (brachycephaly, multiple synostosis, especially of coronal suture and maxillary hypoplasia, radiohumeral synostosis, choanal atresia, arthrogryposis). Abnormal craniofacial appearance can be detected prenatally by 2D/3D ultrasound (26,54–56).

VEIN OF GALEN ANEURYSMAL MALFORMATION

It is a congenital malformation of blood vessels of the brain. The main structure is direct arteriovenous fistulas in which blood shunts from choroidal and/or quadrigeminal arteries into an overlying single median venous sac. Vein of Galen aneurysm is not “aneurysm” but “arteriovenous malformation (AVM).” Vein of Galen aneurysmal malformation (VGAM) is a choroidal type of AVM involving the vein of Galen forerunner. This is distinct from an AVM with venous drainage into a dilated, but already formed, vein of Galen (57). Associated anomalies are cardiomegaly, high cardiac output, secondary hydrocephalus, macrocrania, cerebral ischemia (intracranial steal phenomenon), and subarachnoid/cerebral/intraventricular hemorrhages. The 3D B-flow detection, color Doppler image, and MRI of VGAM are shown in Figure 9.

Pericallosal Lipoma

Intracranial lipomas are congenital malformations composed of mature adipocytes. They are usually located in the midline, particularly in the pericallosal region, a hemispheric location accounting for only 3% to 7% of cases. Two morphologic types of pericallosal lipoma have been described (58,59).

Tubulonodular type with generally greater than 2cm in diameter (often smaller than 2cm in fetal period) has a high incidence of corpus callosum dysgenesis, frontal lobe anomalies, and frontal encephaloceles. *Curvilinear type*, which comprises thin, posteriorly situated lipomas curving around the splenium, is generally associated with a normal corpus callosum and otherwise has a low incidence of associated anomalies. High echogenic mass can be easily demonstrated by ultrasound. Several reports on prenatal diagnosis have been published (60–62).

ACQUIRED BRAIN ABNORMALITIES IN UTERO

In terms of encephalopathy or cerebral palsy, “*timing of brain insult, antepartum, intrapartum, or postpartum?*” is one of the serious controversial issues including medico-socio-legal-ethical problems (15). Although brain insults may relate to antepartum events in a substantial number of term infants with hypoxic-ischemic encephalopathy, the timing of insult cannot always be certain. It is a difficult task to provide a precise prediction of subsequent development of cerebral palsy after a given antepartum event or complication. Fetal heart rate monitoring cannot reveal the presence of encephalopathy, and neuroimaging by ultrasound and MR imaging is the most reliable modality for disclosure of silent encephalopathy. In many cases with cerebral palsy with acquired brain insults, especially term-delivered infants with reactive fetal heart rate tracing and good Apgar score at delivery, recent imaging studies have confirmed the presence of brain insult in utero, suggesting that the majority of cerebral palsy are of antepartum rather than intrapartum in origin.

Figure 10 Intracerebral hemorrhage at 32 weeks of gestation. Transvaginal three-dimensional tomographic ultrasound images show unilateral ventriculomegaly due to cerebral hemorrhage and fresh intracerebral hemorrhage (arrows), which is going to change into porencephaly.

Intracranial Hemorrhage

Intracranial hemorrhage includes subdural hemorrhage, primary subarachnoid hemorrhage, intracerebellar hemorrhage, intraventricular hemorrhage, and intraparenchymal hemorrhage other than cerebellar hemorrhage (63). Hydrocephalus, hydranencephaly, porencephaly, and/or microcephaly are possible secondary complications, which are often detectable by imaging studies. Unilateral ventriculomegaly due to cerebral hemorrhage and fresh intracerebral hemorrhage is shown in Figure 10. The hyperechoic lesion is changing into porencephaly in a short period.

Porencephaly

Porencephaly or porencephalic cyst is defined as fluid-filled spaces replacing normal brain parenchyma and may or may not communicate with the lateral ventricles or subarachnoid space. The causes may be ischemic episode, trauma (64), demise of one twin, Intracerebral hemorrhage, and infection of cytomegalovirus (65). Some cases in utero have been reported (66,67). Porencephalic cyst never causes a mass effect, which is observed in cases with arachnoid cyst or other cystic mass lesions. This condition is acquired brain insult and differentiated from schizencephaly of migration disorder.

FETAL PERIVENTRICULAR LEUKOMALACIA

Multifocal areas of necrosis are found deep in the cortical white matter, which are often symmetrical and occur adjacent to the lateral ventricles. Periventricular leukomalacia (PVL) represents a major precursor for neurologic and intellectual impairment, and cerebral palsy in later life. About

25% to 75% of premature infants at autopsy are complicated with periventricular white matter injury. However, clinically, incidence may be much lower. About 5% to 10% of infants have less than 1500g birth weight. In term infants, PVL is very rare.

CONCLUSIONS

Recent advances of imaging technology have provided us objective neuroimaging diagnosis as shown in this article. Longitudinal and careful evaluation of neurologic short-term/long-term prognosis should be required according to precise prenatal diagnosis, for proper counseling and management based on accurate evidence.

53 Erythroblastosis fetalis

Avinash Patil, Brian Brocato, Rebecca A. Uhlmann, and Giancarlo Mari

INTRODUCTION

Red blood cell (RBC) alloimmunization, or isoimmunization, is the development of maternal antibodies to fetal RBC antigens. Hemolytic disease of the newborn/fetus is a hemolytic anemia that results from the lysis of the fetal RBCs by maternal antibodies. It is often characterized by excessive erythroblasts in the fetal bone marrow and circulation (erythroblastosis fetalis). Other features include generalized edema (hydrops fetalis) and hepatosplenomegaly. Alloimmunization and hemolytic disease of the newborn/fetus most commonly occur when maternal antibodies form against paternally derived Rhesus (D) antigens of the fetus, which is termed Rhesus (Rh) alloimmunization.

HISTORY

A midwife, Louyse Bourgeois, first described hemolytic disease of the newborn in 1609 after delivering a set of twins. One twin was a stillbirth with hydrops and the other with severe jaundice died a few days later. Sylvius, in 1679, reported cases of hydrops combined with severe jaundice, which was thought to be caused by a blockage of the "bile tract." Person and Cheyne, in 1799 and 1802, respectively, reported cases of infant fatalities with severe jaundice in which the autopsy reports showed patent bile ducts. In 1905, Auden described the features of hemolytic disease of the newborn. He noted that the first born was often unaffected and it was the subsequent pregnancies that showed hydrops and jaundice. While reporting a case of hydrops fetalis in 1912, Rautmann was the first to use the term "erythroblastosis." In 1923, Ottenburg wrote a paper in which he discussed "accidental placental transfusion of incompatible blood." This was followed by Darrow's hypothesis in 1938 that hemolysis was caused by the passage of anti-fetal hemoglobin from mother to fetus (1).

It was not until 1940 that the Rh antibody was discovered. Landsteiner and Wiener discovered the agglutination of human red cells when mixed with the antiserum of the *Macacus rhesus* and designated this property of human blood "Rh" (2). Wiener and Peters then demonstrated the transfusion reactions caused by giving Rh-positive blood to Rh-negative patients (1). It was in 1941 that Levine described several cases of infants with erythroblastosis fetalis in which the hemolytic disease of the fetus was caused by maternal Rh isoimmunization (3).

In the 1950s and 1960s, we began to see invasive testing take place to evaluate the fetus at risk for erythroblastosis fetalis. In 1956, Bevis, using spectrophotometry, measured blood pigments in amniotic fluid and suggested that the concentration of bilirubin in the amniotic fluid was an indicator of the severity of the hemolytic process in the baby (4). In 1961, Sir William Liley, using amniocentesis and spectrophotometric measurements, described the use of spectral absorption curves

to measure the degree of fetal anemia and suggested that these findings could be used to select the optimal time for delivery (5). He proposed a graph with three zones to indicate the severity of the disease from 27 weeks of gestation to term, which was known as the Liley method. In 1993, a modification of the Liley method by Queenan et al. expanded the normal spectrophotometric measurements to include 14 to 40 weeks of gestation and proposed four management zones (6). In 2000, Mari et al. proposed a noninvasive method to diagnose fetal anemia by ultrasonographic measurement of the middle cerebral artery peak systolic velocity (MCA-PSV) (7).

Before the 1960s, fetuses determined to be at significant risk for hemolytic disease could only be offered induction of labor at 34 weeks of gestation. Although perinatal mortality was greatly reduced by selective induction, there were no therapies for the severely affected fetus at less than 34 weeks of gestation (8). In 1963, after identifying an anemic fetus, Liley performed the first successful intraperitoneal fetal transfusion at 32 weeks of gestation and again at 33 weeks of gestation (8). At 34 weeks and 3 days of gestation, labor was induced and the mother eventually delivered via cesarean section a viable male infant weighing 2560g (8). The boy was named Grant Liley McLeod (9). In 1964, Freda and Adamson described the first intravascular exchange transfusion at 27 weeks of gestation via hysterotomy (10). A fetal leg was delivered through a small uterine incision, a catheter was placed in the femoral artery, and the transfusion was performed. Thirty-six hours later, preterm labor ensued and the infant died from complications of prematurity (10). In 1966, Asensio performed an intravascular exchange transfusion in Puerto Rico on a severely anemic fetus at 31 weeks of gestation. The technique was similar to that described by Freda and Adamson with a few modifications. The pregnancy continued for 3 weeks postoperatively and eventually delivered via cesarean section secondary to premature rupture of membranes. A viable female infant was born weighing 2034g and was discharged home 18 days after delivery (11). In 1973, Valenti used fetoscopy to perform the first aspiration of fetal blood from the umbilical cord and the blood samples were used to diagnose hemoglobinopathies (12). He proposed that the procedure could be used for intrauterine diagnosis and therapy. In 1978, Rodeck and Campbell described a technique to obtain pure fetal blood via fetoscopy in gestations ranging from 16 to 22 weeks (13). Rodeck proposed that since pure blood can be removed from the umbilical circulation via fetoscopy, transfusion should also be possible, and, in 1981, Rodeck described two cases of fetal blood transfusion directly into an umbilical vessel via fetoscopy (14). Both patients were initially transfused at 23 weeks of gestation: one fetus survived after cesarean delivery at 30 weeks of gestation, while the other underwent

an intrauterine demise at 26 weeks of gestation (14). And in 1982, Bang described a case of ultrasound-guided intravenous fetal transfusion in a fetus severely affected by Rh isoimmunization at 29 weeks of gestation. The patient delivered via cesarean section at 32 weeks of gestation and the neonatal period was unremarkable (15).

PATHOPHYSIOLOGY

Maternal alloimmunization occurs when the gravid patient develops an immune response to a paternally derived antigen found on the surface of the fetal RBC. The most common antigen to cause RBC alloimmunization is Rh (D). The majority of Rh (D) alloimmunization is the result of fetomaternal hemorrhage. Fetomaternal hemorrhage has been shown to affect 75% of pregnancies during or shortly after delivery (16). Less than 0.1 mL of fetal blood entering the maternal circulation causes most cases of alloimmunization (16). There are several clinical scenarios when a pregnancy is at risk for fetomaternal hemorrhage, the most significant of which is at the time of delivery. Other clinical scenarios that have demonstrated fetomaternal hemorrhage and the risk of RBC alloimmunization are found in Table 1.

Once Rh (D) alloimmunization has occurred, it is then possible for the maternal IgG antibodies to cross the placenta, attach to the fetal RBC Rh (D) antigen, and cause RBC destruction in the fetal spleen resulting in a hemolytic anemia. This fetal anemia stimulates erythropoietin and the bone marrow produces more RBCs. If the anemia is severe enough, the bone marrow alone may not be able to produce enough RBCs. In this case, erythropoiesis will take place outside of the bone marrow in sites such as the liver and spleen, causing hepatosplenomegaly. Erythropoiesis outside of the fetal bone marrow also will cause immature erythroblasts to appear in the circulation.

NOMENCLATURE

There are several systems of nomenclature used to classify the Rh antigens. The Fisher–Race is perhaps the most commonly used nomenclature system in obstetrics. In this system, there

are five major antigens: C, c, D, E, and e (note that there is no d antigen). A group of three antigens form one gene complex, such as CDe. One gene complex is inherited from each parent, thereby forming a person's genotype (such as CDe/cDE). The most common gene complexes are CDe, cde, and cDE, which are found in 41%, 39%, and 16% of the Caucasian population, respectively. The terms "Rh (D) positive" and "Rh (D) negative" describe the presence or absence of the D antigen. When a genotype includes the letter "d" (e.g., Cde), this is used to indicate the absence of the D antigen, which results in an Rh (D)-negative phenotype (18). The Rh genes are encoded on chromosome 1p34–p36. Rh (D)-negative status in Caucasians is due to a deletion of the Rh (D) gene on chromosome 1 (18).

In addition to the five major antigens in the Rh system, there are several variants. Of note is the antigen called weak D or Du. Among patients with weak D, alloimmunization is rare and anti-D immunoglobulin is not routinely indicated for prophylaxis (19).

Other antibodies outside of the Rh system have been identified, such as Kell, Duffy, and Kidd. Anti-Lewis antibodies do not cause hemolytic disease of the fetus/newborn because the Lewis antigens do not develop on the fetal RBC until after birth and the anti-Lewis antibody is of the IgM class, making it too large to cross the placenta into the fetal circulation. Table 2 displays a more complete list of antigens known to cause alloimmunization and the associated risks of hemolytic disease.

EPIDEMIOLOGY

The Rh (D)-negative blood type is found in 15% of Caucasians, 8% of African-Americans, and less than 1% of Asian populations. The highest known incidence is in the Basque population, where the rate of Rh (D)-negative status is 30%. In 2003, the incidence of Rh alloimmunization was 6.8 per 1000 live births in the United States (21). Fetal anemia from RBC alloimmunization occurs less than 1% of the time, and only 10% of those neonates will require transfusions.

DIAGNOSIS

All pregnant females should be tested for ABO blood group type, Rh (D) status, and the presence of erythrocyte antibodies at the time of their initial prenatal visit (19). This battery of tests should be repeated at the onset of every pregnancy. The intent of routine screening is to identify Rh (D)-negative females prior to the development of alloimmunization in order to provide Rh (D) immunoglobulin. Anti-D immunoglobulin prophylaxis, when properly administered, prevents more than 99% of cases of alloimmunization. The American Association of Blood Banks recommends reevaluation of Rh antibody status prior to the administration of Rh (D) immunoglobulin, postpartum, and after any traumatic events during the antepartum period. The advantage of a second screening test prior to administration of Rh (D) immunoglobulin at 28 weeks of gestation is the detection of those rare cases in which immunization occurs early in pregnancy. Unfortunately, there is no immunoglobulin available for the prevention of an RBC antigen reaction other than for Rh (D).

Rh (D)-positive females do not require further evaluation. As mentioned previously, mothers who are D positive, but

with D present in reduced quantities, formerly called Du, do not need anti-D prophylaxis. Mothers who are partial D positive, that is, lacking some epitopes of D, should receive anti-D immunoglobulin, since they are at risk for hemolytic disease (19). Rh (D)-negative females without alloantibodies require administration of Rh (D) immunoglobulin at defined intervals during pregnancy (see Management section). Rh (D)-negative females with preformed alloantibodies require further investigation to determine the potential for impact upon the fetus. The least invasive approach involves paternal testing utilizing antisera or DNA (PCR). If the father is homozygous for the D antigen, all his offspring will be at risk for anemia; if he is heterozygous, then 50% of the offspring will be at risk. If the father of the fetus/neonate is definitely known to be Rh (D) negative, neither antepartum nor postpartum anti-D prophylaxis needs to be administered.

Analysis of the fetal genotype is appropriate when the paternal genotype is heterozygous or uncertain. Amniocentesis with PCR of uncultured amniocytes is the most common method utilized, with a sensitivity and specificity of 98.7% and 100%, respectively, and positive and negative predictive values of 100% and 96.9%, respectively (22). Chorionic villus sampling (CVS) also has been utilized for this purpose, but is discouraged due to the increased risk of fetomaternal hemorrhage and alloimmunization (23). Another option is the analysis of maternal plasma or serum for fetal DNA. Greater than 90% accuracy exists in the second trimester due to the high concentrations of fetal DNA in maternal plasma (24–26).

MANAGEMENT OF UNAFFECTED PREGNANCIES

During the 1960s, efforts were made to prevent the formation of maternal antibodies. In 1961, Dr. Ronald Finn proposed that administration of antibodies to Rh (D)-negative mothers could prevent a maternal immune response to Rh (D)-positive fetal blood cells (27). In 1964, Dr. Vincent Freda, at Sing Sing Prison in Ossining, New York, conducted an experiment on Rh (D)-negative male prisoners in which he injected radiolabeled Rh (D)-positive blood cells. The men were then given anti-D serum and it was noted that the radiolabeled cells were removed rapidly from their systems (28). In 1966, RhoGAM[®] was first developed and found to be successful at preventing alloimmunization. It eventually was introduced in North America in 1968.

Anti-D immunoglobulin is routinely administered during pregnancy in Rh (D)-negative women without evidence of alloimmunization. The American Association of Blood Banks recommends dosing at 28 weeks of gestation, postpartum, and after any suspected episodes of fetomaternal hemorrhage. The majority of cases of fetomaternal hemorrhage occur during uncomplicated vaginal deliveries, with an average of 0.1 mL of fetal blood entering the maternal circulation and causing alloimmunization (29–32). Antepartum fetomaternal hemorrhage accounts for 1% to 2% of Rh alloimmunization (33). Common scenarios leading to alloimmunization include spontaneous, threatened, and induced abortions, ectopic pregnancy, CVS, amniocentesis, and external cephalic version.

While a variety of Rh immunoglobulin is available in the United States, RhoGAM was the first approved for clinical use and is the most commonly used. Other products that are available include HyperRHO[®] S/D, Rhophylac[®], and WinRho[®]

SDF. The primary difference in these products is the method of purification and subsequent mode of delivery. RhoGAM and HyperRHO S/D are processed by cold ethanol fractionation, resulting in a less purified product that requires intramuscular administration. By contrast, Rhophylac and WinRho SDF are prepared by chromatography, allowing for intravenous and intramuscular administration routes. Anti-D immunoglobulin is extracted from plasma of individuals with high-titer D IgG antibodies. The risk of transmission of viral infections or side effects is minimal to absent and is not a clinically significant factor.

In the United States, standard dosing of anti-D immunoglobulin for Rh (D)-negative women without evidence of alloimmunization is 300 µg given at 28 weeks of gestation, and again in the postpartum period if the neonate is Rh (D)-positive and delivery occurs at least 3 weeks after the first administration. This practice reduces the incidence of antenatal alloimmunization from 2% to 0.1% (16,34).

An alternate anti-D immunoglobulin prophylaxis regimen, used primarily in the United Kingdom, is 100 µg at 28 and 34 weeks of gestation, as well as after delivery if the neonate is Rh (D) positive. There is a trend for less immunization during pregnancy for all women [relative risk (RR) = 0.42, 95% confidence interval (CI): 0.15–1.17] and for women giving birth to an Rh (D)-positive infant (RR = 0.41, 95% CI: 0.16–1.04) compared with no prophylaxis. Overall risk was lowered to about 0.2% without any adverse effects (35–37). Although trials have shown a nonsignificant reduction in immunization at 2 to 12 months following the birth of an Rh-positive infant in women who had received anti-D (RR = 0.14, 95% CI: 0.02–1.15), they were significantly less likely to have a positive Kleihauer-Betke (KB) test during pregnancy (RR = 0.60, 95% CI: 0.41–0.88) and at the birth of an Rh (D)-positive infant (RR = 0.60, 95% CI: 0.46–0.79) (36). Similarly, in Canada, 100 to 120 µg are administered at 28 and 34 weeks of gestation.

Alloimmunization can infrequently occur prior to 28 weeks of gestation, leading to the recommendation that an antibody screen be performed at the time of immunoglobulin administration to detect preexisting maternal sensitization. One dose of Rh (D) immunoglobulin is effective for 12 weeks, with a half-life of 16 to 24 days, and should be re-dosed after that interval in antepartum patients. The anti-D immunoglobulin affects the antibody screen (38). Usually, the effect of the immunoglobulin is not present until 12 weeks after its administration.

Excessive maternal-fetal hemorrhage may require more than the typical dose of Rh (D) immunoglobulin. The standard dose of 300 µg can protect from maternal sensitization caused by up to 30 mL of fetal whole blood or 15 mL of fetal RBCs in the maternal circulation. Occurrence of maternal-fetal hemorrhage can be determined by the rosette test. The standard dose of Rh (D) immunoglobulin is given for negative results, while a positive result requires further testing. A KB test determines the percentage of fetal blood cells in maternal circulation by utilizing flow cytometry. This value is then multiplied by 50 to determine the volume of hemorrhage, and one unit (300 µg) of immunoglobulin is provided for every 30 mL of hemorrhaged volume. A maximum of five units may be given by intramuscular administration in a 24-hour period; alternatively, 600 µg may be provided intravenously

Figure 1 The steps to correctly sample the middle cerebral artery peak systolic velocity (MCA-PSV). (A) An axial section of the head is obtained at the level of the sphenoid bones; (B) color Doppler evidences the circle of Willis; (C) the circle of Willis is enlarged; (D) the color box is placed around the MCA; (E) the MCA is zoomed; and (F) the MCA flow velocity waveforms are displayed and the PSV is measured at its proximal point, after the origin from the internal carotid artery, and at a 0° angle, thus avoiding angle corrections. *Source:* From Ref. 45.

every 8 hours until the entire dose is given. Some clinicians have advocated the KB test for all Rh (D)-negative women at delivery, since 50% of cases requiring more than the standard postpartum dose of anti-D immunoglobulin can be missed by high-risk situation screening only (39). The risk of fetomaternal hemorrhage greater than 30mL is approximately 0.1% to 0.2%.

Anti-D immunoglobulin given within 72 hours after childbirth is associated with a 96% decreased incidence of Rh (D) alloimmunization 6 months after birth and an 88% decreased incidence of Rh (D) alloimmunization in a subsequent pregnancy in Rh (D)-negative women who have given birth to an Rh (D)-positive infant (40). These benefits

are seen regardless of the ABO status of the mother and baby. Anti-D immunoglobulin can be given as late as 28 days postpartum if indicated but previously not given. Anti-D immunoglobulin is given to all Rh (D)-negative women after confirmation from cord blood of the Rh (D)-positive status of the neonate. Even when immunoglobulin is correctly administered, alloimmunization can still occur in the antepartum period in up to 2% of women with postpartum anti-D administration only. The risk of Rh (D) alloimmunization remains because of inadvertent antepartum or postpartum omission, failure to use the drug due to other antenatal complications, and insufficient dosing at delivery in cases of large volume fetomaternal hemorrhage.

Table 3 Reference Ranges for Fetal Hemoglobin Concentrations as a Function of Gestational Age^a

Week of gestation	Multiples of the median (MoM) grams per deciliter

MANAGEMENT OF RBC-ALLOIMMUNIZED PREGNANCIES

If Rh (D) antibodies are detected in the maternal circulation on the antibody screen, for example, by a positive indirect Coombs' test, the patient is considered alloimmunized. Among Rh (D)-alloimmunized pregnancies, mild-to-moderate hemolytic anemia and hyperbilirubinemia occur in 25% to 30% of fetuses/neonates, and 25% of those can develop hydrops (41). With correct management, the perinatal survival rate in cases of anemia is >90%; when fetal hydrops is present, survival is often >80%. There is no trial that has assessed the best management for RBC-alloimmunized pregnancies, but fetal transfusion is probably the most beneficial of all fetal therapies available. Although it is reported that the risk of fetal demise is between 1% and 2% for each fetal blood sampling (FBS), there are situations in which the risk is much higher, for example, when cordocenteses and transfusions are performed at gestational ages as early as 15 to 18 weeks.

Once the fetal D antigen is known to be present in an alloimmunized pregnancy, antenatal management centers on monitoring the situation and preventing fetal hemolysis. In patients at risk, it is important to perform a first-trimester ultrasound to establish the gestational age. Assessment for the risk of fetal anemia depends on the history of Rh complications in previous pregnancies, the titer of RBC antibodies, and MCA-PSV values (22). Determination of the maternal titer using an indirect Coombs' test is the most common screening tool used to determine the degree of alloimmunization. Titer values represent the highest level of dilution that can produce an agglutination reaction. Critical titers correspond to the level of antibodies that place a fetus at significant risk for anemia/hydrops, with 1:16 = 10%, 1:32 = 25%, 1:64 = 50%, and 1:128 = 75% risk of anemia. The critical titer should be determined in each laboratory due to large differences in measurements between laboratories. In most laboratories, the critical titer for anti-D is approximately 1:16 in albumin or 1:32 using an indirect Coombs' test. For anti-Kell, the critical titer is 1:8. Maternal titers are typically drawn monthly until 24 weeks of gestation and then are repeated biweekly to detect worsening alloimmunization. Antenatal testing from 32 weeks of gestation forward and scheduled induction of labor by 38 weeks of gestation are routinely performed.

Traditionally, spectral analysis of amniotic fluid at 450 nm (ΔOD_{450}) to detect bilirubin levels has been used as a measure of hemolytic activity. Due to its dependence upon gestational age, the ΔOD_{450} is plotted on a Queenan curve (6) (14–40 weeks of gestation) or a Liley graph (8) (27 weeks of gestation to term).

Contemporary management of alloimmunized pregnancies emphasizes the noninvasive detection of worsening fetal anemia through the use of ultrasound. With fetal anemia, decreased blood viscosity leads to increased venous return, consequently increasing cardiac output with increased blood flow velocity in all vessels. Degrees of anemia correlate with corresponding changes in blood velocity. Mari et al. have previously shown that Doppler ultrasound measurement of the MCA-PSV can reliably identify fetal anemia. Compared with amniocentesis for ΔOD_{450} assessment, the MCA-PSV is associated with a 70% to 80% reduction in the number of invasive tests (22). The MCA-PSV is also more accurate than amniocentesis in detecting fetal anemia (7,42–44).

Screening with the MCA-PSV can be started as early as 15 weeks of gestation (8). The main advantage of the MCA is that it is easy to measure at a 0° angle, which is essential for an accurate measurement of the true blood flow. The steps for the correct measurement of the MCA-PSV are (i) an axial section of the head is obtained at the level of the sphenoid bones; (ii) color Doppler evidences the circle of Willis; (iii) the circle of Willis is enlarged; (iv) the color box is placed around the MCA; (v) the MCA is zoomed; and (vi) the MCA flow velocity waveforms are displayed and the PSV is measured at its proximal point, after the origin from the internal carotid artery, and at a 0° angle, thus avoiding angle corrections (Fig. 1). The waveforms should be similar. The above sequence is repeated at least three times in each fetus. Measurement at this point allows the lowest intra- and interobserver variability, as well as standardization of the measurement (46). Multiples of the median (MoM) for the hemoglobin concentration (Table 3) and the MCA-PSV (Table 4 and Fig. 2) correct for

Figure 2 Middle cerebral artery peak systolic velocity (MCA-PSV) values correlated with gestational age. Abbreviation: MoM, multiples of the median. Source: From Ref. 7.

the effect of gestational age on the measurements (22). The MCA-PSV has a sensitivity of 100% (95% CI: 0.86–1.0) for the detection of significant fetal anemia with a false positive rate of 12% at 1.50 MoM (22). The number of false positive findings increases following 35 weeks of gestation (47). The number of false positive cases after 35 weeks of gestation may be decreased by looking at the overall trend of the MCA-PSV, rather than single values (48). An MoM > 1.5 indicates moderate-to-severe anemia and the need for invasive management.

The MCA-PSV may also be used to diagnose anemia of other etiologies, including parvovirus infection, nonimmune hydrops, fetomaternal hemorrhage, and twin-to-twin transfusion syndrome. Severe intrauterine growth restriction (IUGR) is also associated with an increased MCA-PSV (49). This should be taken into account when the MCA-PSV is used diagnostically; however, it is very unlikely that an anemic fetus is also a severe IUGR fetus. Moderate-to-severe fetal anemia may also be suggested by hydropic signs (at least two out of the following: pericardial or pleural effusion, ascites, or skin edema), an increase in size of the fetal liver or placental thickness, or by tricuspid regurgitation.

Once conservative measurements document a worsening hemolysis consistent with moderate-to-severe anemia (MCA-PSV > 1.5 MoM), therapeutic intervention involves intrauterine fetal assessment and transfusion. This process begins with administration of a paralytic [vecuronium bromide 0.1 mg/kg of estimated fetal weight (EFW)] to stop fetal movement, followed by the acquisition of venous blood from the base of the umbilical cord by the placental insertion site. The baseline fetal hematocrit determines the volume of transfusion to yield a target hematocrit of 40% to 50%. This target value takes into

account an expected decline of approximately 1% per day until a subsequent fetal transfusion. Transfusion is performed at the umbilical vein at either the placental insertion or inside the abdomen. Intraperitoneal transfusion is rarely performed and is contraindicated in the hydropic fetus because of poor absorption of blood. Corticosteroids for fetal maturation should be given before the procedure when FBS is performed after 24 weeks of gestation. Type O, Rh (D)-negative, cytomegalovirus-negative, washed, leukoreduced, irradiated packed RBCs cross-matched against maternal blood should be used. The blood usually contains 75% to 85% RBCs, allowing minimal blood volume for the transfusion (50). Transfusions are provided every 14 days until suppression of fetal erythropoiesis is documented; thereafter, the rate of declining hematocrit levels can be used to time further transfusions. Intrauterine transfusions are performed until 35 weeks of gestation, with delivery planned for 38 weeks of gestation (51).

The FBS is performed under continuous ultrasound guidance. Prophylactic antibiotics can be given, although no trial has evaluated their efficacy. Following 24 weeks of gestation, the procedure should be performed after alerting anesthesiology and in a location close to an operating room should an emergency occur. Tubing and syringes should be heparinized. Maternal skin can be anesthetized with 1% lidocaine at the point of needle entry. A 20- or 22-gauge needle is typically used. After entering the umbilical vein, a sample of fetal blood is withdrawn and the hemoglobin concentration is immediately (within 1 or 2 minutes) determined. Fetal anemia is confirmed by a mean corpuscular volume (MCV) > 110 μm^3 . If the hematocrit is below the fifth percentile (0.84 MoM) for gestational age, blood is transfused in a sterile fashion. A computer

program is used to estimate the amount of blood to transfuse based on the initial fetal hematocrit, the EFW, and the concentration of the blood transfused (52,53). A final fetal blood sample is taken a few seconds after the transfusion has been completed. If the fetus is hydropic, it is better to perform another transfusion 3 to 5 days later to increase the hematocrit to the median value for the gestational age. At 24 weeks of gestation or later, the fetal heart rate should be monitored for 2 to 3 hours after the transfusion until fetal movements resume. The risk of fetal death is 1% to 2% per procedure, even with ultrasound guidance, expert operators, and accurate management (54).

Hematocrit decreases about 1% per day post-transfusion in the anemic alloimmunized fetus, and this knowledge helps to assess when to repeat the transfusion. If the fetus is non-hydropic, the second transfusion is often necessary 14 days after the first. After the third transfusion, longer intervals, such as 3 weeks, may be possible, as the fetal RBCs are replaced by donated RBCs. Following three transfusions, 99% of the fetal blood is replaced with the adult transfused blood. The value of a maternal dose of 30mg of phenobarbital three times per day for 7 to 10 days to enhance fetal liver maturity and the ability to conjugate bilirubin has yet to be confirmed by large studies (55).

NEONATOLOGY MANAGEMENT

Neonatology management of an infant with hemolytic disease of the newborn focuses on monitoring the level of anemia and hyperbilirubinemia. Symptoms of anemia, such as tachycardia, usually warrant RBC transfusions. In severe cases, exchange transfusions may be necessary to remove the maternal antibodies from the circulation of the infant. Hyperbilirubinemia clinically presents as jaundice. Bilirubin levels are monitored and controlled with phototherapy and IV hydration.

54 Fetal alloimmune thrombocytopenia

Hung N. Winn

PATHOGENESIS

Alloimmune thrombocytopenia (AIT) is a syndrome that develops as a result of maternal sensitization to fetal platelet antigens. These women who themselves lack the specific antigen produce immunoglobulin G (IgG) antibodies directed against the platelet antigen that the fetuses inherit from their father. The antibodies are then transported across the placenta to the fetal circulation where they result in the destruction of the fetal platelets. Thus, the pathogenesis of AIT is analogous to that of hemolytic (Rh) disease of the newborn. However, unlike Rh disease, prior sensitization to the platelet antigen is not necessary since approximately half of the clinically evident cases of AIT occur in the first pregnancies. This suggests that either the fetal platelets gain access to the maternal circulation more easily than red blood cells, and/or the platelet antigens are highly provocative and therefore stimulate production of IgG antibodies during the first pregnancy (1). In a family with a previously affected infant, the rate of recurrence with an antigen-positive fetus is estimated to be at least 90% (2,3). The recurrence risk of neonatal intracranial hemorrhage (ICH) in a subsequent pregnancy after having a child with ICH due to AIT is about 77% (4). Additionally, it has been a uniform finding that the severity of thrombocytopenia in subsequent infants is either the same or worse than that of the first affected child.

PLATELET SEROLOGY

Platelets possess specific alloantigens that are expressed on the surface membrane glycoproteins. There are five major platelet alloantigen systems, all with biallelic polymorphism and inherited as codominant traits (5). The difference in alleles results from a single base substitution in the glycoprotein deoxyribonucleic acid (DNA) sequence, which ultimately results in a protein recognized as different from its allele (6). The most common antigen associated with AIT is HPA-1A, accounting for approximately 80% of reported cases (7). Other platelet antigen systems involved in AIT are shown in Table 1. The frequency of phenotypes and genotypes for each antigen differs in different ethnic groups.

INCIDENCE/GENETIC ASPECTS OF MATERNAL IMMUNE RESPONSE

Based on prospective analysis, the incidence of AIT is estimated to be between 1 per 1000 and 1 per 2000 births (7–9). The expected incidence in Caucasians based on the 98% frequency of the HPA-A1 allele is 1 to 2 per 100 births. This discrepancy between expected and observed incidence suggests that additional factors contribute to the maternal immune response. The risk of sensitization in HPA-A1 negative women is correlated with the presence of specific maternal human leukocyte antigen (HLA)-associated immune response genes, namely HLA-DR3, and more specifically

HLA-DRW52 (10). The immune response markers are contributory, but not sufficient for the development of alloimmunization, as not all HPA-A1 negative women with an HLA-DRW52 haplotype will deliver thrombocytopenic infants (11). The role of immune responsiveness for other platelet antigens has not yet been established.

CLINICAL PRESENTATION

In typical cases of AIT, the mother is healthy (without thrombocytopenia) and her pregnancy, labor, and delivery are uncomplicated. The neonates who are otherwise normal present with symptomatic thrombocytopenia within several hours of birth. Affected infants often develop a generalized distribution of petechiae, as well as ecchymoses over the presenting fetal part. Visceral bleeding and bleeding during circumcision or venipuncture may be present. Of greatest consequence is the risk of ICH, occurring in up to 30% of cases (3) and responsible for the 6.5% mortality rate (12) and the significant long-term neurologic sequelae, including hydrocephaly and porencephaly. Laboratory data are remarkable for an isolated and often severe thrombocytopenia, with normal or increased numbers of megakaryocytes found on bone marrow aspirate. The hematocrit may be decreased if significant bleeding has occurred. A definitive diagnosis can be made by phenotyping parental platelets and demonstrating antiplatelet antibodies in the maternal serum, which are specific for the antigen incompatibility identified.

Neonatal AIT is usually a self-limiting disorder, often resolving over the course of several weeks, as maternal antiplatelet antibodies disappear from the neonatal circulation. The most serious and feared complication is ICH, and until recently it had been believed that the greatest risk of ICH was at the time of labor and delivery. Hence, obstetric management had focused on the peripartum period and elective cesarean section at term was advocated (13,14). In the neonatal period, the goal was to replenish the neonate's circulating platelets in order to prevent complications secondary to bleeding. These infants should receive compatible antigen-negative platelets from either the mother or compatible donors (15). If the mother's platelets are used, they must be carefully washed in order to avoid introducing additional antiplatelet antibodies into the neonatal circulation. High-dose intravenous immunoglobulin therapy (1–2g/kg over 1–5 days) may provide an additional or alternative therapy (16,17) especially when matched platelets are unavailable.

EVIDENCE OF ANTENATAL ICH

These approaches, however, have no impact on fetal bleeding in utero prior to the onset of labor. In 1979, Zalneratis et al. reported two cases of AIT in which there was good evidence that ICH had occurred in utero (18). Both infants had enlarged

Table 1 Platelet-Specific Alloantigen Systems Involved in Alloimmune Thrombocytopenia

Nomenclature		Platelet glycoprotein (GP)	Alleles
New	Old		
HPA-1	PL, Zw	GP IIIa	HPA-1a, 1b
HPA-2	Ko	GP Ib	HPA-2a, 2b
HPA-3	Bak	GP IIb	HPA-3a, 3b
HPA-4	Pen, Yuk	GP IIIa	HPA-4a, 4b
HPA-5	Br	GP Ia	HPA-5a, 5b

heads (>97%) at birth. The first had bifrontal and left posterior fossa cysts with obstructive hydrocephalus, and the second had a large right parieto-occipital hematoma followed by the development of hydrocephaly and a porencephalic cyst in the same location. Examination of the cyst contents obtained at the time of shunt placement revealed fluid filled with hemosiderin-laden macrophages in the first case and liquefied, “rusty” fluid in the second. The pathologic findings placed the time of bleeding at several months, and 1 to 2 weeks prior to delivery in these two cases, respectively.

Stronger confirmation that AIT could be responsible for cerebral hemorrhage in utero was presented in a series of cases where the diagnosis of porencephaly was made with ultrasound examination in the third trimester in fetuses suspected, and later confirmed, to have this disorder (19).

It is now known that up to 80.5% of ICHs secondary to AIT occur in utero (20). Fetal platelet antigens may be expressed as early as 13 weeks of gestation and ICH may be present by 16 weeks of gestation (21). Hence, in order to be maximally effective, the treatment of AIT must begin in utero.

ANTENATAL MANAGEMENT

Since routine screening for fetomaternal platelet incompatibility is not performed, identifying those fetuses at risk for AIT almost always consists of obtaining the history of a previously affected sibling or other positive family history. The risk to future pregnancies depends on the zygosity of the fetus’s father. When the father is a heterozygote for the alloantigen, each fetus has a 50% chance of inheriting the antigen. In these cases, DNA-based testing of fetal amniocytes or chorionic villi has enabled typing of fetal platelet antigens (6,10). Those fetuses who are antigen negative can be managed routinely, while those possessing the antigen are managed aggressively.

The optimal antenatal management of AIT is still debated in the literature. One approach consists of serial fetal platelet transfusions with antigen-negative platelets (22,23). Evaluation of the fetal platelet counts before and after these procedures reveals that platelet transfusions are effective. However, the platelet count remains normal for less than 10 days, and hence platelet transfusions must be administered weekly. This approach subjects the pregnancy to the risk of fetal loss due to repetitive invasive procedures, which is especially significant since fetuses with AIT are at increased risk for fetal exsanguination associated with cordocentesis (24). The estimated risk for fetal loss from fetal transfusion of platelets through cordocentesis is about 6% and depends on the operator’s experiences (25). A less invasive alternative involves the use of maternally administered intravenous gamma

globulin (IVIG). In the pilot study of 18 patients (26), IVIG with and without steroid therapy was found to significantly increase the fetal platelet count and decrease the risk of ICH. No cases of ICH occurred in that series, in contrast to 10/21 (48%) in untreated siblings.

A large randomized trial was designed to determine whether the addition of daily low-dose steroid therapy (1.5-mg dexamethasone) to IVIG (1 gm/kg/week) was more efficacious than IVIG alone in preventing severe thrombocytopenia and ICH in the antenatal management of AIT (3). Of the 54 women treated, the majority responded to therapy with success rates between 62% and 85%, depending on the definition of response. The addition of low-dose dexamethasone was not found to increase the effectiveness of IVIG alone. In this series, there were no cases of ICH compared with 10 previously affected siblings, and there were no differences in response when steroids were used concomitantly. Ten initial non-responders were entered into the “salvage arm,” which consisted of 60 mg of prednisone daily in addition to IVIG. Half of these patients responded with an increased platelet count.

The largest prospective study of antenatal treatment of 33 pregnant patients (37 fetuses) who had AIT and previous siblings with ICH demonstrated good neonatal outcomes with stratifying patients according to the timing of the previous child’s ICH (4). The patients were classified as extremely high risk (EHR), very high risk (VHR), and high risk (HR) if ICH in the previous child occurred in the second trimester (less than 28 weeks of gestation), the third trimester (28–36 weeks of gestation), or during the perinatal period, respectively. The patients received primary treatment with intravenous immunoglobulin (IVIG) and salvage therapy with prednisone and/or more intravenous immunoglobulin. Only 5 of 37 fetuses developed ICH: (i) two had platelet counts greater than 100,000/ μ L, (ii) one had grade I ICH, and (iii) two had grade III–IV ICH and were demised. The investigators recommended the following guidelines in treating patients with AIT and ICH in a previous child. First, the treatment should be started no later than 12 weeks of gestation. Second, fetal blood sampling should be delayed until 32 weeks of gestation to minimize the complications from the procedure. Third, the fetal platelet counts obtained from the fetal blood sampling would dictate the need for additional salvage therapy (prednisone or additional IVIG) or delivery. The therapeutic regimen includes (i) intravenous IgG (IVIG) 2 g/kg/wk for the EHR group or 1 g/kg/wk for the VHR and HR groups starting at 12 weeks of gestation plus (ii) prednisone 1 mg/kg/day starting at 24 to 26 weeks of gestation for the EHR group or prednisone 1 mg/kg/day or additional IVIG 1 g/kg/wk starting at 20 weeks of gestation for the VHR and HR groups (Table 2).

While these findings are quite promising, there have been reports of unsuccessful response (i.e., ICH in utero) to antenatal IVIG therapy (4,27,28). This could be due to an inconsistent increase in fetal platelets to IVIG infusion despite of a significant increase in maternal and fetal IgG levels (29). The knowledge that (i) not all fetuses will respond to IVIG therapy and (ii) salvage therapy (high-dose prednisone, additional IVIG, or platelet transfusions) is available underscores the need to assess response to therapy with fetal blood sampling to obtain fetal platelet counts. Since fetuses with AIT are at increased risk for

Table 2 Treatment Based on Risk Stratification

Variable	Extremely high risk	Very high risk	High risk
Definition	Previous sibling: in utero ICH in second trimester	Previous sibling: in utero ICH in third trimester	Previous sibling: perinatal ICH
Start	12 wk GA Initially IVIG 2g/kg/wk Add prednisone 1 mg/kg/day at 24–26 wk GA First FBS at 32 wk GA Additional salvage treatment and/or early delivery based on FBS results	12 wk GA Initially IVIG 1g/kg/wk Add prednisone 1 mg/kg/day or second IVIG 1g/kg/wk at 20 wk GA First FBS at 32 wk GA Additional salvage treatment and/or early delivery based on FBS results	
Regimen		If FBS unable to be performed or not performed for other reasons including patient and/or physician choice, salvage therapy could be empirically instituted	
<i>Abbreviations:</i> FBS, fetal blood sampling; GA, gestational age; ICH, intracranial hemorrhage; IVIG, intravenous immunoglobulin. <i>Source:</i> From Ref. 4.			

fatal bleeding at the time of cordocentesis (24,25), it seems prudent to have compatible platelets available and to transfuse if the platelet count is found to be $<50,000/\mu\text{L}$.

CONCLUSIONS

At present, the prospective diagnosis of a fetus affected with AIT relies almost exclusively on the history of a previously affected sibling or other positive family history. Since this disorder can potentially result in death or permanent neurologic sequelae as a result of ICH, the concept of routine screening of pregnant women to detect fetomaternal platelet incompatibility has been proposed. There are limitations to routine antenatal screening. All affected pregnancies may not demonstrate detectable anti-HPA-A1 antibodies and conversely the presence of anti-HPA-A1 antibodies does not invariably predict fetal thrombocytopenia. In addition, not all fetuses with AIT will develop ICH. Fetuses at greatest risk include those with severe thrombocytopenia and those with a previously affected sibling with ICH. Antenatal therapy needs to be directed at this small group of fetuses at risk for ICH in utero. A recent systemic review of the literature and analysis suggested that screening pregnant women for AIT would be cost-effective with a saving of at least 9 million euros per year in Netherlands (30). The analysis was based on i) the incidence of severe fetal AIT being about 40/100,000 pregnancies; ii) the incidence of severe ICH being about 4 children/100,000 pregnancies; and iii) including the costs of initial HPA typing, antibody detection, maternal treatment, and care for the neurologically impaired children.

The optimal antenatal management for AIT remains to be determined. Serial platelet transfusions are efficacious, but necessitate weekly invasive procedures with the additive risks of pregnancy loss. Medical management with maternally administered intravenous gamma globulin appears to be effective in the majority of, but not all, cases. The mechanism(s) of action of IVIG in preventing severe thrombocytopenia is unknown but may reflect i) decreased maternal antibody production, ii) antibody Fc receptor blockade in the placenta, and/or iii) antibody Fc receptor blockade in the fetal reticuloendothelial system. The mechanism by which IVIG prevents ICH in cases where it does not prevent severe thrombocytopenia has also not been elucidated. It is interesting to note that the HPA-A1 antigen is expressed on human endothelial cells as well

as platelets. Hence, it has been proposed that HPA-A1 antibodies may damage these cells resulting in vascular injury (24) and predisposition to intracranial bleeding. IVIG may interfere with this endothelial cell–antiplatelet antibody interaction. Lastly, therapy should be initiated as early as 12 weeks of gestation given the fact that severe thrombocytopenia has been documented as early as 13 weeks of gestation.

56 Fetal arrhythmias

Júlia Hajdú, Valéria Váradi, and Zoltán Papp

Fetal rhythm abnormalities occur in 2% of pregnancies. They are usually identified by the obstetrician or midwives after 20 weeks.

In avian embryos, a pacemaker is first established in the inflow tract at the straight heart tube stage. When the embryonic heart first begins to contract, it has no specialized conduction system. It is thought that the cardiac conduction system is derived from independent parent cells linked together to establish the integrated conduction system of the heart. Terminal differentiation of conduction tissue occurs late in development (1,2). By 6 weeks postconception, atrioventricular (AV) synchrony can be demonstrated using standard Doppler techniques. The heart rate is 150 bpm by 14 weeks; by 20 weeks it is 140 bpm with a gradual decrease to 130 bpm by term (3).

There are different methods used to assess fetal arrhythmias: scalp electrodes attached to electrocardiographic recordings, fetal magnetocardiography (FMCG), fetal electrocardiographic recordings from the maternal abdomen, and fetal echocardiography (M-mode, pulsed Doppler, tissue Doppler).

The usefulness of the invasive method, scalp electrodes attached to electrocardiographic recordings, is limited because it is possible to use only at ruptured membranes. An FMCG provides a noninvasive means of analyzing complex tachyarrhythmia in utero, with efficacy approaching that of postnatal electrocardiographic rhythm monitoring (4–6). The disadvantage of FMCG is that it is expensive.

The fetal electrocardiographic recordings from the maternal abdomen are not performed routinely because of the limited quality of the surface fetal electrocardiographic signal. With newer equipment it was found that electrical PR interval was better than mechanical PR interval at differentiating between normal and prolonged PR in the fetus, and the reproducibility of the PR interval using noninvasive fetal electrocardiography was significantly better than that of the Doppler methods (7–9).

In the fetal heart, electrical activity can be inferred from the timing of the mechanical events. With *M-mode method*, the simultaneous recording of the movement of the right atrial wall or the opening and closing of the AV valves and of the ventricular wall or the opening and closing of the aortic valves make it possible to determine the relationship of the atrial and ventricular electric activity. The fetal M-mode echocardiogram has its limitations: inaccurate measurement of the fetal AV conduction time, the loss of clear markers of atrial and ventricular contractions in hydropic fetuses with hypocontractile myocardium, and the poor picture resolution related to factors such as maternal obesity, fetal position, or polyhydramnios.

The *Doppler method* was found to be superior compared with the M-mode approach when measuring fetal AV time intervals. There are different places where it is possible to

measure mechanical PR interval. The MV-Ao Doppler method is recorded in five-chamber view with the septum in a vertical position, velocities generated by both inflow of blood through the mitral valve (MV) during diastole and by the outflow through the left ventricular outlet (Ao) during systole. The PR interval is measured from the intersection of the mitral E and A waves to the beginning of the ventricular ejection wave (Fig. 1). With simultaneous recording of superior vena cava (SVC) and ascending aorta (AA) flow velocity waveforms (Fig. 2), pulsed-Doppler sample volume is adjusted to encompass both vessels. The AV time interval is measured from the beginning of the retrograde venous A wave to the beginning of the aortic ejection wave (9–13). A PR interval of >150 msec on Doppler, FMCG, or postnatal ECG has been determined to be prolonged. PR intervals can vary in the fetus as they do in neonates or that at birth; changes in AV conduction or autonomic nervous system activity alter the PR interval. In cases with AV time prolongation, the SVC-Ao method seemed superior. Higher heart rates have been demonstrated to result in increasing fusion of the E and A waves in the mitral valve, overlapping the beginning of the A wave and leading to an artifactual shortening of the AV time interval. As the PR interval gets longer with no associated decrease in heart rate, the A wave will have an earlier start in relation to the E wave, in turn causing increasing overlapping of the E wave and an artifactual shortening of the A wave (14).

The newer technique of tissue-velocity Doppler imaging may be helpful when evaluating the fetus with borderline findings and negative maternal anti-Ro/anti-La antibodies (15). With tissue Doppler method, the best correlation was found between postnatal PR time and prenatal PR time with measurement of right ventricular Aa-IV (atrial contraction–isovolumetric contraction) interval (16,17).

The most common fetal rhythm anomaly is the *irregular rhythm*. The causes of irregular rhythm could be most often premature atrial contractions (PACs), premature ventricular contractions, or tachyarrhythmias with AV block.

Extrasystoles are most often “PACs,” which are usually identified in third-trimester fetuses, and their frequency may be highly variable. They may be conducted (Fig. 3) or blocked (Fig. 4) at the AV node. These are usually benign, resolving just before or shortly after birth. The follow-up is necessary because some (1–3%) of the affected fetuses have intermittent runs of supraventricular tachycardia (SVT). PACs identified with cardiomegaly, evidence of ventricular systolic dysfunction, AV valve regurgitation, and/or hydrops could be signs of a temporary SVT. Control of the foetal heart rate on each third day, weekly or biweekly obstetric ultrasound assessment is warranted until they have resolved or until delivery. About 2.5% of affected fetuses have associated structural heart defect—lesions associated with significant mitral or tricuspid

insufficiency, atrial dilatation, intracardiac tumors (Fig. 5), and aneurysm like dilation of the foramen ovale flap (Fig. 6). In such fetuses, the minor hemodynamic alterations that occur with the extrasystoles may not be tolerated.

Premature ventricular contractions are rare (Fig. 7). They are usually benign. It is necessary to rule out myocardial disease or intracardiac tumors. Prenatal and postnatal follow-up is always indicated to confirm the nature of the ectopy and exclude intermittent runs.

Tachycardia is defined as a fetal heart rate that exceeds 180 bpm. The origin of the tachycardia could be ventricular or supraventricular.

Ventricular tachycardia is rare during fetal life. With echocardiography, in the setting of fetal tachycardia, the findings of AV dissociation with a ventricular rate faster than the atrial rate suggest ventricular tachycardia (18). If there is 1:1 retrograde conduction, it is impossible to distinguish between ventricular and supraventricular tachycardias.

Figure 4 Blocked premature atrial beat, Doppler method. Abbreviations: E, E wave; A, A wave; EA, fused E and A waves because of premature beat; V, aortic ejection wave.

A rare presentation of fetal long QT syndrome is second-degree AV block and ventricular tachycardia leading to congestive heart failure. The best method to diagnose QTc prolongation and torsades de pointes is the FMCG. As a sign of torsades de points, the peak-to-peak intervals of AA flow during ventricular tachycardia are markedly irregular (14,18,19).

The therapy of the fetal ventricular tachycardia is difficult. In cases where it is not possible to rule out the ventricular tachycardia, digoxin therapy is contraindicated; rather, amiodarone

is the drug of the choice. If the diagnosis of the ventricular tachycardia is sure, the pregnancy is before 34th week, and there is a sign of the decompensation, then therapy with lidocaine is reasonable with strong maternal control.

“SVT” is the most common cause of the fetal tachycardia. FMCG could help to clarify electrophysiologic patterns of initiation and termination of reentrant fetal SVT. Five distinct patterns of initiation and four patterns of termination were documented, with the most common patterns of initiation

involving reentrant PACs (Wolff–Parkinson–White syndrome, QRS aberrancy, and multiple reentrant pathways). FMCG actocardiography revealed an unexpectedly strong association between fetal trunk movement and the initiation and termination of SVT, suggesting that autonomic influences play a key role (6).

In everyday routine, it is the best to plan the management of the fetal tachyarrhythmia based on analysis of pulsed-Doppler recordings of fetal heart's blood flow. It is a short V-A (ventriculo-atrial) tachycardia, when V-A period is shorter than

A-V (atrioventricular) period (Fig. 8). Short V-A tachycardia with 1:1 AV conduction and with ventricular rates of 230 to 280 bpm suggests reentrant tachycardia, and digoxin is proposed as the first choice drug. Short V-A tachycardia with AV dissociation means that with high probability of junctional ectopic tachycardia, which is usually resistant to digoxin and sotalol, amiodarone could have success. The atrial ectopic tachycardia usually responds to sotalol.

Long V-A tachycardias are seen in sinus tachycardia, in permanent junctional reciprocating tachycardia, or in

Figure 7 Ventricular extrasystole, M-Mode method. Abbreviations: A, atrial contraction; V, ventricular contraction; RA, right atrium; LA, left atrium; RV, right ventricle; LV, left ventricle.

Figure 8 Long V-A tachycardia. The V-A interval is 150 msec, and the A-V interval is 90 msec. Abbreviations: EA, atrial inflow; AO, ventricular outflow; RA, right atrium; LA, left atrium; RV, right ventricle; LV, left ventricle.

atrial ectopic tachycardia. The first-choice drug is sotalol. In intra-atrial reentrant tachycardia, the first-choice drug is digoxin (10,20).

The sotalol was found to be useful in transplacental treatment of atrial flutter and SVT. The daily maternal sotalol dose is linearly related to the maternal plasma concentration. The mean fetal/maternal sotalol plasma concentration is 1.1 (range 0.67–2.87, SD 0.63), and the mean amniotic fluid/fetal blood ratio of sotalol is 3.2 (range 1.28–5.8, SD 1.4). The effectiveness of sotalol therapy could not be extrapolated from

maternal blood levels. A large difference in the sensitivity of sotalol was found. As proarrhythmia is known to be dose related, low initiation doses are preferable and dosage increases should be stepwise. Close monitoring, especially during the initiation phase, is recommended. In addition, maternal potassium levels and magnesium levels should be monitored regularly and supplemented if necessary. The maternal toxic level is 2.5mg/L at which marked QTc prolongation is noted. The F/M ratio of 1.1 shows that the fetus also stays below the “toxic” level (21).

SVT results in reduced diastolic filling time, which, when combined with the normal limitations of relaxation and reduced compliance of the fetal myocardium, leads to increasing atrial and central venous pressures in the evolution of placental edema and dysfunction, which leads to fetal hypoxemia. Treatment of the SVT is proposed for fetuses with the risk of signs of heart failure—incessant SVT and early onset of SVT (<32 weeks). Altered maternal gastric emptying and increased maternal renal clearance could necessitate the use of higher doses. It is important to control the mother, maternal heart rate, serial ECGs and telemetry, and monitoring drug concentration (22). The mortality of SVT was found to be 8% to 10% (23).

In tachycardia with a fast conducting reentrant pathway, atrial contractions occur during ventricular ejection, thus against closed AV valves. Tall reverse “A” waves are present in the venous system of fetuses with reentrant SVT. This type of arrhythmia could induce backward venous congestion and hydrops, even in the absence of myocardial failure. The duration of the process also plays a significant role in the development of hydrops fetalis (24). Hydropic patients have higher ventricular rates (median: 240 bpm, range 240–300 bpm) than non-hydropic fetuses (220 bpm, range 200–310), and the atrial rates are not significantly different. In cases with fetal SVT and hydrops fetalis, flecainide could control the fetal arrhythmia. The therapeutic range is 200 to 700 µg/L. Strong maternal ECG and flecainide concentrations need to be checked out to term to avoid potential maternal and fetal toxicity. There is no evidence that flecainide is concentrated in the fetus (25). Another possibility of drug treatment for hydropic fetuses is digoxin and verapamil (26). In the absence of effective therapy, the mortality of the hydropic fetuses with supraventricular tachycardia approaches 50%, and with treatment, the mortality is 10%. It is recommended the maternal hyperglycemic state in the acute resuscitation of the hydropic fetus with SVT, which in providing metabolic support for the fetal myocardium, may ultimately be used coincident with initiation of antiarrhythmic treatment.

Fetal *atrial flutter* is usually identified late in gestation and is associated with atrial rates ranging from 300 to 550 bpm with variable AV conduction and ventricular rates. The atrial rate is confirmed through M-mode or systemic venous Doppler demonstration of the atrial wave rates.

Action potential prolongation in the absence of conduction slowing seems more effective in the termination of atrial flutter than depression of the excitability. Sotalol (class III drug) seemed to be more efficacious than other drugs in fetal atrial flutter. The proposed protocol in atrial flutter is as follows: 80 mg of sotalol twice daily, increased stepwise with 80 mg per 3 days to a maximum of 160 mg three times daily. Sotalol has excellent transplacental passage. Monitoring of the maternal QT interval is essential in excluding maternal proarrhythmia. Amiodarone (class III drug) has many side effects and does not cross the placenta as readily as does sotalol. The treatment with sotalol as the first drug of choice is more reasonable because transplacental passage is slower for digoxin, relapse into atrial flutter occurs more often at birth, and subjective maternal complaints are prominent with sotalol (27).

Long-standing and/or fluctuating cerebral perfusion as a result of intrauterine atrial flutter is responsible for the

disturbance of the maintenance of adequate cerebral perfusion. It is exposing the brain to ischemia with increased risk of intracranial hemorrhage. It is opted to treat all fetuses with atrial flutter at time of presentation, unless immediate delivery is possible. The stress of the delivery and release of catecholamines may have an influence on retriggering the onset of atrial flutter, such seen in SVT. The early morbidity of atrial flutter is significant, but the long-term prognosis is excellent (28). The risk of neurologic morbidity must be taken into consideration. There are some case reports on probable inherited etiology of fetal atrial flutter (29,30).

IF THE FETAL HEART RATE IS BELOW 120/MIN, IT IS BRADYCARDIA INDEPENDENTLY FROM THE GESTATIONAL AGE

Persistent fetal *sinus bradycardia* is a rare condition and has been reported with central nervous system abnormalities, maternal treatment with beta blockers, excessive vagal tone, hydrops, neonatal long QT syndrome, and intrauterine growth retardation or as an atypical manifestation of congenital parvovirus B19 infection (31). Sinus bradycardia has also been associated with complex heart defects in which absence or hypoplasia of the sinus node is a typical finding (32). Sinus bradycardia has been reported recently as a possible sign of maternal anti-SSA/Ro antibodies. There are findings that in fetuses or newborns who died of congenital atrioventricular block (CAVB), the sinoatrial nodes were hypoplastic and, in some of these cases, surrounded by extensive fibrosis (33).

Prenatal sinus bradycardia or recognition of second-degree AV block may lead to early detection and treatment of *long QT syndrome*. QTc prolongation was found to be more common in utero than postnatally, but it does not necessarily imply that fetal QTc prolongation is a benign condition. Several studies of newborns have suggested that QT prolongation and the concomitant increased risk of ventricular tachyarrhythmias may account for the significant mortality. QT prolongation was the highest in the fetuses with the poorest outcome and was often accompanied by T-wave alternant. Common genetic polymorphisms have been shown to alter the QT interval, and prenatal molecular genetic testing for long QT syndrome has been demonstrated. The recently reported environment–genetic interactions could result in arrhythmias or sudden infant death syndrome (4). Few cases of fetal ventricular tachycardia due to congenital long QT have been reported in the literature. Some cases presented fetal ventricular tachycardia with both bradycardia and AV block (14,18,19).

“CAVB” occurred in 2.6% of a large population of fetuses evaluated for an irregular rhythm. Congenital heart defects, like L transposition (Fig. 9), left isomerism (Fig. 10), cause the AV block at about 50% of cases. If there is no cardiac malformation, the fetal CAVB is the consequence of transplacental passage of maternal autoantibodies (Figs. 11 and 12). CAVB and the neonatal lupus are the model of passively acquired autoimmunity (33). The mean histologic lesion in the heart is fibrosis of the conducting tissue and, in some cases, the surrounding myocardium. The mechanism by which maternal anti-SSA/Ro-SSB/La antibodies initiate and perpetuate inflammation and eventuate in scarring of the AV node is not yet defined. In vitro and in vivo studies suggest that one pathologic cascade leading to scarring may be initiated via apoptosis,

Figure 9 Horizontal cross section of the chest, with univentricular heart, dextrocardia, common atrium, interruption of the inferior caval vein. Abbreviations: Ventr, ventricle; ATR, atrium; AO, aorta; VA, azygos continuation.

Figure 10 Horizontal cross section of the chest, with L transposition. The anatomical right ventricle (RV) is visible on the left side, below the left atrium (LA); the left ventricle (LV) on the right side, below the right atrium (RA). Abbreviations: SP, spine; R, right; L, left.

resulting in the translocation of SSA/Ro-SSB/La antigens and subsequent surface binding by maternal autoantibodies. In CAVB, the maternal anti-SSA/Ro-SSB/La antibodies result in opsonization and inflammatory/fibrotic sequelae. These opsonized cardiocytes are phagocytosed by macrophages, which secrete factors that transdifferentiate fibroblasts into myofibroblasts, a scarring phenotype (34).

The development of CAVB is a two-stage process. In the first step, the maternal autoantibodies are transferred through

the placenta and bind structures in the developing fetal heart, leading to first-degree AV block. This state is spontaneously reversible with further maturation of the fetus. If the second phase is entered, a progression to complete heart block commences. Factors involved in this second phase may be mainly fetal and related to the immunogenetic profile of the individual. A predisposition to an intense inflammatory reaction to the antibody deposition might lead to the reaction to the subsequent mononuclear cell infiltration and fibrosis,

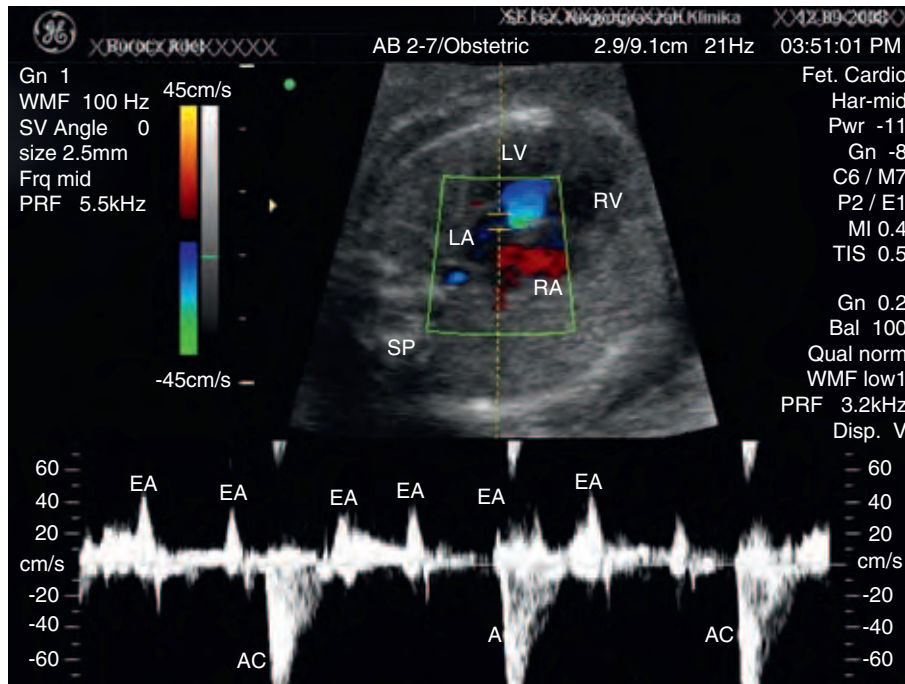

Figure 11 Complete atrioventricular dissociation. Abbreviations: EA, ventricular inflow wave; AO, ventricular ejection wave; RA, right atrium; LA, left atrium; RV, right ventricle; LV, left ventricle; SP, spine.

with a permanent injury as the outcome. The high prevalence of fetal first-degree AV block with normal postnatal PR intervals in a group of fetuses with maternal anti-Ro/La antibodies has been proposed due to a transient biologic response to the transplacental transfer of Ro/La antibodies (3).

If second-degree AV block is present, transplacental steroid treatment theoretically may limit progression. Prophylactic steroid therapy in the fetus without documented AV conduction disease is not warranted due to maternal and fetal side effects. After a high-dose steroid therapy for fetal heart

block, several maternal complications could be found including diabetes, hypertension, infections, bone density loss, and cataract. Fetal risks are oligohydramnios and growth restriction, including the head and possibly central nervous system injury without clear evidence of benefit to fetal cardiac conduction (7).

Early detection of incomplete AV block successfully identifies a group at highest risk developing permanent AV block. Treating this group may incur greater benefit than risk. The anti-inflammatory effects of dexamethasone might have

interrupted ongoing damage to the conduction system secondary to maternal autoantibodies.

The findings of a PR interval of >150 msec at any gestational age should prompt a search for maternal anti-Ro/anti-La antibodies and close follow-up for other complex arrhythmias (11,12,15). The Doppler mechanical PR interval does not distinguish between electrical PR interval prolongation due to AV conduction delay and abnormalities of interatrial conduction. These limitations in Doppler mechanical PR interval measurements can be overcome if FMCG is available. The newer technique of tissue-velocity Doppler imaging may be helpful when evaluating the fetus with borderline findings and negative maternal anti-Ro/anti-La antibodies. May be that PR prolongation represents a variant of a normal, and only in retrospect does it have clinical significance if it is either sustained after birth or progresses to more advanced block. The prolongation of the fetal Doppler mechanical PR interval is not a definitive tool to detect early signs of anti-SSA/Ro-associated CAVB (34,35).

The risk of the third-degree heart block in pregnancies of mothers with a previous child with congenital heart block is 19% and in pregnancies in mothers without previous child with congenital heart block or rash is 4%, suggesting that there must be additional maternal and/or fetal factors that influence disease development and manifestation. The maternal factors may be related to the antibody profile. The fetal factor could be viral infection or genetic predisposition (36).

Advanced block and cardiomyopathy can occur within 1 week of normal echocardiogram without initial first-degree block. This more extensive injury can occur in utero or postnatally, even as late as 9 years of age (35).

In a large study on infants whose mothers had anti-Ro antibodies, the prevalence of hydrocephalus was 8%, which is significantly higher than the prevalence in the general population of 0.048% to 0.081%. It seems to be possible that hydrocephalus and macrocephaly are manifestations of neonatal lupus syndrome and infants born to mothers with anti-Ro antibodies should be carefully monitored for hydrocephalus as part of their routine physical examination (37).

In patients with fetal hydrops, cholestasis and severe and irreversible liver failure could be observed. Histologically, extensive collapse of the stroma and the absence of hepatocytes (foie vide) were observed. Cholestasis has been described in patients with neonatal lupus erythematosus without AV block (25).

When CAVB is associated with *endocardial fibroelastosis* (EFE), there is a very high mortality rate. The etiology of EFE remains unclear, but it may be a result of an autoimmune process. In fetuses or infants born from mothers positive for anti-Ro/La antibodies, EFE and cardiomyopathy with clinically normal conduction systems could conceive. The EFE and CAVB are two separate disease manifestations of neonatal lupus. In the histologic examinations, an active fetal B-cell response was found in addition to the passive deposition of transplacentally passed maternal immunoglobulin. The initial myocardial damage in utero is likely secondary to the passive deposition of maternal anti-Ro and anti-La antibodies, and the progression of EFE may be the result of an ongoing fetal and postnatal autoimmune reaction. The EFE accounted for over 80% of the deaths in these patients. Some cases may go

undiagnosed where there is a fetal demise. Fetal echocardiographic assessment is very subjective and often identifies only the most severe degree of EFE. Idiopathic dilated cardiomyopathy represents unrecognized maternal autoantibody-induced EFE.

There are studies on infants with CAVB who developed late-onset *dilated congestive cardiomyopathy* despite early and adequate institution of cardiac pacing. At the time of clinical presentation, many infants have symptoms or signs of an upper respiratory tract infection, otitis media, or gastrointestinal infection. Myocardial biopsy or histologic examination of the explained heart revealed the following: myocyte hypertrophy, interstitial fibrosis, and myocyte degradation in two subjects. An active inflammatory infiltrate was not detected. An upper respiratory/gastrointestinal infection might have reactivated a previously dormant inflammatory process. The increased rate that followed pacemaker implantation may have provoked a form of tachycardia-induced cardiomyopathy (38). The mortality rate is as high as 25%, and many patients require cardiac transplantation.

THE THERAPY OF THE CAVB

Although the prenatal use of corticosteroids, plasmapheresis, sympathomimetics, and either prenatal pacing or early delivery with postnatal pacing has been proposed, the true efficacy of *therapy of the CAVB* is not clear.

Current approach to affected pregnancies is to initiate dexamethasone therapy at diagnosis of fetal AV block (4 mg/day) and to add maternal sympathomimetics for ventricular rates of <55 beats/min. Weekly-biweekly fetal echocardiograms are used to follow the progress, and an elective delivery by caesarean section at 36 to 37 weeks is planned. If there are signs of fetal compromise, an earlier delivery with aggressive postnatal management is proposed, including early pacemaker placement. When there is oligohydramnios, maternal dexamethasone is tapered off; however, persistence of reduced amniotic fluid may prompt earlier delivery (39). (Prednisone and prednisolone are inactivated by placenta hydroxylases and only less than 10% of the mother blood level can reach fetus; dexamethasone and betamethasone cannot be inactivated.) Some data suggest that prolonged fetal exposure to dexamethasone may impair cerebral development, but there are reports on children treated with dexamethasone prenatally (cumulative dosage 20–260 mg), who were tested postnatally with different scales according to their age and they were found with normal intelligence quotient (40).

Intravenous immunoglobulin (IVIG) is efficient in various immune-mediated conditions. It seems conceivable to employ IVIG in cases of CAVB or neonatal lupus, either administered to the mother or directly through cordocentesis in the treatment of the fetus and neonate with reduced myocardial function suggesting more diffuse disease (41).

PROGNOSIS AND FOLLOW-UP

In an isolated AV block, diagnosed in utero, in neonatal age and in children, anti-Ro and/or anti-La are present in 95% of fetal, 90% of neonatal, but only 5% of children's mothers tested. Patients with CAVB having fetal, neonatal, and childhood diagnosis have a mortality of 43%, 6%, and 0%, respectively, in the first two decades of life. Increased mortality

is associated with a fetal diagnosis of CAVB, fetal hydrops (100%), EFE (100%), and delivery at or before 32 weeks of gestation. Timing of pacemaker implantation differ significantly among fetuses versus neonates and neonates versus children cases. At 20 years of age, only 11% and 12% of CAVB patients with neonatal or children diagnosis, respectively, are not paced. CAVB detected in utero represents a more severe spectrum of the disease than encountered postnatally (39).

The mortality decreased from 45% to 15% with close surveillance, use of maternally administered corticosteroids, delivery at 35 to 37 weeks or earlier with any evidence of fetal distress or cardiovascular compromise, neonatal cardiac intensive care management, and early permanent pacemaker therapy. Among fetuses with AV block only, the survival rate is 82%, with a heart defect; the prognosis is poor, and 50% of the patients survive. Sinus bradycardia is associated with survival rates of 75% (33,42).

All fetal arrhythmias are associated with a moderately high risk for fetal distress. In cases of compromise, fetal and neonatal prognosis is poor and is an indication for perinatal medication. The risk of neurologic morbidity must be taken into consideration.

57 Fetal growth restriction

Daniel L. Jackson, M. Y. Divon, and Hung N. Winn

INTRODUCTION

Low birth weight is an important predictor of neonatal morbidity and mortality. This condition can be the result of either preterm delivery or fetal growth restriction (FGR). Fetuses whose growth has been restricted have an increased incidence of perinatal morbidity and mortality (1). Heinonen et al. have studied the first-year survival of preterm infants born at 26 to 32 weeks of gestation and concluded that FGR was associated with a threefold increase in neonatal mortality (2). Comparing with infants with normal growth, FGR is associated with a higher incidence of low Apgar scores, perinatal asphyxia, hypothermia, polycythemia, hypocalcemia, pulmonary hemorrhage, and impaired immune function (3).

DEFINITION AND CLASSIFICATION OF FGR

Fetal growth rates are determined by comparing the size of the infant at birth with an expected norm for a given gestational age. Birth weight is the most accessible and reliable measure of the newborn and is, therefore, widely used for this purpose.

Fetal size and fetal growth are often confused in clinical practice. FGR denotes a pathologic process. By contrast, small-for-gestational age (SGA) identifies the infant whose birth weight is below an arbitrary percentile for gestational age. The 10th percentile is often used for this purpose; however, birth weights below the 25th, 15th, and 5th percentile or two standard deviations (SDs) below the mean have also been used in the past. Using birth weight criteria as the gold standard for fetal growth presents a few problems. First, the diagnosis of growth restriction is based on a single observation (birth weight) made at an end point (gestational age at delivery). Fetal growth, however, cannot be estimated from less than two measurements separated by a "reasonable" interval.

Second, not every infant whose birth weight is below the 10th percentile for gestational age is small because of a pathologic growth-restrictive process. The constitutionally small infant is indeed small but shows appropriate growth and has no other complications. The converse is also a problem. A dysmature, postdate infant may be subjected to severe growth restriction, yet its birth weight is often above the 10th percentile for gestational age. Thus, a long and very thin infant may be misclassified as appropriately grown. Third, estimation of gestational age presents recurrent problems. An infant may be assigned different gestational ages depending on the specific method used to establish this age (i.e., last menstrual period, early clinical examination, early ultrasound examination, or neonatal assessment).

Several "commonly used" norms for birth weight as a function of gestational age have been described (4). Differences between these norms are due to different geographic origin (differences in altitude are of primary importance), race, ethnicity, parity, and neonatal sex. The mean birth weight at

40 weeks of gestation reported by Lubchenco and coworkers (5) at Denver (high altitude) was 120g smaller than that reported by Brenner and coworkers (6), who studied an east coast (sea-level), racially mixed population (Table 1).

Despite all of these concerns, and probably due to a lack of a more dynamic definition, FGR is often defined as birth weight below the 10th percentile for gestational age. By definition, the incidence of this condition is 10%. Variations of this proportion are caused by using the wrong norm for the population under study.

Identification of FGR by the population norm as described above has inherent difficulty. The "normal" values for preterm infants are determined by infants that were themselves born preterm, a condition that is itself associated with FGR. In order to improve the sensitivity and specificity of the diagnosis of FGR, new standards for defining normal growth have been established. Figueras and Gardosi have reported on optimal weight at term calculated by using maternal height, weight, parity, and ethnic origin (7). Pathologic factors (smoking, hypertension, diabetes, and preterm delivery) are excluded. These factors are used to establish an ideal weight at term that is extrapolated back to establish a customized growth curve for the pregnancy. This method has been demonstrated to be more predictive of actual birth weight in a normal pregnancy than previously established values (7). A proportion of patients identified as associated with FGR by population percentiles are reclassified as normal by customized growth curves. These fetuses have been shown to have no increased risk of adverse outcome. The use of the customized growth curve can thus prevent unnecessary interventions in these pregnancies. Similarly, some pregnancies that fall within the normal range of population-based norms are identified as associated with FGR and at risk by customized growth curves. These pregnancies have been shown to be at risk and can benefit from more intensive prenatal care (7).

Growth and symmetry are affected by the nature and severity of the underlying growth-restrictive process as well as its timing and duration. In 1963, Gruenwald identified two distinct patterns of decreased growth—symmetric and asymmetric (8). Early-phase growth disturbance (typically first semester and early second trimester) often culminates in symmetric growth restriction. Since growth in this phase is primarily due to cell hyperplasia, restriction of growth results in a lower cell number. Thus, the newborn is symmetrically small (i.e., concomitant decrease in the size of the head, trunk, length, and all other body organs). This pattern is often seen in growth disturbance associated with chromosomal anomalies, congenital malformations, and transplacental infections. In the asymmetric type, the growth rate of the trunk is smaller than that of other organs. This is caused by relative depletion of the actively growing liver combined with decreased

subcutaneous fat deposition. Third-trimester growth abnormalities, such as those seen with maternal vascular disease, restrict fetal growth during the hypertrophic growth phase. Due to preferential perfusion of the brain and adequate linear growth, the newborn with asymmetric growth retardation is identified by either an abnormally increased head circumference (HC) to abdominal circumference (AC) ratio or an abnormal ponderal index. The neonatal ponderal index has been suggested as a measure of the proportion between neonatal body mass and length (9). This index is defined as a percentage of birth weight (in grams) divided by body length (in centimeters) cubed. Theoretically, an abnormal ponderal index should differentiate the normal from the wasted and malnourished infant. Miller suggested that a low ponderal index indicates asymmetric growth restriction and that it is a more accurate predictor of fetal morbidity than birth weight alone (10). Defining FGR by an abnormal ponderal index does, however, suffer from several limitations. First, severe, early-onset growth restriction often results in a normal ponderal index due to restriction of both weight and linear growth. Second, accurate measurements of neonatal length are not easy to obtain. A small error in this measurement is cubed when calculating the ponderal index and may lead to erroneous conclusions. Because of these limitations, the ponderal index has not received widespread clinical acceptance in obstetrics. It is necessary to be aware that these symmetric and asymmetric patterns of fetal growth may merge and become indistinguishable. A maternal vascular disease beginning early enough may cause symmetric growth restriction. Likewise, a fetus with asymmetric growth retardation can become symmetric once brain sparing or linear growth is no longer maintained [this phenomenon has been identified as “late flattening of the biparietal diameter” (BPD) and is associated with increased neonatal morbidity]. It is commonly believed that “placental insufficiency” results in asymmetric growth restriction whereas chromosomal abnormalities are associated with symmetric FGR. Data presented by Nicolaides and coworkers (11) indicate, however, that fetal genetic disease may be associated with severe asymmetric growth.

Table 1 Tenth Percentile Birth Weight Values as a Function of Gestational Age

Gestational age (weeks)	Birth weight(g)	
	Brenner et al.	Lubchenco et al.
28	860	770
29	970	900
30	1075	1030
31	1180	1170
32	1290	1310
33	1480	1490
34	1670	1670
35	1860	1930
36	2050	2190
37	2240	2350
38	2430	2510
39	2530	2630
40	2630	2750
41	2675	2790
42	2720	2830

In a study of 752 consecutively born, single, white, term infants, Miller (12) has noted that the ratio of asymmetric to symmetric to “mixed” types of FGR is 4.7:2.7:1.0, respectively. Basel and coworkers reported on longitudinal sonographic biometry performed on fetuses with decreased growth rates and concluded that the type of FGR is determined to a large extent by the timing and duration of the insult rather than the specific etiology (13).

ETIOLOGY OF FGR

Various disease processes may result in FGR. The final fetal size is determined by the severity, gestational age at onset, and duration of the underlying pathology.

Abrams and Newman have examined the relationship between maternal characteristics and the risk of delivering a growth-retarded neonate (birth weight <10th percentile for gestational age) in 2228 women (14). These authors used multivariate analysis to show that the following variables are significant risk factors for FGR: cigarette smoking (odds ratio = 3.18), low maternal weight gain (odds ratio = 2.96), black ethnicity (odds ratio = 2.60), prepregnancy underweight (odds ratio = 2.36), Asian ethnicity (odds ratio = 1.88), primiparity (odds ratio = 1.85), and low maternal height (odds ratio = 1.63). It should be noted that Asian ethnicity and low maternal height may represent predisposing factors for normal, constitutionally small infants. Maternal history of low birth weight and a previous delivery of a low-birth weight infant have been added to the above list by Kramer (15,16).

The etiologic factors that result in the restriction of fetal growth potential can be grouped into intrinsic and extrinsic categories (Table 2). Intrinsic fetal abnormalities, such as genetic and congenital anomalies (Tables 3 and 4), often result in a symmetric FGR. The incidence of chromosomal aberrations in growth-restricted live newborns varies from

Table 2 Etiologic Factors in Fetal Growth Restriction

Intrinsic factors	Extrinsic factors
Chromosomal aberrations	Maternal-placental-fetal infections
Congenital structural defects	Uteroplacental perfusion
Constitutional (genetic heritage)	Chronic maternal disease
	Substrate availability and toxins

Table 3 Chromosomal Anomalies Associated with Fetal Growth Restriction

Common	Rare
Trisomy 13	Trisomy 22
Trisomy 18	Turner’s syndrome
Trisomy 21	4p and 4q syndromes
	5p and 5q syndromes
	13q syndrome
	18p and 18q syndromes
	Trisomy 9 mosaic syndrome
	Triploidy syndrome
	Partial trisomy 10q syndrome
	Ring 1
	Ring 22

30% in severe, early-onset cases to approximately 2.2% for late onset (17,18). FGR and polyhydramnios were the most common associated findings in 386 structurally anomalous fetuses (52% and 54.5%, respectively) reported by Wladimiroff et al. (19). Symmetric growth restriction is also seen commonly with fetal infections (Table 5) and teratogenic agents (Table 6). Other extrinsic conditions, such as maternal vascular and placental causes of FGR (Table 5), often result in an asymmetric growth restriction pattern. Structural anomalies of the placenta and the umbilical cord (Table 7) have not been associated with a particular form of growth restriction.

Antenatal identification of the risk factors for FGR is probably possible in as many as 50% of cases. Various etiologic factors require management decisions and have important neonatal implications. An intensive survey of maternal history (Table 8), physical examination, blood tests, and genetic studies is recommended. The astute clinician should also realize that the fetus of constitutionally small parents will most likely express its genetic heritage in its pattern of fetal growth. When growth restriction is recognized, intensive monitoring of the affected pregnancy is required, and early intervention on behalf of the compromised fetus may be advisable.

SCREENING FOR FGR

First- and second-trimester screening for FGR has not been shown to be clinically feasible. Abnormal maternal serum levels of beta hCG, pregnancy-associated plasma protein A, alpha-fetal protein, and inhibin-A have shown some association with the development of FGR. Unfortunately, the poor sensitivity and specificity coupled with the lack of an effective intervention strategy make this approach impossible to use as an effective and useful screening tool (20–25).

Third-trimester screening for FGR by serial fundal height and maternal weight–gain assessments should be routinely performed during prenatal care. Decreased fundal height may be associated with FGR (oligohydramnios, wrong dates, and fetal malposition should also be considered). The sensitivity of this test may be as high as 50% (26). The false-positive rate is, however, quite high at approximately 56% (27). Beazley and Kurjak (28) reported that 25% of such assessments performed beyond 36 weeks of gestation were inaccurate by >500g and that the error increased at the extremes of the birth weight

Table 7 Placental Factors in Fetal Growth Restriction

 - Environmental: lead, mercury, copper
- First-trimester vaginal bleeding
- Parents’ size

range (when this information is most useful). Similar results were reported by Loeffler (29). Despite these inaccuracies, serial measurement of fundal height is nearly twice as sensitive as palpation for detection of FGR (30). Accuracy can be improved by using a standardized technique of measuring from the fundus to the symphysis along the fetal axis and plotting along a customized growth curve similar to that discussed previously for estimation of fetal weight (31).

Both single and serial third-trimester ultrasound examinations have been evaluated as a screening tool for FGR. Lindqvist and Molin recently demonstrated a sensitivity of 54% for a single scan at 32 weeks (32). A separate study showed a sensitivity for birth weight <10th percentile to be 48% with a false-positive rate of 7% (33).

For pregnancies at high risk for FGR, there is a role for third-trimester screening. A prior history of stillbirth confers a 50% increase in the risk of FGR. Patients with diabetes during pregnancy are traditionally thought of as being at risk for macrosomia. However, these patients are also at a significantly increased risk for FGR, and screening is appropriate (7). Multiple gestation is also a risk factor for FGR. Obesity is not traditionally associated with FGR unless the patient also suffers from some other disorder such as chronic hypertension. Excessive weight gain during pregnancy is associated with macrosomia (34). The use of customized fetal growth curves has demonstrated that a subset of pregnancies in obese women who are categorized as having normal growth by population-based norms in fact have impaired growth and are at increased risk for perinatal mortality (7). While there have been no studies showing improvements in neonatal morbidity or mortality with screening of routine pregnancies for FGR with third-trimester ultrasound examination, it is a reasonable approach in pregnancies at high risk for FGR. Pregnant women whose weight gain is inadequate or fundal height is decreased stand an increased risk of having FGR. Further evaluation by sonographic assessment should be offered to patients with risk factors and a high index of suspicion.

DIAGNOSIS OF FGR

FGR can be manifest by a variety of combinations of decreased fetal weight, body length, HC, AC, and soft tissue mass. Ultrasound is the only direct method available for assessing fetal size. It also provides for an assessment of factors associated with FGR such as fetal anomalies, oligohydramnios, and increased placental impedance. A thorough evaluation should include a detailed study of fetal, umbilical, and placental structural anomalies as well as measurements of the BPD, HC, AC, femur length (FL), and a semiquantitative assessment of amniotic fluid volume in the form of the amniotic fluid index (AFI). Morphometric ratios such as the HC:AC and FL:AC as well as a sonographic estimate of fetal weight can then be derived from these measurements. Umbilical artery (UA) Doppler velocity studies provide data regarding placental impedance to blood flow and may be constructive in patients who are at increased risk for FGR.

Several studies have evaluated the ability of both single and serial ultrasound measurements to identify FGR. The results vary widely, with sensitivities ranging from 44% to 90% (35). These measurements may not identify the symmetrically small fetus.

A strong correlation between fetal FL and neonatal crown to heel length can be demonstrated (36). The experience with this measurement as an independent predictor of FGR is limited. O'Brien and Queenan have shown that the FL helps differentiating between symmetric and asymmetric patterns of growth restriction (37). Overall, both the size of the fetal head and the length of the femur are affected late in most cases of FGR and, therefore, these measurements are too insensitive to be used as independent predictors of FGR.

Measurements of the fetal AC are commonly used as a means for identification of the growth-restrictive fetus. This measurement reflects the size of the liver (which correlates with the degree of fetal malnutrition) as well as the volume of subcutaneous fat. In addition, the AC is decreased in both symmetric and asymmetric growth restriction. Therefore, it is not surprising that sonographic measurements of the AC predict growth restriction more accurately than either the BPD or the FL. In a large study of 3616 sonographically dated pregnancies, Warsof and coworkers (38) have shown that AC measurements predicted FGR with a sensitivity of 61%, specificity of 95%, true-positive rate of 86%, and true-negative rate of 83%. Their results also indicate that the optimal gestational age to screen for FGR is approximately 34 weeks. Similarly, other investigators (39–41) have reported relatively high positive predictive values for this measurement (ranging from 84% to 100%). Ferrazzi and coworkers (42) noted that the positive predictive value of the AC for detection of the growth-retarded fetus increases with gestational age (from 51% at 29–30 weeks of gestation to 71% at term).

Accurate pregnancy dating is essential for the interpretation of AC measurements. However, uncertainty about gestational age occurs frequently and makes the differentiation between the appropriate-for-gestational age and the growth-restrictive fetus difficult. Because growth of the fetal abdomen is linear from 15 weeks of gestation onward, determination of the rate of growth offers a gestational age-independent parameter to identify the FGR fetus. Divon and coworkers (43) found a significant difference in the rate of growth of the fetal AC between FGR fetuses and fetuses that were appropriate for gestational age (6.0 ± 4.9 mm/14 days and 14.7 ± 7.1 mm/14 days, respectively). An increase in fetal AC of <10 mm/14 days had a sensitivity of 85% in identifying the FGR fetus. Thus, the use of serial measurements of AC offers an attractive method of identifying the FGR fetus, especially when gestational age is uncertain.

The comparison of growth in some body organs relative to others has led to the development of a number of morphometric ratios. These ratios are useful in the diagnosis of asymmetric FGR where the AC is smaller than expected when compared with the size of the head or the length of the body. Consequently, abnormally elevated FL/AC or HC/AC aid in the identification of the fetus with asymmetric growth restriction. The average value of HC/AC decreases in a linear fashion from 16 to 40 weeks of gestation. An HC/AC >2 SDs above the mean has been suggested as an abnormal value (44). Kurjak and coworkers correctly identified 80% of growth-retarded fetuses with the use of this ratio (40). By contrast, Divon and coworkers (45) applied this ratio to a population of FGR fetuses of mixed etiologies and reported a relatively low sensitivity of 36%, with specificity of 90%, positive predictive

value of 67%, and negative predictive value of 72%. These authors concluded that the HC/AC ratio tends to be a better predictor of FGR in situations related to third-trimester "placental insufficiency" resulting in asymmetric fetal growth.

Hadlock and coworkers (41) reported on the use of the FL/AC ratio as a gestational age-independent index of fetal growth. From 21 weeks of gestation to term, the normally grown fetus has an FL/AC ratio of $22\% \pm 2\%$ (\pm SD). An FL/AC $>23.5\%$ was associated with a sensitivity of 60% and a specificity of 90% for identification of the growth-retarded fetus. Similarly, Divon and coworkers (43) reported a sensitivity of 55% for the same cutoff value and concluded that this parameter is fairly useful in differentiating between the fetus demonstrating appropriate growth and the growth-retarded fetus when gestational age is uncertain.

The most commonly used definition of FGR is a birth weight <10 th percentile for gestational age. Therefore, it seems reasonable to use sonographic estimation of fetal weight to diagnose FGR in the antenatal period. This parameter would also allow the clinician to evaluate changes in interval growth as compared with normative standards available throughout the latter part of pregnancy. Various equations that incorporate different variables (i.e., BPD, HC, AC, and FL) have been proposed in an attempt to accurately estimate the fetal weight (46). In general, these estimates are associated with a mean percentage absolute error of approximately 7% to 10% (47). Several investigators have evaluated the ability of fetal weight estimates to identify the fetus with growth restriction. Divon and coworkers (45) estimated fetal weight using Hadlock's formula based on BPD, AC, and FL in a population of 127 high-risk patients, 45 of whom delivered FGR neonates. They reported a sensitivity and specificity of 87%, positive predictive value of 78%, and negative predictive value of 92% for estimated fetal weight <10 th percentile for gestational age. Compared with other indices used to detect FGR, such as HC:AC ratio, FL:AC ratio, amniotic fluid volume, and Doppler velocimetry, the best predictor appeared to be an estimated fetal weight of <10 th percentile. Ott and Doyle (36) evaluated 595 pregnancies in which ultrasound examinations were performed within 72 hours of delivery. Fetal weight was estimated using measurements of the BPD and AC. They reported a sensitivity of 90% and a specificity of 80%. All infants with severe growth restriction (birth weight <3 rd percentile) were correctly identified, for a sensitivity of 100%.

Not surprisingly, equations that incorporate head and body proportions as well as body length seem to provide more accurate sonographic estimates of fetal weight. This has been shown to be especially true for the FGR fetus. Guidetti and coworkers (48) showed that estimates of fetal weight that include AC and FL correlated best with birth weight. Overall, 75% of the estimates using the BPD-AC-FL equation were within 10% of the actual birth weight. Clearly, as long as the definition of FGR is based on birth weight and gestational age criteria, the ability to diagnose FGR is significantly dependent on the accuracy of the estimated fetal weight.

Oligohydramnios has long been recognized as a complication of FGR. This is probably caused by decreased urination secondary to decreased renal perfusion reflecting redistribution of blood flow from non-vital to vital organs.

Manning and coworkers (49) used real-time sonography to qualitatively assess amniotic fluid volume in 120 pregnancies in which FGR was suspected. Defining oligohydramnios as the largest vertical pocket of fluid measuring <1 cm, they reported a sensitivity of 84%, specificity of 97%, positive predictive value of 90%, and negative predictive value of 95%. Other investigators, however, have not confirmed these results. Divon and coworkers (45) evaluated 127 patients referred with a clinical suspicion of FGR. Oligohydramnios was defined by the vertical dimension of the largest pocket of fluid measuring <2 cm. They reported a sensitivity of only 16% and a specificity of 98%. The low sensitivity and high specificity of amniotic fluid volume as an indicator of FGR have also been shown by others (50).

An AFI of less than 5 cm has been suggested as a sonographic marker of oligohydramnios (51). However, the reported experience with this cutoff value and its relationship with either diagnosis or outcome in pregnancy complicated by FGR is limited. The presence of oligohydramnios assumes increased importance when gestational age is questionable. If oligohydramnios is present in the absence of ruptured membranes, congenital anomalies, or postdatism, FGR is the most likely explanation. Thus, the presence of oligohydramnios can be considered a gestational age-independent predictor of FGR (49,51-53). Its presence is considered an ominous sign with respect to fetal compromise and is generally accepted as an indication for delivery for fetuses with mature lungs or gestational age of 34 weeks or greater.

Reliable ultrasound growth assessment of the fetus continues to present a clinical challenge. It is possible that as the use of customized growth curves becomes more widely accepted, the ability of ultrasound to accurately identify infants affected by FGR and to differentiate them from those that are constitutionally small will improve. Accurate dating is obviously essential to the diagnosis of FGR using either population-based or customized growth curves. Indicators of fetal growth that are independent of gestational age such as FL:AC ratio, oligohydramnios, and serial sonographic measurements of fetal AC should be considered whenever gestational age is unknown.

ANTEPARTUM FETAL TESTING

Intensive fetal surveillance should be instituted once growth restriction is detected or suspected. The nonstress test (NST) is most commonly used for this purpose. A reactive NST indicates that the fetal central nervous system is well oxygenated and has the ability to integrate autonomic nervous system reflexes that are initiated with body movements and result in an acceleration of the fetal heart rate (FHR). A growth-retarded fetus may be moving less frequently in order to conserve energy or due to asphyxiation as a result of decreased placental function in providing adequate nutrients or respiratory exchange. Under these circumstances, the NST is likely to be nonreactive. A review (54) of NSTs has suggested that fetuses with normal growth have a lower incidence of nonreactive tests when compared with growth-retarded fetuses.

A reactive NST is highly indicative of a well-oxygenated fetus. The false-negative rate of a reactive NST performed twice weekly is approximately 2 to 3 in 1000. The converse,

however, is not true. The association between a nonreactive NST and fetal hypoxia is rather low. The false-positive rate of a 40-minute nonreactive NST is approximately 80% and, therefore, in addition to fetal hypoxia other causes of nonreactivity should be considered (i.e., fetal sleep–wake cycles, prematurity, congenital anomalies, maternal use of medications and drugs). A nonreactive FHR pattern with or without spontaneous decelerations may be the first sign of fetal structural anomalies associated with FGR (55). Therefore, a detailed sonographic evaluation combined with the analysis of fetal karyotype, if significant fetal anomalies are found, should be considered under these conditions. In addition, the growth-retarded fetus is at an increased risk of spontaneous variable FHR decelerations due to cord decompression resultant from oligohydramnios and/or decreased Wharton's jelly. Therefore, an ultrasound assessment of the amniotic fluid volume should be performed whenever variable decelerations are detected during NST.

Several authors have suggested that the presence of severe oligohydramnios in a growth-retarded fetus should be used as an indication for delivery. Recent Doppler studies have shown that oligohydramnios in FGR fetuses is associated with increased resistance to blood flow in the fetal renal artery (56). Decreased renal perfusion in these fetuses is probably part of a compensatory mechanism resulting in redistribution of blood flow from non-vital to vital organs. As long as the central nervous system is adequately perfused, other tests of fetal well-being [such as the NST, contraction stress test (CST), or fetal breathing movements] will be normal. Most clinicians would intervene before the fetus decompensates as manifested by the presence of oligohydramnios combined with an abnormal NST, CST, or biophysical profile (BPP) score.

Chamberlain and coworkers (41) applied a 2-cm vertical "depth" rule to define oligohydramnios and concluded that its presence is an ominous sign with respect to fetal health. The corrected perinatal mortalities for fetuses with marginal and decreased amniotic fluid volume were 37.7 in 1000 and 109.4 in 1000, respectively. These authors concluded that the presence of oligohydramnios should prompt a consideration for a timely delivery.

Additional causes of oligohydramnios should be considered prior to intervention such as premature rupture of the membranes or obstructive uropathy. Differentiating renal agenesis from a structurally normal but growth-restrictive fetus may be more difficult. Fetuses with renal agenesis are often growth retarded. In addition, visualization of the fetal kidneys may be impossible in the presence of oligohydramnios. Instillation of normal saline into the amniotic cavity may improve the quality of the sonographic image.

The high false-positive rate of abnormal NST requires additional testing prior to intervention on a presumed diagnosis of fetal compromise. In the face of a nonreactive NST, fetal well-being is commonly established by BPP scoring. A BPP score of 8 to 10:10 is associated with a low risk for either fetal asphyxia or imminent fetal death. In general, as the BPP score decreases, the likelihood of fetal asphyxia increases. As with NST, BPP scores are, in general, lower in FGR fetuses when compared with other "high-risk" fetuses. Devoe and coworkers (57) noted that their FGR patients accounted for

33% of all abnormal BPP scores, although they constituted only 20% of the tested population.

Gradual deterioration of fetal health is reflected by decreased or absent fetal activity. Therefore, BPP testing represents a rational approach for fetal surveillance. Baskett and coworkers (58) reported that growth-restrictive fetuses were more likely to have perinatal complication with the incidences of 30%, 23%, and 21% for oligohydramnios, decreased fetal body movements, and decreased fetal tone, respectively.

Pollack and coworkers (47) have reported on 4727 patients undergoing NST followed by BPP testing when indicated. FGR was the primary indication for fetal testing in 478 (10%) patients. No fetal deaths were reported in the tested FGR population. In a large study of 19,221 patients, Manning and coworkers (59) noted that 4 of 14 fetal deaths, following normal tests, occurred in FGR pregnancies. These results underscore the fact that intensive fetal testing is associated with an extremely low false-negative rate in the setting of FGR.

Doppler Velocimetry

Normal fetal growth is determined by multiple maternal–fetal variables. Continuous blood flow on either side of the placenta and adequate fetal perfusion are obviously an absolute necessity. Indeed, FGR is associated with various abnormalities of the uteroplacental, umbilical, and fetal circulations (60,61). Doppler devices allow for a noninvasive evaluation of blood flow by displaying Doppler-shifted frequencies that are proportional to the velocity of red blood cells. Qualitative assessment of these waveforms is provided by angle-independent indices that are based on various ratios between the systolic and diastolic components of the waveform. Most studies concur that the simplest index (i.e., the systolic:diastolic ratio, S:D) is clinically as useful as any of the more complicated indices such as the resistance index (RI) [(Peak systolic velocity – end-diastolic velocity)/peak systolic velocity] or the pulsatility index (PI) [(peak systolic velocity – end-diastolic velocity)/average frequency shift].

Maternal and fetal blood flow velocity waveforms are influenced by the stroke volume, pressure gradient, heart rate, vessel wall elasticity, and blood viscosity. Fast heart rates result in a relatively high end-diastolic component, while increased downstream impedance causes low end-diastolic flows. Since blood flow during diastole is mostly passive, as placental impedance increases, the umbilical arterial end-diastolic flow decreases. Therefore, severe placental impedance is associated with low, absent, or reversed end-diastolic umbilical blood flow.

On the maternal side, some evidence (44) suggests that changes in uterine artery velocity waveforms (arcuate arteries) may be detected as early as the second trimester in some pregnancies, which eventually develop pre-eclampsia or FGR. Uterine artery Doppler has a sensitivity rate of 25% to 75% and a false-positive rate of 5% to 10% in detecting early onset of FGR (62–64). Newnham and coworkers (65), who evaluated uteroplacental blood flow at 14, 18, 24, 28, and 34 weeks of gestation, reported that abnormal waveforms were significantly correlated with the future development of fetal hypoxia; however, they were not predictive of subsequent development of FGR. Both Chambers and coworkers (39) and

Jacobson and coworkers (66) concluded that Doppler studies of the uteroplacental perfusion are of a limited clinical value due to their poor sensitivity and high false-positive rate.

Many studies have reported a significant decrease in end-diastolic flow of the UA and the descending aorta of the growth-restricted fetus (61). These studies indicate that some forms of FGR may result from “placental insufficiency” defined by increased placental impedance secondary to a decreased number of intraplacental arterial channels (67–69). A decreased PI in the internal carotid arteries (70) in FGR fetuses probably reflects enhanced perfusion of the brain (brain sparing effect) from redistribution of blood flow.

Trudinger and coworkers (71) have reported on 2178 high-risk pregnancies for which UA velocity waveforms were evaluated. The incidence of FGR (birth weight <10th percentile) in this population was 27%; 50% of their FGR fetuses had an abnormal (>95th percentile) umbilical arterial S:D ratio. The odds ratio of a fetus with an abnormal arterial velocity waveform for being diagnosed as growth restricted by birth weight criteria was 5.9 (95% confidence interval of 4.7–7.3). Moreover, preterm infants with abnormal S:D ratios spent twice as long in the neonatal intensive care unit as those with normal velocity waveforms. These authors concluded that “in high-risk pregnancy, Doppler UA flow velocity waveforms predict the most compromised fetuses in terms of growth restriction and requirement for neonatal intensive care.”

The ability to detect FGR with Doppler velocimetry varies considerably (Table 9). Overall, the odds ratios demonstrate a significantly increased likelihood of delivering an FGR newborn once the Doppler study is abnormal. These studies are hampered by the absence of standard definitions for both FGR and abnormal velocity waveforms. In addition, most studies have preferentially evaluated high-risk populations with an abnormally high incidence of FGR. Furthermore, the positive predictive value of abnormal Doppler velocimetry is influenced by the prevalence of FGR in the population. The prevalence is in turn affected by whether FGR is defined by population-based or customized criteria. Nonetheless, Doppler ultrasound of the UA remains a mainstay of evaluation of the fetus with FGR, and abnormal values are associated with adverse fetal outcomes (72–75).

A few studies have evaluated the usefulness of screening the general population for FGR with the use of UA velocimetry. Beattie and Dornan (76) evaluated a total of 2097 singleton

pregnancies at 28, 34, and 38 weeks of gestation. Less than 20% of this population was defined as “high-risk” pregnancies. The sensitivity of an abnormal S:D ratio for prediction of FGR was rather low (from 31% to 40% depending on the gestational age at the time of the study). Bruinse and coworkers (77) studied an unselected population of 405 pregnant women at 28 and 34 weeks of gestation. Doppler screening for FGR had a low sensitivity of 17% and 22%, respectively. Hanretty and coworkers (78) screened uteroplacental and umbilical arteries in 543 unselected patients at 20 to 30 and 34 to 36 weeks of gestation. They found no difference in the outcome of pregnancies with normal or abnormal uteroplacental waveforms. However, birth weights were significantly lower in patients with an abnormal UA waveform at either gestational age. These studies suggest that Doppler screening of the general population is associated with a low yield. The cost:benefit ratio of such screening programs is unclear.

The combined use of Doppler velocimetry with real-time ultrasound for the diagnosis of FGR was reported by Divon and coworkers (45). The study population consisted of 127 patients referred with a clinical suspicion of FGR. Forty-five infants (35%) were identified as having FGR by birth weight <10th percentile for gestational age. These authors concluded that neither sonographic measurements nor Doppler tests were uniformly successful in identifying the growth-restricted infant. Overall, the best prediction was offered by sonographic estimates of fetal weight, which correctly identified 39 of the 45 FGR infants. An S:D ratio >3 was seen in 49% of the FGR fetuses. All indices similarly predicted the non-FGR infant (range of specificities: 87–98%). Similar results were reported by Kay and coworkers (79) on 48 patients who underwent sonographic measurements and Doppler evaluations of the uterine and umbilical vasculatures. Chambers and coworkers (39) studied 145 pregnancies suspected of being small for dates and found that sonographic measurements of the fetal AC were superior to UA velocimetry for prediction of FGR with sensitivities of 73% and 47%, respectively. It should, however, be emphasized that Doppler can be used as a gestational age-independent index of FGR (i.e., S:D >3.0 is abnormal after 30 weeks of gestation) while evaluation of the AC requires accurate gestational dating.

The utility of Doppler velocimetry in the prediction of adverse outcome in pregnancies at risk for FGR was investigated by Berkowitz and coworkers (80). These authors reported that approximately 50% of their FGR infants had

Table 9 Umbilical Artery Velocimetry for Prediction of Fetal Growth Restriction in High-Risk Pregnancies

First author	Study patients, n (prevalence of FGR)	Definition of FGR	Definition (95% confidence waveform interval)	Odds ratio
Divon (1988)	127 (35%)	BW <10th percentile	S:D >3.0	14.7 (4.6–50.5)
Berkowitz (1988)	168 (25%)	BW <10th percentile	S:D >3.0	6.6 (2.7–16.4)
Schulman (1989)	255 (9%)	BW <15th percentile	S:D >3.0	19.9 (6.9–59.0)
Dempster (1989)	205 (40%)	BW <10th percentile	S:D >95th percentile	3.3 (1.6–6.5)
Sijmons (1989)	400 (22%)	BW <10th percentile	PI >95th percentile	4.4 (2.0–9.4)
Lowery (1990)	146 (14%)	BW <10th percentile	S:D >4.0	10.9 (3.8–32.5)
Gudmundson (1991)	139 (51%)	BW <15th percentile	PI >2 standard deviations above mean	7.1 (3.0–17.2)
Kay (1991)	48 (37.5%)	BW <10th percentile	S:D >2 standard deviations above mean	11.3 (2.1–52.0)
Trudinger (1991)	2178 (27%)	BW <10th percentile	S:D >95th percentile	5.9 (4.7–7.3)

Abbreviations: BW, body weight; S:D, systolic:diastolic ratio; PI, pulsatility index.

abnormal UA velocity waveforms and that these waveforms were valuable in identifying the growth-restrictive infant who was at increased risk for one or more of the following outcome criteria: early delivery, reduced birth weight, oligohydramnios, neonate intensive-care unit admission, and prolonged hospital stay. Reuwer and coworkers (81) reported similar results, demonstrating that Doppler velocimetry allowed accurate and early recognition of those growth-restrictive fetuses that would become compromised antenatally. Several investigators have noted that all their FGR-related neonatal deaths and a majority of their intensive-care admissions were confined to those fetuses with abnormal Doppler velocimetry results (72–75,82–85). While normal UA Doppler cannot definitively guarantee a normal fetus (86), abnormal Doppler values are associated with adverse neonatal outcomes.

Absent or reverse end-diastolic flow is also associated with fetal aneuploidy. Wenstrom and coworkers (87) studied 450 high-risk pregnancies that underwent level II sonograms after 20 weeks of gestation. Twenty-two of these patients had absent or reversed diastolic flow in the UA. Of these, 10 had FGR, 10 had either congenital malformations or were aneuploid, and in 2 cases, the etiology was not identified. Among the four cases with fetal aneuploidy, one had multiple severe anomalies including holoprosencephaly, renal agenesis, and polydactyly, and the other three had FGR. Therefore, a thorough evaluation of fetal anatomy and search for the underlying etiology, which causes absent or reversed diastolic blood flow, should be attempted when managing a patient with FGR. Whether a karyotype should also be obtained in patients with absent diastolic or reversed diastolic flow without major congenital anomalies or severe symmetric FGR needs further evaluation.

MANAGEMENT

Once the diagnosis of FGR is suspected, several management issues should be considered. These include parental counseling regarding a search for the etiology of growth restriction, fetal surveillance, timing of delivery, and neonatal outcome. In addition, the need for bed rest and adequate maternal nutrition should be discussed with the patient. The use of alcohol, tobacco or any other unnecessary toxins should be discouraged.

Evaluation of the FGR fetus with serial ultrasound examinations and Doppler blood flow is a hallmark of the management. Absent or reverse end-diastolic flow in the UA is a useful marker for potential fetal compromise. As many as 40% of acidotic fetuses will demonstrate this finding (88). Overall, absent or reverse end-diastolic flow has roughly a 60% sensitivity and specificity for adverse perinatal outcome (73). Doppler evaluation of the fetal middle cerebral artery (MCA) has also been studied. Multiple studies have demonstrated that lower values of MCA PI are associated with FGR (89–91). Chiba and Murakami (92) measured MCA RI at the time of cordocentesis. They reported that a decreasing MCA RI was associated with increasing PCO₂ in the fetal circulation. Bahado-Singh et al. (93) reported that an abnormal cerebroplacental ratio (MCA PI divided by UA PI) has a statistically significant correlation with adverse perinatal outcome. This preferential shunting of blood to the brain, the so-called brain-sparing effect, can be reversed in a fetus with severe uteroplacental insufficiency. Konje and

colleagues (94) reported a reversal of the brain sparing effect in eight fetuses with FGR, death of half in utero, and the death of the other half during the neonatal period. While MCA peak systolic velocity (PSV) is more classically used in the evaluation of the anemic fetus, Mari et al. have reported that an elevated MCA PSV is the best predictor of perinatal mortality in the fetus with FGR (95).

Researchers have also investigated the use of Doppler of the ductus venosus (DV) as a marker for acute fetal decompensation. Ductus venosus waveforms have been shown to become abnormal about 48 to 72 hours prior to the BPP abnormality (96). The ongoing “Trial of umbilical and fetal flow in Europe” is conducted to define the optimal timing in delivering FGR fetuses using DV Doppler and traditional FHR cardiocography (7).

FHR tracing has also been extensively used in monitoring FGR. Loss of short-term variability is temporally related with abnormal DV Doppler. Due to its high false-positive rate (as high as 50%) (97), the use of FHR alone to monitor FGR pregnancies is inadequate. When used in concert with other monitoring, such as the BPP or DV Doppler, it can be useful. Hecher and associates demonstrated that loss of short-term FHR variability with concurrent abnormalities on DV Doppler is a particularly strong predictor of adverse perinatal outcome (98). The value of the BPP in managing FGR pregnancies is also difficult to determine. As noted above, the BPP has both a very low false-negative rate and a weak correlation between abnormal BPP and fetal acidosis (59). In addition, other studies have shown no association between abnormal BPP and cognitive function later in life (99), suggesting a higher false-positive rate than that may be recognized. Changes in amniotic fluid volume and FHR appear to be the early predictors of impending fetal decompensation, while fetal tone, breathing, and body movement appear to be associated with more advanced stages of fetal deterioration (7).

The increased incidence of perinatal morbidity and mortality among FGR pregnancies often necessitates early delivery. Preterm delivery should be considered in the growth-restrictive fetus when fetal surveillance indicates a high probability of fetal asphyxia. The best method of fetal surveillance in these pregnancies is yet to be determined. The decision regarding when to deliver is further complicated by the fact that a fetus at <10th percentile on a customized growth curve is at risk of demise even with normal UA Doppler studies. Conversely, Boers and associates found no significant differences in neonatal outcome with expectant management of FGR between 36 and 39 weeks of gestation in the DIGITAT study (100). In this study, participants in the expectant management arm had twice-weekly fetal heart tone and UA Doppler evaluation. Management of the FGR pregnancy with a known fetal anomaly or an abnormal karyotype should be tailored to the specific abnormality.

Timing of the delivery of FGR fetuses is predicated on balancing the risks of prematurity with the risk of fetal demise from expectant management. The difficulty lies in the lack of optimal fetal surveillance methods. In the very preterm FGR infant, since the risks of major complications from prematurity are high, it seems prudent to delay the delivery until fetal lung maturity can be documented as long as fetal surveillance is reassuring. On the other hand, Boers and associates (100)

Table 10 Indications for Delivery in Fetal Growth Restriction

Fetal compromise
Deteriorating maternal condition
Term pregnancy with a favorable cervix
Term pregnancy with markedly abnormal umbilical artery velocity waveform
Absence of fetal growth with documented lung maturity

showed no change in outcomes with expectant management of late preterm FGR as compared with early delivery, while Figueras et al. (7) demonstrated that FGR fetuses are at high risk for demise even with reassuring fetal surveillance.

Amniocentesis for documentation of lung maturity should be considered when FGR is present. The benefits of conservative management in the presence of documented lung maturity are probably limited. Possible indications for delivery are shown in Table 10.

LONG-TERM CONSEQUENCES OF FGR

The consequences of FGR extend beyond delivery. FGR is associated with cardiovascular disease, abnormalities of the hypothalamic pituitary axis and structural abnormalities of the cardiovascular system, insulin resistance, and the metabolic syndrome in adulthood (101).

FGR is associated with an increased risk of cardiovascular death as an adult (102). Low birth weight has also been associated with elevated cholesterol when compared with matched appropriate for gestational age controls by the age of 12 years (103). A more recent study demonstrated that FGR was associated with decreased stroke volume, abnormally globular ventricles, higher blood pressure, and increased intima-media thickness in children (104).

The “thrifty phenotype” hypothesis was originally proposed in 1992 and stated that a metabolically deprived developing fetus would become metabolically programmed for insulin resistance and impaired glucose metabolism (101). There was a strong association between FGR and elevated fasting glucose levels, elevated fasting insulin levels, prevalence of type 2 diabetes mellitus, 2-hour postprandial glucose levels, and serum insulin levels (105). Women who were born SGA have elevated dehydroepiandrosterone sulfate levels, elevated follicle-stimulating hormone levels, and a higher incidence of anovulation (106–108).

The metabolic consequences to the FGR project well beyond the womb and predispose the affected fetus to a wide range of health risks. Since there is no effective treatment to reverse FGR, controlling maternal risk factors such as smoking, alcohol consumption, illicit drug use, and preventable infection is important in reducing the perinatal morbidity and mortality and adverse long-term consequences.

CONCLUSION

Fetal growth is an important sign of fetal well-being. The clinical significance of FGR stems from its being a significant predictor of perinatal morbidity and mortality. FGR is an entity whose definition is controversial and whose etiology and natural history are poorly understood. Its antenatal diagnosis is less than optimal and many management issues remain

unresolved. Nonetheless, it is a condition of paramount importance to optimize perinatal outcome by timely and accurate diagnosis coupled with appropriate intervention. Further research is needed to improve our understanding, diagnosis, and management of FGR.

59 Application of 3D and 4D ultrasound in fetal medicine

Eberhard Merz

HISTORY

In 1989, the first commercially available ultrasound scanner (Combison 330) with mechanically driven three-dimensional (3D) probes was launched by Kretztechnik AG, Austria (1). Nevertheless, many investigators with previous experience in 2D ultrasonography took a skeptical attitude toward the new technology.

Several questions continued to be raised by the physicians: “Is 3D ultrasound more useful in prenatal diagnosis?”; “Does it improve diagnostic accuracy, or is it only good to obtain keepsake images for the parents?”; “Does it enable the detection of a greater number of malformations?”; “Is it useful in daily routine, or is it more time-consuming?” (2).

Only since the development of significantly more user-friendly 3D/4D ultrasound scanners that permit even less experienced operators to apply this technique successfully in prenatal diagnosis has 3D/4D ultrasonography found a growing number of advocates worldwide. The technology does not only furnish excellent images, but also enables the preparation of videos of the unborn baby that provide the expert with a new spectrum for fine-tuning the diagnosis while, at the same time, leaving the prospective parents with a lasting impression.

TECHNICAL ASPECTS

In essence, every 3D ultrasound procedure consists of four basic steps (2,3): (i) volume acquisition, (ii) volume display, (iii) volume manipulation/image processing, and (iv) storage of volumes, or rendered images and volume sequences.

Volume Acquisition

In contrast to conventional 2D ultrasound where only single planes are stored, all 3D ultrasound technology is based on the acquisition of multiple adjacent 2D scans that are stored at correlative sites in an electronic memory, where they are assembled to produce a volume data set (3).

Two major technologies are currently available for the acquisition of ultrasound volumes: the freehand technique and the automated technique.

In the *freehand system* (4), scans are obtained with a conventional 2D probe onto which an electromagnetic position sensor has been mounted. This device can sense the exact position and movements of the probe by detecting changes in a magnetic field (3).

All images acquired during the freehand movements of the probe are transmitted via the video signal of the ultrasound unit to an external workstation, which is equipped with a frame grabber. After all individual images have been digitized by the frame grabber, they are stored in the computer memory according to their known location and are finally assembled into a volume.

With an *automated system* a dedicated 3D transducer is matched to the ultrasound system. Volume acquisition is activated at the touch of a button, at which point the transducer element within the probe casing is automatically swept at a specified angle through a fan-shaped pattern (3).

In *3D volume acquisition*, individual volumes are obtained; in *4D volume acquisition*, multiple volumes are acquired successively in the form of a volume sequence.

3D/4D Volume Display

Several grayscale and color modes are available for the demonstration of volumes:

Triplanar Display

In the tri- or multiplanar display, all three mutually perpendicular scan planes (the “orthogonal” planes) are displayed simultaneously on the monitor immediately after volume acquisition (Fig. 1) (3).

The rotation and translation controls can now be used to demonstrate not only conventional section planes but also oblique planes. Starting from a selected plane the volume can be manipulated in all three directions with millimeter precision, enabling a precise tomographic survey of a particular region.

To avoid the occurrence of spatial disorientation during rotation of the individual image planes as to left/right or top/bottom, the application of a standardized procedure as described by Merz et al. (5) 2007 is recommended:

1. In the *primary multiplanar image*, the object should be displayed so that the image at the top left always corresponds to that visualized in the 2D image (Fig. 1). This permits to draw a valid conclusion on the position of the embryo/fetus/uterus at the time of volume acquisition.
2. In the *secondary multiplanar image*, the volume has to be changed by rotation maneuvers to ensure that the embryo/fetus may at all times be visualized in an upright sagittal position in the image at the top right (Figs. 2 and 3). The aim of this image is to present the object on the display screen in such a way as to allow the correct assignment of ventral and dorsal, as well as of right and left to the actual anatomy.

Tomographic Ultrasound Imaging or Multi-Slice Viewing Technique

With tomographic ultrasound imaging [TUI (General Electric)] (= multi-slice viewing technique (Samsung-Medison), it is possible to view parallel 2D section planes through a volume on the monitor as in CT or MRI (6,7) (Figs. 4 and 5). The selection of the direction of the volume analysis and

Figure 1 Triplanar display of a fetus at 35 weeks of gestation immediately after acquisition in cephalic presentation (primary image). Upper left: exact midsagittal scan (= median plane). Upper right: transverse scan at orbit level. Lower left: coronal scan at orbit level. The image at the top left always corresponds to the conventional two-dimensional image during acquisition. cr = cranial, ca = caudal, ve = ventral, do = dorsal (mother). F = forehead, C = chin, a = anterior, p = posterior, ri = right, le = left (fetus).

Figure 2 Fetus after rotation into an upright position (secondary image). The sagittal position of the fetus in the image at the top right guarantees a correct assignment of right and left to the actual anatomy in the coronal and the transverse scans. F = forehead, C = chin, a = anterior, p = posterior, ri = right, le = left (fetus).

the distance of the parallel slices are optional. The choice of the distance between the individual section planes depends upon the gestational age, as well as on the location and size of the anatomic structures to be visualized (7).

Surface Display

The surface modes provide the examiner with rendered 3D images of the fetal surface (2,3) (Figs. 6–10). Various rendering

algorithms can be used in surface rendering: surface mode, smooth surface mode, light mode, and gradient light mode (2,3).

Prerequisites for high-quality images of the fetal surface are the presence of a sufficiently large amniotic fluid pocket in front of the structure being imaged and the absence of overlying or adjacent structures, such as the limbs, the umbilical cord, or the placenta.

Figure 3 Triplanar demonstration of a fetal brain at 19 weeks of gestation after rotation of the fetus into an upright position. Upper left: coronal scan. Upper right: sagittal scan of the right ventricle. Lower left: Axial scan of the ventricles.

Figure 4 Tomographic ultrasound imaging showing several slices of the fetal face at distances of 6.5 mm (coronal views) at 35 weeks of gestation.

The surface modes can be applied not only for the demonstration of outer surfaces, but also to receive a spatial view of inner surfaces or surfaces of section planes.

In contrast to 3D ultrasound where only 3D images are acquired, the 4D technique (= real time 3D) further provides image sequences, which allow the observation of real-time fetal movements as in a movie (2) (Fig. 11).

Transparence Display

The transparent mode (maximum mode) provides a spatial view of the fetal skeleton (Fig. 12) (3,8). Unlike in surface rendering, it primarily displays hyperechoic structures while

greatly attenuating less echogenic structures. This provides an overview of the fetal skeleton, with a demonstration of normal and abnormal ossification. The 4D transparent display may be used to demonstrate movements of the skeleton.

Inversion Display

The inversion mode converts anechoic structures into hyperechoic structures (9). This allows for the 3D display of hollow structures such as the heart chambers, vessels, the stomach, the fetal urinary bladder, or pathologic amounts of liquid in the form of opaque casts.

Figure 5 Tomographic ultrasound imaging of the fetal brain at distances of 6.5mm (sagittal planes). The central image demonstrates the corpus callosum () at

Figure 6 Multiplanar and surface-rendered frontal view of the fetal face at 28 weeks of gestation.

Glass-Body Rendering

The glass body-rendering mode generates a combined display of grayscale values and color Doppler/power Doppler signals. This offers the physician the possibility of presenting the fetal vascular system three dimensionally, as in a glass-body model (2) (Fig. 13). The deletion of the grayscale portion of the image provides a clear 3D color depiction of the flow of blood in fetal blood vessels.

Glass-body rendering can further be applied to visualize placental perfusion (Fig. 14).

Spatiotemporal Image Correlation

The spatiotemporal image correlation (STIC) technique (2,3,10–12) is a useful tool for the depiction of the beating fetal heart in both the grayscale and the color mode (color STIC = STIC + color Doppler). In the first step, images of several cardiac cycles are acquired using a slow-motion volume scan (7.5, 10, or 12.5 sec). The system then analyzes the volume data separately according to their temporal and spatial domains. These measures produce a 4D volume data set of a single cardiac cycle in an endless volume cine loop. The STIC

Figure 12 Transparent view (maximum mode) of the fetal skeleton. (A) Oblique side view of the ossified skull, facial bones, and the metopic and left coronal suture (23 weeks of gestation). (B) Frontal view of the ossified facial bones, the anterior fontanel and the metopic suture (21 weeks of gestation). (C) Bony thorax and ossified spine at 17 weeks of gestation.

Figure 13 Glass-body rendering of the fetal heart and the aorta (25 weeks of gestation).

Figure 14 Glass-body rendering of the placenta and the insertion of the umbilical cord (26 weeks of gestation).

technology does not only permit the storage of a beating fetal heart in a volume and its triplanar visualization, but also aids in the detailed investigation of the heart in the endless volume cine loop following shifting and rotation of the different image planes (2,12). The color STIC technology enables visualization

of blood flow in the fetal heart or fetal blood vessels in the endless volume cine loop display (2,12) (Fig. 15).

However, a prerequisite for the acquisition of an adequate STIC image is a sufficiently regular heart rate pattern. The application of the STIC technique is not suitable in the presence of arrhythmia.

VCAD

The automated multiplanar technique (VCAD) (13) also permits less experienced users to visualize the most important sectional planes of the fetal heart. The image of the heart acquired using the STIC technique is rotated so that the four-chamber view corresponds to the superimposed heart template. With a single keystroke, the relevant planes of the heart as, for example, the left and right outflow tract are automatically shown.

Sonographic Automated Volume Count

Sonographic automated volume count automatically detects low echogenic objects in the fetus (e.g., brain ventricles, stomach, urinary bladder) and analyzes their shape and volume. The calculated volume of the object is then listed according to size.

Volume Manipulation

Comparable with the images generated in 2D ultrasound, images acquired with 3D ultrasound can be manipulated using the following postprocessing procedures: threshold control, speckle reduction imaging (SRI), brightness and contrast controls, and the electronic scalpel.

A number of 3D images, in particular surface images, require postprocessing procedures in order to improve image quality. Because low-level echoes (*speckle*), for example, those found in amniotic fluid, prevent a high image quality, they should be filtered out by increasing the threshold value (3) (Fig. 16) or by using the *SRI technique*. This technique reduces extraneous echoes and artifacts and leads to an improved demonstration of structures and boundaries.

In surface rendering, larger interfering structures, such as loops of the umbilical cord, limbs, or the placenta, may obstruct the view of the fetal face. In approximately 70% of cases, the electronic elimination of these structures using the *electronic scalpel* leads to a substantial image improvement of the depicted surfaces (14) (Fig. 16). The original volume remains unaffected by the cutting procedure.

Brightness and contrast controls can be set interactively in the 3D image as well as in the 4D sequences; all changes are immediately visible on the monitor.

Long-Term Storage of Volumes, Rendered Images, or Cine Sequences

The 3D/4D ultrasound offers an important advantage over the conventional 2D sonography in archiving volumes, rendering images, or cine sequences of volumes instead of individual images. Once the volumes are stored in the memory of the ultrasound unit, they can be sent to various media for long-term storage (external hard drive, MOD, CD, DVD). Digital archiving of the volumes and images guarantees safe storage without quality loss. The examiner can retrieve the volumes and cine sequences at any time and navigate through them in

Figure 15 Triplanar spatiotemporal image correlation demonstration of the fetal heart (26 weeks of gestation). Upper left: Four-chamber view. Upper right: Sagittal scan of left chamber. Lower left: Transverse scan of left and right chambers. Lower right: Surface demonstration of the blood flow into the chambers (four-chamber view).

Figure 16 Surface mode of a fetal face (frontal view) (30 weeks of gestation). (A) The face is obscured by echogenic amniotic fluid (threshold 0). (B) A threshold of 50 reveals the fetal face. (C) Demonstration of the fetal face after removing adjacent gross structures with the electronic scalpel.

the absence of the patient (virtual scan) (3,15). This allows the physician to scrutinize equivocal findings without a time limit or creating undue anxiety in the patient.

DIAGNOSTIC CONSIDERATIONS

The different imaging modes offered by transvaginal and transabdominal 3D/4D ultrasound technology today provide the operator with experience in the diagnosis of fetal malformations with completely new possibilities for systematic fine-tuning of the prenatal diagnosis (Figs. 17–28). This applies to both, the application of these techniques directly on the patient and the detailed assessment of stored volumes with high-quality images in the absence of the patient.

The simultaneous display of all three mutually perpendicular scan planes provided by the triplanar mode (16,17) permits an accurate assessment of the fetal anatomy. It facilitates rapid targeting of a specific biometry or section plane (Fig. 20). The ability to slowly navigate through the

volume data set allows the physician to demonstrate morphologic abnormalities in an optimal plane. The application of the triplanar mode is particularly useful when the left and right sides of symmetrical organs like the brain (18–22) or the orbits are to be compared.

Similarly, the TUI technique enables an exact tomographic demonstration of pathologic findings on the basis of parallel 2D section planes. The direction of the slices as well as the distance between the individual section planes can be changed interactively to ensure the optimal visualization of the defect (Figs. 19 and 21).

Application of the surface mode allows the reliable demonstration and exclusion of suspected pathologic findings. Conclusively demonstrated are in particular less severe surface defects as, for example, encephalocele, cleft lip/cleft palate, spina bifida, defects of the abdominal wall or the extremities, but also visualized are defects such as facial dysmorphism, external ear dysplasia, malformations of the hand, foot, or genital anomalies, as well as angular deformity of the limbs

(17,23–29) (Figs. 17,18,23,25,27,28). Furthermore, internal surfaces and section planes can be rendered in the form of surface images (Figs. 18 and 26).

The transparent mode demonstrates defective ossification, osseous defects, and fractures and axial deviations of the fetal spine or the limb bones (2,17) (Figs. 22 and 27).

The inversion mode is capable of converting anechoic cystic structures such as dilated lateral cerebral ventricles, renal cysts, and cystic tumors of the thorax or the abdomen into hyperechoic structures.

Glass-body rendering is a useful tool for the spatial demonstration of fetal vascular anomalies.

Figure 22 Transparent view (maximum mode) of the fetal skeleton. (A) Normal spine and bony thorax (20 weeks). (B) Hemivertebra () (19 weeks). (C) Severe scoliosis (29 weeks).

Figure 23 Surface-rendered view of myelomeningocele (31 weeks of gestation).

A detailed demonstration of cardiac defects (12) can be accomplished with the STIC technology. An acquired STIC volume data set of the heart can further be used in combination with the TUI technique to visualize a cardiac defect in parallel image planes (Fig. 22).

The 4D ultrasound provides the opportunity to detect abnormal fetal behavior (30). In addition, this technique can be used to record a suspicious site in the moving fetus. Once a

malformation is included in the recorded volumes, the examiner can select the volume that best demonstrates the defect in 3D.

Volume sonography with its broad spectrum of different imaging modes is of particular use when a suspected finding is to be demonstrated to the pediatrician, the facial plastic surgeon or neurosurgeon, the pediatric cardiologist, the heart surgeon, or the pediatric urologist.

Figure 24 Tomographic ultrasound imaging of a spatiotemporal image correlation volume with hypoplastic left heart syndrome and septum defect (→) (21 weeks of gestation).

Figure 25 Surface-rendered view of gastroschisis (21 weeks of gestation).

This is of equal importance for the prospective parents, because a morphologic defect in the fetus can be more convincingly demonstrated (2), enabling them to understand the respective defect significantly better than that from a 2D

demonstration. Conversely, in cases of an increased risk for recurrent malformation, the apprehensive parents can be reassured more impressively of the presence of a normal finding than that with 2D sonography.

KEEPSAKE IMAGES WITHOUT PRENATAL DIAGNOSIS

There is no doubt that surface rendering of the fetus, and here in particular of the fetal face, represents a definite highlight for the parents and can improve maternal–fetal bonding (31). The rising demand for prenatal 3D or 4D images has led to the development of companies in the United States that produce images and videos of the unborn baby, which are acquired outside the clinical setting. In as much as these images may be beautiful and captivating for the prospective parents and the

investigator, the preparation of photos or videos of the fetus is problematic if these are not obtained in the course of a diagnostic medical procedure (32–34).

SUMMARY

The 3D/4D ultrasound technology provides both the physician and the parents with fascinating insights into the embryonic and fetal development. The 3D/4D imaging has been established as a valuable additive technique to conventional 2D

Figure 28 (A) Surface-rendered view of postaxial hexadactyly (31 weeks of gestation). (B) Club foot. The surface-rendered image shows the axial deviation of the foot of 90° (31 weeks of gestation).

sonography, as it provides in particular the experienced ultrasonographer with a significant expansion of the diagnostic spectrum.

60 Prenatal diagnosis of fetal abnormality using fetal cells in maternal circulation

Gian Carlo Di Renzo, Elena Picchiassi, Michela Centra, and Giuliana Coata

INTRODUCTION

The presence of rare fetal cells as well as of cell-free fetal DNA (cffDNA) and mRNA in the maternal circulation over the course of gestation has been quite recently established. The possibility of performing an early noninvasive prenatal diagnosis on fetal cells isolated from maternal peripheral blood is an important goal for modern obstetric care (1–4). Thus, fetal material can be isolated and potentially tested for genetic analysis without the need of sampling by invasive procedures as amniocentesis and chorionic villus sampling (CVS).

The types of fetal cells discovered in maternal blood are various and include lymphocytes, erythroblasts, hematopoietic stem and progenitor cells, mesenchymal cells, and trophoblasts (5,6). The main advantage of using fetal cells rather than cffDNA is that they potentially offer a source of the whole fetal genome and that could be sampled in a noninvasive way for a prenatal detection of fetal aneuploidies (7). Nevertheless, the recovery and analysis of fetal cells from maternal blood is complex, and the sensitivity is still low because of the scarcity of these cells in the maternal circulation and of the lack of universal morphologic or immunocytochemical fetal markers that allow the isolation of fetal cells without contamination of maternal cells.

In this review, we summarize the current state of noninvasive prenatal diagnosis using fetal cells isolated from maternal blood during pregnancy.

DISADVANTAGE OF PRENATAL DIAGNOSIS BY INVASIVE PROCEDURES

Currently, prenatal diagnosis of fetal genetic traits relies on invasive procedures such as amniocentesis and CVS. These tests carry a small but significant risk of fetal miscarriage, and for this reason they are limited to only those women at increased risk of having a fetus with genetic abnormalities. In a recent systematic review of complications related to genetic amniocentesis and CVS, Mujezinovic et al. (8) searched on the Medline database for articles published after January 1995 reporting data for at least 100 women with singleton pregnancies with genetic amniocentesis and CVS carried out transabdominally. They found 29 articles for amniocentesis and 16 for CVS. After the statistical analysis, results demonstrated that the relative risk for fetal loss before 24 weeks was 0.6% for amniocentesis and 1.3% for CVS. They concluded that although the pregnancy loss risk is relatively low, lack of adequate controls in most studies tends to underestimate the true added risks of the procedures. Therefore, only a limited number of pregnant women with maternal age of 35 years or older and/or those having an abnormal prenatal screening should undergo invasive prenatal procedures. A recent retrospective Italian study was carried out by

accessing the results of cytogenetic analysis of amniotic fluid in women with less than and greater than 35 years and performed during years 1995 to 1996 (9). This study reported results of 88,965 amniocentesis and compared the frequencies of chromosomal abnormalities in the two groups of women. The authors demonstrated that the incidence of fetal genetic abnormalities at the amniocentesis is independent from the age of the pregnant women; the results confirmed the age dependency for aneuploidies (>35 years), whereas it did not confirm the age dependency for structural chromosomal abnormalities. These data provide together with other previous findings (10) important information about the actual prenatal counseling and its possible modifications due to the need to recommend noninvasive prenatal tests to all pregnant women.

For all these reasons, new noninvasive prenatal approaches are necessary.

Observation that intact fetal cells can enter and circulate within maternal blood has raised the possibility of noninvasive access to fetal genetic material that would allow the prenatal diagnosis of fetal chromosomal and fetal monogenic disorders.

FETAL CELLS IN MATERNAL CIRCULATION: AN ALTERNATIVE TO NONINVASIVE PRENATAL DIAGNOSIS

The main approaches have principally focused on the detection and genetic analysis of fetal cells and trophoblasts circulating in maternal blood and on the analysis of cffDNA and fetal mRNA in maternal plasma or serum.

History of Fetal Cell Discovery in Maternal Blood

The existence of fetal cells in maternal circulation was reported in 1893 by Schmorl (11), who first described the appearance of fetal trophoblasts in the lung of women who died of eclampsia. For many years, the existence of fetal cells in maternal blood was considered controversial. In 1959, Douglas et al. (12) showed circulating trophoblasts in maternal blood, but the proof of circulating fetal cells in maternal blood during pregnancy was obtained in 1969 from Walknowska et al. (13) reporting observations of 46,XY metaphases in a low number of maternal blood lymphocytes isolated from women carrying a male fetus.

Despite rising interest, no consensus existed by the mid to late 1970s when Herzenberg and colleagues (14) first isolated fetal cells from maternal blood using a fluorescence-activated cell sorting (FACS) and they assumed the fetal origin of these cells for the presence of a paternal allele not present in the mother. Other investigators made similar observations until the 1990s when the fields have begun to take a more optimistic turn with the advent of several new molecular genetic

technologies such as fluorescence in situ hybridization (FISH) and polymerase chain reaction (PCR).

For the first time, Bianchi and colleagues (15) identified fetal erythroblasts by the detection of Y chromosome sequences in male pregnancies after a FACS enrichment and PCR analysis. The ability to select the fetal erythroblasts and to couple it with FISH using appropriate chromosome-specific probes permitted Bianchi and other authors to identify fetal aneuploidies (16–18). Later, other successful results were obtained using trophoblasts and fetal stem progenitor cells (19,20).

Finally, the discovery of cfDNA by Lo et al. (21) and more recently fetal RNA by Poon et al. (22) in maternal plasma provided other new perspectives for fetal genotyping exploitation and placental gene expression, which could have diagnostic importance for fetal pathology.

Fetal Cell Trafficking in Pregnancy

Although the placenta was traditionally seen as a barrier that separate mother and fetus, many studies have demonstrated that a variety of fetal cells and cfDNA and mRNA circulate into maternal blood throughout pregnancy and that the trafficking of this material is a frequent phenomenon occurring during every pregnancy (23). It has also been observed that the trafficking between the mother and the fetus occurs in both directions. The same bidirectional traffic seems also to take place with plasma DNA, because maternal DNA has been found in cord blood of about 30% of samples tested (24).

The entity of the trafficking of the fetal cells depends by many factors such as complicated pregnancies and by the modes of releasing them in maternal circulation. This is due to their location inside the placenta and, as a result, different cell types are released by different modes (25).

Appearance of Fetal Cells in Maternal Blood

Data indicate that the timing appearance of fetal trafficking into maternal circulation exists (17,26,27). In accordance with placental growth, the interface between fetal and maternal tissues expands, such that more fetal cells may cross the placental barrier in the early stages of gestation. Some studies provided evidences that fetal cells are present in the maternal circulation in early gestational samples. The existence of circulating fetal material was documented by the detection of Y chromosome-specific DNA sequences in pregnant women bearing male fetuses from 8 to 12 weeks of gestation (28). In 1995, Thomas and colleagues (29) provided evidence that Y DNA fetal cell equivalents from cellular fractions were present in peripheral blood of two pregnant women after in vitro fertilization program as early as the 5th and 6th weeks of gestation, respectively.

Frequency of Fetal Cells in Maternal Blood

The major limitation that continues to overwhelm the clinical use of fetal cells is their extremely low number into maternal circulation, considered not yet sufficient to perform an accurate genetic analysis.

Until now, there is no consensus about the exact number of fetal cells circulating in the maternal blood because it depends on different factors such as the fetal cell type and the form of

cellular enrichment and identification techniques used, the weeks of gestation at sampling, and the presence of aneuploid pregnancies and/or pregnancy-related disorders.

Many attempts have been pursued to determine the precise number of these cells in order to individuate the best target cells for developing noninvasive prenatal testing and the best timing for their recovery. Considering their extremely low number and the absence of a specific fetal cell marker, most research groups have proceeded to apply various cellular enrichment procedures before trying to identify and count the fetal cells; consequently, only one cell category is usually isolated and examined leaving other fetal cells uncounted. Besides, it is likely that after a cellular enrichment, a large number of these rare fetal cells are lost in any case.

Therefore, few studies have striven to quantify the absolute number of all categories of fetal cells without prior enrichment. Bianchi et al. (30) determined the number of fetal-cell DNA equivalents present in the maternal whole blood samples using a quantitative PCR method aimed to identify fetal cells and Y chromosome-specific sequences as fetal marker. The mean number of male fetal-cell DNA found varied from 0.1–91 Y-cell equivalents in 16 mL of maternal blood with an average of 19 Y-cell equivalents. Using a real-time PCR analysis, Ariga et al. (31) surveyed 20 pregnant women with male fetus during the entire pregnancy and found that the best time for recovering fetal cells from maternal circulation is between 10 and 12 weeks of gestation. They also reported that the level of Y signals was higher in plasma than in cells except in these two weeks of gestation where cellular amount of fetal material was higher than that in plasma. Other studies confirmed these results. In particular, Zhong et al. (32), using a novel robust real-time quantitative PCR assay, demonstrated that the number of fetal cells ranged approximately from 0.5 to 2.3 fetal cells/mL of whole blood. All the data, obtained without enrichment and using quantitative PCR assays, demonstrated that it is possible to isolate approximately 1 fetal cell/mL of whole maternal blood.

To actually count cells rather than cell equivalents, another strategy was used that was aimed to estimate the total fetal cell number by the fetal genetic identification using the FISH or primed in situ labeling (PRINS) analyses without enrichment procedures. The most important study in this field was conducted by Hamada et al. (26) and more recently by Krabchi et al. (33). Krabchi visualized and counted fetal nuclei using, as fetal marker, the chromosome-specific probes for X and Y chromosomes, in pregnancies bearing male fetuses. They estimated that the total number of male fetal cells/mL of maternal blood varied from two to six cells with a median value of 4 fetal cells/mL of maternal blood within a group of normal pregnancies using both FISH and PRINS.

An elevated number of fetal cells in maternal blood have been observed in some pregnancy-related disorders and as pregnancies affected by fetal trisomies, pre-eclampsia, eclampsia, intrauterine growth restriction, or polyhydramnios with respect to normal pregnancies (25). Several studies have suggested that an abnormal structure of the placenta may result in an increased fetal cell trafficking to maternal circulation. Thus, an alteration of the placental barrier might explain this high number.

It has been reported that a high number of fetal cells are present in maternal blood when the fetus is aneuploid. In two consecutive studies, Krabchi and coworkers (34,35) noted a significant increase in total number of fetal cells in pregnancies carrying aneuploid fetuses. The methodological approach was similar to their previous study; the only difference was in the use of appropriate chromosome-specific probes in accordance with the chromosome to be visualized in the fetal nuclei, and aneuploidies were detected when an extra autosomal signal was observed. In the case of fetus with trisomy 21, the authors found the number of fetal cells three to five times higher than that from a normal pregnancy. The range varied from 6 to 32 fetal cells/mL of whole maternal blood with an average of 12.87 fetal cells. Similar results were obtained in the second study performed by the same group (35) in pregnancies affected by fetuses with trisomies 18 and 13. Also if the number of fetal trisomic cells was slightly less than those from fetus with trisomy 21, it has been observed as an increase of two to five times than that in normal pregnancies.

These studies, designed to detect all categories of fetal cells using cell-type-independent markers, such as aneuploidies and Y chromosome, have allowed to reach important information about the number of cells and the fact that these cells are consistently found in the blood of all women either with normal or pathologic pregnancies. Therefore, fetal cells can be reliably identified using FISH analysis in the diagnosis of fetal aneuploidies.

Enrichment, Identification, and Analysis Techniques

The absence of specific fetal antigens and the small number of fetal cells in maternal blood are the two principal caveats limiting their use in noninvasive prenatal diagnosis of fetal aneuploidies since the biologic samples to be investigated have a wide abundance of maternal cells creating a confounding background for genetic analysis.

For this reason, many attempts have been performed to isolate or enrich fetal cell populations by using numerous strategies in order to find biologic and antigenic differences between the mother and the fetus.

The most frequently used methods to enrich fetal cells from whole maternal blood are constituted by multistep procedures; usually the initial step is a density gradient separation followed by FACS or magnetic-activated cell sorting (MACS) technologies. While the first step is aspecific and allows only to reduce the abundance of maternal cells, the second step is specific since it is based on an antigen-antibody recognition using specific antibodies for a cell category of interest. Other technologies used for the enrichment of particular fetal cell population are micromanipulation based on morphologic nucleated red blood cell (NRBC) identification under microscopic observation of stained slides (36); ISET (isolation of epithelial tumor cells) technology, which allows to isolate trophoblasts on the basis of cell size by filtration (37); galactose-specific lectin-based enrichment, a method specific for isolation of fetal NRBCs, which are rich in cell-surface galactose and therefore they can be easily adsorbed to slides containing galactose sites (38); and laser microdissection and pressure catapulting, which can isolate a cell type discriminating it by morphology, fluorescence, or transfection markers (39).

Since the enrichment methods supply fetal cell samples still contaminated by maternal cells, scientific community has focused on the research of a specific fetal cell marker for their identification. Until now, fetal cell markers widely used are fetal hemoglobin, as a protein marker and Y chromosome, as a genetic marker. It has been shown that fetal hemoglobin is not a particularly relevant marker because it is partially present in maternal cells. Fetal cell identification based on Y chromosome by using cytogenetic (FISH) and biomolecular (PCR) techniques is an effective approach but it is limited to women carrying male fetuses.

For this reason, non-fetal gender-dependent approaches have been studied to distinguish fetal cells from maternal cells. Samura and coworkers (40) have experimented a PCR system based on analysis of microsatellite marker sequences (short tandem repeat), while the research group of Hultén (41) has detected differences in the length of telomeres in maternal versus fetal cells. The possibility of discriminating fetal and maternal cells by using these methodologies could allow the selection of fetal cells by the methods of cell isolation described above.

However, the markers used until now have shown to be rather unspecific since they are present also on a significant subpopulation of maternal blood cells.

Therefore, until now it is not possible to obtain a pure population of fetal cells, and their identification and genetic analysis are complicated by the high presence of maternal blood cells.

The genetic analysis of fetal cells has been mainly performed by PCR and FISH technologies. FISH can mainly analyze fetal gender and aneuploidies while PCR permits analysis of mutations in single-gene disorders, as well as fetal gender, rhesus blood type, and Mendelian diseases.

Since Price et al. (17) reported the first case of fetal trisomy 21 diagnosed by isolation of NRBCs from maternal blood, the FISH method has been used for noninvasive prenatal diagnosis of fetal aneuploidies, as well as fetal gender.

However, as long as new technologies for the isolation of pure fetal cell population will not be developed, the genetic analysis will be always hampered by maternal cell contamination.

TARGET CELLS FOR NONINVASIVE PRENATAL DIAGNOSIS

Leukocytes

Fetal leukocytes were the first type of fetal circulating material identified and enriched from maternal circulation. Fetal leukocytes were isolated by FACS with antibodies against paternally derived HLA-A2 antigens, and fetal gender and HLA type were successfully predicted (42). Despite these initial good results obtained, noninvasive clinical applications were considered unfeasible, principally due to the lack of monoclonal antibodies specific to fetal leukocyte antigens. Consequently, there is the necessity of performing HLA typing of both parents prior to flow sorting (1). Further limitation was their potential longevity. Some studies have shown that fetal leukocytes could persist in maternal blood for a period of up to 6 years postpartum, creating a state of long-term fetal microchimerism (1). This increases the risks of obtaining cells from previous pregnancy and therefore produces a confounding factor for prenatal diagnosis.

Trophoblasts

Trophoblasts are the first fetal cells that have been documented to enter into the maternal circulation at a very early stage of gestation, approximately from the 6th week (43).

Trophoblast invasion involves two types of cells, interstitial trophoblasts, and endovascular trophoblasts. The majority of circulating trophoblast material is constituted by interstitial trophoblasts that are deported passively into the maternal circulation by the shedding of syncytial fragments. The release of trophoblast material from placental villi is due to an apoptotic mechanism of normal turnover of this epithelium. Therefore, multinucleated syncytiotrophoblast cells cannot be recognized as circulating fetal cells because the structure is not as a cell but rather as a fragment of a multinucleated syncytium. These syncytial fragments can be detected in the uterine vein and peripheral circulation, but their isolation appears difficult since they are immediately trapped and destroyed by maternal pulmonary circulation as a consequence of their large size.

The other and predominant cell type of trophoblasts that circulates in the maternal blood is the HLA-G-positive uninucleate endovascular trophoblast. The cells, located in the lumen of spiral arteries, are in direct contact with maternal blood (25,44).

Since the release of trophoblast material occurs through an apoptotic mechanism of the epithelium turnover, a major source of cfDNA circulating in maternal blood is possibly of trophoblastic origin, and although the quality of this DNA is limited (because it is apoptotic), the amount is much higher and is suitable for fetal genomic analysis by PCR-related methods (45).

Trophoblasts have been isolated from maternal blood by several different methods related to surface antigen expression, for example, HLA-G, and cell size and proof of fetal origin were accomplished with FISH and PCR-related methods (44). However, the use of these cells for noninvasive prenatal diagnosis has encountered several difficulties. Common to all circulating fetal cells studied until now is their extremely low number in maternal blood. This is principally due by the fact that multinucleated syncytiotrophoblast cells are rapidly cleared by maternal pulmonary circulation (46) and by the lack of specific monoclonal antibodies against trophoblast surface antigens that allow the isolation of a pure cellular fraction without the contamination of maternal cells. Furthermore, the syncytiotrophoblast cells are multinucleated (2–80 nuclei) and not suitable for chromosomal analysis when FISH is used. Another disadvantage of using these cells is the extra embryonic origin that could imply a discrepancy between fetal and placental karyotypes because trophoblasts could exhibit confined chromosomal mosaicism in around 1% of cases (47).

However, despite these obstacles, the HLA-G-positive uninuclear endovascular trophoblasts appear to be the most amenable kind of trophoblast cell type for the purpose of noninvasive prenatal diagnosis. The HLA-G antigen recognized by monoclonal antibody (McAb) G233 is expressed only by endovascular trophoblasts, and using this antibody for immunocytochemical identification followed by XY-FISH, van Wijk et al. (48) demonstrated the presence of these fetal cells in maternal blood. Moreover, the same authors

established the frequency of these cells on average of about one fetal trophoblast expressing HLA-G per mL of maternal blood between 9 and 13 weeks of gestation. Furthermore, the same isolation and detection procedure has been used for prenatal diagnosis of Down syndrome and allowed confirmation of the presence of a partial hydatidiform mole (49). Hawes et al. have also accurately detected a fetal beta-globin mutation in trophoblasts present in maternal blood. Vona et al. (37) developed a strategy called ISET that is able to enrich circulating trophoblasts from maternal blood since they are larger than the peripheral blood cells. The isolated cells are individually microdissected with a laser microscope and their fetal origin was confirmed by genotyping using short tandem repeat markers. Furthermore, this method was applied to 12 pregnant women at risk of having a child affected by spinal muscular atrophy and 3 mothers were identified who were carrying an affected fetus (50).

In order to overcome the problem of the low number of these cells, Guetta et al. (19) studied the possibility to expand *in vitro* the trophoblasts expressing HLA-G cells in order to improve their number and possibly enable metaphase chromosome analysis. After sorting, the cells were analyzed directly or after culture. The confirmation of fetal origin was achieved by XY-FISH in samples of pregnant women carrying male fetus predicting fetal gender. The authors reached a significant fivefold increase in the yield of fetal cells compared with the sample directly analyzed. The gender prediction was successful in 93%. This approach might represent an important progress in this field.

Fetal Erythroblasts or NRBCs

NRBCs are mononuclear and relatively well-differentiated cells (51).

They are abundant in the fetal circulation during early pregnancy since they are the first hematopoietic cell lines produced during fetal development (52). They have a short life span compared with fetal lymphocytes given their limited proliferative capacity (53), making them unlikely to persist after pregnancy.

Fetal NRBCs carry a representative complement of fetal karyotype without mosaic characteristic, unlike trophoblast cells, and are consistently present in maternal blood during pregnancy. Kleihauer et al. (54) were the first to describe this effect in 1957, by developing a staining procedure specific for fetal hemoglobin, and successively Clayton et al. (55) confirmed the observation in 1964. However, only in 1990 Bianchi et al. (15) provided the definitive proof of fetal origin of erythroblasts by isolating them from maternal blood and enriching them using FACS with antibodies specific for transferrin receptor (CD71) and by evidencing the presence of male DNA.

This last discovery was important since in that period it was thought that NRBCs were rare in adult peripheral blood (56) and consequently the most of erythroblasts present in maternal circulation should have been of fetal origin. However, cell enrichment systems developed later demonstrated that a large population of NRBCs circulate during pregnancy, but most of them are of maternal origin (57). This evidence was confirmed by others, such as Troeger et al. (58), which using single-cell PCR analysis on single micromanipulated NRBCs identified by

May-Grunwald–Giemsa staining, demonstrated that only half of NRBCs in maternal blood were of fetal origin.

Nevertheless, the characteristics of NRBCs make them particularly suitable for the development of noninvasive prenatal diagnostic tests as proved by others, who assessed the potential of these cells by using a general setup based on enrichment, isolation, and genetic analysis as described above for the other cell types.

From the first isolation and enrichment methods developed by Bianchi et al. (15), other methods were designed based on density gradient centrifugation and on the presence of specific erythroblast surface antigens (17,59,60). These approaches based on the presence of specific surface antigens such as CD71, CD36 (thrombospondin receptor), and GPA (glyphorin A) allowed fetal NRBC isolation from blood samples of all pregnancies and not only from HLA-informative couples, such as for the lymphocytes. Among these surface antigens, CD71 was the most utilized and in particular the research was focused on the development of several anti-CD71 monoclonal antibodies and on the optimization of protocols for the isolation of NRBCs from peripheral maternal blood. An attempt was conducted by Alvarez (61), who developed a specific erythroblast antibody, named 2F6.3, and compared it with a commercial anti-CD71 antibody by using blood samples from pregnant women suffering from pregnancy-induced hypertension and in a control group of pregnant women without clinical features suggesting an increased risk of developing pre-eclampsia. They demonstrated that the antibody 2F6.3 succeeded in isolating a significantly higher number of erythroblasts with less maternal cell contamination than the commercial antibody in both women with pregnancy-induced hypertension and the control group.

More recent strategies of NRBC enrichment were based on the adsorption of these cells to slides containing galactose sites by galactose-bearing conjugation via soybean agglutinin, a galactose-specific lectin (62), and on microfluidic approach that consisted of microfluidic chip size-based cell separation and a magnetic device for hemoglobin-based cell isolation (63).

The possibility to enrich fetal NRBCs from maternal blood opened new perspectives of genetic analysis for noninvasive prenatal diagnosis. The main technologies used for genetic analysis were FISH (64) and PCR (65), as for the other cell types. Another molecular-cytogenetic approach employed with NRBCs was the comparative genomic hybridization (66), which allows the analysis of copy number changes (gains/losses) in the DNA content of a given subject by using fluorescently labeled DNA in order to detect unbalanced chromosome changes.

The development of all these strategies could improve the NRBC utilization in noninvasive prenatal diagnosis, even if their genetic analysis shows considerable challenges, given their limited number.

Many attempts have been performed in order to quantify fetal erythroblasts present in maternal blood because they are considered one of the most suitable target cells for developing noninvasive prenatal tests. The first studies performed in order to establish the number of fetal erythroblasts in maternal blood were carried out by Bianchi et al. (15) and Price et al. (17) analyzing flow-sorted erythroblasts on the basis of CD71-positive cells and using PCR and FISH

techniques to identify Y sequences. They obtained a ratio of fetal erythroblasts to maternal cells of $1:10^7$ to $1:10^8$ showing the reliability of isolating fetal cells from maternal blood although their number was extremely low. Moreover, the study conducted by Price et al. gave the first demonstration of the feasibility of performing prenatal detection of fetal aneuploidies on flow-sorted erythroblasts and chromosome-specific probes.

However, some recent results revealed that the analysis by FISH of fetal erythroblasts enriched from maternal blood gave low levels of diagnostic sensitivity due to the inability of detecting fetal erythroblasts by this technique. This thesis was explained by the demonstration that NRBCs have an abnormally dense nucleus with an apoptotic character, which renders it impervious to hybridization by FISH probes (62).

This finding did not dissuade the researchers from the study of the potential implications of NRBCs in noninvasive prenatal diagnosis since many clinical trials have been performed by using this kind of cells.

Hematopoietic Stem Cells and Progenitor Cells

As the other typologies of circulating fetal cells, hematopoietic stem cells and progenitor cells (HSPCs) enter into maternal circulation after accidental breakage of the villi, where it is supposed are encapsulated, or by conditions that promote exposure of the fetal endothelium and subsequent vessel breeching (25).

In reference to phenotype, stem cells express different antigenic surface markers, but the antigen mainly expressed in several stem cells lineage is the “hematopoietic” CD34 antigen. Therefore, hematopoietic CD34+ cells are the most representative cells in stem cell population. The CD34+ antigen, an integral membrane glycoprotein of 90 to 120 kD, functions as a regulator of hematopoietic cell adhesion to stromal cells of the hematopoietic microenvironment (67,68).

First-trimester fetal blood contains a higher frequency of hematopoietic CD34+ stem cells and the number circulating in fetal blood peaks in the second trimester. Hematopoietic CD34+ stem cells together with the mesenchymal stem cells represent about 0.4% of circulating cells in fetal blood during the first trimester of pregnancy in humans (23). Several reports have demonstrated the presence of circulating fetal hematopoietic CD34+ stem cells (fetal CD34+ cells) in maternal blood during pregnancy. Besides, it has been demonstrated that these cells have a clonogenic capacity of colony formation, since this type of cell can be induced to divide and proliferate in vitro. The clonogenic capacity of isolated fetal CD34+ cells from maternal circulation has been demonstrated through the formation of typical colonies such as fetal colony-forming unit—erythroid (CFU-E), erythroid burst-forming units (BFU-E), and granulocyte–erythrocyte–megakaryocyte–monocyte colony-forming unit (CFU-GEMM) by several authors (6,20,69). For this reason, among circulating fetal cells, fetal CD34+ cells appear to be one of the most promising candidate cell of fetal origin for noninvasive prenatal diagnosis. By this way, it is possible to increase the quantity of fetal material, overcoming the scarcity of the cells, for a reliable genetic analysis.

The first attempt to demonstrate the presence of these cells and their number in maternal circulation during pregnancy

was done by Hall and Williamsons (70), who developed a purification method using an antibody directed against CD34; fetal cells were present in a range of $1/4.75 \times 10^6$ to $1/6 \times 10^7$ of the nucleated cell fraction of maternal blood. Successively, Little et al. (6) quantified fetal CD34+ cells present in maternal blood of women bearing a male fetus. After a FACS and a Y chromosome–specific probe identification, they detected a range of 0 to 7 male fetal CD34+ cells in 20 milliliter of maternal blood. More recently, other investigators (71,72) established the number of these cells by using the MACS enrichment approach and the CD34 antibody coupled with the FISH analysis and the Y chromosome–specific probe. The results of the studies were very promising because they confirmed the presence of these cells in maternal blood, also if the number was low as that observed for the other categories of circulating fetal cells.

Several groups have conducted studies for identification of these cells present in maternal blood and their potential expansion.

The first evidence of feasibility of culturing fetal erythroid cells with clonal properties was achieved by Lo et al. (73). They demonstrated the selective enhancement of fetal erythroid cells with a purity rate of 0.01% to 0.25% after a coculture of male fetal liver–derived hematopoietic cells, with a ratio of fetal/maternal cells ranged from 1/400 to 1/9500.

After this pioneering study, other investigators, using different antibodies against fetal clonogenic cells and semisolid medium for their expansion, confirmed the capacity of expandability of fetal cells isolated from maternal blood. Valerio et al. (69) used peripheral blood from pregnant women and enriched erythroid cells by MACS coupled with a biotin-labeled erythropoietin antibody. They identified fetal colonies after cultivation reaching a fetal colony purity rate of 18%.

Later, fetal CD34+ cells in maternal blood were quantified in first-trimester samples by Little and colleagues (6). These authors studied the frequency of CD34+ cells of fetal origin in maternal blood and their *in vitro* proliferation. After 5 days of culture, a slight but significant expansion of fetal cells was observed. The number of cultured fetal cells ranged from 0 to 35 fetal cells in 20 milliliter of maternal blood. The fetal origin was confirmed using FISH and probes specific for chromosomes X, Y, and 21.

A further definitive confirmation of the clonogenic potential of fetal CD34+ cells was acquired by our group (20). We cultured in a semisolid culture medium, unenriched peripheral blood mononuclear cells, and enriched hematopoietic CD34+ cells by MACS from maternal blood of women bearing male fetus. Cells were then cultured for 14 days and frequencies of the expanded fetal cells were established by the use of XY-FISH. The numbers of BFU-E/CFU-E and CFU-GM colonies obtained by enriched cellular fraction were increased by 33 and 16 times respectively to unenriched cellular fraction. By FISH, we identified a suitable number of male fetal cells and a good fetal/maternal ratio even in normal pregnancies. Others studies from Tutschek et al. (74), Campagnoli et al. (75), and Guetta et al. (72) have positively raised the interest about the prospect of using fetal cell culture expansion for genetic testing. They showed, with different methodological approach, the successful clonal expansion of

fetal cells combining micromanipulation and fluorescent PCR or FISH technique alone. In particular, Guetta et al. (72) demonstrated a significant 2.4-fold increase in the number of fetal cells detected by FISH, after culture with respect to samples directly analyzed after CD34+ cell sorting.

In contrast to these attempts, others have not confirmed the potential for generating pure fetal hematopoietic colonies. Chen et al. (76) cultured erythroblasts from 16 maternal blood samples in a semisolid medium with and without prior enrichment by MACS using an erythropoietin antibody. They were not able to demonstrate a conclusive fetal colony by PCR for either Y-specific sequences or autosomal microsatellite markers.

In the studies of Zimmermann et al. (77) and Manotaya et al. (78), the demonstration that maternal blood contains fetal clonogenic erythroid cells failed; they were not able to expand fetal cells because, after culture, any colonies among those isolated and analyzed by PCR and FISH technique were of fetal origin.

Unfortunately, a direct comparison of results among all these contrasting studies is not possible principally due to the differences in the methods employed for sample processing and analysis utilized by different authors.

Several authors have reported that some types of circulating fetal cells, in particular cells with stem cell–like properties, as the fetal CD34+ cells, can persist in the maternal circulation for decades after delivery, creating a state of long-term fetal microchimerism (23,79–81).

This fact has, to date, limited their use in the development of noninvasive testing, as they could still be present in the maternal circulation and potentially create a confounding factor for prenatal diagnosis. In other words, incorrect interpretation of the prenatal tests in parous women could be possibly due to circulating fetal cells from previous pregnancies.

Many researchers have focused their attention on this observation. Recently, we performed a study to verify whether the culture expansion could increase the number of these persisting CD34+ cells from previous pregnancies and whether their expanded number could interfere with a subsequent prenatal diagnosis (82). The results demonstrated that the presence of cells from previous pregnancies does not affect prenatal fetal diagnosis in current pregnancies.

Clinical Trials for Detection of Fetal Aneuploidies

The main advantage of using fetal cells enriched from maternal blood with respect to cfDNA is that they potentially offer a source of complete fetal genetic material (7) for a noninvasive prenatal diagnosis; this is an essential prerequisite for genetic diagnosis of the main fetal pathologies, as the fetal trisomies, which cannot be easily met via the analysis of cfDNA. For this reason, the use of fetal cells appears the only way for reaching the goal of the detection of fetal aneuploidies in a noninvasive manner.

Several investigators have developed and pursued strategies for detecting fetal aneuploidies within fetal cells isolated from maternal blood. For the first time, in the year 1992, Elias et al. (18) diagnosed a fetal trisomy 21. One year later Gänshirt-Ahlert et al. (83) confirmed the feasibility to diagnose fetal aneuploidies on enriched fetal erythroblasts.

They correctly diagnosed 5 cases of trisomy 18 and 10 cases of trisomy 21. After these first observations, several other investigators confirmed this diagnostic approach and also demonstrated that it is possible to diagnose several other fetal chromosomal disorders as fetal trisomy 13, fetal triploidy, and sex chromosome mosaicism.

Reports of identification of aneuploid fetal cells in “clinical” series are present in the scientific literature and results varied widely on the consistency with which they may be found in maternal blood (Table 1).

The National Institute of Child Health and Human Development Fetal Cell Isolation Study was the first prospective multicenter clinical project, started in 1994, with the aim of examining the feasibility of using fetal erythroblasts from maternal blood for the detection of fetal aneuploidies (84). The study was performed enrolling 2744 pregnant women considered at high risk for fetal aneuploidies. The NRBCs were isolated from maternal blood and enriched in part by FACS and in part by MACS technology and their interphase nuclei were analyzed by FISH using probes specific for 13, 18, 21 X, and Y chromosomes. The data of FISH analysis were compared with fetal karyotype obtained by amniocentesis or CVS. From these findings, it was evident that target cell recovery and fetal cell detection were better obtained using MACS than FACS technology. Blinded FISH assessment of samples from women carrying singleton male fetuses found at least one cell with an X and Y signal in 41.4% of cases with a false-positive rate in gender detection of 11.1%. The diagnostic sensitivity in fetal aneuploidy diagnosis was 74.4%, with a false-positive rate ranging between 0.6% and 4.1%. The results of this clinical trial were not excellent, since the sensitivity in noninvasive prenatal diagnosis of fetal aneuploidies was comparable with that of a single marker prenatal serum screening. A possible limitation of this study could have been multiple processing protocols, which could have affected the diagnostic sensitivity in fetal aneuploidy detection.

Another study, carried out to analyze the potentiality of fetal trisomy detection by using fetal NRBCs from maternal blood (85), was performed on a large scale by testing a unique standardized protocol, overcoming in this way the limitation of the previous trial. The authors enrolled 230 pregnant women at 10 to 14 weeks of gestation, isolated NRBCs by

triple-density centrifugation and by anti-CD71 magnetic cell sorting and performed FISH analysis for fetal trisomy detection. Fetal karyotype was normal in 150 cases and abnormal in 80 cases, including 36 cases with trisomy 21. From the analysis of the study results, it was evident that the cutoff setting was of crucial importance for establishing the diagnostic performance of the protocol. In fact, while using a 21 chromosome-specific probe, three-signal nuclei were present in at least 5% of the enriched cells from 61% of the trisomy 21 pregnancies and in none of the normal pregnancies, for a cutoff of 3% of three-signal nuclei, the sensitivity for trisomy 21 was 97% with a false-positive rate of 13%. Similar values were obtained in trisomies 18 and 13 using the appropriate chromosome-specific probe. Therefore, this study showed that the examination of fetal NRBCs from maternal blood could provide a noninvasive prenatal diagnostic test for trisomy 21 with the potential of identifying about 60% of affected pregnancies.

Although the research group of Al-Mufti performed a trial using a standardized protocol, it is clear that it did not reach optimal results. This fact could be explained by the poor efficiency of MACS enrichment protocol. In fact, a study carried out by Parano et al. (86) achieved promising results employing a novel procedure for NRBCs separation, which involved direct micromanipulator isolation of histochemically identified fetal hemoglobin–positive nucleated cells to obtain fetal NRBCs of high yield and purity. Using this technique, followed by cell-by-cell multicolor FISH analysis of purified fetal erythroblasts, they were able to detect Down syndrome, Klinefelter syndrome, and Patau syndrome, in 33 pregnant women. The procedure provided complete concordance with the results of amniocentesis.

The results obtained from this last study were encouraging, but clinical trials on large scale using this approach were not performed, most probably because this protocol would have been too much complex and time consuming to be introduced in clinical routine.

Therefore, until now the relative rarity of fetal NRBCs in maternal blood and the difficulty to establish their fetal origin remained the two principal problems hindering the successful spreading of noninvasive prenatal diagnosis based on fetal cells in maternal blood.

Table 1 Principal Reports Present in the Scientific Literature Focusing on Prenatal Diagnosis of Fetal Abnormalities Using Fetal Cells in Maternal Circulation

Date	Author	Target cell	Methodology	Aneuploidies diagnosed	Detection rate (%)
1994–2002	Bianchi	NRBCs	MACS or FACS + FISH	Trisomies 13, 18, and 21	74.4
1999	Al-Mufti	NRBCs	MACS + FISH	Trisomies 13, 18, and 21	60
2001	Parano	NRBCs	Direct micromanipulator isolation of histochemically identified hemoglobin-positive nucleated cells + FISH	Trisomies 13, 21, and Klinefelter syndrome	100
2000	Valerio	Hematopoietic progenitor cells	Double-density gradient centrifugation + culture + FISH	Trisomy 18	100
2001	Coata	Hematopoietic CD34+ cell	MACS + culture + FISH	Trisomies 18, 21, and Klinefelter syndrome	100
2006	Di Renzo	Hematopoietic CD34+ cell	MACS + culture + FISH	Trisomies 13, 18, and 21	100 ^a

^aData not published.

To test the feasibility of using expanded fetal stem and progenitor cells isolated from maternal circulation in clinical practice, some researchers performed a study aimed to verify their applicability in the detection of fetal trisomies by interphase cytogenetic diagnosis. As it occurs for the other fetal cell types, detection of aneuploid cells is facilitated by the increased number of fetal cells detectable in the mother bearing a chromosomally abnormal fetus.

In several original reports, Valerio et al. (69,87,88) demonstrated the practicability to sort fetal hematopoietic progenitor cells from the maternal blood of all aneuploid pregnancies and successfully expand them in culture. By this way, the authors obtained an acceptable fetal cell purity that allowed them to diagnose all the cases of aneuploid

pregnancies investigated. It was possible to detect six fetal trisomy 21, three fetal trisomy 18, and one trisomy 13. Fetal trisomies were documented by FISH analysis with appropriate chromosome-specific probes and confirmed by fetal karyotype.

Another study adding possibility of culturing fetal CD34+ cells was obtained by our group. We confirmed the feasibility of utilizing fetal CD34+ cells isolated from maternal blood between 11 and 16 weeks of gestation and before any invasive procedures, for the prenatal diagnosis of fetal aneuploidies (20,71). In the first report we were able to diagnose two fetuses with trisomy 21 and we found a considerable number of trisomic fetal cells after expansion, with a ratio of 1/34 and 1/12 between fetal to maternal cells (Fig. 1). In the second

Figure 1 The figures show fetal nuclei presenting a trisomy 21 indicated by white arrows. In the nuclei, the three red signals represent chromosome 21.

Figure 2 (A1 and A2) The figures show fetal nuclei presenting a trisomy 18 indicated by white arrows. In the nuclei, the three red signals represent chromosome 18. (B) The figure shows a metaphase presenting a trisomy 18.

study, we correctly detected three fetal trisomies 21, one fetus with Klinefelter syndrome and one fetal trisomy 18. For the first time, we were able to document the fetal origin of the expanded cells in culture by a fetal metaphase of trisomic nuclei from the fetus with a trisomy 18 (Fig. 2).

Since 2006, our group has been performing a clinical trial with estimated completion date on 2010. The purpose of this study is to validate our developed combined methodology for noninvasive prenatal identification of fetal aneuploidies and fetal gender with blood samples from pregnant women who are scheduled to undergo an amniocentesis or CVS procedure. The obtained results are then comparing with those obtained by fetal karyotype. The enrollment criteria of pregnant women are very strict and include only those women at high risk for fetal chromosomal abnormalities, providing written informed consent.

The study design involves the isolation of fetal CD34+ cells from maternal blood, the in vitro cell expansion, and FISH analysis for recognizing and counting chromosomes 13, 18, and 21 and sex chromosomes.

Our preliminary results, based on the analysis of 500 blood samples, have shown a sensibility of 100% for the identification of each studied trisomy, while the specificity have varied from 94% and 96% for trisomy 13 and 21 respectively and to 100% for the trisomy 18.

In the same context, we evaluated whether the effect of the delay in the initial fetal cell enrichment processing of maternal blood samples from blood sampling could compromise the ability to recover fetal cells. We analyzed 45 maternal blood cells after one or more days from blood sampling. We observed a significant reduction of the CD34+ cells with respect to those samples immediately processed (usually within 1 hour). The reduction of these cells was more than 50% and this was very dangerous for our test because the fetal cells of our interest are present in this subset of cells. Consequently, we obtained a very low sensibility and specificity of the test (less than 90%), with false-positive and false-negative results (data not yet published) in the detection of fetal trisomies. From this observation, it is essential to process immediately the maternal blood samples (within 1 hour from the sampling) in order to avoid the loss of fetal cells when we have to utilize them for the noninvasive genetic tests.

CONCLUSION

Since the demonstration of fetal cells and fetal nucleic acids in the maternal circulation, the aim of many research laboratories around the world has been to isolate fetal material for applying to genetic analysis. Nowadays, we may state that fetal nucleic acids can be reliably utilized for rapid gender detection (89–91), RhD status (92,93), and some monogenic disorders, but the application for the detection of aneuploidies although positively attempted (94–96) is still far behind. Instead the use of fetal cells and particularly erythropoietic stem cells looks as the most promising approach for the detection of aneuploidies at least limited to chromosomes 13, 18, 21, X, and Y, which represent the vast majority of fetal chromosomopathies amenable of a meaningful prenatal diagnosis. Our studies and our preliminary results are positively showing that in this direction we are pretty close to offer a reliable noninvasive diagnostic test.

However, the definitive answer will come when we will be able to develop a surface monoclonal antibody toward a fetal specific antigen, which will allow us to obtain a population of fetal cells free of maternal background to which genetic analysis can be applied.

61 Recent developments in fetal therapy

Gihad E. Chalouhi and Yves Ville

The developments of ultrasound imaging prenatally as well as the implementation of ultrasound screening in pregnancy in most developed countries lead to an increasing number of fetal anomalies to be diagnosed before birth. The issue of fetal treatment is raised when the anomaly is diagnosed at an early stage and when its natural history suggests that the most likely outcome is either perinatal death or severe handicap irrespective of pediatric management. The management of fetal anomalies is ruled in each country by different laws regulating the indications for termination of pregnancy (TOP). Since many women wish to carry on with their pregnancy and TOP cannot be performed either at all or above a certain gestational age, fetal therapy has gradually developed since the early 1980s. Fetal therapy or surgery can be implemented with the aim to stabilize the effects of the anomaly on fetal development or to cure the disease itself (1). This might be either by anatomical correction of the malformation or by arresting the progression of the disease, delaying its definitive repair until after birth (2).

Only few examples fulfill these criteria (Table 1) (2,3). Since most attempts of fetal surgery concern treating rare and severe fetal conditions, they carry a large component of medical innovation, scientific research, as well as technical prowess, which unfortunately sometimes leads to procedure-related complications.

The first invasive fetal intervention began in 1963 with Liley (4). It was a blind intrauterine intraperitoneal blood transfusion. The evolution of fetal surgery has progressed since then with historical surgeries and a countless number of animal experiments. Fetal surgery is now a clinical reality (3) validated by randomized trials for a number of fetal pathologies but remains investigational for many others. The concept of fetal surgery is subjected to skepticism due to lack of clinical evidence, ethical issues, and public perception (5). Clinical trials are ethically challenging and difficult to organize and finance. This, however, should be no excuse to address all pertaining relevant issues appropriately (6).

MULTIPLE MONOCHORIONIC PREGNANCIES

Specific complications related to monochorionicity are based on hemodynamic imbalance between the twins, which are essentially normal as in twin-to-twin transfusion syndrome (TTTS) or in cases with a normal twin and its abnormal co-twin with the extreme form of the acardiac twin (7). When TTTS develops in the second trimester, the natural history leads to intra- or perinatal death in 90% of the cases, and up to 50% of the survivors show impaired neurologic development as a consequence of the death of their co-twin in utero or in the context of extreme prematurity. In all cases, intrauterine fetoscopic selective occlusion of the vascular anastomoses is attempted on the

chorionic plate (Fig. 1). In more severe forms where one twin is normal and the other shows severely impaired development, selective feticide using umbilical cord occlusion of the affected twin appears to be the safest method to protect the normal twin (8–10).

The technique of selective laser coagulation of placental vessels has paved the way for fetal surgery in a minimally invasive way for the pregnant woman. Initially performed using a 5-mm hysteroscope inserted through a purse-stringed hysterotomy after exposure of the uterus with a small laparotomy (11), the technique was greatly simplified by a minimally invasive percutaneous approach under ultrasound guidance and under local or epidural anesthesia that has transformed the prognosis of the disease (8,12–15). An endoscope of 1.3 to 2mm in diameter is introduced in a 3-mm trocar. A Nd:YAG or diode laser fiber is passed through the operative channel of the endoscope. It allows coagulation of the anastomotic vessels joining the two fetoplacental circulations (Fig. 2). This technique has been developed over 15 years and has proven to be the best first-line treatment with the highest degree of evidence, leading to survival rates of around 75% with severe morbidity in less than 10% of the survivors (9). These results are stable through to long-term follow-up and up to the age of 6 years (16).

Several techniques for selective feticide of a monochorionic fetus have been described and used, including ultrasound-guided fetal cord ligation or compression (17), bipolar coagulation, laser coagulation, transection with harmonic ultrasound scalpel (18), thermocoagulation (19), and radiofrequency ablation (20). Bipolar coagulation technique remains a gold standard for cord coagulation (21) because of the short duration of the surgery, its relative technical simplicity, and availability (21).

Bipolar umbilical cord coagulation is performed using a bipolar forceps (2.5-mm diameter). The procedure aims at coagulating the cord at placental or abdominal insertions, depending on their accessibility. A longitudinal portion of the cord is exposed to the bipolar forceps with its jaws perpendicular to the cord. After grasping the cord, an initial coagulation is performed using 15 W for 15 to 60 seconds. The efficacy of the procedure is judged by the appearance of echogenic steam bubbles and increased echogenicity of the coagulated portion of the cord. In the absence of bubbles, the power is increased in 5-W increments up to a maximum of 50 W. When the appropriate power is obtained, the coagulation is continued for 1 or 2 minutes, without releasing the cord. A second segment of the cord is then systematically coagulated following the same procedure. The interruption of blood flow in the coagulated cord is checked by ultrasound during the procedure.

Table 1 Criteria for Fetal Surgery (2,3)

- 1 Accurate diagnosis and staging possible, with exclusion of associated anomalies
- 2 Natural history of the disease is documented, and prognosis established
- 3 Currently no effective postnatal therapy is available
- 4 In utero surgery proven feasible in animal models, reversing deleterious effects of the condition
- 5 Interventions performed in specialized multidisciplinary fetal treatment centers within strict protocols and approval of the local ethics committee with informed consent of the mother or parents

CONGENITAL DIAPHRAGMATIC HERNIA

Thoracic anomalies are the most illustrative to view fetal surgery in both historical and technical perspectives. These anomalies have in common to interfere with lung development through the mass effect leading to pulmonary hypoplasia that is often lethal when compression develops during the second trimester of pregnancy (22). Ultrasound screening in the second trimester depicts the majority of these severe anomalies at an early stage that is potentially amenable to fetal surgery. Thus fetuses with the most severe forms of congenital diaphragmatic hernia (CDH) can also benefit from intrauterine fetal surgery (10).

Figure 1 Vascular anastomoses between the circulations of the two twins in a monochorionic diamniotic pregnancy complicated: (A) and (C) nonselective anastomoses passing under the amniotic membrane; (B) and (D) selective. Laser fiber can be visualized at 12 o'clock in (A) and (B).

Figure 2 Selective laser coagulation of placental vessels in a twin-to-twin transfusion syndrome. Donor stuck twin in anhydramnios (A, B, C). Vascular anastomoses (D, E, F) coagulated with a laser fiber seen at 12 o'clock (D, F).

Figure 3 “Plug the lung until it grows” strategy. Fetoscopic access to the fetal trachea (A, B) reaching the carina (C), and inflating a balloon, 1 cm above the carina (D, E, F).

CDH of intra-abdominal organs in the thorax, when it is not associated with other anomalies, allows survival between 0% and up to 85% of the cases depending upon the degree of lung development. Prenatal evaluation of the volume of the contralateral lung has been the subject of continuous research for the last 20 years. To date, the simplest evaluation of the relative size of the lung mass to the head circumference [lung-to-head ratio (LHR)] has the best prognostic value. When expressed as a proportion compared with what is expected in a normal fetus (observed/expected LHR), this prediction is independent of gestational age (23). The presence of the liver in the thorax is another independent factor of poor prognosis. Fetuses with CDH and $LHR < 1$ with liver up in the thorax are almost certainly destined to die in the perinatal period despite advanced neonatal care (24).

History of fetal CDH surgery begins with pediatric surgeons who operated newborns. The initial prenatal approach consisted of patch closure of the diaphragmatic defect (25,26). Fetal surgery followed the rules of neonatal surgery with the aim of curing the defect through very invasive modalities for the pregnant woman, including laparotomy, hysterotomy, and aggressive tocolysis. Delivery was then doomed also to be performed by cesarean section at any gestational age, owing to the recent uterine scar, whether the child was dead or alive (27). This approach was based on successful sheep experimental surgery for 10 years but failed 20 years later for the very reason that the human uterus is far more sensitive to preterm labor triggered by uterine surgery than sheep. The natural history of yet another congenital malformation, tracheal atresia, showed the rationale for palliative intrauterine surgery in CDH. This condition causes pulmonary hyperplasia by increasing bronchial pressure and the possibility of a temporary obstruction proved successful to stimulate the growth of hypoplastic lungs in a sheep model (28).

Tracheal occlusion was first clinically achieved by laparotomy, hysterotomy, neck dissection, and tracheal clipping (29) with impressive results on lung growth in a subset

of fetuses but with a low survival rate. The first *percutaneous* endoluminal occlusion was reported by Quintero et al. (30). Unfortunately, the device failed to occlude and the baby died in the postnatal period.

In Europe, a clinical technique via a 3.3-mm percutaneous access was developed with balloon removal initially at the time of an *ex utero* intrapartum treatment (EXIT) procedure (31,32). General anesthesia was used at first but was soon replaced by regional and local anesthesia with fetal sedation and immobilization. This approach is often referred to as the “plug the lung until it grows” strategy (33). This surgery consists of accessing the fetal trachea using a 1.2-mm endoscope as described in placental surgery (see above) and inflating a balloon in the fetal trachea, 1 cm above the carina (Fig. 3). This is usually performed at 26 to 34 weeks and the balloon is removed 8 weeks later. Removal can either be performed following the same procedure, be deflated by needle puncture under ultrasound guidance or following neonatal intubation immediately after birth. Preliminary results in over 200 human fetuses with a poor prognosis where the expected survival was around 10%, the observed survival was 55% (24). The results depend upon estimated fetal LHR to reach 78% for LHR between 0.8 and 1 (34). However, although uterine tolerance to endoscopic fetal surgery is good, the risk of preterm rupture of the membranes in up to 20% before 32 weeks remains a challenge to the development of this surgery, which has to address at least two other issues: (1) to establish itself through a randomized study against postnatal management only. (2) to evaluate later intervention in the forms with less severe prospect based on $LHR > 1$ in order to decrease prematurity-related risks. In the latter group, a previous randomized study with suboptimal design suggested that prenatal management was not beneficial, but the suboptimal design significantly biased the result of the trial (35).

Jani et al. (36) recently reported results of 210 severe CHD treated with fetal endoscopic tracheal occlusion. They concluded that their treatment is associated with a high

incidence of preterm premature rupture of fetal membranes (PPROM) (16.7% cases) and preterm delivery (30.9% of patients delivered before 34 weeks) but a substantial improvement in survival. Forty-eight percent of infants were discharged from the hospital alive. They therefore increased survival in severe cases with left-sided CDH from 24.1% to 49.1%, and in right-sided CDH from 0% to 35.3% ($p < 0.001$) (37). The strongest predictors of survival are observed/expected LHR *prior* to the procedure, the absence of PPRM, and gestational age at delivery.

Although many recent nonrandomized reports of success with balloon tracheal occlusion (and release) are promising, prenatal therapy should not be widely adopted until a well-designed prospective randomized trial demonstrating efficacy is performed (38).

This surgery has also demonstrated that the fetal airways were directly accessible to prenatal local administration of drugs opening new perspectives for gene therapy in congenital severe respiratory diseases such as cystic fibrosis.

FETAL LOWER URINARY TRACT OBSTRUCTION (39)

Lower urinary tract obstruction (LUTO) encompasses different malformations of the urethra including posterior urethral valves (PUV) (60%), urethral agenesis, and atresia (40%) and has a prevalence of around 2/10,000 births. The related mortality and morbidity are high and related both to progressive renal dysfunction and/or to dysplasia secondary to parenchymal compression and pulmonary hypoplasia related to oligoanhydramnios in cases with complete urethral obstruction.

Symptomatic fetal treatment should optimally rely on vesico-amniotic shunting, as it proved to work in animal models. The use of a double pigtail catheter placed into the fetal bladder as a temporary therapeutic intervention to allow obstructed urine to flow into the amniotic space has met with inconsistent success. Anhydramnios often found in LUTO presents a technical challenge when placing a vesico-amniotic shunt because the distal end of the shunt catheter needs to be placed into a pocket of amniotic fluid. Amnioinfusion allows to re-expand the amniotic cavity with fluid for successful shunt placement.

Technically, the placement of a vesico-amniotic shunt is done under local anesthesia and continuous ultrasound guidance. The two-pushrod shunt procedure, which we describe here, is the most used technique nowadays. The fetal bladder is accessed lateral to the midline below the abdominal cord insertion. Doppler is used to localize the umbilical arteries and confirm that the trocar will not injure them on passage through the abdominal and bladder walls.

First, the trocar is introduced into the amniotic space close to the lower fetal abdomen. An adequate pocket of amniotic fluid needs to be present in which to drop the distal end of the double pigtail catheter on exiting the fetal abdomen. As indicated above, an amnioinfusion is done in case of anhydramnios or insufficient fluid space. The trocar is then inserted into the bladder and positioned into a central location. The double pigtail catheter is then completely threaded into the trocar sheath. A short push rod is introduced and used to push the proximal pigtail of the catheter

into the bladder. The shorter push rod is then removed and a long push rod is gently introduced until it comes in contact with the distal tip of the shunt catheter within the trocar sheath. The push rod is then held in place while the shaft of the trocar sheath is slowly pulled back about 2 cm. At this point, the trocar sheath should lie just outside the fetal abdomen, with the straight segment of the shunt catheter traversing the region of abdomen between the bladder and amniotic space. The trocar sheath is then tilted to direct it away from the insertion site and the long push rod advanced to displace the distal pigtail of the catheter into the amniotic space (40).

Although the overall benefit of bladder shunting seems to translate into increased survival (OR 2.5; 95% CI, 1.0–5.9; $p < 0.03$) especially in the most severe cases (OR 8; 95% CI, 1.2–52.9; $p < 0.03$) (41), this hardly translates into improved renal function. Several potential explanations have recently been identified:

1. Shunting is performed under local anesthesia to the mother as well as fetal analgesia and curarization. Shunts most commonly used are 2.5 mm in diameter and placed through a 3.5 mm trocar introduced percutaneously into the uterus and into the fetal bladder. It is not an easy procedure to perform and one-fourth to one-third of shunts get displaced.
2. Shunting should optimally be performed when renal function is still normal. The best single parameter seems to be beta-2-microglobulin in fetal blood since fetal urine analysis and ultrasound assessment of the kidneys have a poor predictive value.
3. The diagnosis of PUV is the only one amenable to significant improvement in survival and renal function. However, the diagnosis is rightly made in only around 60% of the cases in experienced hands.
4. Overall, it is likely that shunting is too often being placed to late in the course of the natural history of the disease.

LUTO is yet another example of failed open surgery that has been abandoned in the late eighties. The encouraging results from meta-analysis on bladder shunting are calling for a randomized controlled trial that has been initiated as the PLUTO trial (percutaneous shunting in lower urinary tract obstruction: www.pluto.bham.ac.uk). Recruitment is slow and it is hoped that 200 cases could be included over a 5-year period to compare outcomes in fetuses with normal renal function and oligohydramnios at less than 26 weeks following either early bladder shunting or expectant management in utero.

A recent advance in this respect is in utero cystoscopy (42). Ruano et al. (43) recently reported a large series of PUV treated with fetal cystoscopy and laser fulguration. They proved it to be feasible and suggested that it might prevent renal function deterioration.

The same technique of shunt placement is also used for some compressive thoracic processes such as congenital hydrothorax or macrocystic congenital cystic adenomatoid malformation (CCAM) (40).

COMPRESSIVE FETAL PLEURAL EFFUSION AND OTHER COMPRESSIVE LUNG MALFORMATIONS

Fetal pleural effusions have a prevalence of 1/10,000 to 1/15,000 births. Irrespective of the underlying etiology, around one-fifth resolve spontaneously. However, compressive pleural effusion that is characterized by either mediastinal shift or compression in unilateral and bilateral effusions, respectively, is associated with a poor prognosis when it leads to polyhydramnios through esophageal compression and hydrops through impaired venous return and cardiac tamponade. Indeed, unilateral effusions, with spontaneous resolution and absence of hydrops, are associated with 100% survival but progressive hydroptic cases are associated with less than 50% survival. Furthermore, other malformations can be found in 25% of the cases and prolonged compression during the canalicular phase can lead to pulmonary hypoplasia (44,45).

Although no randomized studies have been published, thoracentesis or thoracoamniotic shunting are likely to benefit hydroptic cases by increasing survival in hydroptic fetuses from roughly 40% to over 60% (46–48). This should apply at any gestation in order to facilitate neonatal resuscitation, even late in the third trimester. For non-hydroptic fetuses, the benefit of shunting is less clear (49,50).

The technique is similar to that described for vesicoamniotic shunting in this chapter. Fetal anesthesia is mandatory and paralysis is optional. Ideally, the trocar should be inserted perpendicularly through the fetal chest wall into the effusion as close as possible to the mid-axillary line at the level of the base of the scapula. This should best prevent active removal of the catheter by the fetus. One half of the catheter is placed inside the effusion and the other half is left in the amniotic cavity.

In case of bilateral effusions, an attempt to rotate the fetus using the trocar loaded with a blunt stylet is made in order to avoid a second insertion in the maternal abdomen and uterus. The lower the gestational age, the easier this is (51).

Weekly ultrasound surveillance is recommended following shunt insertion. Technical failures are reported in 20% to 25% of the cases, including removal by the fetus within days after the procedure. Repeating the procedure may be justified in a large proportion of cases.

Macrocystic forms of congenital adenomatoid malformations of the lung when they are compressive are often associated with hydrops although does not usually develop when it is not present at the time of diagnosis. In these hydroptic cases of CCAM, survival is around 25% if untreated, and nonrandomized studies suggest that cyst aspiration/shunting procedures could improve survival dramatically (52–54).

Although less frequent in cases of bronchopulmonary sequestration (BPS), shunting of the compressive associated pleural effusion also seems beneficial (55). In addition, two hydroptic fetuses with large BPSs have been treated by ultrasound-guided Nd:YAG laser ablation of the feeding vessels with subsequent resolution of hydrops and delivery of healthy infants at term (56).

MYELOMENINGOCELE

Intrauterine surgery requesting maternal open surgery has not taken off anywhere in the world outside the United States not only in view of the poor results of CDH programs but also due

to the obvious conflict of interest between the pregnant woman and her fetus. This conflict relies largely on the risk of severe maternal morbidity in balance with mainly poor perinatal outcomes. It is also related to the laws regulating TOP for fetal indications in most countries. It is not surprising that this technique remains in a country where all forms of TOPs cannot be performed after 24 weeks, especially when fetal therapy has been initiated. Enrollment of women in these fetal surgery programs could be motivated by the potential fetal benefit, but the contradictory hope for the loss of a severely affected fetus cannot be entirely ruled out.

This apparent ambiguity is particularly questionable in a nonlethal condition such as spina bifida with an often-dismal neurologic motor development (57) and little prospect of improvements in postnatal management.

The rationale for in utero intervention is based on the “two-hit hypothesis” (58,59) that states that primary congenital abnormalities in anatomic development allow a relatively normal spinal cord to become secondarily damaged by amniotic fluid exposure, direct trauma, hydrodynamic pressure, or a combination of these factors. It is this secondary damage that may be ameliorated by early fetal surgical repair (60).

The National Institute of Child Health and Human Development decided to sponsor the Management Of Myelomeningocele Study (MOMS) trial, which involves three clinical centers: the Children’s Hospital of Philadelphia, Philadelphia, Pennsylvania; the University of California at San Francisco, San Francisco, California; and Vanderbilt University Medical Center, Nashville, Tennessee (61). The future of open fetal surgery is therefore largely dependent upon the results of this unblinded randomized controlled trial (www.spinabifidamoms.com). This is evaluating the benefits of palliative intrauterine surgery covering the neural tube defect in order to protect the nerves from amniotic fluid detrimental effects (62).

Preliminary studies suggested that fetal surgery results in reversal of hindbrain herniation (the Arnold–Chiari malformation), a decrease in shunt-dependent hydrocephalus, and possibly improvement in leg function, but these findings might be explained by selection bias and changing management indications. The current study is experiencing difficulties to recruit patients due to the alternative of TOP but suggests that maternal morbidity can be safely handled. However, this study is somehow challenging several ethical principles including the confusion between evaluation and direct benefit when advertising for the study and therefore influencing the emotional component of the women’s decision to participate (63). If the “MOMS” trial demonstrates a decreased morbidity in survivors, open fetal surgery will inevitably be put back on the European agenda.

In brief, this fetal surgery is performed between 19 and 25 weeks of gestation. In the operating room, after laparotomy and hysterotomy, the fetus is positioned with the myelomeningocele (MMC) lesion visible through the uterine incision. The cystic membrane of the MMC is carefully excised and the attachments of the meninges to the skin and soft tissues are detached. If possible, native dura alone is closed over the spinal cord as a first layer, followed by closure of paraspinous myofascial flaps, and then the skin surrounding the lesion is

carefully mobilized and closed over to complete the repair. When the skin cannot be closed primarily, acellular human dermis graft can be used to complete the closure (60).

As an unanticipated side effect, the MOMS trial apparently slowed down the clinical development of minimally invasive techniques to perform this operation in the United States (3). Nevertheless, endoscopic coverage of the defect is currently explored by several teams, experimentally and also clinically (64,65).

CRITICAL AORTIC AND PULMONARY STENOSIS

Severe and complex cardiac malformations are among the most difficult situations to handle antenatally in making the diagnosis, in assessing the prognosis, and in the perspective of continuing the pregnancy with the prospect of difficult and often multiple surgical interventions that often lead to palliative care.

Left or right heart hypoplasias are currently associated with a 60% survival rate at 5 years with mostly univentricular cardiac function. A well-recognized common pathway leading to these conditions is the critical stenosis of the aorta or the pulmonary artery respectively. Although postnatal dilatation of the stenotic vessel improves the prognosis, the hypoplastic ventricle remains nonfunctional and a univentricular cardiac function is the rule. The hypoplasia-related hypertrophy of the affected ventricle alters the coronary circulation and pulmonary venous return, weighing heavily on the overall prognosis. The first attempt to catheterize a fetal critical aortic stenosis dates back to 1991. Since then, around 30 cases have been reported with much heterogeneity in the case-selection process as well as in their management and success rates (66,67). All procedures were performed no sooner than early third trimester, which is probably too late in the natural history of most cases but is the result of a technical compromise that is required to access the affected vessel and to keep procedure-related mortality and morbidity to an acceptable level (68).

Pulmonary or aortic valve perforation or dilation can be performed under local or general maternal anesthesia. The latter performed with inhalational agents promotes uterine relaxation and facilitates fetal manipulation for positioning. The fetus is premedicated with intramuscularly administered analgesics and curarization. Under continuous ultrasound guidance, manual version is performed to optimize the fetal position. If the optimal position is not achieved or imaging is inadequate, some authors perform a limited maternal laparotomy without uterine exteriorization or incision (69). The right ventricle (RV) or left ventricle (LV) outflow tract is accessed through direct puncture, by using a 19-gauge ultrathin-walled cannula. With the cannula tip in the RV or LV outflow tract, the atretic valve is perforated with the stylet of a 19-gauge cannula. A 0.014-inch floppy-tipped guidewire is then positioned, and a coronary angioplasty balloon is inflated across the valve. After the final balloon deflation, the wire, balloon, and cannula are removed. Color Doppler ultrasound flow imaging demonstrates the success of the valvuloplasty with an antegrade jet of flow across the patent valve.

This form of minimally invasive surgery is however questioning the issue of the learning process inasmuch as that of defining clear and indisputable indications (69). Answers

should ideally be reached through an exemplary collaboration between fetal medicine specialists and interventional pediatric cardiologists. This would ensure appropriate fetal access as well as adapted pediatric follow-up within an optimally run specialized perinatal network. Rather than await a proliferation of such procedures at centers that are unlikely to amass a critical volume of experience to ensure clinical competence, a prospective multicenter trial should be considered to address the nuances of technical performance of the procedure, to evaluate the short- and midterm results, and to compare these results with those of children undergoing various forms of palliation for hypoplastic left heart syndrome (70). Moreover, the perceived benefits of prenatal treatment have to be weighed against steadily improving postnatal surgical and hybrid procedures, which have been shown to reduce morbidity and mortality for these complex heart defects (71).

Furthermore, criteria to define a successful intrauterine procedure are still unclear: permeability demonstrated by Doppler flow through the valve is an immediate but incomplete one that hides somehow the significant perioperative short- and mid-term mortality and morbidity. Less than 30% of the cases reported to date following critical aortic stenosis dilatation in utero have a biventricular cardiac function. However, owing to the high incidence of TOP following prenatal diagnosis of these conditions, comparative studies are going to be difficult to set.

EXIT PROCEDURES

The EXIT procedure can somehow be considered as a fetal surgery. It is a procedure performed while the baby is still on placental support. Initially described in 1997 for the reversal of tracheal occlusion at the time of delivery in fetuses that had undergone in utero tracheal occlusion for severe CDH (72,73), its use has expanded to convert an emergent crisis (airway obstruction mainly) into a controlled situation (74). Its indications include now not only fetal neck masses, congenital high airway obstruction but also large thoracic lesions, CDH, conjoined twins, unilateral pulmonary agenesis, and cardiac lesions where neonatal resuscitation may be compromised (75–78).

In brief, a multidisciplinary team is implicated in an EXIT procedure (pediatric surgeons, obstetrician, neonatologist, anesthesiologist, and nurses).

In the EXIT procedure (74), high concentrations of inhalational anesthetics and additional tocolytics, if necessary, are used to provide uterine relaxation and preserve placental perfusion. The time between induction of anesthesia and cord clamping is kept as long as it is clinically required. A low transverse maternal laparotomy incision is performed allowing a quick assessment of placental position with a sterile intraoperative ultrasound. While one assistant stabilizes fetal position, hysterotomy is performed. Only the fetal head and upper torso are delivered through the hysterotomy in order to maintain uterine volume. Amniotic fluid volume is maintained with the infusion of warm Ringer's lactate. Fetal well-being is continuously monitored by a pulse oximeter and by continuous echocardiography. Fetal venous access can be obtained with a peripheral intravenous line for fetal volume loading or drug administration. The procedures that can be performed on the fetus during EXIT range from direct

laryngoscopy, rigid bronchoscopy, tracheostomy to secure the fetal airway, to resections of neck masses and thoracic masses, to the placement of extracorporeal membrane circulation cannulas. Prior to clamping of the umbilical cord and delivery of the baby, communication between the surgical and anesthesia teams is essential to prevent uterine atony and excessive maternal hemorrhage. The inhalational agent is decreased and oxytocic bolus followed by a continuous infusion is administered and titrated to uterine tone, and the umbilical cord is then clamped and divided and the newborn taken to a separate operating room for further management.

OPEN FETAL SURGERY

CCAM, bronchopulmonary sequestration (BPS), and sacrococcygeal teratoma (SCT) are most frequently benign lesions managed expectantly during the prenatal follow-up. At present, the development of early fetal hydrops is considered by some authors to be the only criterion for fetal open surgery, because it is a predictor of extremely poor prognosis (55). For the fetus with a life-threatening malformation, the risk of the procedure is small when compared with the potential benefit of salvage. The risks and benefits for the mother are more difficult to assess. We provide in the following a general description of open fetal surgery as described by Adzick (79).

Patients are admitted immediately prior to the operation for obstetric monitoring and initiation of tocolysis. Indomethacin and antibiotics are given preoperatively. Maternal general and epidural anesthesia provides anesthesia for the mother and the fetus and ensures good uterine relaxation. The uterus is exposed through a low transverse abdominal incision. Sterile intraoperative ultrasound is used to delineate the fetal position and placental location. The position and orientation of the hysterotomy is planned to stay parallel to, and at least 6cm from, the placental edge and still allow exposure of the appropriate part of the fetus. For the fetal portion of the procedure, the fetus is positioned with the appropriate fetal anatomy visible through the uterine incision. Intraoperative fetal monitoring is provided by a miniaturized pulse oximeter and continuous intraoperative fetal echocardiography. The fetus is kept warm in the uterus by the continuous administration of 38–40°C Ringer's lactate solution. A fetal intravenous line is placed for infusion of fluid, blood, and/or medications. After the fetal procedure, a watertight two-layer uterine closure is performed with double-armed full-thickness 0 PDS interrupted stay sutures followed by a running 2-0 PDS suture. Approximately 400mL of warmed Ringer's lactate containing 500mg of oxacillin is instilled into the amniotic cavity just prior to completing the running layer and is continued until sonography shows an adequate amniotic fluid volume (79).

In SCTs, open fetal resection of predominantly extra-pelvic tumors has been reported in five cases (80). Mean age at birth was 30 weeks and four survived long term. There is also anecdotal experience of less invasive techniques, arresting flow in feeding vessels either by fetoscopic laser (81), interstitial thermocoagulation (82), or radiofrequency ablation (83). Needle-guided intravascular embolization with alcohol or histoacryl or coils has been reported, but without measurable success (84).

FETAL ANALGESIA

The issue of fetal analgesia touches on the surgical approach itself as much as the "primum non nocere" principle (85). It is well established that very preterm neonates experience pain, and related autonomous neural connections are operating from around 22 weeks of gestation. It is therefore important and beneficial that any directly invasive fetal procedure be preceded by appropriate fetal analgesia (86). Sufentanyl is the drug of choice and can be administered under ultrasound guidance either intravascular in the umbilical cord or intramuscular. Dose regimens are established in relation to fetal estimated weight. This should be considered independently of curarization that can be requested for technical considerations but is totally ineffective in relieving fetal pain or awareness in these situations (87).

62 Chorionic villus sampling

Giovanni Monni, Maria Angelica Zoppi, and Carolina Axiana

INTRODUCTION

Invasive prenatal diagnosis methods have gradually seen their importance grow to advances in embryo–fetal medicine, ultrasound imaging, cytogenetic analysis, and molecular biology. Such progress has deeply impacted reproduction behavior for couples at high risk for genetic pathologies.

Information from such methods can reassure couples carrying a pregnancy or, in cases of a positive diagnosis, put the couple in a position to achieve the most appropriate decision, including voluntary pregnancy interruption, fetal therapies, delivery timing and method, and postnatal interventions.

The most widespread invasive techniques employed in prenatal diagnosis centers are chorionic villus sampling (CVS), amniocentesis, and cordocentesis. Each of the techniques has its own advantages and disadvantages, including a miscarriage risk. This risk is related to operator expertise, the method itself, the equipment employed, the sampled quantity, the gestational age at sampling, and maternal age (1–5).

HISTORICAL ASPECTS OF CVS

Research studies of the 1960s and 1970s showed that the chorion could be biopsied through a catheter and that enough placental cells could be obtained so as to allow specific genetic analyses to be done earlier in pregnancy than through amniocentesis. In 1968, in Scandinavia, Mohr made the first attempts of early antenatal genetic diagnosis using sampled chorionic villi (6). He performed a transcervical biopsy of the chorion under direct endoscopic visualization using a straight 6-mm diameter fiber optic device and a sharp blade. The sample was often mixed with amniotic membranes and blood, but it was suitable for chromosomal analysis. Despite his report of a 96% success rate in obtaining chorionic material, this approach was abandoned because of an unacceptably high miscarriage rate and the difficulty in growing chorionic villi cells. Later, fetal chromosome analysis from transcervical placental biopsy prior to termination in early pregnancies was reported by Kullander and Sandahl in 1973 and Hahnemann in 1974 (7,8). In 1975, researchers at the Tietung Hospital in Anshan, China, announced the first successful prenatal diagnostic use of CVS. In an essentially blind approach, the CVS was performed through transcervical aspiration using a 3-mm metal cannula. After its insertion, when soft resistance was encountered, a smaller internal tube was further advanced, and placental material was acquired by syringe suction. Fetal sex was established from chorionic villi cells in early pregnancy according to the presence or absence of sex chromatin (the Barr body) for the purpose of sex preselection. Prenatal losses and spontaneous abortion occurred in 4% to 5% of the cases (9).

Many researchers attempted to sample chorionic villi under endoscopic visualization for first-trimester antenatal

diagnosis, but it was the arrival of real-time ultrasound and the advancement in molecular genetics that rekindled the desire for earlier and safer antenatal diagnosis of genetic diseases.

In 1980, for the first time reported in the literature, Kazy et al. described using ultrasound guidance during chorion sampling (10). Adopting either an endoscopic or an ultrasound-guided approach, they performed fetal sexing and biochemical analyses on chorion tissue biopsied at 6 to 12 weeks of gestation. Instead of cannulas, they used biopsy forceps.

Improved methods for culturing fibroblasts from trophoblast villi were reported by Niaz et al. in 1981 at the St. Mary's Hospital, London (11).

Old et al., from Great Britain, announced using real-time ultrasound and a 1.5-mm biopsy instrument for CVS for diagnosing hemoglobinopathies through molecular methods (12).

In 1983, Ward in London carried out transcervical chorionic sampling with ultrasonic guidance applying a 1.5-mm soft polyethylene catheter and syringe suction (13). His group declared a sampling success rate of 67%, including seven patients for hemoglobinopathy diagnosis through molecular methods.

The success rate of obtaining chorionic material rose from 75% to 96% under ultrasonic guidance, as was demonstrated by Brambati et al. in Milan in 1983. Brambati used a 1.5-mm polyethylene tube with a soft, stainless-steel, malleable obturator inserted into the 1-mm internal barrel. For many years, this device has been the most common design in use (14,15).

Other researchers, such as Dumez in Paris, used a 2-mm rigid biopsy forceps (16).

In 1983, Simoni et al. in Milan described a technique from first-trimester chorionic villi that could be used for direct chromosome preparation and karyotyping as well as for enzyme analyses without needing preliminary culture (17). Chorionic villi were obtained by aspiration or through biopsy from the chorion frondosum, at the edge of the placental disk. With the technique they proposed, in the freshly sampled villus, the inner cytotrophoblast layer (containing actively mitotic cells) could be separated from the outer syncytiotrophoblast cells. All analyses could be performed from these fresh whole villi.

In 1984, transabdominal fine-needle villus aspiration under ultrasound guidance was introduced by Smidt-Jensen and Hahnemann in Copenhagen (18). They registered considerable success in acquiring samples at the first attempt, thus preventing further infective complications and pregnancy loss.

CVS has achieved significant improvements since then, including perfecting the instruments so that they are relatively

easy to manipulate. In addition to advancements in sample acquisition, laboratory techniques have evolved, including those for direct karyotyping, tissue culture, and molecular and biochemical assays of chorionic villi.

The transabdominal approach instantly proved easy to learn and relatively safe. While it registered a higher detection rate, it also guaranteed comfort and privacy to the women undergoing the procedure. It could be practiced at any gestational age, thus spreading quickly in many centers and becoming today the most popular approach of chorion sampling. One particular advantage of CVS is the possibility of performing the procedure very early in pregnancy, starting from the 6th week (although it is generally recommended from the 10th to 12th week). In this way, it is a method that is highly accepted by couples and one apt to diminish physical and psychologic issues related to late diagnosis and eventual voluntary pregnancy interruption due to genetic diseases (19).

INDICATIONS

CVS was initially applied for fetal sexing and prenatal diagnosis of hemoglobinopathies by DNA analysis. However, since then, cytogenetics and DNA analysis techniques have shown serious advances and broadened the number and types of genetic conditions detectable in the antenatal period. As a consequence, the demand for CVS in first-trimester prenatal diagnosis is accordingly making a steady increase.

At present, the primary indications of CVS are chromosomal studies, DNA analysis of genetic disorders, and the prenatal diagnosis of inborn errors of metabolism (Table 1).

Regarding chromosomal studies, CVS is primarily indicated for advanced maternal age (35 years or more), a previous pregnancy with a chromosomal abnormality, a previous pregnancy with multiple anomalies, X-linked diseases, parents with balanced chromosome rearrangements (translocations and inversions), parents with aneuploidies, a past history of recurrent miscarriages, an abnormal ultrasound scan, and oligo-anhydramnios.

It should be noted that the demand for CVS is greater than ever now that first-trimester screening methods for the detection of fetal chromosomal anomalies are developing. As a matter of fact, the risk for fetal aneuploidies related to advanced maternal age remains a common indication for CVS, but the CVS indication has expanded to be employed for

quickly confirming an abnormal karyotype in the first-trimester fetus if a chromosomal abnormality has been suggested by ultrasound and/or biochemical screening. In the last 20 years, the screening of women for fetal Down syndrome has progressed to the evolution of numerous proficient and complex screening strategies that provide the advantages of allowing both superior detection and lower false-positive rates at earlier gestational ages. First-trimester risk assessment of chromosomal defects by the ultrasound measurement of fetal nuchal translucency and the evaluation of the nasal bone (Fig. 1), combined with a biochemical test (pregnancy-associated plasma protein-A, free beta human chorionic gonadotropin), reach a very high detection rate at more than 90% (20–26). Therefore, the choice that patients make should be based on the risk that screening tests generate and not on their age alone (27,28).

In a report in January 2007, “Screening for chromosomal abnormalities,” the American College of Obstetricians and Gynecologists (ACOG) Practice Bulletin advised new guidelines that seek to offer risk evaluation and invasive genetic diagnosis of fetal karyotype to all pregnant women requiring prenatal care before 20 weeks of gestation, regardless of maternal age (29). Among such less common indications for fetal karyotyping are maternal anxiety, polyabortivity, and assisted reproductive techniques by intracytoplasmic sperm injection (30).

The DNA-based diagnoses of single-gene disorders such as cystic fibrosis, hemophilia, muscular dystrophy, and hemoglobinopathies form a group that is expanding with the advance of technology and knowledge of the human genome. About 1% of live births is affected by single-gene disorders, which may be autosomal recessive, autosomal dominant, or X-linked recessive. They imply a high risk of recurrence and are often inadequately treated so that prenatal diagnosis with termination of affected pregnancies is a significant option for couples at risk.

The purpose for prenatal diagnosis of genetic disorders is to determine the carrier status in order to help with genetic counseling of at-risk couples. Most carrier recognition and genetic counseling are retrospective, that is, after the birth of an affected child. Nonetheless, several programs related to

carrier screening have been launched for populations known to be at risk for specific disorders, as is the case of beta-thalassemia in the Mediterranean area. Beta-thalassemia is the most common single-gene disorder among Italians, where 13% of the people on the Sardinia Island are healthy carriers. Ongoing programs of screening have proved quite effective, and they have resulted in a noticeable decline in the incidence of thalassemia major. Screening programs for Sardinians are based on carrier detection by employing hematologic methods, and genetic diagnoses can be made by identifying specific mutations through DNA analysis in carrier couples. In this way, prenatal diagnosis can be accomplished by mutation analysis on PCR-amplified DNA from chorionic villi (31). Because of advances in molecular techniques, the number of single-gene disorders offered for wide-based population screening will undoubtedly grow.

Ultrasound screening of Down syndrome in the first trimester of gestation may sometimes reveal several fetal abnormalities. Holoprosencephaly, omphalocele, cystic hygroma, diaphragmatic hernia, and megacystis are widely recognized features either of aneuploidies or of certain syndromes. When these are detected in the first trimester, taking advantage of CVS can prompt fetal karyotyping or definitive DNA studies (32).

The inborn errors of metabolism form a vast group of disorders that are individually rare, yet all together embody a major source of human disease and suffering. The majority of these are caused by defects in single genes responsible for encoding enzymes that facilitate conversion of various substrates into different products. Usually, the basis of the problems is the accumulation of substances that are noxious or hamper the normal function as well as the effects of inability to synthesize essential compounds. The basic biochemical defect has been so far identified in more than 300 different inborn errors of metabolism. The greater part of these conditions are indeed rare and new prenatal diagnosis methods for specific disorders are continually being presented; therefore, it is recommended to check with a specialist referral center on the current availability and preferred prenatal diagnosis method. Usually, family history of the disorder with a well-established primary diagnosis in the index case is the indication for prenatal diagnosis but in some cases ultrasound recognizable fetal features may also prompt the prenatal diagnosis.

Sometimes, the chorion tissue must undergo various preparations because more than one analysis is required. Taking into account that chromosome abnormalities are discovered in approximately 1 in 156 live births, and in about 50% of first-trimester spontaneously aborted fetuses, fetal chromosome investigations are an important matter. However, there are cases in which the villi are sampled for other indications (33). As a matter of fact, fetal karyotyping is quite often necessary in addition to the most significant test, even in the absence of specific indications for chromosomal analysis.

Fetal HLA typing could likewise be done in pregnancies of couples at high risk of diseases amenable of treatment by stem cell transplantation, as with beta-thalassemia. In some cases, an alternative to pregnancy termination in the case of an affected fetus could be the prospect of bone marrow

transplantation with an HLA well-matched sibling (34). By CVS, certain congenital infections can be detected such as rubella, toxoplasmosis, cytomegalovirus, and parvovirus (35–37).

Practicing CVS by any means should be a choice contingent on the possible benefits overcoming risks linked to the procedure.

COUNSELING

Before any CVS procedure, adequate genetic counseling is mandatory in order to inform the couple about prognosis, treatment, possible outcomes, complications, and recurrence risks associated with the genetic disease under investigation. In particular, the geneticist or obstetrician should detail advantages and disadvantages in terms of risks associated with the procedure itself, with mention of the abortivity measured in the prenatal diagnosis center providing the care and the one reported in the literature. Information should be included on diagnostic accuracy (i.e., false positives, false negatives, and misdiagnoses), timeline of diagnostic response, gestational age at sampling, success and fail rate of sampling, and all other possible complications. Consent, preferably written, will be given by a woman only after comprehensive, informative, and nondirective counseling.

SAMPLING PROCEDURE

Performing CVS must always be under direct ultrasound visualization through the vagina and the cervix (transcervical, TC-CVS), through the vagina only (transvaginal, TV-CVS), or through the maternal abdomen (transabdominal, TA-CVS) (Table 2).

Transcervical Route

A Chinese group reported success of fetal sexing achieved by transcervical withdrawal of chorionic villi, and this encouraged the development of a number catheters or cannulas for transcervical insertion, all different in material (silver or polypropylene), flexibility, and handling. The instruments employed have gone through variations and there have been alternative methods of obtaining villi; currently, the most common are under transabdominal ultrasound guidance by means of aspiration, by either a cannula or a catheter, and by means of rigid biopsy forceps (38).

For the transcervical procedure, the woman is set in the lithotomy position with comfortable leg supports. The woman’s vulva, perineum, and vagina are cleansed with an antiseptic solution. A sterile speculum (or valve) is inserted into the vagina and opened, and the cervix is swabbed with the same solution. With the speculum in situ, the course of the cervical canal and a more detailed location in the sagittal and transverse view of the uterus is achieved. During the procedure, the assistant (or the operator himself) takes care

to establish the placental site and its relation to the cervical canal, so as to guide the instrument toward the site of sampling. Sometimes it is necessary to use a tenaculum or a vulsellum for steadying the cervix and passing through the cervical canal.

The aspiration technique represents maybe the most common method of TC-CVS (Fig. 2). It is carried out using a 1.5-mm (16-gauge) cannula of polyethylene with a 1-mm malleable stainless-steel or malleable stylet. To facilitate the transcervical passage into the uterus, the distal 3 to 5 cm of the cannula is slightly curved. The cannula must be passed through the cervix without touching the vaginal walls, and sometimes it is required to steady the cervix until any loss of resistance is perceived at the internal os. The cannula tip is visualized at this point by real-time ultrasound and is advanced under direct visualization into the chorion frondosum. The cannula is positioned parallel to the axis of the developing placenta and advanced almost to its distal end. The metallic obturator (stylet) is then removed, and a 20-ml syringe containing 5 ml of growth medium with heparin is attached to the end of the cannula. Chorionic villi are finally aspirated by applying negative pressure with the syringe while moving the catheter several times through the placenta in the longitudinal axis. The cannula and the attached syringe are then withdrawn. The syringe is to maintain suction throughout sampling and the withdrawal of the catheter to favor villi removal (14).

For sampling with rigid forceps, the woman should be in the same lithotomy position. After thorough local cleaning and accurate ultrasound evaluation, the forceps are introduced under direct transabdominal ultrasound monitoring. They are then gently directed to the sampling site, away from the choriodecidual junctions and margins of the chorionic plate (Fig. 3). The diameter of the forceps is only 2 mm, so care must be taken to constantly visualize the forceps tip, the chorionic plate, and the amniotic sac in order to avoid creating a false passage. Once the site is reached, the sampling itself is performed by opening the jaws and advancing the forceps further into the placenta. They are then closed, and the forceps are slowly withdrawn. Chorion biopsy can be performed using a number of different forceps devices (15). In Europe, a 2-mm straight rigid

forceps (Storz) and a thin-gauged transcervical round-tip steel biopsy forceps with a curved shank (snake forceps, 1.9 mm in diameter, 25 cm in length) are mostly employed.

Transvaginal Route

Transvaginal sampling by a needle guide attached to the vaginal ultrasound probe has also been used. The preparation of the woman is the same as for transcervical sampling. A vaginal 5- to 7.5-MHz ultrasound probe enwrapped in a sterile envelope is inserted into the vagina and connected to a sterile needle guide. Chorionic villi sampling is then accomplished by either a 20-gauge needle with a stylet or a double-needle system, which are transvaginally and transmurally pushed forward into the chorion frondosum and moved to and fro. A target line on the ultrasound monitor sets the puncture depth and ensures reaching the desired biopsy site. Such transvaginal techniques were mostly adopted from vaginosonographically guided puncturing of follicles for oocyte harvesting. They allegedly prove more practical in cases of a fundal placenta with a retroverted uterus; however, this technique is found altogether less advantageous than TA-CVS and transabdominally guided TC-CVS (39).

Transabdominal Route

In the mid-1980s, the transabdominal approach was introduced using either a double- or a single-needle technique, and nowadays, it has become the most widespread technique. The woman should lie on her back on an examining table. The specific area on the woman's abdomen must be adequately cleansed with an aqueous betadine solution (antiseptic). A sterile oil is used so as to allow scanning by the transducer probe, which is commonly wrapped in a sterile drape or glove. The needles and the syringes need to be heparinized prior to skin puncture.

For the double-needle system, special needle guide adapters are necessary. They are available from ultrasound manufacturers and can be coupled with specific probes where the needle passes through a fixed path, either parallel or at an angle to the ultrasonic beam (Fig. 4) (18). First of all, a needle of 1.2 mm outer diameter (18 gauge) is inserted into the needle guide up to the basal plate of the placenta. After that, the stylet

Figure 4 Transabdominal chorionic villi sampling by double-needle system.

Figure 5 Transabdominal chorionic villi sampling by freehand technique. The needle is inserted longitudinally to the probe.

is removed and an aspiration needle of 0.9 or 0.8mm (20 or 21 gauge) is introduced into the first needle and pushed forward into the chorion.

Regarding the single-needle technique, a suitable place of chorion must be identified on the scanner monitor. The puncture is then done freehand by a single 20-gauge spinal needle, inserted tangentially to the greater side of the probe, simultaneously visualizing the needle tip going into the placenta and straight through the shortest route so that only the needle tip is displayed (Fig. 5) (40,41). An oblique insertion, needling at the extremity of the probe, allows observing fully the needle throughout sampling but implies a lengthy course (Fig. 6). Newer needles have a special external coating and emit echo-luminance so as to enhance needle placement.

By adopting the freehand technique, after having reached the sampling site, the needle is connected to a 2.5-mL syringe with a small amount of culture medium or sterile

solution. The displayed needle tip is moved up and down 5 to 10 times in order to favor detachment and suction of villi. All the while, negative pressure must be applied by manual aspiration through the syringe, which is maintained throughout sampling and withdrawing. Some operators use a 30-mL syringe mounted on a holder as an alternative (42).

The need for the transducer probe to be manipulated by the same operator must be emphasized because it results in better hand-eye coordination and the reduction in the number of multiple insertions and the failures associated with the procedure. The single-operator freehand technique necessitates the same operator holding both the probe and the needle during insertion, thus having the sensibility to direct the proper placement of the needle. Sonographic guidance is crucial, but tactile sensation is important as well.

In fact, most procedures require at least three hands. Some operators actually need an assistant to hold the transducer during the connection of the syringe and after withdrawal, while they verify the sampling adequacy and the patient is waiting on the examination table. Other operators hold the transducer in their own hand and ask for assistance for drawing up the tissue.

If obtaining an adequate sample fails, a second insertion is performed. It is important to point out that the procedure is not to be carried out unless the operator is sure of the safe access to the intended chorion site. When difficulties are anticipated, the opinion of a more experienced physician should be sought.

Complications increase significantly if three or more insertions are attempted; therefore, no more than two needle insertions should be performed per session.

According to our own experience, a second attempt to obtain villi is rarely necessary. When the procedure seems too hard and an adequate sample is still not obtained after repeated passes, it may be wise to postpone it to the following days or week. An experienced operator should be consulted for any of these procedures if two attempts at uterine insertion fail to produce an adequate sample for analysis.

CVS Setting

CVS, in any employed route, is generally performed in an outpatient facility or the health-care provider's office. Local anesthesia is not required since it does not deal with sources of pain in the peritoneum and the uterine wall; neither any preoperative nor postoperative medical treatment is usually necessary. Before the CVS procedure, the woman can eat and drink as usual. She may need her partner or another close contact to accompany her to the appointment and support her emotionally or to drive her home afterwards. Based on the clinical experience at our institution, the procedure proves more expeditious if the woman is at ease. The complex range of various psychologic issues related to genetic diagnosis and emotional needs of a woman experiencing CVS requires that the team who performs CVS also develops great sensitivity to the patient's apprehension and anxiety. It appears very helpful to actively involve the woman and maintain a dialogue between her and the operators during the procedure and the fine-tuning of the technical aspects of the CVS, as this minimizes the discomfort and ensures a trusting environment.

During transcervical CVS, the passage of the instrument through the cervix and the suction of villi may prove a cause for cramping, a pinching feeling, and general discomfort (nausea and anxiety). After the sampling, women may experience mild to moderate spotting for the first week.

Regarding TA-CVS, the entire procedure is completed in approximately 10 minutes. Most of the time is usually dedicated to the ultrasonographic investigation and sampling set preparation while the needle insertion itself lasts for a maximum of 10 seconds. On rare occasions, women complain of a rapidly resolving stinging sensation or cramping with the needle penetrating the skin and the uterus. A higher level of pain is likely to be experienced by patients with a thicker abdominal wall (greater than 40mm). At the end of the procedure, all symptoms are resolved. CVS may generate considerable anxiety, but most women find the pain equivalent to that of an intramuscular puncture. A recent study evaluating the woman's experience of pain during TA-CVS reports that the sampling procedure seems most painful at the approach of thicker needles, so the need to use a 19-gauge needle is questioned as acceptable results are obtained with a 20-gauge needle as well (43).

Particular angles of access are also recommended by some experts but the data gathered so far are not exhaustive enough to guide practice. A randomized trial by van Schoubroeck et al. showed that injection of local anesthetic did not reduce pain scores as reported by women undergoing transabdominal punctures (44).

Rhesus status must be considered in every case. According to the guidelines of the ACOG (2001), Rhesus prophylaxis with anti-D immunoglobulin (200–300µg), intramuscularly, should be offered to Rh-negative unsensitized women after each procedure (45,46). However, in cases of being already sensitized, the CVS is contraindicated.

Normally, in a few hours after the sampling, the woman will likely be able to resume normal activities and return home. They are counseled to contact medical staff only if they experience pain, heavy bleeding, or febrile episodes. An ultrasonographic follow-up is recommended when the

diagnostic result is available so as to verify the fetus's well-being and to exclude chorionic hematomas.

MULTIPLE PREGNANCIES

Multiple pregnancies are not, as a general rule an impediment to CVS, but they require a greater amount of expertise and manual skills in order to insure that all fetuses are correctly sampled. Sampling is straightforward when placentas are well separate, but in cases of close proximity, it becomes more complex, as needles need to be serially in all placentas, possibly close to the umbilical cord insertion, in order to insure complete sampling without double passing across the same chorion point. Needles need to be replaced for each sampling (47,48).

In pregnancies with high genetic risk, CVS is better suited than amniocentesis, as an eventual procedure of selective fetus reduction is much simpler and less risky when performed during the first trimester of pregnancy. Careful evaluation and documentation of gestational sacs, fetuses, placentas, and umbilical cords are mandatory when CVS is performed to correctly identify the fetuses when discordant results are obtained and the patient desires selective termination. Sampling error in multiple pregnancies is between 0% and 10% and depends critically on the expertise of the operator. Miscarriage risk is 2% to 4% (49–54).

CONTRAINDICATIONS

Absolute contraindications to TC-CVS are vaginismus and major anomalies of the cervical canal. Cervical polyps and large myomas of the lower uterine segment may represent an important obstacle to the cannula or biopsy forceps. Likewise, a fundal placenta or a posterior placentation in a retroverted uterus may be very difficult to sample by this approach. The transcervical route should be considered a risk of ascending infections in women with active genital infection, even if appropriately treated.

Conversely, it is almost always possible to obtain a sample by the transabdominal route. Actually, there are no valid contraindications to TA-CVS. An appropriate scanner pressure and an accurate bladder filling may favor reaching the sampling site and avoiding intestinal loops in front of the uterus. Myomas may be avoided by real-time guide of needle insertion. In cases of uterine retroflexion, a gentle cervico-vaginal manipulation of the uterus by an assistant may be needed (Fig. 7).

Uterine contractions are occasionally seen, which can interfere with sampling; it is advisable to wait for 10 to 20 minutes for these contractions to cease, even through the help of an antispastic drug.

Some contraindications are common for either TC-CVS or TA-CVS.

In any case of active vaginal bleeding, it is advisable to reschedule any sampling procedure to a few days after the bleeding has stopped.

The occurrence of areas of retrochorionic hemorrhage at ultrasonic examination before CVS usually prompts extreme care to avoid it by the cannula or needle.

In cases of preoperative abundant sub-chorionic hemorrhage, deferral is mandatory until after a well-established resolution or to amniocentesis in the second trimester.

Figure 7 Cervico-vaginal manipulation in cases of uterine retroflexion.

Systemic maternal diseases do not represent a contraindication to CVS.

In the presence of inherited bleeding disorders, as in cases of hemophilia carriers with less than 50% factor VIII coagulant activity, prophylactic intravenous infusion of desmopressin (1-deamino-8-D-arginine vasopressin) just before CVS can be offered. This synthetic analog of vasopressin causes an immediate increase in the plasma concentration of factor VIII, von Willebrand factor, and platelet adhesiveness thus preventing abnormal bleeding with few side effects except mild facial flushing and headache (55).

A potential risk exists for maternal–fetal virus transmission as well as patient–clinician transmission in cases of women with blood-borne virus. The fairly small studies available for hepatitis B show no evidence of a transmission risk so that the risk is expected to be very low. The “e” antigen status is likely to be significant for maternal–fetal transmission (56). Although most studies examining human immunodeficiency virus (HIV) suggest that invasive testing may be a risk factor in transmission and recommend avoidance, several authors more recently have suggested that the current risk of HIV vertical transmission associated with early invasive diagnostic techniques is lower than previously reported, provided that antiretroviral therapy is being used (57).

COMPLICATIONS

TA-CVS has a reported abortivity risk around 1%, when performed by an expert hand. Randomized clinical trials have reported a similar fetal loss rate after CVS in the first trimester when compared with amniocentesis at the 16th week. In evaluating the fetal loss rate, spontaneous abortivity in the general population between the 10th and 12th week always needs to be taken into account. Post-procedural complications are highly dependent on the operator’s expertise, gestational age, maternal age, the amount of chorion tissue sampled, the number and duration of needle insertions, bleeding prior to the procedure, and concomitant uterine pathologies.

Minor complications have been reported, like bleeding, spotting, intracervical hematoma, but without sizeable effects on perinatal outcome. In the early 1990s, fetal limb reduction defects have been reported after CVS performed before the

10th week in centers without a proven track record that did not employ standardized techniques. Wider studies on reference centers have however reported rates of limb reduction defects for CVS after the 9th week that are similar to the rates for the general population (5.4/10,000). Accordingly, the WHO-sponsored committee concluded that there is little evidence to suggest a significant risk of congenital defects when CVS is carried out after the 8th completed gestational week and recommended that CVS be performed in referral centers following 9 weeks after the last menstrual period by qualified operators who are adequately trained (58–65).

ANALYSIS

Diagnostic procedure is correlated to the level of expertise of the operator, the cytogeneticist, and the molecular biologist.

The sample of chorionic villus should contain enough material for genetic analysis, generally around 20 to 30mg. The sample of chorionic tissue should be placed in nutrient medium if cytogenetic analysis has been planned and in a sterile hydro-saline solution for other analyses. The specimen might be mailed to be analyzed but never frozen and should be examined within 24 to 48 hours. Sampled villi need to be examined under an inverted microscope to detect contamination with maternal decidua, which need to be separated so as not to affect diagnosis with unwarranted interpretations.

Two methods are currently available to fully evaluate the fetal karyotype from a CVS specimen: the direct (or short-term) method and the indirect or culture method.

Chorionic villi consist of two cells types: cytotrophoblast cells and mesenchymal core cells. In freshly sampled chorion tissues, the villus inner cytotrophoblast layer beneath the outer syncytiotrophoblast layer contains mitotically active cells, which are rapidly dividing cells, many of which are already in metaphase. These cytotrophoblast actively mitotic cells would provide a reliable means of predicting the fetal karyotype for direct metaphase analysis, without culture. Although the direct analysis of cytotrophoblasts can provide welcome rapid results (24–72 hours), the quality of metaphases obtained is usually less than that obtained by culture.

To enhance the accuracy of CVS results, it is a good practice that villi tissue be analyzed by both the direct (or short-term)

and the indirect (long-term or cultural) method. The first method allows analysis in a few hours, although an incubation of at least 24 hours is recommended with a diagnostic response in 3 to 5 days. The second method analysis is completed after 7 to 10 days.

Currently, confined placental mosaicism is considered the main cause of ambiguous results, which might result in false-positive diagnoses. Following the direct analysis, the majority of discordant findings between chorionic villus samples and the fetus have been false-positive results (1–2%) and only very few have been false negative (1/3000).

With the use of both direct and cultured villus analyses, the incidence of true false-positive results can be greatly reduced (to 1/20,000) and that of true false-negative results can be eliminated. However, when a mosaicism is found after CVS, follow-up amniocentesis and/or cordocentesis is required to clarify results.

Fluorescence in situ hybridization (FISH) can also be performed on noncultured chorion cells following CVS, by using chromosome-specific probes to determine the aneuploidies of chromosomes 13, 18, 21, X, and Y. This has allowed a rapid diagnosis of some selected chromosomal anomalies. It has also enabled the detection of subtle cytogenetic aberrations with a resolution equal to the size of the probe (50–200Kb) that are associated with a clinical phenotype (66,67). Despite the high sensitivity and specificity of interphase FISH for trisomy 13, 18, 21, and sex chromosome aneuploidy (99%), culture failure or noninformative results occur in up to 5.7% of cases and false-positive and false-negative results, although rare, have been reported. For that reason, the American College of Medical Genetics does not recommend therapeutic action on the basis of the results of FISH alone.

An implementation of the chromosomal evaluation in chorion tissue, in the 1990s, was the quantitative fluorescence polymerase chain reaction (QF-PCR), which was derived from the association of techniques of molecular biology to FISH. The technique is based on the amplification of chromosome-specific highly polymorphic DNA short tandem repeats, using fluorescence primers and PCR on chromosomes 13, 18, 21, X, and Y. The QF-PCR, which has comparable sensitivity to the FISH, consents easier identification of maternal contamination and is much less expensive because it is almost entirely automated. QF-PCR is now more common than FISH and many European laboratories consider it the method of choice for rapid aneuploidy testing complementary to full karyotype analysis and, in some specific cases, as an alternative to conventional cytogenetics analysis.

FISH and QF-PCR allow only the detection of aneuploidies involving chromosomes that are specifically tested, usually trisomies of chromosome 13, 18, 21, and sex chromosomes. It means that aneuploidies involving other chromosomes and balanced chromosomal rearrangement can be missed. By using QF-PCR as a stand-alone test, the chances of missing the most common, and the only chromosome anomalies that do not increase in frequency with maternal age, are approximately 1 in 150 abnormal karyotypes, or 1 in 10 to 30,000 samples, based on age distribution; these error rates may be acceptable, although most structural anomalies will be missed (68).

Since chorionic tissue cells provide large sources of DNA suitable for DNA analyses, consequently, CVS is at present the

technique of choice for prenatal diagnosis of genetic diseases with known molecular defects or when a linkage analysis is feasible (i.e., thalassemia, cystic fibrosis, Duchenne muscular dystrophy, hemophilia A, fragile X).

When a specific molecular defect is already known, the research of the defect is performed by different methods using the DNA extracted from villi and amplified by PCR (69).

For DNA-PCR diagnosis of disorders like β -thalassemia, a very small specimen of 1 to 3 mg of chorionic tissue, supplying approximately 1 to 3 μ g of DNA, will suffice, but at least 3 mg of chorionic villi is requested to reduce the risk of co-amplifying the DNA from maternal decidua.

These techniques of PCR-DNA analyses, which enable reliable analysis of a small specimen of villi in 1 to 2 days, are highly efficient and accurate. Misdiagnosis and diagnostic errors are very uncommon (less than 1 in 10,000) in qualified centers when well-defined methods such as variable number tandem repeats are applied to rule out contamination by maternal decidua and blood (31,70).

In utero infections can be documented for agents such as rubella, toxoplasma gondii, cytomegalovirus, varicella zoster, and parvovirus. Diagnosis can be made by extraction of DNA or RNA from chorionic villi and amplification of some well-recognized genes of the suspected infectious agent (35–37).

GUIDELINES

In conclusion, the CVS procedure, when performed by experienced hands, is associated with an approximately 1% to 2% pregnancy loss rate. Adjusting for confounding factors such as gestational age, the procedure-related miscarriage rate following CVS at 10 weeks or later, in very experienced hands, is the same as midtrimester amniocentesis (at best 1 in 300). In less experienced hands, the risk may be higher.

CVS is presently recommended through the transabdominal route after the 9th week of pregnancy with an experienced operator and after genetic counseling. An operator is considered an expert when performing at least 100 samples per year. The training period comprises at least 50 samples under the supervision of a senior tutor. Each operator should undergo yearly audits to verify success rates of samples, fetal loss rate, diagnostic accuracy, and neonatal outcome. Data should be compared with what is reported in literature for reference centers. The analysis laboratory should also ensure an adequate number of exams in order to guarantee the highest degree of certainty (71–73).

63 Amniocentesis

Aris Antsaklis and Marianna Theodora

HISTORY

Amniocentesis is the oldest invasive procedure for prenatal diagnosis. It was first used toward the end of the 19th century for evacuative paracentesis in pregnancies complicated by hydramnion (1). At the beginning of the 1950s, it was used to determine the amniotic fluid composition in cases of Rhesus isoimmunization (2). However, amniocentesis was used for diagnostic reasons in the 1950s, as a method for sex determination by the identification of Barr bodies in the noncultured amniocytes (3). About 10 years later, the karyotype of the embryo was determined through an amniotic fluid cell culture (4). Since then, amniocentesis has been established as a basic invasive method for the prenatal diagnosis of various pregnancy-related conditions, such as fetal karyotyping, diagnosis of metabolic or enzymatic diseases, assessment of the severity of hemolytic disease, establishment of lung maturity, and diagnosis of fetal infections. Additionally, amniocentesis is used for the infusion of various drugs into the amniotic cavity, determination of the composition of the amniotic fluid, and finally for evacuation of hydramnion.

INDICATIONS

Amniocentesis is used for both prenatal diagnosis and fetal therapy (Table 1).

Chromosome and DNA Analysis

Examination of the number and structure of fetal chromosomes (fetal karyotyping) is the main indication for amniocentesis. It is offered to women in cases when the risk for fetal aneuploidies is high such as advanced maternal age (traditionally ≥ 35 years), previous fetal aneuploidy, parental balanced translocation, positive screening test in the first or second trimester, identification of aneuploidy markers in genetic sonogram, and so on. Another indication is an ambiguous result from a previous test such as karyotype mosaicism obtained by the chorionic villus sampling (CVS). Fetal karyotype is examined either in cultured cells or with PCR technology. However, the result of the latter technique should always be confirmed with culture.

Fluorescent-labeled in situ hybridization allows for DNA study, with direct probing, and therefore the diagnosis of fetuses with gene diseases such as hemophilia, b-thalassemia, cystic fibrosis, and so on.

Fetal Infection

Diagnosis of fetal infection from *Toxoplasma gondii*, cytomegalovirus, and so on, in cases of maternal seroconversion is possible by examination of amniotic fluid with PCR-based technologies.

Lung Maturity

Fetal lung maturity can be assessed indirectly using both qualitative and quantitative characteristics of amniotic fluid.

Pulmonary maturity can be assessed by the measurement of lecithin/sphingomyelin ratio or the concentration of phosphatidylglycerol in amniotic fluid. Similarly, the detection of lamellar bodies and the study of other characteristics of the amniotic fluid may give information about lung maturity. However, the improvement in neonatal care and the accurate confirmation of gestational age with ultrasound early in pregnancy have diminished the need for examination of amniotic fluid and thus amniocentesis in order to confirm lung maturity.

Chorioamnionitis

Premature rupture of the membranes (PROM) and preterm labor have been associated with amniotic fluid bacterial colonization (5). Amniocentesis and gram stain, microscopy, and culture of the amniotic fluid have been advocated in cases of premature rupture of membranes or premature labor. Researchers who advocate for amniocentesis state that early diagnosis and management are possible and may result in better perinatal outcome. However, spontaneous labor within 24 hours after membrane rupture is very common and thus there are no data to support amniocentesis as a clinical standard in cases of PROM.

Biochemistry

Amniotic fluid collection and estimation of enzyme level were used in order to diagnose metabolic diseases and other conditions such as cystic fibrosis or congenital adrenal hyperplasia before DNA techniques were applied. This practice has been replaced by the most accurate detection of gene mutation responsible for the disease in fetal cells collected by amniocentesis or CVS.

Another past indication of amniocentesis is the evaluation of fetal hemolytic anemia in cases of Rhesus alloimmunization. Amniocentesis and amniotic fluid spectrophotometry are performed less since middle cerebral artery Doppler velocimetry has been proposed as a routine test for the evaluation of hemolysis and fetal anemia.

Obstetric Cholestasis

Amniocentesis is used in obstetric cholestasis in order to diagnose meconium-stained amniotic fluid, which is a common complication of this pregnancy-related disorder and related to intrauterine fetal demise. However, improvements in understanding both the pathophysiology of the disease and the management of these cases have led to decreased need for amniocentesis in this context.

Fetal Therapy

Amniocentesis is used for uterine decompression in case of hydramnios and twin-to-twin transfusion syndrome in

Table 1 Indications for Amniocentesis

monochorionic (MC) twins. Amnioinfusion has been used in cases of severe oligohydramnios, but research is needed in order to define both the indications and the outcome of such an intervention. Finally, thyroxin has been injected into the amniotic sac to treat goitrous hypothyroidism of the fetus.

TECHNIQUE

Amniocentesis is mainly performed during the second trimester but can be performed also during the third trimester when certain indications stand. Amniocentesis for prenatal diagnosis of genetic diseases of the fetus is traditionally carried out between 15 and 18 weeks of gestation when the fundus of the uterus is easily accessible. Additionally in this gestational age, the volume of amniotic fluid is 150 to 200mL, which permits the removal of 15 to 20mL of amniotic fluid, which is adequate for this test without creating problems. Moreover, at this gestational stage, the relationship between the viable and nonviable cells of the amniotic fluid is the optimal in order to have results. For the above reasons, amniocentesis should be carried out at this time (6). Early amniocentesis (between 11 and 14 weeks) has been associated with increased risk of fetal malformations, mainly clubfeet, and has been abandoned.

In any case, before amniocentesis is performed, pregnant women should receive appropriate genetic counseling concerning the risks, the limitations, and the benefits of the procedure and the tests. Informed consent should be obtained before the procedure. A detailed ultrasound examination must be done in order to determine the number of fetuses, gestation age, cardiac function, possible abnormal formation, amniotic fluid quantity, position of the placenta, existence of fibromas in the uterus, existence of adnexal masses, and finally possible cervical inadequacy. When this ultrasound examination has been completed, the entry site of the needle into the amniotic cavity is determined (7,8). Preferred pockets are located away from the fetal face. Sites that must also be determined and avoided as much as possible during amniocentesis is the umbilical cord—depending on its position—and the placenta. However, none of these is absolutely necessary to obtain amniotic fluid safely. The skin around the entry site of the needle is carefully cleaned with an antiseptic solution.

A disposable 22-G spinal needle (Fig. 1) is carefully guided into the amniotic cavity under continuous ultrasound monitoring. When the needle enters the corresponding area, the inner needle is removed and a syringe is attached to the needle hub. If freely flowing fluid is not obtained, the needle is then repositioned. Failure to aspirate amniotic fluid is most commonly due to membrane tenting. When this occurs, the needle appears inside the amniotic cavity, but the needle tip has not actually penetrated the amniotic sac. This usually occurs when an early amniocentesis is carried out, when the amnion and the chorion have not yet fused. In this case, it is recommended that the inner needle is replaced and the needle's entry point to the amniotic cavity is carefully changed so as to avoid injuring the fetus or the umbilical cord. Another reason for failing to take a sample of amniotic fluid is when the fetal membranes plug up the opening of the needle, due to the negative pressure that is exerted here. If this occurs, we then slightly change the needle site without exerting negative pressure. The first 1 to 2 cc of amniotic fluid that is aspirated is discarded because in theory it may contain maternal cells and thus gives us inaccurate results. An amount of approximately 20-cc amniotic fluid is considered to be enough for the results we require when amniocentesis is carried out between the 15th and 20th weeks of gestation. An ultrasound examination is performed after the amniocentesis is completed to document fetal cardiac activity and to look for evidence of bleeding into the amniotic cavity. The pregnant woman is then advised to rest and avoid intercourse for 15 days and informed about possible complications, such as persistent uterine cramping, fever, bleeding, or leakage of the amniotic fluid, which she must report timely.

AMNIOCENTESIS COMPLICATIONS

Amniocentesis is an interventional procedure, and since the fetomaternal unit is injured, a number of complications can ensue. Maternal complications are rare and include perforation of the intra-abdominal viscera with subsequent intra-abdominal infection, sepsis, bleeding, blood group sensitization, and uterine contractions (9). On the other hand, fetal complications are more of a concern and include fetal

Table 2 Fetal Loss Rate in Review by Seeds (15)

loss, needle puncture injuries, placenta abruption, preterm labor, injury due to withdrawal of amniotic fluid (e.g., amniotic bands), and rupture of the membranes. Amniocentesis may also cause intra-amniotic infections through the introduction of microorganisms into the amniotic cavity via the needle. This may eventually lead to the abortion or death of the fetus. In order to eliminate the possibility of an infectious complication, rules of aseptic procedures, which apply in all surgical procedures, must be applied here, such as the aseptic cleaning of the skin and using septic gloves and needles. However, endometrial infections are not always related to amniocentesis, but may exist before the prenatal intervention (10,11).

Fetal Loss

Fetal loss is the major risk of second-trimester genetic amniocentesis. When amniocentesis was first introduced in the clinical practice, the risk of miscarriage related to the procedure was not clear mainly because there was lack of ultrasound guidance and lack of determination of fetal viability before the procedure. Since fetal miscarriage does not occur only in association with amniocentesis, it is essential to take into consideration the background loss rate, which is associated with the gestation age, parity, and any other underlying risk factors such as pathologic conditions of the mother (e.g., uncontrolled diabetes mellitus, severe hypertension induced by lupus, etc.) and the fetus (e.g., structural anomalies, chromosomal abnormalities, etc.) as well. Gestational age at the procedure is an important determinant of the observed fetal loss rate, since the earlier the pregnancy, the greater is the pre-procedural risk of miscarriage.

The safety of amniocentesis has been evaluated by several series from single centers and a number of multicentric studies. The difficulties in evaluating the procedure-related loss rate have been shown by the controversial results of these studies.

In 1976, the National Institute of Child Health and Human Development conducted a case-control/cohort study to evaluate the safety and accuracy of second-trimester amniocentesis for prenatal diagnosis and reported that the study group that underwent amniocentesis had a 3.5% total loss rate while the controls had 3.2% (9). The authors also concluded that the loss risk was unrelated to previous miscarriage,

volume of aspirated fluid, or number of attempts. In the same year, the Canadian Collaborative Study reported a loss rate of 3.2%, but there were no controls (12). In this study, an increased risk of loss was reported in cases of failed attempts and large bore needles (>19). The third collaborative case-control study was conducted by the British Working Party on amniocentesis in 1978 (13) and the writers reported a loss rate of 1.5% related to amniocentesis. They reported a 2.4% fetal loss rate <28 weeks in the study group and 1.2% in controls. This study however was strongly criticized mainly on the selection of control individuals who were recruited in the study later in gestation and on the replacement of some of the matched controls who had aborted.

The only randomized trial for the estimation of miscarriage risk related to amniocentesis was done in Denmark in 1986 (14). This study randomized 4606 low-risk women aged 24 to 35 years to have or not to have an amniocentesis, which was carried out using a 20-gauge needle under real-time ultrasound guidance. Most procedures were performed between 16 and 18 weeks of gestation. The amniocentesis group had a loss rate, which exceeded the control group by 1% (1.7% and 0.7% respectively), a figure which has often been quoted in counseling. More than half of the procedures were performed by one operator and the rest by four less experienced operators. The placenta was avoided whenever possible but was perforated in 15% of cases and the study indicated that perforation of the placental was associated with a relative risk of 2.6 for miscarriage.

Since then, a lot of studies reported amniocentesis-related fetal loss rate between 0.2% and 0.9%.

In 2001, Seeds performed a systematic review of 29 controlled and uncontrolled studies with a total of 68,119 amniocenteses (15) and he concluded that amniocentesis with concurrent ultrasound guidance in controlled studies appears to be associated with a procedure-related rate of excess pregnancy loss of 0.6% (95% CI, 0.31, 0.90) (Table 2). The use of concurrent ultrasound guidance appears to reduce the number of punctures and the incidence of blood-stained fluid and eliminates the direct fetal needle trauma. Finally, the review did not substantiate an increased rate of pregnancy loss if placental puncture is required.

In 2006, another trial was published in order to quantify the contemporary procedure-related loss rate after midtrimester amniocentesis using a database generated from patients who were recruited to the First- and Second-Trimester Evaluation of Risk for Aneuploidy trial (16). A total of 35,003 unselected patients from the general population with viable singleton pregnancies were enrolled in this trial and 3096 of them underwent midtrimester amniocentesis. The total spontaneous fetal loss rate less than 24 weeks of gestation in the study group was 1.0% and was not statistically different from the background 0.94% rate seen in the control group ($p=0.74$, 95% CI, 0.26%, 0.49%). The researchers stated that the odds of pregnancy loss were actually *lower* in patients who underwent amniocentesis because of advanced maternal age or screen positive results compared with those who did not. They concluded that this is likely due to the fact that spontaneous pregnancy loss is so strongly associated with aneuploidy, and patients who have an amniocentesis would presumably terminate aneuploid fetuses in most cases before a spontaneous loss could occur. They stated that it is not surprising that patients in these categories who elected not to undergo amniocentesis had a higher rate of spontaneous loss because they were carrying a higher proportion of aneuploid fetuses.

Recently, Mujezinovic and Alfirevic compiled a systematic review of complications related to genetic amniocentesis and CVS to provide benchmark data for counseling and performance assessment of individual operators (17). Twenty-nine articles of amniocentesis were included and pooled pregnancy loss within 14 days was 0.6% (95% CI 0.5–0.7), rising to 0.9% (95% CI 0.6–1.3) for pregnancy loss before 24 weeks and 1.9% (95% CI 1.4–2.5) for total pregnancy loss (Table 3). However, the authors noted that since most of the reviewed studies do not take into account the background risk and therefore do not address the issue of added procedure-related risk, these figures may be useful only for counseling purposes in a broad sense. The authors identified five studies that have included control groups in order to quantify the background risk. Overall, these studies reported higher pregnancy losses compared with uncontrolled case series and the pooled results showed a relative increase of 25% for total pregnancy loss after amniocentesis and 46% for pregnancy losses before 24 or 28 weeks of gestation. However, the results for the latter were

quite heterogeneous, resulting in very wide, statistically no significant confidence intervals. The absolute risk difference between cases and controls was quite similar, showing that second-trimester pregnancy loss and total fetal loss after an amniocentesis increase by approximately 0.6%. The reviewers noted that although the risk of pregnancy loss is relatively low, lack of adequate controls tends to underestimate the true added risk of prenatal invasive procedures.

Midtrimester amniocentesis does not appear to further increase the already increased risk for second-trimester spontaneous abortion in women with uterine myomas (18).

Preterm Delivery

The association of second-trimester amniocentesis and delivery before 37 weeks was evaluated by a case-control study in 2003 by the EUROPOP Group (19). During 1994 to 1997, 3091 preterm births and 5298 controls randomly selected from singleton births born at term were analyzed. An increased risk of preterm delivery was found in women having second-trimester genetic amniocentesis after taking into account other risk factors and confounding variables (OR 1:59, 95% CI 1.31–1.92). The association was statistically significant and similar for spontaneous preterm delivery and induced preterm delivery. Since the data are limited, further research is needed on the causative role of amniocentesis.

Fetal Trauma

The risk of direct fetal needle injury often is presumed to be reduced with the use of simultaneous ultrasound guidance, but several case reports document or attribute cases of fetal injury to the amniocentesis needle, despite the use of simultaneous guidance for the procedure (15). Although several case reports document or attribute cases of fetal injury to the amniocentesis needle (20–22), the attribution has been generally by association only and not on the basis of direct evidence (21,23–31).

Alloimmunization

Feto-maternal hemorrhage occurs in approximately 50% of all women (32) and during amniocentesis on one out of six (33). The attributed risk is 1% greater than the background risk of 1.5% (34). As for preventing the Rhesus sensitization of the mother and when the husband is Rhesus positive, every

Table 3 Pregnancy Loss After Amniocentesis

Type of pregnancy loss	Combined total (n/N)	Combined proportion %	95% CI
Less than 20 weeks of pregnancy	22/2133	1.1	0.7–1.5
More than 20 weeks of pregnancy	17/1775	0.9	0.5–1.4
Less than 24 weeks of pregnancy	122/14,057	0.9	0.6–1.3
More than 24 weeks of pregnancy	57/4195	1.0	0.5–1.8
Less than 28 weeks of pregnancy	283/14,915	1.7	1.3–2.2
More than 28 weeks of pregnancy	134/14,596	0.9	0.7–1.2
Less than 14 days after AC	102/17,047	0.6	0.5–0.7
Less than 30 days after AC	85/10,727	0.8	0.4–1.2
Less than 60 days after AC	66/9406	0.7	0.5–0.9

Rhesus-negative mother must be given 300- μ g anti-D immunoglobulin after amniocentesis, provided of course the indirect Coombs is negative (35,36).

Other means to minimize the risk is the use of small-gauge needles and to avoid transplacental approach (36).

Respiratory Distress

A significant although small increased risk of neonatal respiratory distress was noted in some studies but not in others (9,37). This complication has been attributed to chronic oligohydramnios, which might follow amniocentesis.

Orthopedic Abnormalities

The British collaboration study (13) implied that amniocentesis is associated with talipes equinovarus, congenital dislocation, and subluxation of the hip. This trend was not confirmed by other studies. This complication has been attributed to chronic oligohydramnios, which might follow amniocentesis.

Transmission of Viral Diseases

Before antiretroviral therapy (ART) use, maternal HIV infection was considered a relative contraindication for amniocentesis and invasive prenatal procedures. Since maternal ART has been used, amniotic fluid viral load is usually undetectable even if the virus was detectable in maternal blood samples. This finding raises the possibility to perform amniocentesis, when it is indicated, to provide the mother with an adequate antiretroviral treatment (38).

Leakage of Amniotic Fluid and Vaginal Bleeding

Uterine contractions and vaginal spotting are quite common (2–3%) after amniocentesis; however, they are almost always transient and self-limited. Leakage of amniotic fluid occurs in 1% of women who underwent second-trimester amniocentesis. It is usually small amount and the outcome is normal in 90% of the patients who experienced fluid leakage (39).

SPECIAL CIRCUMSTANCES

Discolored Amniotic Fluid

The presence of blood in the amniotic fluid occurs in a very small number of cases. It is usually of maternal origin and under no circumstances does it affect the culture or multiplication of the cells. However, the presence of blood in the amniotic fluid is related to the increased possibility that the outcome of the pregnancy will not be good. Thus, the percentage of fetal losses in these cases reaches 33% of all losses (40–42). If at the same time the blood-stained or discolored amniotic fluid is accompanied by increased levels of alpha-fetoprotein (AFP), then in almost all instances the prenatal results will not be good.

Amniocentesis in the Presence of Bleeding

The fetal loss following amniocentesis in women who had bleeding before the procedure is probably increased. Antsaklis et al. found an excess loss rate of 0.6% in women who had experienced bleeding before amniocentesis (43).

History of bleeding is not a contraindication for the procedure but patients should be counseled about the risks.

AMNIOCENTESIS IN MULTIPLE GESTATIONS

Amniocentesis has been recognized as a relatively safe procedure for prenatal diagnosis in singletons. It has been a common practice to extrapolate data derived from singletons to multiples. However, implementation of invasive prenatal diagnostic modalities in twins or higher order pregnancies seems to be more complex. Amniocentesis can be safely performed on twins or higher multiple gestations as long as the sacs have been defined through ultrasound examination. The management and the prenatal diagnosis of a multiple pregnancy are challenging, not only related to the number of fetuses, but also strongly influenced by chorionicity. Chorionicity refers to the placentation whereas zygosity implies the genetic profile of the pregnancy and therefore determines the degree of risk and whether or not the fetuses may be concordant or discordant for chromosomal abnormalities.

The amniocentesis technique in multiple gestations is different from that used in a single gestation and therefore women should be referred to experienced centers. The number of fetuses, their positions, the number of gestation sacs and placentas, the gender, the age and the degree of development of each fetus, and finally the fetal anatomy are all-important and necessary elements of the ultrasound examination that precedes amniocentesis. An important element before amniocentesis is determining the position of each fetus, which is achieved by mapping the site of the placenta that is feeding the specific fetus, because the position of the placenta changes very little over time while the position of the fetus never remains stable. Consequently, in the case where after amniocentesis the problem of selective feticide arises due to an abnormal result, we must know which is the specific fetus in question and its reference point so that we can pinpoint it. This is nothing more than determining the position of the placenta, as determined by the mapping that was carried out before amniocentesis.

The Risk of Aneuploidy in Multiple Gestations

As far as zygosity represents the genetic makeup of the developing entity, accurate determination of this parameter is considered a prerequisite in multiple pregnancy prenatal screening for aneuploidies. In the clinical setting, zygosity is usually inferred from the ultrasound diagnosis of chorionicity (44), the latter best achieved in the first trimester. In diamniotic (DA) pregnancies with fused placentas, measurements of the thickness of the dividing membrane using a cutoff value of 2 mm can differentiate MC from dichorionic (DC) twinning, though a high inter- and intra-observer variability has been reported. Sonographic detection of the “lambda” or “twin peak” sign is reported as a more reliable indicator of DC placentation with an accuracy of 100% in 10 to 14 weeks of gestation (45). Delayed sonographic evaluation in the second trimester is associated with a 10% to 12% chorionicity misinterpretation rate (46,47), while after 20 weeks of gestation, the determination may turn out impossible. Therefore, in the absence of the “lambda” or “twin peak” sign in a DA twin pregnancy, single placentation and monozygosity is concluded, when the rare cases of MC-DZ (dizygotic) gestations following ART reported are not taken into consideration. However, when a single amniotic sac is

detected, monochorionicity is indisputable. Given that the great proportion (80–90%) of DC twins are DZ (48,49), chorionicity may roughly correspond to zygosity (50).

Monozygotic (MZ) twins are always of the same sex and genetically identical and therefore the risk for chromosomal abnormalities does not differ from that in singletons. Very infrequently, mutations can cause genetic discordance between MZ siblings, involving mosaicism, skewed X-inactivation, differential gene imprinting, and small-scale mutation (51). Heterokaryotypia is used to define the rare karyotypic discordance, most commonly expressed by one fetus affected by Turner syndrome whereas the other presents either a normal male or normal female karyotype (52–54). MZ discordance for trisomy 21, Klinefelter syndrome, Patau syndrome, trisomy 21, and 22q11 deletion syndrome has also been described (54–58).

However, these unusual discrepancies are not taken into consideration when calculating aneuploid risk, though should always be assumed when invasive prenatal diagnosis is performed dictating sampling from both sacs.

In DZ twins, each embryo has an independent risk for aneuploidy and therefore the risk that at least one fetus being affected will be almost twice the maternal age risk for a singleton. The probability of both fetuses being involved is minimal (59). In cases with uncertain chorionicity and thus zygosity, aneuploidy risk assessment requires an estimation of the most likely zygosity, which may vary according to maternal age and race. In general, given that one-third of all twin pairs are MZ, the risk for one twin being aneuploid in case of unknown zygosity is calculated to five-thirds that of the singleton risk (46,50).

Based on these estimations, a 33-year-old woman bearing twins has a risk for at least one aneuploid offspring, comparable with the risk of a 35-year-old woman bearing a singleton. On this assumption, such women should be offered prenatal testing (60). However, despite these aspects, reported series show a lower risk for fetal chromosomal abnormalities in live-born twins and this fact is probably due to the higher incidence of spontaneous loss of fetuses with aneuploidy.

Technique

Three methods of tapping multiple sacs have been described so far. The first and most common one, initially described by Elias et al. in 1980, involves two or more needle insertions, one for each sac, also called the *technique of double amniocentesis* (61–63) (Fig. 2). In a twin or higher order multiple pregnancy, two or more 22-gauge 3.5-inch spinal needles are separately and sequentially inserted transabdominally under ultrasound visualization into each sac and about 20 mL of amniotic fluid is readily aspirated and sent for cytogenetic evaluation or fetal karyotyping. A problem not infrequently faced with this technique is erroneously sampling the same amniotic sac twice. In order to eliminate this possibility, the sampled sac is marked with a blue dye ensuring that the sac is tapped only once. For this purpose, indigo carmine has been successfully used without any adverse effects (64), though a mild vasoconstrictive effect following intravenous injection has been described. However, the instillation of a foreign substance into the amniotic cavity is of concern. A technical disadvantage with the instillation of indigo carmine is that the

dye tends to concentrate at the bottom of the sac taking some time before the stained fluid surrounds the fetus. Methylene blue used as a marker dye in the past has been linked to certain toxic manifestations such as fetal hemolysis, fetal small bowel atresias, and fetal death (65–70). Nevertheless, the high-resolution ultrasound equipment currently available, in expert hands, may ensure accurate sampling from each sac (71,72), reserving the installation of dye for cases of amniotic volume discordance where detection of the septum is uncertain or high-order pregnancies where documentation and “labeling” of sacs turn out insecure (73).

An alternative approach first described by Jeanty et al. in 1990 is the *single-needle insertion technique* (74). The needle entry is made into the proximal sac near the insertion of the dividing membrane and 20 mL of amniotic fluid is retrieved. After the stylet is replaced, the needle is advanced through the second sac under direct ultrasound guidance. In order to avoid contamination, the first few milliliters of amniotic fluid are discarded and aspiration of 20 mL from the second sac integrates the procedure. Many advantages linked to this technique have been reported: requiring only one needle insertion and being swifter and shorter reduces woman’s discomfort as well as the risk of post-procedural complications. Moreover, advancing the needle through the septum between the two sacs under ultrasound guidance provides positive proof of tapping both of them, diminishing the need for dye insertion. However, potential disadvantages render this approach less popular. Possible contamination of the second sample with amniotic fluid and fetal cells from the first one may lead to an incorrect diagnosis of mosaicism in the second fetus. This complication can be avoided by strictly adhering to the technique, by replacing the stylet prior to intertwin membrane penetration and by discarding the first few milliliters from the second sac. Besides, the possibility of converting DA to pseudo-MA twin pregnancy with the correspondence risks for cord entanglement and the formation of the amniotic band syndrome cannot be precluded (75). In addition, a technical difficulty in penetrating a “tenting” dividing membrane has been reported.

Figure 2 Amniocentesis in twin gestation, which is performed on each gestation sac separately and sequentially (white arrow pointing tip of the needle in one sac and red arrow pointing septum).

Another approach called *double simultaneous amniocentesis* was introduced by Bahado-Singh et al. in 1992 (76). This technique involves two needles inserted separately into the amniotic sacs under ultrasound visualization like in the *technique of double amniocentesis*. The difference is that after aspiration of the amniotic fluid from the first sac, the needle is left in place indicating the sampled cavity and the second insertion is made into the other sac. The main advantage seems to be the documentation of correct sampling from each sac. However, it is not widely used mainly because it is more time consuming and thereby the experience with this approach is limited.

Amniocentesis, like all prenatal diagnostic invasive procedures, must be preceded by a detailed ultrasound evaluation of the multiple pregnancy involving chorionicity and amnionity determination and documentation of the location of the placenta(s). Moreover, relative position, size, and anatomy of each fetus should be specified and “labeling” of the multiples using text and diagram should be performed to ensure correct sampling from each of them. Recently, the role of amniotic fluid alpha-fetoprotein values was evaluated in confirmation of both sacs in a dichorionic pregnancy being sampled (77).

Concern regarding potential post-amniocentesis increase in fetal loss rate in multiples has led to a plethora of studies evaluating this parameter.

The percentage of total fetal loss, as expressed by spontaneous abortions, stillbirths, and neonatal deaths, is approximately 10.8%, a percentage that is almost the same as the statistical miscarriage percentage that is observed in every twin gestation after the 17th week of gestation (42,78).

Early reports suggested a higher fetal loss rate in twin pregnancies than in those with singletons (79–81). However, these studies did not take into account the possibility that the increased fetal wastage might be attributed to the twin pregnancy itself rather than the invasive procedure. Later on,

it was reported that the maternal history of twins per se carries a pregnancy loss rate up to 24 weeks of about 6.3% and severe prematurity (24–28 weeks) rate of about 8% (82). Most series of pregnancy outcome following second-trimester amniocentesis report loss rates before 20 weeks of gestation of between 1% and 2.5% and a much higher loss rate before 28 weeks. In a multicenter European study, the pregnancy loss rate was estimated to be 2.3% and 3.7% before 20 and 28 weeks of gestation respectively (83). In a case-control study, a similar fetal loss rate was reported between sampled twins and unsampled matched twin controls (3.5% vs. 3.2%) (84).

According to other studies, the percentage of fetal losses up to the 28th week of gestation in twin gestations after amniocentesis ranges from 3.57% to 3.78% versus 0.6% for single gestations. This means that the comparatively increased fetal losses observed in twin gestations versus singletons after amniocentesis are not due to amniocentesis, but rather due to the normally increased statistical percentage for abortions seen in twin gestations.

In a recent review by Weisz and Rodeck (85), the pooled data regarding the pregnancy loss rate after amniocentesis are comparable with these background loss rates for twin pregnancies (Table 4).

Finally, amniocentesis post multifetal pregnancy reduction (MFPR) does not seem to significantly increase the rate of fetal loss. However, one group has shown that amniocentesis post MFPR was significantly associated with increased risk of preterm delivery at 25 to 28 weeks (86).

Early Amniocentesis

Early amniocentesis was thought as an alternative option for early prenatal diagnosis in centers in which CVS was not offered. It was suggested to be performed between the 12th and 15th gestational weeks. The technique used for

performing early amniocentesis is similar to that used in classical amniocentesis and the amount of amniotic fluid removed is equal in milliliters to the weeks of gestation (87). Failure or difficulty in taking out the sample was due to tenting of the membrane caused by the needle (88). Since amniocentesis was performed quite early, it was thought that it could give the opportunity to examine the karyotype of the fetus and determine the AFP and acetylcholinesterase for the early detection of those cases that show increased risk for nervous system abnormalities (89–91) with the same safety as midtrimester amniocentesis. These expectations were confirmed by observational studies although definite conclusions could not be drawn because of the small numbers (92).

The safety of early amniocentesis was not completely clear until the Canadian trial. In two randomized studies (93,94), fetal loss rate was significantly higher for early amniocentesis when compared with transabdominal CVS (TA-CVS). In another randomized trial (95), which compared the first-trimester and midtrimester amniocentesis, fetal losses were more frequently observed after first-trimester than after midtrimester amniocentesis. Additionally, early amniocentesis had a significantly higher rate of amniotic fluid leakage than TA-CVS and midtrimester amniocentesis.

Excessive risk for talipes equinovarus has been uniformly observed in all early amniocentesis studies, with an even greater likelihood when physician confirms amniotic fluid leakage (17.7% vs. 0.5%) (93). Talipes can occur without apparent leakage of amniotic fluid, which likely results from a reduced amniotic fluid volume via transfer of amniotic fluid to the extra-embryonic coelomic space. TA-CVS did not have any effect on malformation rate. The Canadian study therefore indicated that early amniocentesis should be performed only if there is no alternative.

In 2005, Alfirevic et al. conducted a systematic review (96) for the Cochrane collaboration, and the pooled total pregnancy loss after early amniocentesis was 7.6% compared with 5.9% after midtrimester amniocentesis. Similarly, the number of talipes equinovarus was higher in cases of early amniocentesis (1.3% vs. 0.09%). In the same review, combined total loss of pregnancy after early amniocentesis was 6.3% compared with 5% after CVS.

It is therefore justified to say that early amniocentesis should be performed only in extenuating circumstances, especially since TA-CVS has undoubtedly been proved a safe and more effective alternative (97).

64 Fetal echocardiography

Caroline K. Lee, Erik C. Michelfelder, and Gautam K. Singh

INTRODUCTION

Two-dimensional (2D) ultrasound imaging of the fetal heart has been steadily evolving since its original descriptions in the early 1980s (1,2). Using current ultrasound platforms, it is now possible to image the fetal heart with a high degree of spatial and temporal resolution, which allows clinicians to make precise anatomic and functional diagnoses in the fetus with acquired or congenital heart disease (CHD). Use of color flow and pulsed-wave Doppler techniques in fetal cardiac imaging has further augmented the diagnostic capabilities of fetal echocardiography, to the point where diagnostic accuracy in many regards rivals that of trans-thoracic echocardiography. Understanding the capabilities and limitations of fetal cardiac assessment is particularly important in the current era, where the possibility of fetal therapy is now possible. It is also important in the current era to understand the broadening indications for fetal echocardiography, particularly as it pertains to fetal therapy.

It is the purpose of this chapter to review the current status of fetal echocardiography with regard to (i) indications for and timing of fetal cardiac evaluation, (ii) standard imaging views and anatomic assessment, (iii) methods of assessing fetal cardiac function and rhythm, (iv) counseling the patient with fetal heart disease, and (v) highlight some of the newer advances and innovation in fetal echocardiography and fetal cardiology.

INDICATIONS FOR FETAL ECHOCARDIOGRAPHY

Cardiac defects in fetuses are one of the most frequently missed findings on prenatal ultrasound evaluation with significant complex consequences. This is partly related to the experience of the scanning examiner, capability of the scanning equipment used, natural history of evolution of CHD, and the number and timing of the scan. Therefore, specific indications for a detailed fetal echocardiographic evaluation at centers with appropriate expertise and facilities to screen for cardiac anomalies in fetuses at high risk have evolved. Although most of the infants are born to mothers who have no known risk factors, the yields of detection of CHD in fetuses in high-risk groups have been significantly higher than those in low-risk groups (3). A detailed fetal echocardiographic evaluation has been indicated in high-risk conditions (Table 1). The yield for the detection of CHD is variable with different indications. The family history as indication has 2% to 10% yield for detecting fetal heart defects, depending upon the number of previous siblings affected, type of CHD in the index sibling, associated syndrome, extracardiac malformations with CHD in the siblings, or parental heart defects (4,5). In contrast to this low-yielding indication, an abnormal obstetric sonogram suspecting anomalies of cardiac position or structures on screening examination has the

highest yield of 50% to 60% as an indicator (6). Fetal arrhythmias and extracardiac anomalies of gastrointestinal system and genitourinary system have intermediate yield of 25% to 30% as indicators (7,8). Nuchal translucency thickness of more than 5.5 mm (above 95th percentile) has a prevalence of major CHD ~20% (9). Table 1 does not include the indications for fetal echocardiography in low-risk groups. Fetal echocardiographic screening in low-risk groups has been undertaken in some centers and countries with conflicting results. With advancement in screening program in all groups, early detection of CHDs in fetuses may prove beneficial in terms of outcomes of fetal cardiac intervention in the future.

Early fetal echocardiography with the use of high-resolution transvaginal ultrasound between 13 and 16 weeks of gestation has provided the capability to demonstrate all cardiac structures and the majority of major CHDs. However, the reported sensitivity for detection of CHDs by early fetal echocardiography is up to ~65% (10). Limitation to the detection of some CHDs such as ventricular septal defect (VSD), double-outlet right ventricle (RV), as well as late-onset appearance of cardiac anomalies such as hypoplasia of one cardiac chamber/great artery in the presence of outflow tract obstruction and cardiac tumors suggest that early screening by transvaginal echocardiography should be followed by mid-gestational transabdominal echocardiography, which may yield an additional ~20% detection of CHDs (10).

STANDARD IMAGING VIEWS AND ANATOMIC ASSESSMENT OF THE FETAL HEART

Fetal echocardiography is commonly performed between 18 and 22 weeks of gestational age (11). In later gestation, imaging may be more difficult due to increasing calcification of fetal ribs and a relative decrease in amniotic fluid volume. High-resolution ultrasound equipment with transducer frequencies from 5 to 7MHz should be used, with capabilities to perform M-mode, color Doppler, and spectral Doppler interrogation.

A comprehensive fetal echocardiogram includes 2D imaging of the cardiac anatomy, spectral and color Doppler assessment of blood flows, and evaluation of cardiac function and rhythm. Multiple tomographic planes used to image the fetal cardiovascular system have been described (11,12) (Figs. 1,2).

Fetal Position and Abdominal Situs

The first step in the evaluation of the fetal heart is to establish fetal position within the maternal abdomen (vertex, breech, transverse, supine, prone) and to establish fetal left and right sides. From a transverse section of the fetal abdomen, visceral situs is assessed by demonstrating the relative position of the stomach, hepatic vessels, abdominal aorta, and inferior vena cava (IVC). Normal abdominal situs (situs solitus) is characterized by the stomach bubble on the fetal left side,

Table 1 Indications for Fetal Echocardiography in Subpopulation at High Risk for Congenital Heart Disease (CHD)

Increased risk based on family history	
Positive family history of CHD in previous child/children and parents	
Positive family history of syndromes or malformations associated with CHD	
CHARGE, DiGeorge, Holt–Oram, Marfan, Noonan, Williams–Beuren	
Increased risk due to maternal conditions	
Maternal diseases	
Diabetes mellitus	
Phenylketonuria	
Collagen vascular disease	
Exposure to teratogens in pregnancy	
Teratogenic drugs: alcohol, amphetamine, anticonvulsants, lithium, retinoic acid, warfarin	
Intrauterine infections	
Rubella, myocarditis from cytomegalovirus, coxsackievirus, and parvovirus	
High doses of ionizing radiation	
Increased risk due to fetal conditions	
Documented fetal anomaly	
Abnormal obstetric sonogram	
Suspected cardiac anomaly, abnormal cardiac position	
Extracardiac malformations frequently associated with cardiac anomaly	
Ectopia cordis, microcephaly, VACTERL, omphalocele, horseshoe kidney, single umbilical artery	
Arrhythmia	
Bradyarrhythmia	
Tachyarrhythmia	
Complete heart block	
Nonimmune hydrops fetalis	
Nuchal edema or hygromata, increased thickness of nuchal translucency	
Amniotic fluid abnormality	
In utero diagnosed chromosome anomaly	
Twin gestation	
Monozygous twin	
Conjoint twin	

Abbreviation: VACTERL, vertebral abnormalities, anal atresia, cardiac abnormalities, tracheoesophageal fistula and/or esophageal atresia, renal agenesis and dysplasia, and limb defects.

liver with hepatic vessels on the right side, abdominal aorta to the left of the fetal spine, and IVC to the right of the fetal spine and slightly anterior to the aorta (Fig. 3). In situs inversus, there is a mirror-image arrangement of these organs and vessels. Situs ambiguous denotes when neither situs solitus nor inversus is present; this is also referred to as heterotaxy and is commonly associated with complex congenital heart defects and splenic abnormalities (asplenia or polysplenia).

Four-Chamber View

Moving the transducer cephalad from the abdominal transverse view to a transverse view of the fetal chest should demonstrate the heart in the left hemithorax with the apex pointing to the left (levocardia). Also with this sweep, entrance of the IVC into the right atrium (RA) is demonstrated. Dextroposition of the heart is present when the fetal heart is found in the right hemithorax, such as when the heart is

externally shifted to the right by a left-sided diaphragmatic hernia or cystic adenomatous malformation, or when hypoplasia of the right lung is present; however, the cardiac apex still points to the left. The term “dextrocardia” denotes the apex of the heart is pointed to the right. Dextrocardia in the presence of normal situs solitus is associated with CHD in 95% of cases (13). By contrast, in situs inversus totalis, where both stomach and heart are on the right side, heart defects are rare.

A transverse section of the fetal chest provides a four-chamber view of the heart, and this is usually easily obtained (Fig. 4). The heart should fill about one-third of the thoracic area or about half the thoracic circumference (14,15). Cardiac axis refers to the angle between a line along the interventricular septum and the thoracic anteroposterior midline and is normally around $45^\circ \pm 20^\circ$ (16–18). Significant levorotation of the cardiac axis is often the first clue to the presence of a congenital heart defect (17,18).

In the normal four-chamber view, the RA and left atrium (LA) are approximately equal in size, and the RV and left ventricle (LV) are also approximately equal in size and thickness, with the RV becoming slightly larger than the LV as gestation progresses (14). The LA is the most posterior cardiac chamber and lies anterior to the descending aorta. The flap of the foramen ovale (septum primum) moves from the RA into LA, billowing about half-way into the LA, consistent with the right-to-left direction of foramen ovale flow in fetal circulation. The RV is the most anterior cardiac chamber and sits just posterior to the sternum. The LV cavity comprises the cardiac apex. The RV can be identified by the moderator band that courses across the lower part of the RV, from the interventricular septum to the RV free wall. The RV is also identified by the tricuspid valve that inserts into it. The atrioventricular valves are slightly offset from each other, with the tricuspid valve attaching slightly more apically than the mitral valve. From the four-chamber view, a posterior sweep will show the coronary sinus, which should be a thin structure that courses within the LA (Fig. 5). A dilated coronary sinus is seen when a persistent left superior vena cava (SVC) or anomalous pulmonary veins are present.

Addition of color Doppler in the four-chamber view will demonstrate inflow from atria to ventricles. A small amount of tricuspid regurgitation may be seen in the normal fetus (19). Pulmonary venous flow is seen entering the LA; at least one pulmonary vein from both the left and the right should be demonstrated. Evaluation of atrial and ventricular septa by color Doppler to assess for septal defects is best undertaken in planes perpendicular to the septa. Foramen ovale flow is seen from RA to LA, and VSDs in the muscular and inlet parts of the ventricular septum may be seen in this view. Small muscular VSDs may be seen throughout gestation, and many spontaneously close prior to delivery.

In addition to VSDs, other heart defects may be identified in the four-chamber view (20). Ebstein’s anomaly of the tricuspid valve is characterized by apical displacement of the septal leaflet of the tricuspid valve with associated tricuspid regurgitation and atrialization of the RV. Atrioventricular canal (endocardial cushion) defects result in a spectrum of defects ranging from a primum atrial septal defect (ASD) with cleft mitral valve, to a complete atrioventricular canal defect

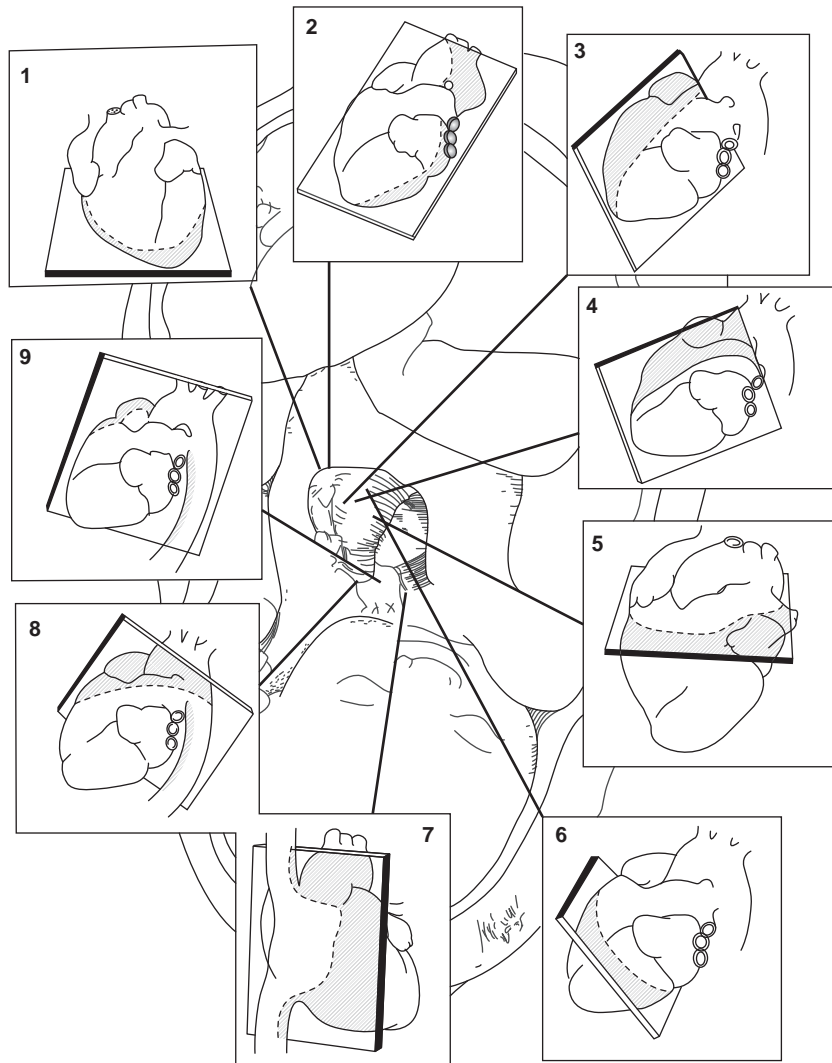

Figure 1 Illustration of the tomographic planes used to image the fetal cardiovascular system. 1, apical (four-chamber) view; 2, apical (four-chamber) view angled toward the aorta; 3, long-axis view of the left ventricular outflow tract; 4, long-axis view of the right ventricular outflow tract; 5, short-axis view at the level of the great vessels; 6, short-axis view with caudad angling at level of ventricles; 7, caval long-axis view; 8, ductal arch view; 9, aortic arch view. *Source:* From American Society of Echocardiography.

with a single common atrioventricular (AV) valve, primum ASD, and inlet VSD. A primum ASD is seen when the inferior aspect of the atrial septum is deficient. An inlet VSD is seen when the ventricular septum adjacent to the AV valves is deficient. An atrioventricular canal defect should be suspected when the AV valves appear at the same level in the four-chamber view, without the usual offset of tricuspid and mitral valves.

Ventricular hypoplasia or dilation is easily appreciated in the four-chamber view. A hypoplastic RV is seen in tricuspid atresia and in pulmonary atresia with intact ventricular septum. A small LV is seen in hypoplastic left heart syndrome; this is characterized by severe stenosis or atresia of the mitral and aortic valves and severe hypoplasia of the aortic arch. Other complex, functionally single ventricle lesions include double-inlet LV and unbalanced atrioventricular canal defects with hypoplasia of either ventricle. The latter are commonly associated with heterotaxy syndromes (situs ambiguous with asplenia or polysplenia) (13).

Ventricular dilation may signify the presence of regurgitation of the respective AV valve or obstruction of the respective

proximal outflow tract, and the addition of color and spectral Doppler should be used to assess these areas. RV dilation with RA dilation and tricuspid regurgitation is seen when there is obstruction to the ductal arch (e.g., premature ductal closure) or aortic arch (e.g., coarctation of the aorta).

Importantly, the four-chamber view is inadequate for excluding transposition of the great arteries and conotruncal defects such as tetralogy of Fallot and truncus arteriosus.

Long-Axis View

While the four-chamber view is the only view of the heart required for standard second- and third-trimester fetal examinations, the addition of outflow tracts has been shown to yield higher detection of congenital heart anomalies than the four-chamber view alone (21–23). From the four-chamber view, sweeping cephalad will demonstrate the ventricular outflow tracts and the relationship of the great arteries. The aorta arises from the posterior LV and aims toward the fetal right shoulder (Fig. 6). The pulmonary artery (PA) arises from the anterior RV and courses leftward and posteriorly, crossing the aorta, extending to the ductus arteriosus, which then meets the

Figure 2 Illustrations of the anatomical correlates for each of the designated tomographic imaging planes used for imaging the fetal cardiovascular system. Each numbered view relates to the clockwise illustration of the fetal heart in Figure 1. *Abbreviations:* Ao, Aorta; IVC, inferior vena cava; LA, left atrium; LV, left ventricle; MV, mitral valve; PA, pulmonary artery; PD, patent ductus; RA, right atrium; RV, right ventricle; SVC, superior vena cava. *Source:* From American Society of Echocardiography.

descending aorta. Continuity between the mitral and aortic valves is demonstrated in this view, and the anterosuperior aspect of the ventricular septum can be interrogated to rule out a VSD. Discontinuity of the mitral and aortic valves is characteristic of double-outlet RV lesions.

An aorta that overrides a large malalignment VSD is seen in tetralogy of Fallot, where there is associated pulmonary

outflow tract obstruction, and in truncus arteriosus, where there is a single semilunar (truncal) valve and the branch pulmonary arteries usually arise from the ascending aorta.

The subaortic area is also visualized in the long-axis view. Posterior malalignment of the ventricular septum produces a VSD and crowding of the left ventricular outflow tract producing varying degrees of subaortic obstruction. In these

instances, obstruction or interruption of the aortic arch may also be present.

If the anterior vessel is the aorta, then transposition or malposition of the great arteries is present. D-Transposition of the great arteries is recognized by the anterior RV giving rise to the aorta and the PA arising from the LV. The outflow tracts do not cross normally and instead travel in a parallel fashion. VSDs may also be seen with transposition of the great arteries.

In the normal fetal heart, the pulmonary valve and PA are slightly larger than the aortic valve and proximal aorta, and normal reference values based on gestational age have been reported (24). If the PA is hypoplastic, pulmonary stenosis or tetralogy of Fallot should be suspected, and the valve morphology and Doppler gradient be carefully evaluated. The aorta is often dilated in tetralogy of Fallot and truncus arteriosus. If the aorta is small, aortic stenosis and/or other left heart obstructive lesions such as coarctation of the aorta or interrupted aortic arch may be present.

Three-Vessel View

Sweeping further cephalad in a transverse plane will produce the three-vessel view. This is a cross-sectional view at the level of the superior mediastinum, displaying the normal relationship and size differences of the PA, aorta, and SVC (Fig. 7). The PA is seen in long axis in this view and is the larger, most anterior, and leftward vessel; the aorta is slightly smaller, to the right, and posterior to the PA; and the SVC is the smallest, most posterior, and rightward vessel. Discrepancies in the size of the PA and aorta may signify subtle pathology of the outflow tracts or arches, and a dilated SVC may be seen when an interrupted IVC with azygous continuation or vein of Galen aneurysm is present (25).

Short-Axis View

The short-axis view is obtained by rotating perpendicular to the long-axis view. This view is important in confirming the normal relationship of the great arteries. The aorta is seen in

Figure 7 Three-vessel view. Abbreviations: PA, pulmonary artery; Ao, aorta; SVC, superior vena cava; Sp, spine.

Figure 8 Short-axis view. Abbreviations: LA, left atrium; AS, atrial septum; IVC, inferior vena cava; RA, right atrium; TV, tricuspid valve; RV, right ventricle; PV, pulmonary valve. The aortic valve is seen in cross section in the middle of the short-axis view.

cross section as a circular structure, with the PA wrapping around the aorta as it arises from the anterior ventricle (Fig. 8). The main PA can be seen bifurcating into the ductus arteriosus and right PA and slight angulation to fetal left will show the left PA.

Slight inferior angulation from the short-axis view of the great arteries shows the ventricles in short axis. Quantitative assessment of RV and LV function can be made from this view, and M-mode interrogation through the ventricles allows measurement of RV and LV systolic and diastolic dimensions (26). These dimensions can be used to quantitatively assess ventricular function by calculating a shortening fraction (end-diastolic dimension – end-systolic dimension/end-diastolic dimension). Normal shortening fraction for the RV and LV is $34 \pm 3\%$ (27).

Figure 9 Ductal arch view. The ductus arteriosus arises from the anterior right ventricle and connects to the descending aorta, making a "hockey-stick" configuration.

Figure 10 Aortic arch view. The aorta arises from the central thorax and normally gives rise to three brachiocephalic vessels. The aortic arch makes a "candy cane" configuration.

Ductal View

The ductal view is obtained in the fetal sagittal plane. The ductal arch has a flatter contour ("hockey-stick" shape) than the aortic arch as it arises anteriorly from the PA and connects to the descending aorta (Fig. 9). It lies more caudally than the aortic arch. Color Doppler interrogation demonstrates the normal right-to-left ductal flow (PA to descending aorta). Direction of ductal flow is reversed (aorta to PA) when there is obstruction to pulmonary blood flow, as in pulmonary atresia or severe pulmonary stenosis.

Aortic Arch View

The aortic arch is also best viewed in a sagittal plane and is obtained from the ductal view by slight angulation of the transducer. The aortic arch arises centrally from the heart in the mid-thorax and aims toward the fetal head. It has a "candy cane" contour and is identified by the three brachiocephalic vessels that arise from it (Fig. 10). Color Doppler interrogation confirms antegrade flow through the ascending aorta and

Figure 11 Bicaaval view. Abbreviations: IVC, inferior vena cava; SVC, superior vena cava; RA, right atrium; RV, right ventricle.

aortic arch. Both spectral and color Doppler are used to assess for obstruction; however, even in the setting of a normal-appearing arch, coarctation of the aorta cannot be ruled out owing to the presence of a large ductus arteriosus. Retrograde aortic arch flow from the ductus arteriosus is seen in critical left heart obstructive lesions such as hypoplastic left heart syndrome and critical aortic stenosis.

Caval Long-Axis View

This view is obtained from the aortic arch view by sliding from the left parasagittal chest to the right. Bicaaval return to the RA can be seen (Fig. 11). The septum primum is seen extending into the LA and use of color Doppler demonstrates the normal right-to-left flow across the foramen ovale. Reversal of foramen ovale flow, from LA to RA, is seen in critical left heart hypoplasia/obstructive lesions. The ductus venosus, a fetal shunt connecting the umbilical vein (UV) with the IVC, can be seen entering the left hepatic vein-IVC junction just below the diaphragm and RA.

It is important to note that even with a comprehensive fetal echocardiogram, there are congenital heart defects that cannot be ruled out. As flow normally occurs across the atrial septum via the foramen ovale, the presence of an ASD cannot be excluded, particularly of the secundum type. Coarctation of the aorta may be difficult to exclude in the presence of a large ductus arteriosus; secondary findings of RV dilation and tricuspid regurgitation may be seen with a significant coarctation and are clues to its presence.

FETAL CARDIAC FUNCTIONAL ASSESSMENT

The 2D and Doppler echocardiography have become not only an integral component in the assessment of anatomic anomalies of the fetal heart, but also an important tool in the assessment of fetal hemodynamic status. Various techniques for assessing fetal cardiovascular function exist and can be utilized to assess fetuses with cardiovascular compromise due to a variety of cardiac and noncardiac causes (Table 2). As many of the conditions associated with fetal cardiac

Table 2 Examples of Conditions Associated with Fetal Cardiac Compromise

Condition	
Cardiac disease	Severe valve regurgitations Tetralogy of Fallot with absent pulmonary valve AV septal defect with AV valve regurgitation Ebstein anomaly of the tricuspid valve Elevated ventricular afterload Bilateral semilunar valve stenosis Constriction of the ductus arteriosus Fetal arrhythmia Fetal tachyarrhythmia Complete AV block Restrictive foramen ovale
Noncardiac disease	Volume overload/high cardiac output lesions Fetal anemia Arteriovenous fistulae Sacrococcygeal or cervical teratoma TRAP sequence Placental chorioangioma High cardiac afterload Recipient twin in TTTS Placental insufficiency Congenital cystic adenomatoid malformation
Abbreviations: AV, atrioventricular; TRAP, twin reversed arterial perfusion; TTTS, twin-twin transfusion syndrome.	

compromise now have fetal therapeutic options, understanding and identifying fetal cardiac dysfunction in the current era assume even greater importance, because accurate description of cardiac natural history should become an important component in determining patient selection and timing of intervention.

This section reviews common 2D and Doppler methods of assessing fetal cardiovascular status, describes the changes in these indices that are characteristic of fetal cardiac compromise, and offers a clinical approach to the comprehensive assessment of fetal cardiovascular function. The components of the complete fetal cardiac assessment are outlined in Table 3.

Assessment of Systolic Ventricular Function in the Fetus

The fetal myocardium differs maturationally from the “adult” state, and these features must be considered when evaluating cardiac function in the setting of altered loading conditions (28,29). The fetal myocardium responds to preload with higher resting and reduced active tension generation, due in part to higher concentrations of noncontractile proteins in the fetal versus the mature heart. The fetal response to afterload is also different, with a significant reduction in fiber shortening in the setting of increased afterload (29). These differences must be kept in mind when evaluating ventricular systolic function in settings where pathologic loading conditions likely exist.

2D Assessment of Fetal Systolic Function

In the past, assessment of fetal ventricular systolic function has often consisted of qualitative assessments. Current practice is generally more quantitative. On initial 2D imaging of the fetus, it is important to note the presence of hydrops fetalis and/or

its component findings. Overall, cardiac size is often a sign of altered hemodynamics in the fetus; in addition to qualitative assessment, the cardiothoracic ratio can be used to quantitatively express the degree of cardiac enlargement. In our lab, we utilize the ratio of the cardiac area (in the four-chamber view) to the thoracic area in the same view (Fig. 12), with normal values generally being <0.35 (30). It is also useful to examine why the heart is large, which may be due to ventricular enlargement, atrial dilation, ventricular hypertrophy, or a combination of these findings, as this may provide further clues as to the etiology of the cardiac abnormality. On 2D and/or M-mode imaging of the RV and LV, quantitative assessment of both RV and LV shortening fraction is also possible (27,31–33) (Fig. 12). In addition to subjective assessment of ventricular wall thickness, quantitation of RV and LV wall thickness is possible, and there are published normal values against which measurements can be compared (34).

Doppler Assessment of Fetal Cardiac Function: General Comments

The 2D and M-mode imaging can be limited on fetal echocardiography due to marginal acoustic windows or fetal

position, sometimes limiting the utility of these methods. There are now a number of Doppler indices—sometimes more readily obtained in the setting of marginal 2D imaging windows—on fetal echocardiography that describe systolic and diastolic cardiac functions. Classically, Doppler characterization of systemic venous flow—in the IVC, ductus venosus, UV, and artery—has been utilized to identify changes associated with elevations of central venous pressure and changes in vascular flow distribution. More recently, the Doppler myocardial performance index has emerged as a promising new index for assessment of global—systolic and diastolic—ventricular function.

Doppler Assessment of Fetal Systolic Function Myocardial Performance Index

The myocardial performance index (MPI) was originally described by Tei and colleagues in 1995 (35). The MPI is in actuality an index of *global* ventricular function, as calculation of the index incorporates both diastolic and systolic time intervals into assessment of ventricular function. The MPI is calculated as

$$(IRT + ICT)/ET,$$

Table 3 Elements of Comprehensive Cardiovascular Functional Exam in the Fetus

	Echocardiographic Assessment
General	Presence of hydrops fetalis Cardiothoracic area ratio
Systolic function	Color flow Doppler evaluation of AV valve regurgitation The 2D or M-mode assessment of RV and LV shortening fraction Myocardial performance index (global function) Ventricular dP/dt (when AV valve regurgitation present)
Diastolic function	Tricuspid and mitral AV valve inflow profile (E and A velocity, E/A wave ratio, presence of monophasic inflow profile) Myocardial performance index (global function) IVC or hepatic venous flow (ratio of reverse flow VTI and forward flow VTI) Ductus venosus flow (presence or absence of absent or reverse end-diastolic flow, increased pulsatility index) Umbilical venous flow (presence or absence of pulsations)

Abbreviations: AV, atrioventricular; IVC, inferior vena cava; LV, left ventricular; RV, right ventricular; VTI, Doppler velocity–time integral.

Figure 12 Left panel: Assessment of cardiothoracic ratio (CTR). The cardiac area in the four-chamber view is divided by the thoracic area. In this example, the CTR is mildly elevated at 0.37 (normal, ≤ 0.35). Right panel: Quantitation of ventricular shortening fraction (SF). In this example, M-mode through the right ventricular (RV) short axis allows measurement of the RV end-diastolic dimension (solid arrow) and end-systolic dimension (dashed arrow). The RV SF is calculated as (RV end-diastolic dimension – RV end-systolic dimension)/(RV end-diastolic dimension).

where IRT is the isovolumic relaxation time, ICT is the isovolumic contraction time, and ET is the ventricular ejection time. The sum of IRT and ICT can be derived from subtracting the ET from the time period “A” between cessation of atrioventricular valve inflow and onset of atrioventricular valve inflow in the next cardiac cycle (Fig. 13). With systolic dysfunction, ICT lengthens and ET shortens; diastolic dysfunction will manifest as prolonged IRT. Therefore, an elevation in the MPI indicates ventricular dysfunction, although the index does not allow specific identification of diastolic or systolic dysfunction. Normal values for both RV and LV MPI have been reported. In our laboratory, normal RV and LV MPI are 0.32 ± 0.08 and 0.33 ± 0.05 , respectively. Both Eidem and Mori et al. reported comparable normal values for RV MPI to be approximately 0.35 ± 0.06 (36,37), although higher LV MPI in normal fetuses (0.55 ± 0.13) has been reported (38). The MPI in the fetus has shown to be significantly elevated in a number of disease states, including twin–twin transfusion syndrome (39,40), fetuses of diabetic mothers (41), constriction of the ductus arteriosus (37), and cardiomyopathy (42).

Color Flow Doppler Assessment

In addition to the quantitative techniques described above, it is important to evaluate atrioventricular valve function—specifically, for evidence of valve regurgitation—by color flow Doppler imaging. Tricuspid and mitral regurgitation—with normal valve anatomy—often develops in the setting of fetal cardiac compromise (27,39,43–46) and should be evaluated during echocardiography in any fetus with suspected cardiac dysfunction.

Assessment of Diastolic Ventricular Function in the Fetus

Diastolic ventricular function is also “immature” in the fetal heart (28,47,48). Fetal ventricular relaxation is reduced in the fetus, although there are progressive changes in ventricular inflow Doppler patterns that demonstrate improving ventricular relaxation throughout gestation (47,49).

Ventricular compliance characteristics demonstrate increased “stiffness” of the fetal heart (50). In fact, it is likely that diastolic dysfunction precedes overt ventricular systolic dysfunction or hydrops in a number of settings, making an understanding of the Doppler manifestations of fetal diastolic dysfunction important. For example, it has been reported that Doppler evidence of diastolic dysfunction will often be present prior to onset of ventricular systolic dysfunction in recipient twins in the setting of twin–twin transfusion syndrome (39,40), as well as in fetuses with growth restriction (31).

Doppler assessment of diastolic function in the fetus consists of two primary components: (i) assessment of Doppler flow patterns in the fetal venous system and (ii) assessment of Doppler flow patterns across the atrioventricular valves.

Assessment of Doppler Flow Patterns in the Fetal Venous System

There is a large body of literature describing changes in fetal venous Doppler flow patterns in a variety of disease states. In all of these conditions, changes in Doppler venous flow patterns are felt to be a reflection of elevated central venous pressure related to increased ventricular filling pressures. The magnitude of these changes has been correlated to severity of compromise in several studies (51–55).

The central finding in the compromised fetus is an increase in the magnitude of the blood flow away from the heart during atrial systole. This is manifested as changes in the Doppler flow profile in several important vessels:

1. IVC/hepatic veins
2. Ductus venosus
3. UV

It should be noted that as fetal cardiac compromise leads to elevation of central venous and ventricular filling pressure, venous flow reversals during atrial systole will manifest first proximally, in the IVC and hepatic veins. As compromise worsens, findings will then move distally—or “upstream”—into the ductus venosus and UV (43).

Figure 13 Simultaneous pulsed-wave Doppler of left ventricular inflow (below baseline) and outflow (above baseline). The mitral valve inflow is characterized by an early diastolic E-wave and a late diastolic A-wave (see text). The myocardial performance index is calculated as: $(A - ET)/ET$ (see text).

IVC and Hepatic Veins

In the IVC and hepatic veins, normal venous flow consists of a phasic low-velocity pattern consisting of an S wave during ventricular systole, a D wave during passive diastolic filling, and a small reversal in flow—the A wave—during atrial systole (Fig. 14). Normal values for IVC and hepatic venous S, D, and A waves throughout gestation have been reported (56); interestingly, the magnitude of the atrial systolic flow reversal diminishes in the course of normal development, suggesting improvements in ventricular compliance (57,58). Another method of evaluating the magnitude of the atrial systolic flow reversal is as a ratio of reverse flow to forward flow. The time-velocity integral of both reverse and forward flow are measured and expressed as a percentage; it has been reported that ratios in excess of 7% are abnormal (43) (Fig. 14).

Ductus Venosus

Doppler assessment of the ductus venosus (DV) is important to incorporate into the comprehensive fetal echocardiogram, particularly if cardiac dysfunction is suspected, as changes in the DV and UV are reflective of the central venous and/or right atrial pressures. In some cases, this is not always a poor prognostic sign, as in the case of right heart obstructive lesions (59), such as tricuspid atresia or pulmonary atresia with intact ventricular septum, where the entire systemic and umbilical venous return is forced to cross the foramen ovale. In this setting, abnormalities of venous Doppler flow may be noted in a setting where fetal cardiovascular compromise is quite rare.

UV

The presence of umbilical venous pulsations is a finding associated with severe cardiovascular compromise and has

been correlated to poor prognosis in the setting of non-immune hydrops due to cardiomyopathy (44), twin-twin transfusion syndrome, arrhythmia, and structural heart disease (55,60). It has been suggested, however, that, although specific, UV pulsations are not sensitive enough to be clinically useful in identifying fetal cardiovascular compromise at a time when poor outcome could be avoided (61). Further work should probably be focused on which venous Doppler changes—in IVC, DV, or UV—have the greatest clinical utility in early identification of the fetus in distress, so that management may be initiated before the fetus presents in a pre-morbid state.

Doppler Assessment of AV Valve Inflow Doppler Flow Profile

Pulsed-wave Doppler assessment of both trans-mitral and trans-tricuspid flow patterns should be performed during fetal cardiac functional evaluation. The Doppler E-wave velocity reflects early diastolic ventricular filling, where the A wave reflects ventricular filling that occurs during atrial contraction (Fig. 13). In the fetus, the AV valve Doppler E-wave velocity is lower than the A-wave velocity. The ratio of E wave to A-wave velocity increases progressively during gestation (49,62), reflecting more rapid myocardial relaxation in diastole. In pathologic circumstances, a number of changes in AV valve inflow Doppler profiles have been described. In twin-twin transfusion syndrome and fetal cardiomyopathy, the AV inflow E- and A-wave velocity ratio increases (39). However, in other settings, the E- and A-wave ratio has been noted to decrease, such as in the setting of intrauterine growth restriction (31,63) or fetuses of diabetic mothers (64). In the most severe cases of

Figure 14 Hepatic venous Doppler evaluation. Normal hepatic venous flow (panel A) is characterized by a systolic S-wave, early diastolic D-wave, and an A-wave of reversed flow during atrial contraction (open arrows). The calculation of the forward and reverse (A-wave) velocity-time integral (VTI) is shown in red. With increasing central venous pressure, the magnitude of the hepatic venous A-wave will increase (solid white arrows, panel B).

ventricular dysfunction, the AV inflow profile becomes monophasic (Fig. 15), which is a finding consistent with severe diastolic dysfunction.

Doppler Assessment of “Critical” Outflow Tract Obstructive Lesions

Another “functional” aspect of fetal echocardiographic assessment is identification of critical outflow tract obstruction, for example, in the setting of severe pulmonary stenosis (RV outflow tract obstruction) or severe aortic valve stenosis (LV outflow tract obstruction). In these settings, identification of “reversed” physiologic shunting in the fetus can allow clinicians to make the diagnosis of critical outflow tract obstruction and make the appropriate perinatal management decisions for each case.

In the setting of RV outflow tract—or more specifically, pulmonary outflow tract—obstruction, identification of reversed flow in the ductus arteriosus (from aorta to PA) heralds a fetus who will require maintenance of ductal patency to avoid critical hypoxemia related to pulmonary outflow tract obstruction after birth (65). In the setting of a left heart obstructive lesion such as aortic stenosis, left to right flow across the foramen ovale and reversal of flow in the aortic arch can be identified and used to confirm the diagnosis of critical left heart obstruction (65). In this setting, maintenance of ductal patency postnatally will prevent compromise of systemic perfusion and impending shock.

In all of these settings, the physiologic data obtained on fetal echocardiography can be used to determine severity of the anatomic lesion and make appropriate management decisions, for example, delivery at a level III perinatal center, institution of prostaglandin infusion to maintain ductal patency, and transfer to a pediatric cardiac center, in advance of birth.

FETAL ARRHYTHMIAS

The fetal arrhythmias encountered in fetal cardiology practice can be broadly categorized into tachyarrhythmias, bradyarrhythmias, and irregular cardiac rhythms with a normal heart rate.

Fetal Tachyarrhythmias

Fetal arrhythmia causing tachycardia is an important cause of fetal morbidity and mortality (66–69). Fetal tachycardia is defined as a fetal heart rate ≥ 200 beats per minute (bpm) (69). Both sustained tachycardia (present ≥ 12 consecutive hours) (70) as well as intermittent tachycardias are risk factors for fetal congestive heart failure (67,71).

The majority of fetal tachycardias are due to supraventricular tachycardia (SVT). Characteristically, it shows 1:1 atrioventricular contraction sequence, abrupt onset and termination, and minimal (within 10bpm range) or no heart rate variability. The fetal heart rate can range from 220 to 300 bpm. Atrial flutter due to intra-atrial reentrant mechanism

Figure 15 Pulsed-wave Doppler evaluation of mitral valve inflow. The Doppler sample volume is below (downstream) the mitral valve. In this fetus with severe biventricular dysfunction, the mitral valve inflow pattern is consistent with a narrow, monophasic Doppler flow profile (white arrows). Note the absence of a normal E-wave/A-wave complex (see also Fig. 12).

is common next to atrioventricular reentrant SVT (68). In atrial flutter, the atrial rate is in excess of ventricular rate. It ranges from 300 to 500 bpm with variable atrioventricular block leading to a ventricular rate ranging from normal to ≥ 300 bpm. The ventricular rate is often irregular in contrast to the minimal variability seen in SVT.

Mechanistically, almost 90% of SVT in fetuses are due to atrioventricular reentrant tachycardia via common type of accessory pathway (67). SVT can also be due to atrioventricular nodal, permanent junctional, or multiple reentrant pathways as well as due to automatic ectopic focus confined to the atrium. These types of SVTs are much less common during fetal age (67,72,73).

Junctional ectopic tachycardia and ventricular tachycardia (VT) are rare in fetal life. In contrast to atrial flutter, they are characterized by ventricular rate in excess of the atrial rate and are often difficult to distinguish from each other. VT is often seen in association with fetal long QT syndrome, which arises due to gene mutations coding for different proteins in ion channels. Measurement of the QT interval by echocardiography is not possible, but this diagnosis can be suggested often by the presence of sinus bradycardia between the episodes of VT.

Fetal Bradyarrhythmias

Fetal arrhythmia causing bradycardia may be associated with significant fetal morbidity and mortality. Fetal bradycardia is defined as a persistent heart rate < 100 beats/min. Most commonly, fetal bradycardia is due to sinus bradycardia. It shows 1:1 atrioventricular contraction sequence, slow onset, and beat-to-beat heart rate variability. It is often seen in fetuses suffering from significant hypoxic insult and raised intracardiac volume due to inhibitory vagal reflexes initiated by umbilical cord and other vessel compression. A sustained fetal sinus bradycardia with blunted or no heart rate variability is often a predictor of impending morbidity and mortality. Sinus bradycardia is often seen in fetuses with heterotaxia syndrome with atrial laterality abnormalities and AV canal defect. Fetuses with long QT syndrome may present with sinus bradycardia (74).

Fetuses with frequent or multiple premature atrial beats, which are not conducted to the ventricle, will have overall decreased ventricular rate and may have bradycardia due to it. This is a benign self-resolving condition and most of them resolve by the third trimester and certainly by the first weeks of postnatal life. Nonconducted premature atrial beats can occur after every two, three, or four normal beats setting up atrial bigeminy, atrial trigeminy, or atrial quadrigeminy patterns, respectively. Only occasionally, premature atrial beats can be a harbinger of SVT by initiating reentry mechanism in the presence of an accessory pathway.

Atrioventricular block due to AV node or ventricular conducting pathway abnormalities are the most common cause of persistent fetal bradycardia. The atrioventricular block can be of first degree, which demonstrates prolonged AV interval > 150 msec (75); second degree, which has a fixed atrioventricular conduction block (2:1 or 3:1 block) or progressive prolongation of the AV interval until an atrial beat is nonconducted (Wenckebach); or third degree, which has permanent atrioventricular block (complete heart block)

with complete dissociation between atrial and ventricular contractions.

Complete heart block can occur in fetuses either with malformed hearts or in otherwise structurally normal hearts. Fetuses with malformed hearts (corrected transposition of the great arteries, atrial isomerism, or atrioventricular canal defect) and complete heart block or with a ventricular rate < 55 bpm carry a very poor prognosis (76,77). Complete heart block, when found beyond the stage of embryogenesis in a structurally normal heart, has been associated with mass lesions of the conducting system, or more frequently as a consequence of initial insult by maternal antibodies to SS-A/Ro and SS-B/La antigens in fetal heart and subsequently leading to degeneration of the conduction system. Persistent bradycardia can occur in fetuses with long QT syndrome due to atrioventricular block secondary to prolonged refractory period of the ventricle (78).

Diagnosis of Arrhythmia by Fetal Echocardiography

In practice, fetal arrhythmias are diagnosed by M-mode, pulsed Doppler, or color flow encoded M-mode fetal echocardiography. The M-mode, with cursor oriented across atrial and ventricular cavities, reveals the relationship of atrial and ventricular contractions and their individual rate of contraction. Alternatively, pulse Doppler interrogation with a wide sample placed at mitral–aortic continuity can be employed, which demonstrates the rate of and relationship between inflow and outflow. In normal synchronized atrioventricular conduction, each atrial contraction is followed by a ventricular contraction, and both have the same and normal rate. In atrial flutter, ventricular contraction rate is a fraction of the atrial rate due to variable atrioventricular block (Fig. 16). In SVT, both atrial and ventricular contractions are synchronized and have the same rate, but their rates are between 220 and 300 beats/min (Fig. 17). Types of SVT can be differentiated according to the ventriculoatrial (VA) time interval (72) illustrated in Figure 18. The majority of SVT have short VA times, which are characteristic of atrioventricular reentry via common type of accessory pathway. The long VA time is typical of permanent junctional reentrant tachycardia or atrial ectopic tachycardia. Simultaneous pulse Doppler interrogation of the inflow and outflow can also reveal irregular heart rate due to blocked premature atrial beats (Fig. 19). Furthermore, a simultaneous Doppler interrogation of venous flow (superior vena) and an adjacent artery (aorta) can reveal AV and VA intervals (equivalent of PR interval and RP interval, respectively, on electrocardiogram) (Fig. 20).

In sinus bradycardia there is a 1:1 atrioventricular conduction with both atrial and ventricular rates the same but < 100 bpm on M-mode and Doppler interrogation. Atrioventricular block of all degrees is assessed by using both M-mode and Doppler echocardiography to examine the relationship between contraction of the atrial and ventricular walls and their individual contraction rates. The latter provides the information about the (second or third) degree of heart block.

Assessment of Fetal Cardiac Structure and Function

In addition to discerning the diagnosis of the fetal arrhythmia, a thorough fetal echocardiographic evaluation should be undertaken to evaluate the cardiac structure, function,

Figure 16 M-mode fetal echocardiogram shows both fast atrial and ventricular contractions in a 27-week-old fetus with atrial flutter. The atrial rate (inverted arrow) is 400bpm, and ventricular rate (upright arrow) is 200bpm, with 2:1 AV block.

Figure 17 Pulsed-Doppler fetal echocardiogram shows both inflow waveforms due to atrial contractions (above the base line, labeled as A) and outflow waveforms due to ventricular contractions (below the base line, labeled as V) at a rate of 236bpm with 1:1 atrioventricular conduction in a 30-week-old fetus with supraventricular tachycardia.

associated cardiac defects, hemodynamics, and presence of fetal hydrops as outlined in the previous sections.

Structural malformations of the heart are seen in up to 5% of the fetuses with tachyarrhythmia, which include Ebstein

anomaly of the tricuspid valve, AV canal defect, hypoplastic left heart syndrome, and rhabdomyoma (66,68,69). Ventricular dysfunction can occur. The severity of tachycardia-induced ventricular dysfunction can be assessed by fractional

Figure 18 Pulsed-Doppler fetal echocardiogram shows the measurements of atrioventricular intervals in a 27-week-old fetus with supraventricular tachycardia and a heart rate of 260bpm. The inflow Doppler waveforms due to atrial contraction (above the base line, labeled as A) and outflow Doppler waveforms due to ventricular contractions ((below the base line, labeled as V) with 1:1 atrioventricular conduction show that the A-V interval is shorter than the V-A interval, which is characteristic of atrioventricular reentry via common type of accessory pathway.

Figure 19 Pulsed-Doppler fetal echocardiogram shows inflow (below the baseline) and outflow (above the baseline) Doppler waveforms in a 30-week-old fetus with a nonconducted (blocked) premature atrial beat (buried in outflow waveform, marked by an arrow). Preceding and following inflow waveforms have normal early (E) and atrial (A) diastolic inflow waveforms. The premature atrial beat is blocked because of A-V node and ventricular refractory phase and is manifested by a late inflow valve opening (E-wave after the arrow), followed by a pause and normal atrial (first A-wave after the arrow) inflow waveform.

shortening, the degree and persistence of AV valve incompetence, and alternations of venous blood flow in IVC and ductus venosus (79,80). Fetal hydrops is characterized by the presence of any two or all of the following signs: skin edema, ascites, pericardial effusion, and pleural effusion (Fig. 21) carry a much higher mortality than a nonhydropic fetus.

Approach to the Treatment of Fetal Tachyarrhythmias

In order to avoid significant morbidities associated with preterm birth, the approach to the management of fetal arrhythmias is to strive to deliver fetuses at or near term in

normal sinus rhythm by intrauterine therapy, which mostly employs maternal administration of antiarrhythmic pharmaceutical agents. The mothers carrying fetuses with incessant tachycardia, tachycardia and major heart defects, or hydrops should be hospitalized to initiate the treatment with loading dose of antiarrhythmic agent, to monitor closely for adverse effects, and to modify the treatment. Continuous cardiac telemetry, serial ECG to assess the cardiac effects of the drug, serum chemistries, and repeated serum drug concentrations in the mother should be obtained. Both the mother and the fetus should be closely observed for any adverse effect of the

Figure 20 A simultaneous Doppler interrogation of superior vena cava and aortic flow shows reverse waveform due to atrial contraction (A) and outflow waveform in aorta with measured atrioventricular interval (A-V interval 125 ms), which is equivalent to PR interval of electrocardiogram.

Figure 21 Two-dimensional fetal echocardiogram of a hydropic fetus shows pleural effusion in the chest cavity (A) and a rim of pericardial effusion around the heart (B).

treatment. Once the fetal cardiac rhythm or rate is controlled and maintenance therapy is instituted, the mother can be discharged for regular outpatient follow-up. A detailed discussion on antiarrhythmic drug treatment is out of the purview of this chapter. In general, digoxin has been the first choice followed by flecainide for the maternal administration of antiarrhythmic agent in nonhydropic fetuses and amiodarone in hydropic fetuses (81–83). Depending on the fetal gestation, cardiac function, success rate of triple antiarrhythmic drugs, and parental wishes, urgent delivery may have to be undertaken. A multidisciplinary team including perinatologist, pediatric and adult cardiologists, and neonatologist should be involved in the management of such fetuses and neonates.

PATIENT COUNSELING IN FETAL CARDIAC DISEASE
 Counseling of the mother who is carrying a fetus with significant CHD can be a complex and lengthy process. As accurate diagnosis is critical to reliable counseling, and as the medical and surgical management of cardiac anomalies is often complicated, collaboration with a fetal cardiac specialist is usually warranted, particularly in complex cases. Nonetheless, it is important for all fetal echocardiography providers to be prepared to provide basic counseling to patients in whom fetal cardiovascular anomalies are suspected.

In addition to accurate anatomic diagnosis of fetal cardiac anomalies, it is useful to categorize the various fetal cardiac lesions with regard to severity. One approach is to classify lesions based on need and complexity of

Table 4 System for Classifying Severity of Fetal Congenital Heart Disease

<i>Low-risk congenital heart disease</i>	
Minimal impact on quality of life or longevity	Atrial septal defect Small VSD Mild pulmonary stenosis
<i>Moderate-risk congenital heart disease</i>	
Low mortality for surgical/catheter intervention, likely to impact long-term survival	Atrioventricular canal defect Coarctation of the aorta DORV Ebstein's anomaly of the tricuspid valve Large VSD Tetralogy of Fallot Totally anomalous pulmonary venous connection TGA, simple
<i>High-risk congenital heart disease</i>	
High mortality for surgical/catheter intervention, requiring multiple interventions, likely residual cardiac compromise, significant impact on longevity	Aortic stenosis, severe DORV, complex Ebstein's anomaly, severe cardiomegaly Heterotaxy with atrioventricular canal defect, complete heart block Hypoplastic left heart syndrome Pulmonary atresia with intact ventricular septum Pulmonary atresia, VSD, major aortopulmonary collateral vessels Single ventricle, complex Totally anomalous pulmonary venous return, obstructed TGA, complex Tricuspid atresia Truncus arteriosus

Abbreviations: VSD, ventricular septal defect; DORV, double-outlet right ventricle; TGA, transposition of the great arteries. *Source:* From Ref. 68.

surgical repair/palliation and the likelihood of residual cardiac disability. An approach for categorizing congenital heart defects in this fashion has been proposed by Allan and colleagues (84) and is presented in Table 4. This approach involves characterizing fetal cardiac anomalies as either low, moderate, or high risk based on expected impact on quality of life and longevity, as well as the complexity, mortality risk, and “completeness” of available surgical palliative procedures.

Making predictions regarding the need for perinatal medical and/or surgical management is also helpful. Identification of “reversed” physiologic shunting in the fetus with either right or left ventricular outflow tract obstruction can allow clinicians to make predictions about the need for prostaglandin infusion to maintain ductal patency and the need for transfer to a cardiac center for management of critical outflow tract obstruction. In our center, fetuses fitting this clinical description are routinely started on prostaglandin infusion following recommended delivery at a level III perinatal center and transferred to our cardiac intensive care unit for management. Examples of common lesions presenting in this

Table 5 Risk of Chromosomal Anomalies in Common Congenital Heart Lesions

<i>High-risk congenital cardiac anomalies</i>	
Risk of chromosomal anomalies >10%	Absent pulmonary valve syndrome (20%) Atrioventricular canal defect (35%) Coarctation of the aorta (29%) Double-outlet right ventricle (12%) Mitral valve atresia (18%) Tetralogy of Fallot (27%) Totally anomalous pulmonary venous return (30%) Truncus arteriosus (14%) Ventricular septal defect (48%)
<i>Low-risk congenital cardiac anomalies</i>	
Risk of chromosomal anomalies <10%	Hypoplastic left heart syndrome (4%) Pulmonary stenosis/atresia with intact ventricular septum (5%) Transposition of the great arteries (0%) Tricuspid valve anomaly/Ebstein's (5%)

Source: From Ref. 6.

manner include pulmonary stenosis/atresia, tetralogy of Fallot, tricuspid atresia, aortic stenosis, or variants of hypoplastic left heart syndrome. Other lesions that are routinely started on prostaglandin and transferred to the cardiac unit are severe coarctation and transposition of the great arteries. Generally, septal defects such as ASD, VSD, and AV canal defect do not require immediate intervention and can be evaluated more electively (after a confirmatory postnatal echocardiogram) at the birth hospital. In our center, all variants of single ventricle are delivered at a level III center and transferred to the cardiac unit for evaluation, given the complexity of cardiac issues involved in these cases. Given the complexity and diversity of congenital heart lesions, collaboration with a fetal cardiologist is important in arriving at a disposition for these complex fetuses.

Another major issue is genetic counseling for patients with the diagnosis of fetal CHD. Although we generally recommend genetic counseling for all mothers diagnosed with fetal CHD, it is known that certain cardiac lesions carry a particularly high risk of chromosomal abnormalities (6); these groups are outlined in Table 5. In addition to screening for aneuploidy, clinicians should also screen for microdeletions in chromosome 22, which is associated in high frequency with conotruncal defects and aortic arch anomalies. The presence of a significant chromosomal anomaly, as well as other extracardiac anomalies, has surgical implications, as most studies have identified these as risk factors for increased morbidity and mortality during surgical palliation, particularly in complex congenital heart defects.

ADVANCES IN FETAL CARDIAC DIAGNOSIS AND THERAPY

Evaluation of Fetal Arrhythmias by Magnetocardiography
Magnetocardiography elucidates electrical signals in the fetal heart by detecting and analyzing the related magnetic fields. It processes the sequence of electrical events rather than mechanical events of the heart and can provide the capability of measuring different electrical time intervals such as QRS and QT intervals (85). Therefore, potentially it can reveal the

Figure 22 A vector velocity imaging (VVI) of 24-week gestation fetus of a diabetic mother shows the magnitude and direction of the longitudinal strain of the left ventricle (LV) indicated by the length and direction of arrows along the endocardial border of the LV (A) in transverse view. The VVI of the same infant at 1 week of age after birth shows the magnitude and direction of the longitudinal strain of the LV in four-chamber view (B).

mechanisms of fetal arrhythmias and aid in the differential diagnosis of fetal tachycardia such as in distinguishing VT with 1:1 conduction versus SVT as well as VT with AV dissociation versus junctional ectopic tachycardia (73). Discerning the mechanisms of fetal arrhythmias will help select the appropriate anti-tachyarrhythmic agents and unify the approach to the treatment of fetal arrhythmias. This modality is not in clinical use yet because of its need to be performed in a magnetically shielded room. Advancement has been made in the use of the technique at the bedside in an unshielded environment, which may bring it for wider use in the clinical practice (85).

Evaluation of Fetal Cardiac Function by Strain Imaging

Cardiac function in fetuses has traditionally been measured by subjective assessment of contractility and observation for hydrops fetalis. Currently, myocardial functional assessment in the fetus has been limited by the reduced reproducibility due to the requirement for correct alignment to the structures being interrogated, lack of a concurrent electrocardiogram to time mechanical events accurately and unique properties of the fetal myocardium, which is made up of primarily noncontractile elements with fewer myocytes. Furthermore, most noninvasive methods of evaluation of cardiac function are load dependent (86). A novel method based on speckle-tracking techniques, including vector velocity imaging, has emerged that uses frame-by-frame tracking of myocardial speckles in 2D echocardiographic images to provide velocity and displacement data and permit quantification of the degree of myocardial deformation or strain (87) and strain rate, which is relatively load independent (88). The new method allows assessment of function independent of fetal lie, thus simplifying more sophisticated measures of function, such as strain and shear stress (89) (Fig. 22). This will help to improve the objectivity, reproducibility, and monitoring of fetal cardiac function.

Fetal Cardiac Intervention

Fetal cardiac intervention is a burgeoning field. Endeavors are being made in some centers to prevent fetal hydrops due to congenital heart defects, to recruit hypoplastic ventricles, to create a two-ventricle circulation after birth, and to remodel

the fetal pulmonary vascular bed whose outlet is obstructed (90). A successful open heart surgery in the fetus has yet to be done, but catheter-based interventions for improved cardiac outcomes are now being taken up.

Fetal echocardiography can identify midgestation fetuses with aortic and pulmonary outflow obstruction, which are at high risk for developing hypoplastic left and right heart syndromes, respectively. With the development of novel techniques, risk reduction to the fetus and the mother, timely and successful valve dilation may prevent left or right heart growth arrest and may result in normal ventricular anatomy and function at birth (91,92). There is an important learning curve for these procedures, and much remains to be learned about the selection of appropriate fetuses for prenatal intervention and further refinement in techniques of echocardiography, approach, and risk reduction in fetal intervention.

65 Assessment of fetal behavior

Asim Kurjak, Milan Stanojevic, Badreldeen Ahmed, Guillermo Azumendi, and Lara Spalldi–Barisic

Three-dimensional (3D) ultrasound has been available for more than 15 years. During its continuous improvement and development, several different kinds of modes have been created. They include multiplanar imaging, volume rendering, surface rendering, 3D color Doppler, 3D volumetry, cine-loop animation, and post-processing and cutting. However, the 3D image freezes the object and therefore does not provide information on movements or any information about the dynamic changes of the object of interest. A technique was needed that would enable 3D imaging to be performed in a real-time mode. This technique can be called live 3D ultrasound (3D-US) or 4D ultrasound (4D-US), as coined by a manufacturer, because time becomes a parameter within the 3D imaging sequence. Human eyes are known to be able to differentiate between images up to a frequency of about 12 images per second; consequently, production of an appropriate frame rate with specially designed probes and a fast computer rendering device is required. At the moment, 4D-US scanning is not real time and available machines can reach up to about 20 images per second, depending on volume size, resolution, and the mechanics of the probe. Nevertheless, even at these relatively slow frame rates, the ability to study fetal activity is strikingly good enabling the continuous monitoring of the fetal face and other surface features of the fetus such as fetal extremities. This was the beginning of investigation of the relatively unexplored area of fetal behavior as a possible measure of neurologic maturation.

Fetal behavior could be described as any fetal action or reaction observed by the mother or other more objective method, as actocardiocography or ultrasonography. Although there are more than 100 years of curiosity in fetal behavior and more than three decades of sustained awareness and research, the study of fetal behavior has not achieved widespread acceptance in perinatal medicine. For centuries, maternal registration of fetal movements and obstetrician auscultation of fetal heartbeats were the only methods of the follow-up of fetal well-being in utero. It has been shown that fetal activity occurs as early as the late embryonic period, which is far earlier than a mother can sense it. A turning point in the assessment of fetal behavior was the introduction of real-time ultrasound. As it is not yet possible to assess functional development of the central nervous system (CNS) directly, investigators have started to analyze fetal behavior as a measure of neurologic maturation including properties of fetal hemodynamics and the muscular system, as well (1). This technique allowed the investigation of spontaneous fetal motor activity in utero. For the first time, studies of spontaneous prenatal movements and behavior were performed and published. Since fetal body movements give

important information about the condition of the fetus, their quantitative as well as qualitative aspects were analyzed.

NEW ADVANCES IN NEUROPHYSIOLOGY

Development of the CNS and Prenatal Motor Development in the First Trimester

Development of the human CNS begins in the early embryonic period and proceeds through a sequence of very complicated processes long after delivery. It is important to point out that the caudal region of the neural tube gives rise to the spinal cord, and the rostral region becomes the brain. The initial development is completed at 7 weeks of gestation (5 weeks after conception), when all five major subdivisions of the brain are clearly visible: the telencephalon, diencephalon, mesencephalon, metencephalon, and myelencephalon (Fig. 1) (2).

The earliest interneuronal connections, the synapses, can be detected in the spinal cord shortly before the onset of embryonic motility, at 6 to 7 weeks of gestation. Therefore, the neural activity leading to the first detectable movements is considered to originate from the spinal motor neurons. Another important prerequisite for the motility is the development and innervation of muscular fibers. It is well known that primitive muscle fibers (myotubes) are able to contract as soon as they are innervated by motor neurons. Between 6 and 8 weeks of gestation, muscle fibers can be formed by fusion of myoblasts, efferent and afferent neuromuscular connections can be developed, and spontaneous neural activity causing motility can begin.

The main events in the development of the CNS and motor development during the first 8 weeks of pregnancy are presented in Figure 1. The first spontaneous embryonic movements are gross body movements and they can be observed at the 7 to 7.5th weeks of gestation. They consist of slow flexion and extension of the fetal trunk, accompanied by the passive displacement of arms and legs. These so-called vermicular movements appear in irregular sequences. Simultaneously with the onset of spontaneous movements, at the 7.5th week of gestation, the earliest motor reflex activity can be observed, indicating the existence of the first afferent–efferent circuits in the spinal cord. The first reflex movements are massive and indicate a limited number of synapses in a reflex pathway. General movements (GMs) are the first complex, well-organized movement pattern, which involve head, trunk, and limb movements. This pattern has been interpreted as the first sign of a supraspinal control on motor activity and can be recognized from 8 to 9 weeks of gestation onward.

It is very important to note that even at this early stage of development, embryonic and fetal movements appear in recognizable temporal sequences, without any amorphous or

Figure 1 The main events in the development of the central nervous system (CNS) and motor development during the first 8 weeks of pregnancy.

random movement. The explanation for this fascinating phenomenon lies in the intrinsic properties of neurons. That means that neural cells begin to generate and propagate action potentials as soon as they interconnect. The interconnected neurons generate patterned activity because of endogenous properties of the neurons. Recent investigations have shown that neurons are able to communicate through non-synaptic mechanisms even before the onset of synaptogenesis.

The brain stem is fashioned around the 7th week of gestation, and basic structures of the diencephalon and cerebral hemispheres are formed by the end of the 8th gestational week. The remarkable expansion of the cerebral hemispheres follows during the remainder of gestation. The development of synapses in the human cerebral cortex begins after the formation of the cortical plate, at the end of the 10th week of gestation.

The brain stem consists of the medulla oblongata, pons, and midbrain (Fig. 2). It forms and matures in a caudal to rostral direction. That means that the phylogenetically older structures, such as the medulla oblongata, will form and mature earlier in the gestation. The major structures of the medulla oblongata are fashioned by the 7 to 8th week of gestation and are completely matured by the 7 months of gestation. In addition to its many subnuclei, the medulla gives rise to a variety of descending spinal motor tracts that reflexively trigger limb and body movements. It also hosts the five cranial nerves (VIII–XII), which exert tremendous influences on gross body movements, heart rate, respiration, and the head turning. As the medulla matures in advance of more rostral structures of the brain stem, reflexive movements of the head, body, extremities, as well as breathing movements (Fig. 2) and alterations in heart rate appear in advance of other functions.

The formation of pons begins almost simultaneously, but its maturation is more prolonged. The structures of the pons include the V to VIII cranial nerves (vestibular nuclei of the nerve VIII) and the medial longitudinal fasciculus, pontine tegmentum, raphe nucleus, and locus coeruleus, which exert widespread influences on arousal, including the sleep–wake cycles. Facial movements, which are also controlled by V and VII cranial nerves, appear around 10 to 11 weeks.

At 10 weeks of gestation, lateralized behavior may be observed, and the fetus begins to show the earliest signs of right- or left-handedness. Stimulation of the brain is known to influence brain organization and it is argued that fetal motor activity may eventually stimulate the brain to develop “handedness” and subsequent lateralization of the function. From 10 weeks onward, the number and frequency of fetal movements increase and the repertoire of movements begins to expand. Qualitative changes in GMs can be also observed. These movements, which are slow and of limited amplitude during 8 and 9 weeks, become more forceful at 10 to 12 weeks. After the 12th week, they become more variable in speed and amplitude. The isolated limb movements seen at the 9th week of gestation are followed by the appearance of the movements in the elbow joint at 10 weeks, changes in finger position at the 11th week, and easily recognizable clenching and unclenching of the fist at 12 to 13 weeks. Finally, at 13 to 14 weeks, isolated finger movements can be observed, as well increases in the activity and strength of the hand/finger movements. Using 4D sonography, Kurjak and collaborators have found that from 13 gestational weeks onward, a “goal orientation” of hand movements appears and a target point can be recognized for each hand movement (3). According to the spatial orientation, they classified the hand movements into several subtypes:

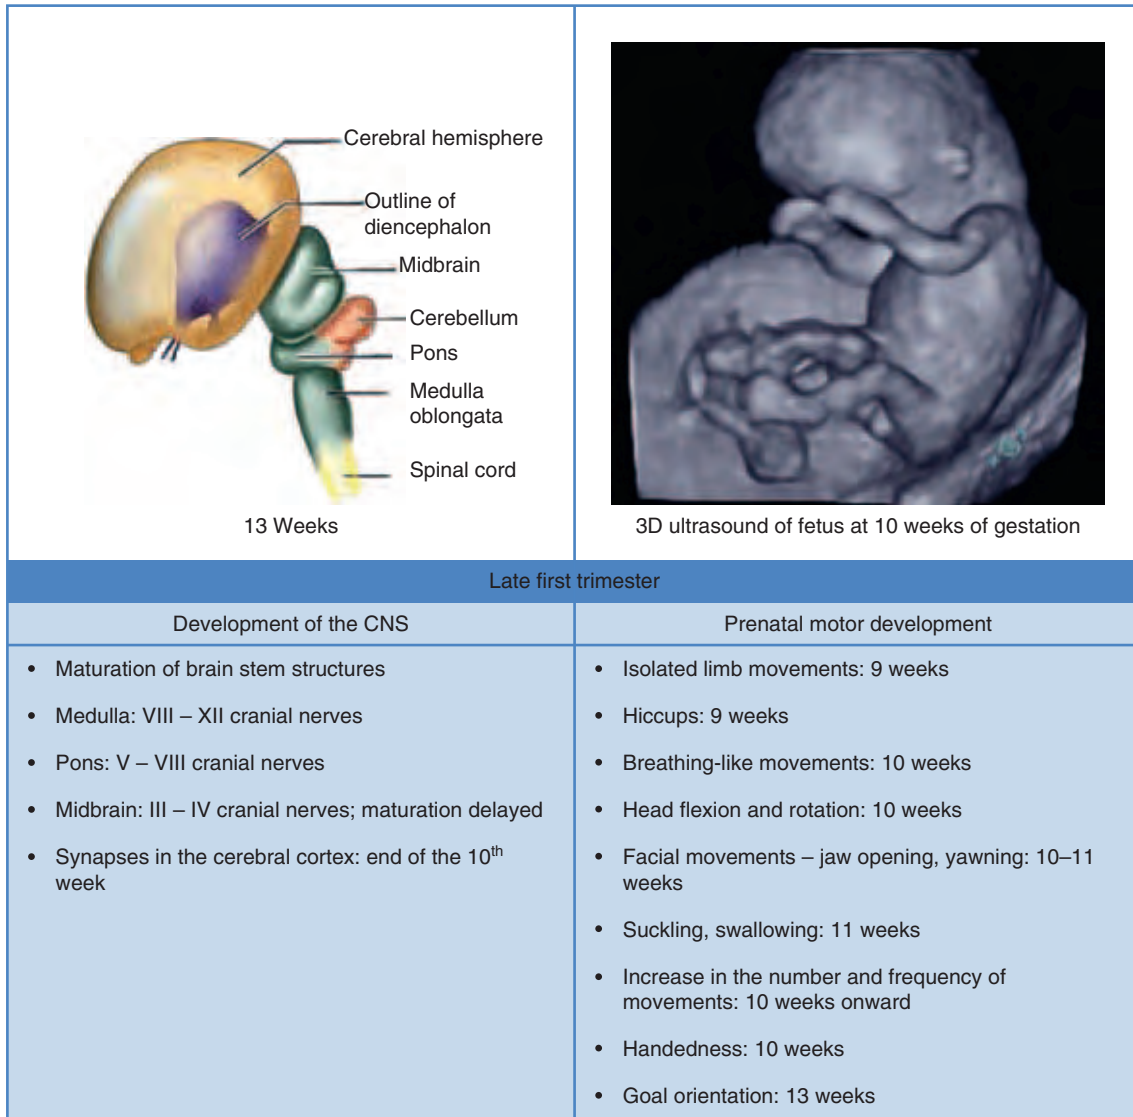

Figure 2 The main events in the development of the central nervous system (CNS) and motor development during the last 6 weeks of the first trimester.

hand to head, hand to mouth, hand near mouth, hand to face, hand near face, hand to eye, and hand to ear. Our recent longitudinal study, performed by 4D ultrasound in 100 fetuses from all trimesters of normal pregnancies, has shown increasing frequency of various movement patterns, such as GMs, isolated arm and leg movements, stretching, as well as head movements, during the first trimester (4). Only the startle movement pattern seemed to occur stagnantly in this period of gestation. Using 4D sonography, GMs were found to be the most frequent movement pattern between 9 and 14 weeks of gestation. Furthermore, the advanced ultrasonic techniques, 3D and 4D, significantly improve the assessment of structural and functional development of embryonic and fetal CNS. Figures 3 and 4 are showing the main events in the development of CNS and motor development during the second and third trimesters (2).

Onset of Specific Fetal Behavioral Patterns

The First Trimester

In the first trimester of pregnancy, 3D-US allows precise morphologic examinations, important for early detection of serious fetal malformations, such as anencephalic fetus and

spina bifida (5). Using 4D-US, quantitative assessment of fetal motility can be performed almost equally precisely as by conventional 2D-US even at the very early period of gestation, at the onset of fetal motility. The qualitative assessment might be even more informative because 4D-US allows the simultaneous visualization of the whole body (Fig. 5).

However, our own study showed that we can use both 2D and 4D sonography to assess movements in the first trimester (6).

The early embryonic development is characterized by the immobility of an embryo. Most types of movement pattern emerge between 7 and 15 weeks of gestation. From the 15th week onward, distinct patterns can be seen (6). These movements remain present during the entire intrauterine development. Just discernible movements were found between 7 and 8 weeks of gestation by de Vries and coworkers (7). They reported not only how to describe a particular movement, but also how these movements were performed in terms of speed and amplitude (7,8). Goldstein and colleagues as well as other investigators found embryonic body movements between 8 and 9 weeks of gestation by 2D transvaginal sonography (7,9–11). First spontaneous fetal movements were

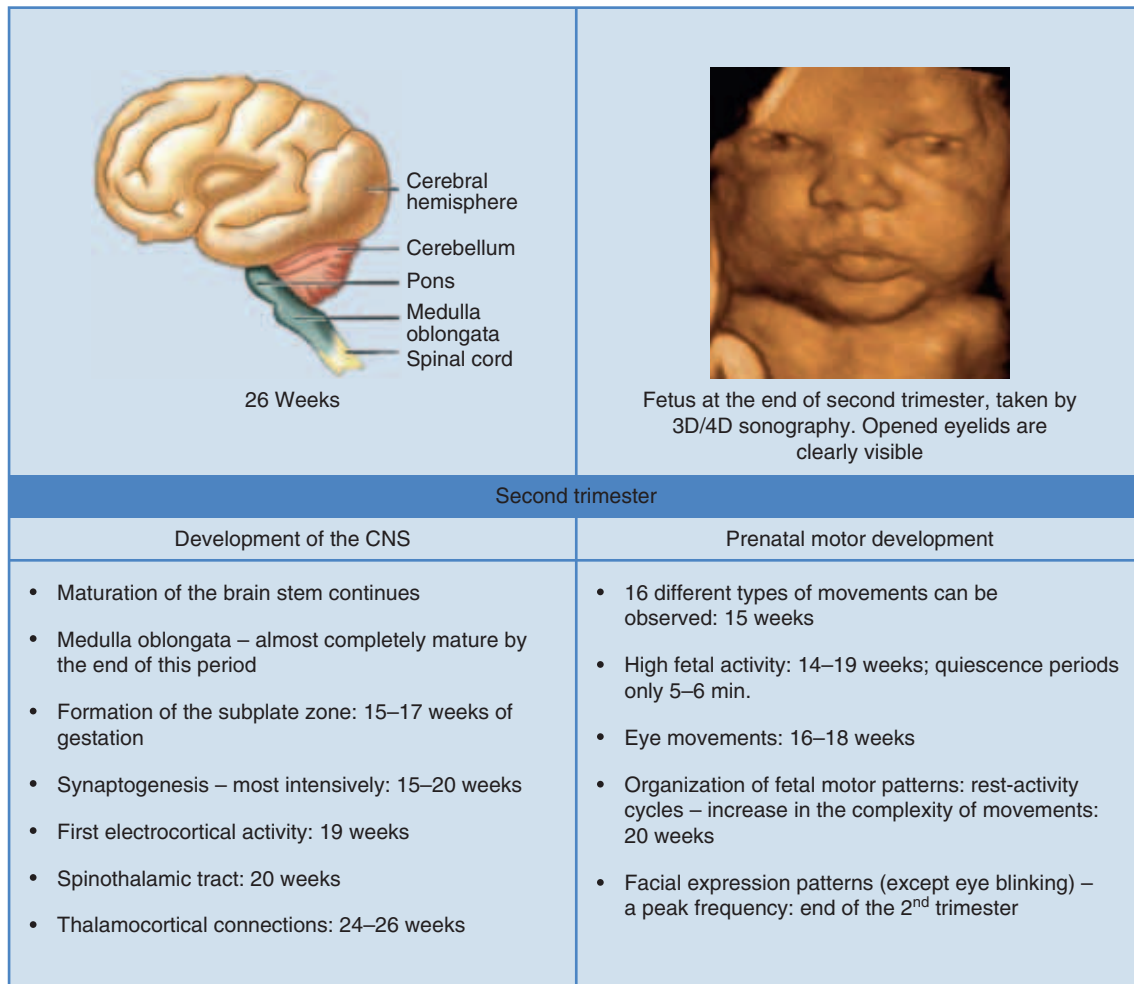

Figure 3 The main events in the development of the central nervous system (CNS) and motor development during second trimester.

described as consisted of slow flexion and extension of fetal trunk accompanied by the displacement of arms and legs and appearing in irregular sequences that were described as “vermicular” (12). The earliest signs of fetal motility coincide with the occurrence of first synapses, around the seventh postconceptional week and with the earliest electrical activity and transmission of information.

The aim of the first studies from Zagreb group on fetal behavior and 4D sonography was to classify first-trimester embryonic and fetal movements in normal pregnancies as seen by 4D sonography (13,14). In order to achieve this goal, we examined a total of 98 pregnant women at gestational age (GA) from 6 to 12 weeks. Matters of interest were the GA at which the movements appeared and their visualization with 4D-US. For each embryonic structure, there is a period between genesis and ultrasonic visualization. As technology advances, the period becomes shorter. Three types of movements can be visualized in the first trimester: gross body movements between 7 and 8 weeks, limb movements after 10 weeks, and complex movements after 11 weeks of gestation (Fig. 6).

An alteration from the given pattern of motoric development should be considered as an indication for further investigation (14).

By another study, the Zagreb group has evaluated the advantages of 4D over 2D real-time sonography in the assessment of early fetal behavior (15,16). The aim of the study was to classify types of first-trimester embryonic

and fetal movements in normal pregnancies as seen by 4D sonography. We found gross body movement at 7 weeks and limb movements at weeks 8 to 9 (Fig. 7).

Body and limb movements can be visualized by 4D sonography a week earlier than by 2D. Since 4D ultrasound enables visualization of more details of the dynamics of small anatomical structures, it should thus enable the diagnosis of motoric development failure at the end of the first trimester.

With 4D transvaginal sonography, we found body movements at 7 weeks of pregnancy (15). The observed body movements consisted of the changing position of the head toward the body. However, embryonic movements are not frequent and consist mainly of the moving of the head toward the rest of the body. At 8 to 9 weeks, the head is less flexed and the changes of the position of the head toward the body are clearly visible (17). Vermicular movements are visible for less than 2 weeks. A startle is the next movement with participation of the fetal body. Startles were found between 8 and 9 weeks of gestation and lasted for about 1 sec (18). Observations were performed using transabdominal sonography, and it is entirely possible that, with better resolution of the transvaginal transducer (either 2D or 4D), some of these movements may already be present at somewhat younger age.

In a little while, these first simple movements are replaced by different GMs that include head, trunk, and limb, such as “rippling” seen at the 8th week, “twitching” and “strong twitching” at 9th and 9.5th weeks respectively, and “floating,”

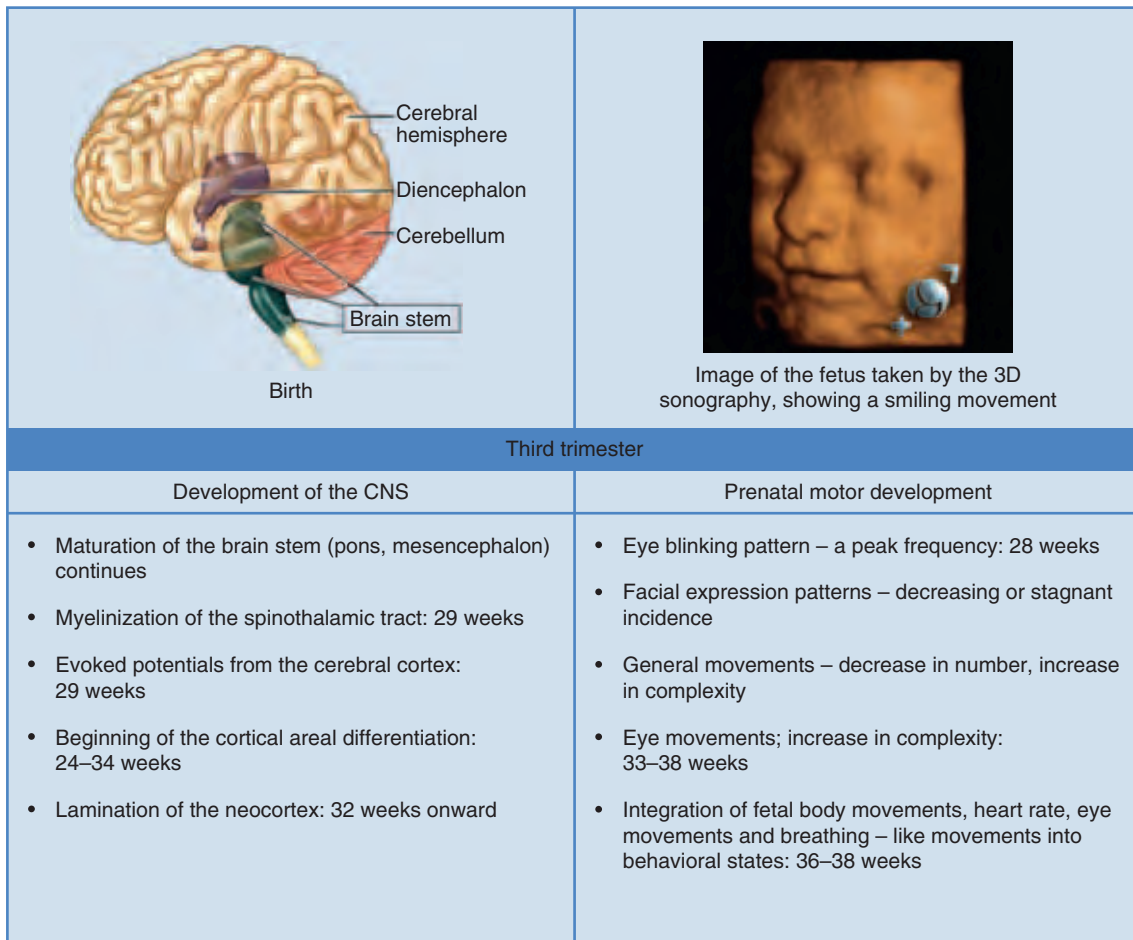

Figure 4 The main events in the development of the central nervous system (CNS) and motor development during third trimester.

“swimming,” and “jumping” at 10th week (13). At first, GMs are slow and of limited amplitude. At 10 to 12 weeks, GMs become more forceful but are smooth in appearance and of large amplitude. We can suppose that the generating neural network responsible for GMs could be primarily located in the brain stem and spinal cord, higher structures of the brain playing more subtle role in modulating quality, and, perhaps, time patterning of the different movement patterns (19). Isolated limb movements emerge almost simultaneously with the generalized movements. In the literature, there is a range between the 8th and 12th weeks concerning the first appearance of limb movement. De Vries found isolated arm and leg movements at the 8th week of gestation (7). With 4D-US, limb movements at the 8th to 9th weeks were found. Organization of the appearance of the movement pattern occurs with the increasing frequency. It seems that fetal arms explore the surrounding environment and cross the midline, while the palmar surface is oriented toward the uterine wall. The fetal legs are extended to the uterine wall (Fig. 8).

More limb joints are active and move simultaneously, such as extension or flexion in arm and elbow or hip and knee. The elevation of the hand, extension of the elbow joint, with a slight change in direction and rotation, can be seen simultaneously. From the 10th week onward, the number and frequency of fetal movements increase and the repertoire of movements begins to expand. The isolated limb movements seen at the 9th week are followed by the appearance of the movements in the elbow joint at the 10th week, changes in

finger position in the 11th week, and by easily recognizable clenching and unclenching of the fist at the 12th to 13th week.

After the 9th gestational week, the repertoire of movements expands rapidly. Hiccups appear, often in series, for up to several minutes, and isolated arm and leg movements can be observed. This is remarkable in two respects. First is that the young fetus is able to perform isolated movements of one limb at an age when one would expect a longer period of diffuse and generalized motor activity. The second is the unexpected finding of the simultaneous onset of arm and leg movements, unexpected because of the long-held principle of a cephalo-caudal development in spinal motor functions. After 10 weeks, head movements of various types can be seen. They consist of lateral rotation of the head and overextension of the neck (20). At about the same age, hand–face contact is seen for the first time. Usually, this is an accidental contact of a hand with the face or the mouth. Between 10.5 and 12 weeks, the fetus starts to make breathing movements. At 11 weeks, three new patterns, namely, the opening of the jaw, bending forward of the head, and complex stretch movements, are added to the repertoire (Fig. 9).

Somewhat later than the irregular jaw movements, yawns occur. These have the same pattern as in children and adults and hence are easily recognizable (20).

To determine the accuracy of 4D sonography in the assessment of embryonic and early fetal motor activity in the first trimester of normal pregnancy, in comparison with the 2D sonography, the Zagreb group conducted a study with

Figure 5 The whole body of the fetuses 9 (A) and 10 (B) weeks of gestation depicted by 3D ultrasound.

Figure 6 Complex movements of the trunk, limbs, and head in 12-week fetus depicted by 3D ultrasound.

50 pregnant women between 6 and 14 weeks of gestation. The 2D and 4D recordings were displayed on the screen and recorded on the videotape during the 15-minute observation period. The earliest embryonic movements were detected at the 7th week of gestation. The movements that involved the

whole body, such as GMs and startles, occurred most frequently, although in 8-week-old embryos, isolated arm and leg movements could have also been observed. All the above described movement patterns were also recognizable by both 2D and 4D imaging methods in fetuses studied between

Figure 7 Gross body movements of the 8-week embryo depicted by 3D/4D ultrasound.

Figure 8 Fetal legs extended to the uterine wall (3D ultrasound of 10-week fetus).

the 9th and 14th weeks of gestation. Several movement patterns, such as sideway bending, hiccup, fetal breathing movements, and facial movements could not be observed by 4D-US imaging technique, although they were clearly visible

by 2D-US. The authors concluded that at the time, both 2D and 4D methods were required for the assessment of early fetal motor development and motor behavior. It was reasonable to expect that such technologic improvement may provide some new information about the intrauterine motor activity and facilitate the prenatal detection of some neurologic disorders (20).

To investigate the natural course of fetal hand and finger positioning, Pooh and Ogura examined 65 normal fetuses by 3D/4D ultrasound (21). Each appearance of fingers, thumb, and wrist was confirmed by viewing on three orthogonal planes. At 9 weeks and at the beginning of the 10th week, fetal hands were located in front of the chest and no movements of wrists and fingers were visualized. From the middle of 10th week of gestation, active arm movements were observed associated with active body and lower limb movement. Despite active movements of glenohumeral and elbow joints at this stage, wrist and finger movements were not visualized in most cases. At 11 weeks, a change in finger positioning was seen. At this stage, all fetuses still opened their palms, but five digits were no longer on the same layer. Mild adduction of the thumb and atonic fingers were observed and the palm appearance was clearly different from that at 9 and 10 weeks. At 12 weeks of gestation, fetuses started to mildly clench and unclench their fists (21). Confirming the feasibility of early dynamic observations in pregnancy, these studies also showed the capacity to obtain much better defined images as the whole fetus could be visualized.

In the first trimester, one could notice a tendency toward an increased frequency of fetal movement patterns with increasing GA. Only the startle movement pattern seemed to occur stagnantly during the first trimester (22).

The Second Trimester

Only a few studies are available on fetal movement patterns during the second trimester (3,7,23–27). De Vries and

Figure 9 Fetus at 11 weeks depicted by 3D ultrasound showing addition of complex movements of the head, body, and limbs to the repertoire of movements.

colleagues studied fetal movements from 20 and 24 postmenstrual weeks onward (7). During the second trimester of pregnancy, the incidence of body movements increases considerably. The periods of quiescence become longer and eye movements (EMs) are clearly visible with significant trends in fetal EM organization (26). The earliest EMs appear at the developed by the end of the first trimester, indicating that some facial grimaces could appear at the 16th to 18th week of gestation, as do sporadic movements with a limited frequency. Isolated eye blinking patterns appear more frequently and begin to consolidate at the 24th to 26th week of gestation.

The incidence of hiccups startles and stretches decreased, whereas other movement patterns (jaw movement, hand–face contacts, and head movements) showed no clear developmental changes (24). At 28 postmenstrual weeks, Roodenburg and associates presented the following ranges and median values based on 1-hour observations: jaw movements, 60–460, median 300; hand–face contact, 30–190, median 95; head rotations, 20–125, median 37; head retroflexions, 4–29, median 12 (17). From a developmental point of view, one could say that in the second trimester the development continues, but there are no new movements appearing for the first time.

Spontaneous movements in fetuses from 12 to 35 weeks of gestation were described by Sparling and coworkers and they documented the typical hand movement (26). Many movements were shown to be straightforward, to a body part or uterine wall. The hands moved with different frequencies and force. Sparling also described repetition of head flexion movements, resulting in a “somersault” that makes possible for the fetus to change position within the uterine cavity throughout GAs. The hands of fetuses were extended and manipulated body parts and feature of the surroundings, for example, the umbilical cord. In a longitudinal study of fetal behavior from 14 weeks until neonatal period, Sparling and

Wilhelm concluded that fetal and neonatal movements appeared to be directed to specific targets to the head and face (27). They stated that the most useful predictors of neonatal movement were the observations performed at 32 weeks of gestation.

After 12 weeks, GMs become more variable in speed and amplitude. We already know that most of the qualitative features of GMs are already present during the 4th to the 5th months of gestation, with minor changes occurring in the last trimester of pregnancy.

Using 4D sonography, the Zagreb group has found that from the 13th gestational week onward, a “goal orientation” of hand movements appears and a target point can be recognized for each hand movement (3). According to the spatial orientation, the hand movements were classified into several subtypes: hand to head, hand to mouth, hand near mouth, hand to face, hand near face, hand to eye, and hand to ear and its incidence were determined. The investigation included 25 fetuses in uncomplicated pregnancies: 15 fetuses at 13 to 16 weeks and 10 fetuses at 30 to 33 weeks of gestation. After standard assessment in 2D real-time B mode, a 4D mode was switched on and further examination lasted a maximum of 15 minutes. All recordings were performed between 14 and 17.30 hours, and no meals were taken within 2 hours of the beginning of the study. Patients with multiple or diabetic pregnancy at presentation were excluded from the study. In the first part of the study, GA was determined using biparietal diameter measurement, while in the second part of the study, GA was estimated from the first day of the last menstrual period and confirmed by the first-trimester sonographic examination.

Isolated hand movements with subtypes of hand movements and facial activities with different forms of expression were easily recognized by 4D-US. All subtypes of hand to head movement could be seen from 13 weeks of gestation, with

fluctuating incidence. Among facial expressions, two types could be easily differentiated: smiling and scowling. One could recognize that the amount of isolated arm movements decreased gradually from 13 to 16 weeks. The incidence varied between 50 and 120 with a median value of 60 at 13 weeks, 17 and 27 with a median value of 23 at 14 weeks, 0 and 6 with a median value of 2 at 15 weeks, and 18 and 28 with a median value of 25 at 16 weeks. The highest range was registered at 13 weeks of gestation. The incidence of hand to head movement decreased, followed by a plateau at 14 weeks of gestation. The incidence varied from 4 to 29 at 13 weeks and from 0 to 7 at 16 weeks of gestation. The highest range of hand at mouth was found at 15 weeks of gestation; at 13 weeks, a plateau was observed and with mild fluctuations the plateau continued until 16 weeks. The incidence varied between 0 and 4 with a median value of 2 at 13 weeks, and between 0 and 2 with a median value of 2 at 16 weeks. In contrast to most other movement patterns, hand near mouth movements decreased gradually from 13 weeks onward with a single fluctuation in the 14th week. One can recognize that the incidence of hand near face movement is stable between 13 and 16 weeks of gestation with a slight increase at 14 and 15 weeks. At 13 weeks, the range was the widest. The incidence of hand to ear movement showed a rapid trend of decrease between 13 and 16 weeks while the incidence of the hand to eye movement pattern showed the same developmental trend as the hand to head and hand to face movement patterns (28). The incidence varied between 4 and 12 with a median value of 8 at 13 weeks, and 0 and 3 with a median value of 0 at 16 weeks. The incidence of the hand to eye movement pattern showed the same developmental trend as the hand to head and hand to face movement patterns. At 13 weeks, the incidence was between 4 and 12 occurrences per 15-minute observation time with a median value of 8. At 16 weeks, the range was from 0 to 3 with a median value of 1. The authors concluded that 4D-US is superior over 2D real-time ultrasound for the qualitative, but inferior for quantitative analysis of hand movements. Thus, 4D-US makes it possible to determine exactly the direction of the fetal hand, but the exact number of each type of hand movements still could not be determined. The advantage of 4D over real-time 2D-US is that isolated hand movements can be determined with confidence. The 2D sonography easily recognizes hand movements associated with body movements, but there are problems in the recognition and differentiation of isolated hand movements and hand movements associated with leg movements. In this situation, 4D-US is the method of choice for the reliable recognition of the isolated hand movements. Another advantage of 4D-US is the precise assessment of the direction of the hand movement and target of the fingers. Real-time 2D-US provides a tomographic image of the fetal head and visualizes hand movements in two dimensions. The 4D sonography provides surface-rendered images of the fetal head, and visualization of hand movements in three dimensions allows further differentiation of hand to head movements (3).

In another study, the same group of authors confirmed that in the second trimester, the number of head and hand movements decreased gradually compared with the first trimester. The highest incidence was registered for head retroflexion pattern, with a range of 15 to 42 and a median of 25.

Among facial expressions, the highest incidence was found for sucking, with the range between 3 and 30 and a median of 9 (28).

Kuno and coworkers evaluated fetal behavioral patterns in the early second trimester in 11 healthy pregnant women at 14 to 18 weeks of gestation and they found that the most active fetal behavioral pattern was arm movement in each fetus, whereas the least active was mouth movement. Each fetal movement was synchronized and harmonized with other fetal movements during this period of pregnancy (24).

Kurjak et al. reported the first study with the 4D-US techniques used for obtaining longitudinal standard parameters of fetal neurologic development in all trimesters of a normal pregnancy (4). Valid reference ranges appropriate for GAs are essential for comparisons with former or future measurements of patients. For that purpose, a group of 100 healthy normal singleton pregnancies were recruited for longitudinal 4D-US examinations to evaluate fetal neurodevelopmental parameters between 7 and 40 weeks of gestation. The patients were assigned to the study if they met inclusion criteria, if the fetus and the mother were considered "normal," 2D ultrasound and clinical assessment were uneventful, and the neonates, eventually delivered at term, had normal 1- and 5-minute Apgar scores. Pregnancies that were subsequently found to be complicated by congenital abnormalities, gestational diabetes, and hypertensive disorders in pregnancy, preterm deliveries, and abnormal Apgar scores were excluded. Those fetuses from the second and third trimesters whose examined parts of the body were not able to be visualized in one region of interest were also excluded from the study. In the first trimester, eight fetal movement patterns were analyzed and 14 parameters of fetal movement and fetal facial expression patterns recorded thereafter for the construction of fetal neurologic charts. Standard parameters of fetal movements and facial expressions in all trimester of pregnancy are presented in Figures 10 and 11.

The statistical analysis of the incidence of fetal movements and facial expressions studied in the first trimester revealed statistically significant changes in GMs, stretching, isolated arm and leg movement, head retroflexion, head rotation, and head retroflexion. At the first trimester, a tendency toward increased frequency of fetal movement patterns with increasing GA has been noticed. Only in the startle movement pattern, it seemed to occur stagnantly during the first trimester (Fig. 10B). In this type of movement, there was no significant correlation with GA, as shown by the large dispersion of scatter points around the regression line (r 0.673; p 0.506). At the first trimester, a tendency toward increased frequency of fetal movement patterns with increasing GA was noticed. During the second and third trimesters, multiple regression and polynomial regression revealed statistically significant changes in tongue expulsion, grimacing, swallowing, head movements, and all hand to body contact movements ($p < 0.05$). The authors found a tendency toward an increase in the frequency of fetal movement patterns at the beginning of the second trimester. They noticed fluctuation and dispersion of the incidence of all facial expressions as seen in the polynomial regression diagram (Figs. 11I–N). All types of facial expressions display a peak frequency at the end of the second trimester, except in isolated eye blinking, which increases at

the beginning of 24th week. At the beginning of the third trimester, the fetuses display decreasing or stagnant incidence of fetal facial expression. However, all types of head movements and hand to body contact movements indicated a decrease in frequency from the beginning of the second trimester to the end of the third trimester. This longitudinal study establishes reference ranges with GA for suggestible used fetal neurobehavioral development parameters in respected number of normal singleton pregnancies. Standard of movement pattern and facial expression pattern curves are constructed through all the trimesters of pregnancy. Results from Yigiter et al. are similar to that study, as they found a significant correlation between all head movements and hand to body contact patterns during the second and third trimesters except for head anteflexion, which did not show a significant change during the second half of pregnancy (22). It has also been suggested that there is a tendency toward decreased frequency of observed facial expressions and

movement patterns with increasing GA (4). All types of facial expressions display a peak frequency at the end of the second trimester, except in isolated eye blinking, which increases at the beginning of 24th week (4).

The Third Trimester

During the second half of pregnancy, motor behavior becomes increasingly frequent and variable. Patrick and colleagues ultrasonically studied fetal stretching and rolling movements during the last 10 weeks of pregnancy and found that fetuses on average made 31 gross fetal body movements per hour that accounted for 10.2% of time (29). In a behavioral study of 20 healthy preterm infants (GA from 28 to 34 weeks), an obvious developmental improvement in orienting responses and in motor performance was assessed (29). Prechtl and colleagues showed that the development was intraindividually characteristic and consistent, but interindividually variable (30). In short, a rich

Figure 12 Fetal face depicted by 3D ultrasound with details and facial expression.

variety of fetal and premature movements has been described and it has been shown that the repertoire of fetal movements consists exclusively of motor patterns that can also be observed postnatally and that there is a high degree of continuity of behavior before and after birth. However, the newborn's behavioral repertoire rapidly expands with patterns never observed in the fetus, such as the Moro response. Significant developmental changes in specific movement patterns during the last trimester of pregnancy are in EMs: isolated EM was observed since the 16th week of gestation and rapid eye movements (REMs) since the 19th week (31).

The parameters that could be detected and analyzed during the third trimester are fetal heart rate (FHR) pattern, and eye and body movements (1). The association of these movements increases steadily, and in the last weeks of pregnancy, fetal behavior can almost completely be described in terms of behavioral states, which are stable over time and recur repeatedly, not only in the same infant, but also in similar forms in all infants (32–34). The concept of behavioral states has been used as a descriptive categorization of behavior, and also as an explanatory concept in which states are considered to reflect particular modes of nervous activity that modify the responsiveness of the infant (32).

By term, normal number of generalized movements per hour was found to be approximately 31 with the longest period between movements ranging from 50 to 75 minutes (7). This reduction is considered as a result of cerebral maturation processes, rather than a consequence of the decrease in the amniotic fluid volume (AFV). Simultaneously, with the decrease in the number of generalized movements, an increase in the facial movements, including opening or closing of the jaw, swallowing, and chewing can be observed. These movements can be seen mostly in the periods of absence of generalized movements and that pattern is considered to be the reflection of the normal neurologic development of the fetus (7). However, the changes not only in the quantity of

movements, but also in their quality are shown to be the result of maturational processes.

The incorporation of 3D-US technology into clinical practice has resulted in remarkable progress in visualization and anatomic examination of the fetal face. 4D-US, in turn, provided for the first time an opportunity to evaluate subtle fetal facial expressions, which can be used to understand fetal behavior (35). The 4D-US has additional advantages in studying fetal activity in the surface-rendered mode and is particularly superior for fast fetal movements. Because of its curvature and small anatomic details, the fetal face can be visualized and analyzed only to a limited extent with 2D-US (Fig. 12) (5).

The entire face cannot be seen on a single 2D-US image, but 3D-US allows spatial reconstruction of the fetal face and simultaneous visualization of all facial structures such as the fetal nose, eyebrows, mouth, and eyelids. The standardized image display helps sonologists to understand fetal anatomy better and to communicate complex observations to both parents and less experienced observers. This technique does not replace conventional real-time 2D-US imaging, but rather supplements it. The 3D-US requires an investment of additional time in each case; therefore, it is predominately used, presently in conjunction with 2D-US, as a problem-solving tool.

Although facial movements, which are controlled by V and VII cranial nerves, appear around 10 and 11 weeks, the exact onset of facial expressions has not been determined and it is still unclear whether their appearance is GA related (35). The possibility of studying such subtle movements might open a new area of investigation.

Simultaneously, with the decrease in the number of GMs, an increase in facial movements, including opening or closing of the mouth and swallowing, can be observed. This pattern is considered to be a reflection of the normal neurologic development of the fetus. An important diagnostic aim of the observation of facial expression is prenatal diagnosis of facial paresis. The criterion for the diagnosis is asymmetric

facial movement and detection of the movement is limited to only one side of the face. Unfortunately, during the relaxed phase, it is not possible to evaluate the status of the facial nerve. Therefore, during the active phase, the fetus should be scanned by 4D-US. Because the origin of facial expression can be influenced by external forces, before the final diagnosis, examiners should be aware of this pitfall. For example, force of the fetal hand can alter the facial expression on one side of the face, causing asymmetry. This kind of asymmetry, however, should be differentiated from pathologic features such as unilateral facial paresis (35).

Zagreb group evaluated fetal behavioral patterns in the third trimester between 30 and 33 weeks of gestation in 10 gravidas (3). The incidence of eyelid movements ranged between 4 and 20 with a median value of 17, mouthing movements ranged between 2 and 19 (Fig. 13) with a median value of 12, and

mouth and eyelid movements ranged between 0 and 13 with a median value of 5. The incidence of pure mouth movement such as mouth opening ranged between 4 and 13 with a median of 5, tongue expulsion (Fig. 14) ranged between 0 and 2 with a median of 2, yawning ranged between 0 and 2 with a median of 1, and pouting ranged between 0 and 9 with a median of 3.

The incidence of facial expressions such as smiling ranged between 2 and 7 with a median of 2, and scowling between 2 and 4 with a median of 2. It is evident that eyelid and mouthing movements dominate at this GA (3). Pure mouth movements such as mouth opening, tongue expulsion, yawning, and pouting are present, but at a significantly lower incidence. Facial expressions such as smiling (Fig. 15) and scowling can be observed. Surface-rendered images that were used in this study depict the entire face and the relationship

Figure 13 The 3D surface-rendering mode of the fetal mouthing in the third trimester. Mouthing movements dominate at this gestational age.

Figure 14 The 3D surface-rendering mode of the fetal tongue expulsion in the third trimester.

between facial structures such as the nostrils, opened or closed eyelids, and mouth on a single image. Furthermore, depiction and observation of the orbital region and the status of fetal eyelids can be easily performed by this mode. However, EM cannot be registered because of the character of 4D-US that allows visualization exclusively of superficial structures such as the eyelids. Simultaneous visualization of EM and mouthing can therefore not be achieved. The focus of interest in that study was the analysis of eyelid movements and mouthing both separately and together. Since there is a relationship between mouthing and non-REMs, the group of authors hypothesized that non-REM phases correlate with closed eyes and mouthing phenomenon, and that this pattern can be indirectly determined by 4D-US. Using 3D-US it was not possible to determine the beginning of mouth opening or smiling or the beginning of mouth opening, mouthing, or yawning. Therefore, 3D-US is not suitable for the observation of facial expression. Furthermore, as well as the duration of single facial movement or expression, complex facial movements such as the simultaneous movement of the two facial organs—mouth and eyelids—can be depicted. Mouthing, mouth opening, and yawning simultaneous with eyelid opening can thus be seen only using 4D-US.

The next study by this team showed the ability of 4D sonography to depict different facial expressions and grimacing (Fig. 16), which might represent fetal awareness (36). This was based on the consideration that “the face predicts the brain” because of the same embryologic origin for many facial and encephalic structures (37). Very early in pregnancy fetuses are reactive to stimuli, but the reaction does not provide any evidence that the fetus actually experienced the stimulus. It has been shown that noxious stimuli can initiate physiologic, hormonal, and metabolic responses, but these neither imply nor preclude suffering, pain, or awareness. Is it the facial expressions of the fetus that can help to understand what the fetus would like to communicate? We can see on the fetal face whether it is satisfied or unhappy, smiling or worried, self-confident or uncertain, but it is questionable whether the expression of the fetal face predicts its normal neurologic development. Whether the fetal face is an “organ that expresses awareness” with very complex functions is still questionable, because we need more scientific confirmation of what constitutes fetal awareness.

The study included 99 patients, 40 of whom were in the second and 59 in the third trimesters of pregnancy. Positive observation has been defined as a facial expression or

Figure 15 Smiling fetus (3D ultrasonography).

Figure 16 The 3D surface-rendering mode of the fetal grimacing in the third trimester. This movement is shown to have the continuity in its quantity and quality in the neonatal period.

movement noted at least once during the observation of one examinee. A tendency toward increased frequency of observed facial expressions with increasing GA was noted, but the difference between the second- and third-trimester fetuses was not significant due to the low frequency of movements. As at that time the images were only near real time, they were able to study only the quantity and not the quality of facial movement patterns with the possibility that some very subtle facial movements may have been missed.

In the recent study by Yan and his group, 10 healthy fetuses aged from 28 to 34 weeks were recorded continuously for 15 minutes with a 4D ultrasonographic machine, and the occurrence rates of blinking, mouthing, yawning, tongue expulsion, smiling, scowling, and sucking were evaluated (38). As in previous reports, mouthing was found to be the most active facial expression during this gestational period (3,36). However, the frequency of blinking was lower in this study. This could be due to the differences in the characteristics of the samples recruited and differences in interpreting the definition of each facial expression.

During the last trimester of pregnancy, significant developmental changes in specific movement patterns can be observed. Isolated EMs can be registered from 16 gestational weeks onward and REMs from 19 weeks (39). The EM patterns begin to consolidate at 24 to 26 weeks of gestation, and the periods of EMs begin to alternate with non-eye movement periods (NEM). During the last 10 weeks of gestation, both switching and maintaining mechanisms responsible for this ultradian rhythms mature, and constant mean values of duration of EM and NEM periods are achieved by 37 to 38 weeks. At that time, EM and NEM lasted 27 to 29 and 23 to 24 minutes respectively, which is similar to the values in the neonate (40). From 33 weeks onward, both REM pattern and slow rolling movement pattern can be registered, and the periods of REM alternate with periods of NEM. At 36 to 38 weeks of gestation, they become integrated with other parameters of fetal activity, such as heart rate and fetal movements, into organized and coherent behavioral states (41,42). This indicates that the pontine and thalamocortical connection area neurons start functioning at that time. Regular mouthing concurred closely with the non-REM period from 35 weeks to term, whereas random mouthing movement was observed predominantly during the EM period and was unrelated to the advance of GA (3).

Fetal Behavior as an Indicator of Fetal Brain Impairment

The integrity of fetal nervous system could be assessed at least by two available methods. The first is assessment of previously described behavioral states, and the second is the qualitative assessment of GMs (43). Maturation of behavioral states was shown to be disturbed in risk pregnancies, like pregnancies with intrauterine growth restriction (IUGR), diabetes mellitus, or alcohol consumption. Even maternal emotions, like anxiety, have influence on the quantitative distribution of fetal behavioral states. The drawback is the unspecific nature of these changes in development limiting the clinical significance for predicting later impairment, which is in agreement with the findings on abnormal states in the neonate. Qualitative and quantitative changes of the state variables are unspecific sign of neural dysfunction and poor basis for prediction of later

neurologic outcome. State assessment can be used as an indicator of an unspecific developmental delay. Qualitative assessment of GMs was underestimated for a long time due to the “subjectivity” of method that includes the observation of fetal movements. For many years, the interest of obstetricians was focused on the quantity of fetal movements, which was considered as an indicator of fetal well-being. Later studies on the subject have shown that movement counts are a poor indicator of brain damage, mainly because the great intra- and interindividual differences and the large overlap between normal and abnormal, which makes this method clinically useless. On the other hand, changes in the elegance and fluency, as well as the variability and fluctuation of intensity and speed of motor performances, were shown to be prominent in the sick preterm infants. It became evident that the qualitative changes in motor patterns of both the fetus and the neonate precede quantitative changes when the integrity of the nervous system is impaired. It must be admitted that it is more difficult to objectify complex qualitative changes than it is simply to count certain events when they occur, but the Gestalt perception is an excellent method for dealing with such phenomenon. Important step is video recording of movements of sufficient length to make a selection of several movements from one recording session. The observed GMs are diagnosed as normal if the movements are complex, including neck, trunk, and limb movements in a variable sequence, and are fluent and wax and wane in their intensity. GMs are selected for judgment only if they last for 20 seconds or longer. If the GMs are monotonous, have less complexity, and are repetitive in pattern, they are judged as abnormal and as being of “poor repertoire.” Other abnormal patterns are the “cramped-synchronized” type, when the movements occur in block with almost simultaneous muscle contraction and relaxation. Besides that movements may occur in a jerky and exaggerated manner and in chaotic order. If the movements last very shortly and, hence, they are difficult to be judged, then we speak of “hypokinesia.” Several studies employing this new assessment have been carried out and they showed that the early normal or abnormal findings of the GM quality are highly predictive for later outcome (43,44).

Assessment of GMs is based on the concept of ontogenetic adaptation corresponding to the development of human organism, which is during each developmental stage adapted to the internal and external requirements. Prechtl stated that spontaneous motility, as the expression of spontaneous neural activity, is a marker of brain proper or disturbed function (7,9). The observation of the unstimulated fetus or infant, which is the result of spontaneous behavior without sensory stimulation, is the best method to assess its CNS capacity. All endogenously generated movement patterns from an unstimulated CNS could be observed as early as from the 7 to 8 weeks of postmenstrual age, with a reach repertoire of movements developing within the next 2 or 3 weeks, continuing to be present for 5 to 6 months postnatally.

The identification of “CNS depression” during fetal life is based on pre-competences (opening of the eyes, variety of facial expressions), primary reflexes (rhythmical bursts in the sucking pattern), and quality of GMs (44–46). The addition of cranial signs (such as insufficient head growth and overlapping sutures) to neurologic signs could be a valuable complement

(44,45). Moreover, the identification of dynamic and static patterns of the symptoms may be as helpful to date the insult as it is postnatally: the more stable the signs, the more precise is the timing of the insult. In the presence of neurologic signs in fetuses, the next step is to proceed to the clinical synthesis. In order to do so, all examinees should be followed till the age of 2 years, when their categorization to disabling or nondisabling cerebral palsy (CP) can be possible, based on clinical neurologic findings and presence or absence of the ability to walk.

Obstetricians would have a great benefit if it were possible to assess the condition of the fetal nervous system especially due to the fact that in many cases obstetricians are held responsible for brain damage in neonates, regardless of a growing pool of evidence that most of such damages are consequences of prenatal complications. Even after the fetal brain anatomy can be visualized by ultrasound and the development of the fetal brain is well understood, not much is known about the functional development of the fetal CNS. In other words, the fetal CNS is not accessible. It is possible only to ascertain the output of the CNS, that is, "fetal behavior." Observation of fetal behavior provides a direct assessment of the most important human organ. It is possible to look closely at the functioning of the CNS and the brain. Prenatal motility is considered not only to reflect the developing nervous system but also to involve functional and maturational properties of fetal hemodynamic and the muscular systems (8). Prechtl and his coworkers have explored spontaneous motility during human development (43). They introduced the concept of ontogenic adaptation, meaning that during each developmental stage, the functional organization has to take into account internal and external requirements. Any fetal brain damage will interfere with endogenous motor activity. Therefore, spontaneous movements, as an expression of neural activity, could be used as a marker for fetal brain status. Consequently, the observation of the unstimulated fetus or infant should contribute significantly to the assessment of CNS function. Even after delivery, behavioral patterns frequently provide the most useful indicators of brain function in spite of having extending access to neurologic, physiologic, and pharmacologic measures (8). This remarkable continuity of endogenously generated activity from prenatal to postnatal life may allow identifying those fetuses and infants with emerging neurologic impairment.

During the 9 months of gestation, the repertoire of fetal activities constantly expands, correlating precisely with structural development of the CNS (19). Major developmental events, such as the establishment of neural connections in the different regions of the brain, are accompanied by the occurrence of new patterns of fetal activity or with the transformation of the existing patterns. The organization of behavioral states during the final weeks of pregnancy shows that the connection between cerebral cortex and periphery is established and that the cerebral cortex takes control over fetal activity. This also indicates the ability of the fetus to perceive and process external signals. Furthermore, the latest results indicate that even higher brain functions, such as learning, develop in utero during the last weeks of gestation (19).

The major problem with the study of fetal behavior is that it is very time consuming and not enough functional for routine

clinical practice. The question of subjectivity should be overcome using recording of information. Nevertheless, there is no other possibility of assessing the function of the CNS in utero, and this is needed for the understanding of the hidden information in the neurodevelopmental pathways of the fetal CNS. Only if normal behavior is fairly understood, it is possible to identify and to perceive abnormal behavior before birth (15,47).

First reports on fetal behavior obviously suggested that these studies should be standardized as much as possible. An objective analysis with strict application techniques and the use of valid reference ranges appropriate for the GA are essential (1). Without such standardization, comparisons with former or future measurements of patients and comparable studies cannot be made. In order to achieve this goal, the Zagreb group published the first study, which described the 4D sonographic techniques used for obtaining longitudinal standard parameters of fetal neurologic development in all trimesters of a normal pregnancy (4). Measurement of 7 parameters in the first trimester and 11 parameters in the second and third trimesters correlated with GA. Those parameters have been followed longitudinally through all trimesters and showed increasing frequency of fetal movements during the first trimester. A tendency toward decreased frequency of facial expressions and movement patterns with increasing GA from second to third trimesters has been confirmed (4).

Despite the long-standing conclusion that it is possible to make valid conclusion about brain function from observed, no generalized antenatal behavior screening has been developed to identify fetuses that may have CNS defects. Recent study from Morokuma tried to produce screening test that would be less time consuming and in that way cost effective as compared with their previous study (48). They devised a brief ultrasound examination to distinguish fetuses with compromised CNS function from the general population and evaluated it with their study (49). The study design compared findings on five behavioral patterns obtained by retrospectively reviewing the ultrasound examinations of 5 fetuses that had abnormal behavior with prospectively obtained findings of 29 normal fetuses. Median time for brief examination criteria was 50 minutes (range 30–60 minutes) with the only case undetectable by this brief ultrasound examination had an EM period significantly longer than the normal upper limit.

Improvements in technology and procedures that provide direct access to the fetus in utero are generating the impetus for prenatal developmental research to move beyond the simple documentation that behavioral abnormalities during pregnancy can produce effects that are evident in their offspring after birth. Rather, we see a growing need for developmental researchers to focus attention on how prenatal events affect the fetus, its behavior, and its relationship with environmental conditions in utero. Investigation of behavioral potentials in the fetus will promote understanding of the mechanisms of normal and abnormal development that lead to predictable behavioral outcomes after birth. In other words, behavioral study of the fetus will be necessary to understand the origins of motor and sensory capabilities of infants and the mechanisms of altered developmental outcomes (45).

Awareness of changing risk, and the potential for significant neurodevelopmental problem, is an underlying principle of

Figure 17 Nuchal cord around the (A) neck and (B) eyes.

perinatal medicine. Unfortunate neurologic outcomes often result from a delay in recognizing or responding to CNS developing risk. This factor may necessitate the timely referral of individuals to an appropriately staffed facility. The timing of referral can be critical, but there are obvious difficulties that may result in the decision to refer being considered unnecessary or, on the other hand, too late.

In the following chapter, we review the literature on the behavior in the high-risk pregnancies for CP that were defined according to our previous study (50,51). Although we were aware that major prenatal pathologies associated with CP are prematurity, antepartum hemorrhage, complications of multiple pregnancy, genetic disorders, intrauterine infection, IUGR, multiple congenital anomalies, maternal diseases (hypothyroidism, diabetes, drug abuse, severe pre-eclampsia, viral illness), placental pathology, tight nuchal cord (Fig. 17), fetal hemorrhage, and fetal rhesus disease, we also included prenatal history of neuromuscular disease, which can adversely affect fetal movements and their inadequate interpretation (52). Main focus was on maternal pathologic conditions, while fetal behavior in multiple pregnancies is described in detail elsewhere in the book.

Fetal Behavior in Pregnancies Complicated by Maternal Diabetes Mellitus Type I

Among previously mentioned risk states for disturbed fetal behavior and motility, one of the most investigated is maternal diabetes mellitus, mostly type I. Those pregnancies were shown to be often complicated by early fetal growth delay and congenital malformations that frequently involve the nervous system. Both abnormal embryogenesis and early growth restriction are suggested to shear the common mechanism. Main findings on the subject are given in Table 1.

The new findings were made when the emergence of frequently occurring movement patterns was plotted against fetal crown-rump length, which is usually smaller in diabetic pregnancy, and there was still a general delay in comparison with the control group. It was concluded that delay in motor

development therefore does not run completely parallel with the delay in growth, which indicates the possible existence of a specific diabetes-related influence on the functional development of the embryonic and fetal nervous system. Hyperglycemia was considered to be responsible, as the delay in the emergence of fetal GMs was most profound in the women whose periconceptional quality of glucose control was poor. When investigators looked into the developmental trends in the occurrence of movement patterns in diabetic pregnancies, they found the similarity to those in the control fetuses, with the exception of startles. It was found that before the 9th week of gestation, fetal movements occurred less frequently, which was related to the quality of maternal glucose control. After 12 weeks, the overall incidence was higher than that in the control group, due to an increase in the incidence of breathing movements that was generally slower than that in the control group (57).

For further investigation of the impact of early growth delay on subsequent growth (birth weight) and functional development near term (organizational level of fetal behavioral states), the same group investigated 21 and 10 fetuses of diabetic women, respectively (59). They found no relationship between the degree of early growth delay and birth weight, while the mean growth delay per fetus in early diabetic pregnancy was negatively correlated with the occurrence of no coincidence between behavioral state parameters at 36 weeks. Those results have shown that disorders occurring in early life may underlie abnormal functional development in later life, whereas (catch up) growth is mainly determined during the second half of pregnancy. These results corroborate their following findings in the fetuses at 32 to 38 weeks of gestation in type I diabetic pregnancy (60).

To assess the effect of type I diabetes on the quality of GMs, Kainer and coworkers analyzed GMs longitudinally in 12 human fetuses at 2-week intervals from 16 weeks until delivery (63). All fetuses showed normal GMs at 16 weeks, but from 20 weeks onward until delivery five fetuses developed abnormal GMs. The diabetes optimality score was significantly

lower in the group with abnormal GMs whereas the pregnancy optimality score did not differ between fetuses with normal and abnormal GMs. These results indicate that type I diabetes can have a negative impact on prenatally observed GMs and that consistently normal GMs indicate normal neurodevelopmental outcome at 10 months. Although it is the very important observation on the effect of type I diabetes on the quality of GMs, relatively small number of observed fetuses cannot be denied.

To synthesize we can say that all mentioned published studies confirmed at least slight impact of maternal diabetes mellitus on fetal and even embryonic movements and behavior. The delay of emergence of spontaneous motility was shown to be independent on growth delay and changes of motility could not be explained by the glycemic control of the mother. Disturbed organization of behavioral states and GMs in fetuses in pregnancies complicated by the diabetes mellitus demand further investigation by the 3D and 4D technologies that will clarify the neurobehavioral changes in these fetuses.

Fetal Behavior in Pregnancies Complicated by IUGR

Studies dealing with fetal behavior in IUGR pregnancies are presented in Table 2.

One of the first studies on the impact of growth restriction on the fetal behavior focused on fetal breathing and on the course of behavioral state (67). To achieve that goal, Van Vliet and his group used real-time ultrasound scanners to detect

fetal eye, body, and breathing movements, and the FHR of 12 growth-retarded fetuses between 36 and 40 weeks of gestation. The mean incidence of fetal breathing was greater during periods of fetal activity (body and eye movements present, greater heart rate variability) than during quiescence (body and eye movements absent, narrowed heart rate variability) at all GAs studied in both low-risk and growth-retarded fetuses. During periods when one of the state variables was in its active condition while the other two were quiet, or the reverse, the incidence of fetal breathing was intermediate between those found when all three state variables were in agreement. After behavioral states had developed, at 38 and 40 weeks, the mean incidence of fetal breathing in the low-risk fetuses was greater during active states than during the quiescence. There was no apparent increase in the degree of linkage between fetal breathing and other expressions of fetal activity after the emergence of behavioral states (67). In another study by the same group, behavioral state observations were carried out on 12 fetuses, which subsequently had birth weights below the 10th percentile (68). Their GAs at the time of study ranged from 32 to 40 weeks. Real-time ultrasound scanning was used to detect fetal body and eye movements, and the FHR was continuously recorded using a clinical fetal monitor. The appearance of states seemed to be delayed in the growth-restricted fetuses since states were present in only three of eight growth-restricted fetuses studied at 40 weeks. Also at 40 weeks, the proportion of discordant association of the state variables

was increased in the growth-restricted fetuses as compared with the control. There were no consistent differences between the two groups in the occurrence of defined combinations of parameters of the state variables at earlier ages. The results from this study showed that the growth-restricted fetuses have impaired quality and quantity of somatic motility in comparison with low-risk fetuses of equivalent GA. These observations suggest that some aspects of CNS function are disturbed in growth-retarded fetuses, even in the absence of fetal distress (68).

The implementation of 4D sonography was necessary to find out whether the quantity of fetal facial expression and quality of body movements can be used as an additional diagnostic criterion for prenatal brain impairment in fetuses with growth restriction. For that purpose, a prospective study was conducted in 50 pregnant women with a growth-restricted fetus and in 50 uncomplicated healthy women in the third trimester of pregnancy (73). The 4D ultrasound observation was specially designed to assess whether functional brain impairment and fetal growth restriction had prenatally occurred by the utilization of several behavioral patterns. The results showed that the median value of all movement patterns in the normal fetuses differed from fetuses with IUGR. Statistical evaluation revealed significant differences in the distribution of the movements between these groups. A tendency that IUGR fetuses have less behavioral activity than normal fetuses was noted in all observed movement patterns. Correlation reached statistical significance between normal and IUGR fetuses in the third trimester in hand to head, hand to face, and head retroflexion. Statistically significant differences could be shown in the distribution of the median values of observation over the five qualitative categories of head and hand movements. These recent data on IUGR fetuses obtained by 4D sonography are stimulating and might result in a more effective strategy to assess development before birth and may encourage future use of 4D ultrasound for quantitative and qualitative assessment of fetal behavior as possible indicators of the neurologic condition in IUGR fetuses (73).

Fetal body movements and breathing movements as a variables of fetal biophysical profile (BPP) have been shown to be predictable of impending fetal infection in patients with premature rupture of the membranes (74) (Table 3).

Some viral and bacterial pathogens have been shown to influence fetal motility. For example, transplacental infection with coxsackie B3 confirmed by molecular techniques resulted in severe reduction of fetal movements at the 27th week detected by prenatal 2D ultrasound. Late onset of fetal akinesia deformation sequence with mild arthrogryposis was the finding at fetal autopsy following interruption of the pregnancy (75). *Listeria monocytogenes* has been increasingly

recognized as a cause of intrauterine sepsis with associated perinatal wastage. The most common presentations in pregnancy include premature labor, an influenza-like illness, and reduced fetal movements (76).

Intraamniotic infections often result in preterm premature rupture of membranes (PROM). In a prospective study, fetal behavior was observed in 41 cases complicated with PROM (77). The length of time and the number of fetal breathing and gross body movements were correlated with the amniotic fluid culture results. An episode of fetal activity (body movements and breathing movements) of greater than or equal to 30 seconds during 30 minutes of observation was associated with the absence of intraamniotic infection in 100% of the cases. On the other hand, the absence of fetal breathing movements and gross body movements of less than a 50-second duration during 30 minutes of observation was associated with positive amniotic fluid cultures in all cases. If an episode of fetal breathing movements was present but lasted less than 30 seconds and/or the total time of gross body movements was greater than 50 seconds, 64% of patients had an intraamniotic infection. The conclusion was that the breathing movements could be used as a predictor of intraamniotic infection. On the contrary, study by Del Valle and his group, which enrolled 68 women with the diagnosis of PROM, showed that the BPP with breathing movements included and the nonstress test (NST) are poor predictors of perinatal infectious complications (78).

To investigate the relation between AFV and fetal movements at less than 32 weeks of gestation as assessed by routine BPP, the study included 352 consecutive nonhypertensive, nondiabetic patients (79). The results revealed a significant correlation between decreased AFV and decreased fetal movements. Fetal presentation and GA were not significantly different between patients based on the score of fetal movements. The authors concluded that decreased AFV is associated with decreased fetal movements irrespective of fetal presentation or GA (79).

Nicotine was shown to have impact on fetal motility and there are recently published studies on fetal movement in early pregnancy that were qualitatively and quantitatively observed by ultrasound monitoring in women smokers and in controls (Table 4) (80).

The study included three groups of 20 pregnant women each: nonsmokers (group 1), smokers of an average of 10 cigarettes daily (group 2), and smokers of an average of >20 cigarettes daily (chronic smokers; group 3). The 2D US study was performed once during gestational weeks 10 to 20 by the then standard method of fetal movement monitoring: (i) quantitative measurement of global fetal movements qualitatively verified as brisk or sluggish, (ii) quantitative measurement

of isolated spontaneous head movements, (iii) quantitative measurement of isolated spontaneous arm movements, (iv) quantitative measurement of isolated spontaneous leg movements, and (v) M-mode measurement of FHR. The results showed that the ratio of brisk to sluggish fetal movements was higher in nonsmokers compared with smokers. The rate of isolated spontaneous head and arm movements and of the upper cerebral pattern (head and arm movements) was statistically significantly lower in group 3 as compared with groups 1 and 2, whereas no statistical significance was recorded in isolated spontaneous leg movements. The rate of fetal tachycardia was also significant in group 3, whereas tachyarrhythmia was recorded in seven children born to group 3 mothers. The described study of the effect of chronic tobacco hypoxia on the components of fetal behavior revealed a positive correlation between global and isolated fetal hypokinesia of the upper cerebral pattern, fetal tachycardia, and tachyarrhythmia in the group of mothers who were chronic smokers (80).

To determine the effects of maternal smoking on fetal spontaneous behavior and auditory processing, Cowperthwaite and coworkers examined 38 fetuses of smoking and nonsmoking mothers, stratified by GA and observed at

least 1 hour following smoking (81). Observations included spontaneous FHR and body movements (20 minutes) followed by a 2-minute audiotape of the mother reading a story while FHR and body movements were recorded. They found that the fetuses less than 37 weeks of GA of mothers who smoke throughout pregnancy have a delayed onset of response to the maternal voice, a subtle difference that may have implications for later language development for prematurely born infants.

The relationships between maternal blood pressure (BP) and fetal behavior were examined in hypertensive compared with normotensive women at 33 and 36 weeks of GA (79). As expected, maternal BP was negatively related to GA at birth and birth weight (82). On average, fetuses of hypertensive women were born 2 weeks earlier (38 weeks of GA) and 340 g lighter. Maternal systolic BP was negatively related to the number of spontaneous body movements observed on ultrasound scan over 20 minutes and the magnitude of the FHR acceleration elicited by a vibroacoustic stimulus. At 36 weeks of GA, vibroacoustic stimulation elicited differential responding with fetuses in the hypertensive compared with the normotensive group having fewer body movements, a lower magnitude of FHR acceleration, and a lack of cardiac-body

movement coupled responses. These findings suggest a relationship between maternal BP and fetal behavior and differential functional development of sensory-motor response systems, which need to be characterized in the subgroups of hypertensive disorders observed during pregnancy.

Recent meta-analyses were conducted on archival data of human fetal behavior to identify differential behavior among high-risk fetuses in pregnancies complicated by threatened preterm delivery, maternal hypertension, or diabetes compared with low-risk fetuses in uneventful pregnancies, delivering as healthy, full-term infants (83). There were no differences in spontaneous behaviors when scored using clinical criteria for the NST and BPP; however, there were differences in the magnitude of the behaviors measured in the tests. Developmental differences were observed between those threatening to deliver early and the fetuses of hypertensive and diabetic mothers. The latter two groups differed little from one another but differed from low-risk fetuses in their response to auditory stimulation. It was concluded that differences in

behavior among high-risk groups suggest that atypical fetal behaviors may represent adaptation to condition-specific insult rather than a generalized response to insult per se. The finding that high-risk fetuses showed atypical responses to auditory stimuli indicates a need to examine the relation between fetal auditory function and later language acquisition.

Behavior in Fetuses with Congenital Disorders

Although behavior of fetuses with congenital disorders has been investigated and published in many, mostly case report publications, systematic approach to the issue lacks mostly because of high diversity of disturbances. Although estimation of neurodevelopmental outcome of the fetuses based on the following studies could be possible, a direct precise prognosis is still not available during the prenatal period. The use of 4D US recording could provide more information about the quality of fetal movements leading to the better prediction of neuronal development.

De Vries conducted a literature search on motility in fetuses with congenital disorders. The review included 48 articles

Figure 19 Fetus with arthrogryposis—reduced movement pattern by 4D ultrasound.

describing motility of 104 fetuses (84). The author divided abnormal motility into two main subcategories: hypo- and hyperkinetic with posture affected in 40/60 hypokinetic and 4/44 hyperkinetic moving fetuses. The majority of the disorders resulted in an adverse outcome. Fourteen percent survived with a handicap, depending on the underlying disorder. The 16 disorders with hypokinetic motility had mainly an autosomal recessive etiology with no possibility of invasive prenatal diagnosis or conclusive sonographic structural anomalies, in contrast to the 17 disorders with hyperkinetic motility. Within the limitations of the studies, a deeper understanding of affected milestones in motor development can be obtained. The author concluded that broadening motor assessment procedures from quantitative to qualitative aspects, including the assessment of behavioral states, and emphasizing onset and continuity of motility before and after birth will enhance the reliability and predictive value of motility as a parameter in the assessment of fetal condition (84).

Ahmed and his group established a behavioral state profile in eight high-risk fetuses by 4D US recording (85). In the study, the authors tried to observe all the behavioral parameters that are related to CNS function. In anencephalic case and cephalocele case, they noticed excessive hypertonic movements, while fetuses affected by homocystinuria and Meckel–Gruber syndrome demonstrated hypotonia. The sequence of occurrence of behavioral parameters was clearly abnormal in those fetuses affected by anencephaly (Fig. 18) and cephalocele.

These findings fully agree with their previous case report on the behavior of an anencephalic fetus (51).

Normal quantity and quality of behavioral parameters were noted in fetuses affected by prune belly, diaphragmatic hernia, achondrogenesis (Fig. 19), and hydrothorax. The quality and quantity of fetal movement in the fetus affected by achondrogenesis were normal, but it was difficult to observe the movement of extremities due to abnormal fetal posture.

In conclusion, one can say that fetal behavior serves as a good indicator of impaired CNS development. Since the frequency of different neurologic disturbances united in a term of CP has not declined in spite all improvements in prenatal care, fetal behavior assessment could be of great help in neurologic assessment particularly of fetuses in high-risk pregnancies.

66 Umbilical artery doppler sonography for fetal surveillance: Principles and practice

Dev Maulik, David Mundy, and Timothy Bennett

INTRODUCTION

Antenatal fetal monitoring is an essential component of modern obstetric care in pregnancies at high risk for adverse perinatal outcomes. Technical and clinical advances during the past few decades have resulted in the development of several methods of antepartum fetal surveillance that include fetal heart rate (FHR) monitoring, ultrasound assessment of fetal biophysical status, and Doppler velocimetry of fetal and uteroplacental circulation. This chapter presents a general background of Doppler ultrasound for fetal surveillance with emphasis on an evidence-based approach for its clinical application. The review is focused on the Doppler of the umbilical artery (UA), as it is the only fetal surveillance tool that has shown clinical effectiveness in improving perinatal outcome. Extensively revised since the last edition of the book, this chapter presents the following aspects of Doppler fetal surveillance:

- A brief history of diagnostic Doppler ultrasound
- Principles of Doppler velocimetry
- Doppler velocimetry of the UA
- Other fetal surveillance tests
- Clinical effectiveness of Doppler velocimetry for fetal surveillance
- Guideline for the clinical application of the Doppler fetal surveillance

For a more comprehensive review of the various clinical and basic aspects of Doppler sonography in obstetrics, a dedicated text or reference book is recommended (1).

A BRIEF HISTORY OF DIAGNOSTIC DOPPLER ULTRASOUND

Doppler sonography is based upon the physical phenomenon of Doppler shift first described by Austrian mathematician and physicist Christian Andreas Doppler in 1841. Doppler first reported this phenomenon at a meeting of the Natural Sciences Section of the Royal Bohemian Society in Prague, a meeting with only five members of the society in attendance and a transcriber. His paper, entitled "On the Colored Light of the Double Stars and Certain Other Stars of the Heavens," was published in 1843 in the society's proceedings (2). To Doppler's disappointment, however, the paper was not enthusiastically received by the scientific community of his time, although his principle has been extensively used in science and technology since the beginning of the twentieth century.

The history of diagnostic Doppler ultrasound has been reviewed in greater detail elsewhere (3). The premier medical use of Doppler sonography occurred during the late 1950s. The use of Doppler sonography for the investigation of human fetal circulation was first reported by FitzGerald and Drumm

in 1977 (4). Maulik and coworkers further reported the feasibility of the Doppler ultrasound for fetal circulatory assessment (5). During the following years, many investigators used this technique to characterize most major fetal circulatory systems. In 1986, the National Institute of Child Health and Development organized a workshop that highlighted many issues pertaining to Doppler ultrasound measurement of maternal–fetal hemodynamics (6). These issues were also addressed by many investigators and discussed in several scientific societies around the world including the International Perinatal Doppler Society. For a decade and a half, the latter acted as a unique scientific forum dedicated to the obstetric applications of Doppler ultrasound and critically contributed to its introduction into the clinical practice through research and education. The diagnostic efficacy and clinical effectiveness of the Doppler technique has been extensively investigated. Of the various modalities of fetal surveillance, only the Doppler ultrasound of the UA has been shown to improve the perinatal outcome by randomized clinical trials (RCTs) and meta-analyses, and has now become a standard for fetal surveillance in most parts of the world.

PRINCIPLES OF DOPPLER VELOCIMETRY

Doppler Frequency Shift

When relative motion occurs between a source of wave transmission and an observer, the observed changes in the frequency of energy wave transmission is defined as the Doppler effect. The change in the frequency is called the Doppler frequency shift or just the Doppler shift:

$$f_d = f_t - f_r \quad \text{Equation (1)}$$

where f_d is the Doppler shift frequency, f_t is the transmitted frequency, and f_r is the received frequency. When the source and the observer move closer, the wavelength decreases and the frequency increases. Conversely, when the source and the observer move apart, the wavelength increases and the frequency decreases. The principle applies to all forms of energy wave propagation including sound. The utility of the Doppler effect originates from the fact that the shift in the frequency is proportional to the speed of movement between the source and the receiver and therefore can be used to assess this speed.

The phenomenon of the Doppler effect is observed when an ultrasound beam encounters a scatterer in motion. The scatterer acts first as a moving receiver and then as a moving source. This forms the basis for restating equation (1) as

$$f_d = 2f_t v/c f_r \quad \text{Equation (2)}$$

where f_d represents the Doppler frequency shift, f_t the frequency of the incident beam (transducer frequency),

v the velocity of the scatterer in a given direction, and c the propagation speed of sound in the medium. Note that the transmitted ultrasound undergoes double Doppler shift before returning to the receiving transducer, the scatterer acting first as a receiver and then as a transmitter. This accounts for the factor of 2 in the above equation. In blood circulation, millions of red cells act as moving scatterers of an incident ultrasound, which consequently will undergo frequency shift proportional to the speed of red cell movement and therefore to blood flow velocity.

When the incident beam incurs an angle (θ) to the direction of blood flow, the v in the Doppler equation is replaced by the component of the velocity in the direction of the flow obtained by the cosine of the angle ($\cos \theta$); (Fig. 1):

$$f_d = 2(f_t \cos \theta v) / c \quad \text{Equation (3)}$$

To determine the velocity of the scatterer, equation (3) can be rewritten as follows:

$$v = f_d c / 2 f_t \cos \theta \quad \text{Equation (4)}$$

Thus, if the angle of beam incidence and the Doppler shift are known, the velocity of blood flow is also known assuming that the transducer frequency and the velocity of sound in tissue remain relatively constant. The above equation forms the basis for the clinical application of the Doppler principle.

Circulatory Information from Doppler Shift

Doppler sonography can yield a variety of clinically useful hemodynamic information. This includes quantification of flow and study of the flow velocity waveform (Table 1). Volumetric flow can be measured by integrating the average velocity across the vascular lumen with the vascular cross-sectional area. In the fetus, the Doppler technique has been used to measure umbilical venous flow (7), descending aortic flow (8), and fetal cardiac output (9). The clinical utility of Doppler flow quantification has remained limited because of its systemic unreliability related to errors in determining the vascular cross-sectional area and the Doppler angle. Consequently, the main perinatal use for Doppler sonography has been the indirect assessment of downstream impedance by Doppler waveform analysis. However, several investigators have now improved the Doppler flow quantification method paving the way for its future potential clinical application (10). Current advances in Doppler and non-Doppler ultrasound methods for volumetric flow measurement have been recently reviewed (11).

Doppler Waveform Analysis

Doppler waveform analysis is usually based on the following characteristics of the maximum frequency shift envelope (Fig. 2): the peak systolic value (S), end-diastolic value (D), and the average value over the cardiac cycle (A). These three parameters have been used to develop indices describing the pulsatility of the Doppler waveform. A Doppler index is calculated as a ratio and is, therefore, virtually independent of the angle of insonation. Of the numerous indices, the pulsatility index (PI) (13), the resistance index (RI) (14), and the S/D ratio (15) are most commonly used in obstetric applications. Maulik and coinvestigators used the receiver

Figure 1 Graphic depiction of the principles of Doppler equation and the proportional relationship between the Doppler shift and the velocity of blood flow. Abbreviations: f_t , Doppler frequency shift; f_r , transmitted frequency; f_d , Doppler frequency shift; v , velocity of blood flow; θ , the angle of insonation between the ultrasound beam and the direction of flow; c , velocity of flow in tissue.

Presence of normal flow in expected location
Presence of flow in unexpected location
Absence of flow in expected location
Speed of blood flow
Direction of flow
Circulatory impedance in the arterial circulation
Volumetric flow
Disturbed hemodynamics, e.g., turbulent flow

Figure 2 Doppler indices estimated from the maximum frequency shift (MFS) envelope. Abbreviations: S, peak systolic frequency shift value of the envelope; D, end-diastolic frequency shift value of the envelope; A, average value of the envelope over one cardiac cycle, RI = (S-D)/S6; PI = (S-D)/A5; S/D ratio 7; D/A ratio 9. Source: From Ref. 9.

operating characteristic (ROC) technique (Fig. 3) to investigate the comparative efficacy of the umbilical arterial Doppler indices for predicting adverse perinatal outcome and showed that the RI had the best discriminatory ability when compared with the S/D ratio ($p < 0.05$), the PI ($p < 0.001$), and the D/A ratio ($p < 0.05$) (16). Although more comprehensive approaches to Doppler waveform analysis have been described (17,18), there is little evidence that these are superior to the traditional Doppler indices. The

hemodynamic, angiomorphic, and pathophysiologic justifications for Doppler waveform analysis are discussed below.

Hemodynamic Rationale of Doppler Waveform Analysis

Doppler waveform from an arterial source represents the arterial velocity waveform and is configured by both the upstream and downstream circulatory factors. Analysis of the waveform should, therefore, yield information on downstream impedance to flow. Obviously, this requires verification. Although the term “peripheral vascular resistance” has been traditionally used for describing opposition to flow in an arterial tree, it is applicable only to a steady non-pulsatile flow state. Opposition to flow in a pulsatile circulation is more accurately expressed by the concept of vascular impedance, which also includes the resistance. An integral component of this concept is the phenomenon of wave reflection in a vascular tree. Configuration of pressure and flow waves at a specific location results from the interaction of the forward propagating (orthograde) waves with the reflected backward propagating (retrograde) waves (19). The observed pressure waves, which are produced by the summation of orthograde and retrograde waves, show an “additive” effect; by contrast, the observed flow (or flow velocity) waves demonstrate a “subtractive” effect (Fig. 4). Wave reflections arise whenever there is a significant alteration or mismatching in vascular impedance in a circulation, and the arterial–arteriolar junctions serve as the main source of wave reflections in an arterial tree. Vasodilation leads to a fall and vasoconstriction to a rise in impedance and wave reflection.

The hemodynamic validation studies may be grouped as those relating to the peripheral resistance and those involving the impedance. However, as mentioned above, vascular impedance is the appropriate descriptor of opposition to flow in a pulsatile circulation. This was investigated by Downing and coworkers in a chronic lamb model and it was observed that a significant correlation exists between the PI and the impedance parameters, provided the reflex heart rate changes are suppressed. Evidently, the Doppler indices reflect changes in the downstream impedance (21). The greater the fetoplacental vascular impedance, the lower the end-diastolic flow in the UA and the higher the indices. A more comprehensive review of the hemodynamic interpretation of Doppler waveforms from an arterial system is available elsewhere (22).

Angiomorphologic Validation of the Doppler Indices

Several investigators have demonstrated that abnormal fetal placental angiogenesis is characterized by sparse, elongated, uncoiled, and less ramified terminal capillary loops as the major lesions in growth-restricted pregnancies with abnormal umbilical arterial Doppler (23,24). These observations suggest that aberrant fetoplacental angiogenesis results in an increase in impedance, which is associated with enhanced pressure and flow velocity wave reflections. The reflected flow velocity waves propagate retrogradely and change the shape of arterial flow velocity waves, which show decreased end-diastolic flow and increased pulsatility. Doppler insonation of the appropriate arterial tree identifies this circulatory phenomenon by demonstrating abnormal Doppler waveforms and indices.

Figure 3 Receiver operating characteristic curves of umbilical arterial Doppler indices. Data points are the measured values of indices. Note that the resistance index shows the most and the pulsatility index shows the least diagnostic efficacy. RI, S:D, D:A, PI. Source: From Ref. 12.

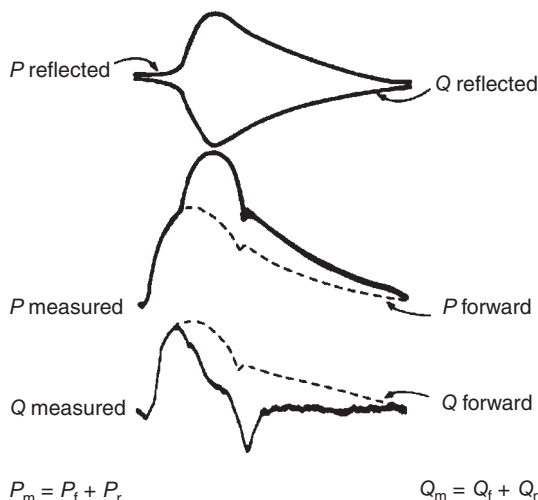

Figure 4 The influence of pulse wave reflections on ascending aortic pressure (P) and flow (Q) waveforms. Incident or forward (f) and backward or reflected (r) pressure and flow waves are summed to yield measured (m) pressure and flow waveforms. The forward pressure and flow waves are identical and so are the reflected waves except that the reflected wave form is inverted with impact to the reflected pressure wave. Source: From Ref. 20.

Pathophysiologic Rationale for Doppler Fetal Surveillance

Antepartum challenge to fetal well-being may arise from chronic nutritive and respiratory deprivation. A spectrum of obstetric complications, including fetal growth restriction (FGR) and hypertension, may expose the fetus to such risks. Although an immense amount of information is available on acute and subacute fetal respiratory deficit, the pathophysiologic mechanism of chronic fetal stress has been less clear. However, significant advances have been made recently providing considerable insight into the mechanisms of fetal

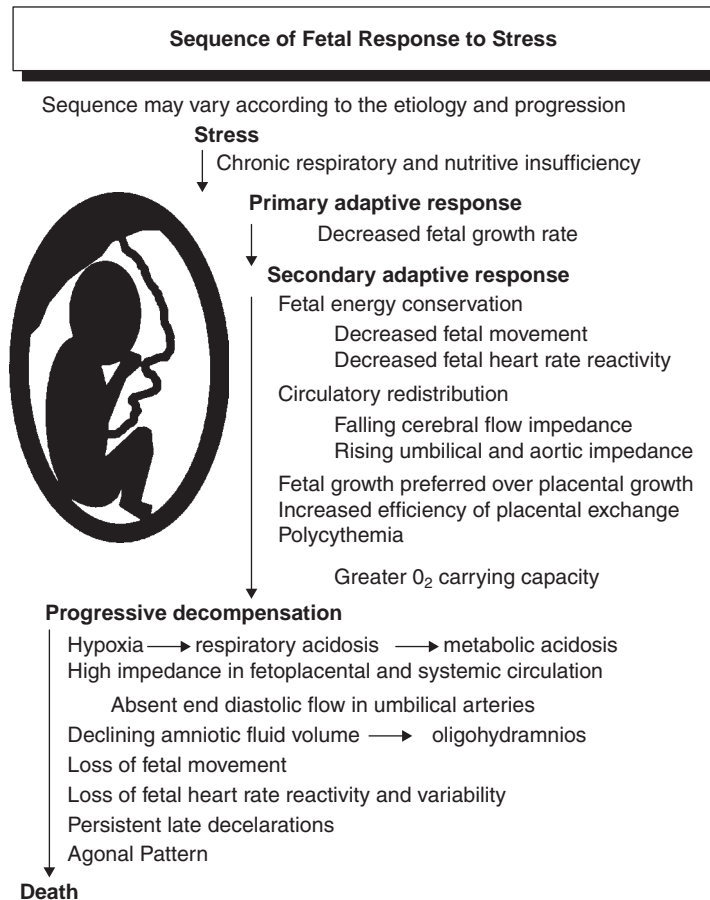

Figure 5 Summary of fetal sequential response to progressive stress. Note that the depicted sequence is an approximation and the actual course may vary depending on the characteristics of the chronic deprivation and the individual fetal ability to cope. Source: From Ref. 25.

compensation and decompensation. There is emerging evidence that, encountering sustained stress, the fetus appears to mobilize a spectrum of defensive responses that include preferential preservation of fetal growth over placental growth, changes in fetal movement pattern, and the eventual deceleration of the fetal growth rate (Fig. 5).

In the face of continuing deprivation, compensation gives way to decompensation. For example, growth-restricted human fetuses with abnormal UA waveforms have been shown to develop chronic hypoxia and acidosis. A critical component of fetal homeostatic response involves flow redistribution that favors perfusion of the vital organs (the brain, heart, and adrenals) at the expense of flow to muscle, viscera, skin, and other less critical tissues and organs (26). Underlying this phenomenon are the diverse changes in blood flow impedance in fetal regional circulations. Doppler velocimetry thus elucidates these circulatory changes associated with fetal compromise and allows perinatal prognostication. This constitutes the rationale for using Doppler ultrasound for fetal surveillance in complicated pregnancies.

DOPPLER VELOCIMETRY OF THE UA

Normative Data

The UA was the first fetal vessel to be evaluated by Doppler velocimetry and has since become the most widely investigated fetal circulation. Typically, Doppler interrogation of the umbilical arterial circulation is performed during fetal apnea

(see below). In our experience, the inter- and intra-observer variances of the S:D ratio and the RI, as determined by continuous-wave Doppler, were 9.8% and 11.1%, and 4% and 8%, respectively (27). In normal pregnancy, the umbilical arterial Doppler indices are affected by gestational age, FHR, fetal breathing, and the site of measurement in the cord.

Gestational Age

As pregnancy advances, umbilical arterial Doppler waveforms show a progressive rise in the end-diastolic velocity, which results in a concomitant fall in the pulsatility (Fig. 6). This trend is consistent with a gradual decline in the fetoplacental flow impedance with the advancing gestation (29). The Doppler indices reflect these changes in the waveform (Fig. 7).

FHR

A statistically significant effect of the heart rate on Doppler indices has been reported by a number of investigators (31). It has been shown that changes in the heart rate occur primarily due to alterations in the duration of the diastolic component of the cardiac cycle (32) and that the effect of the FHR may contribute to 15% to 18% of the variance of the Doppler indices (27). However, it is not certain that correcting the Doppler indices for FHR changes would improve the diagnostic efficacy of the indices and may not be clinically significant so long as the heart rate remains within the normal range.

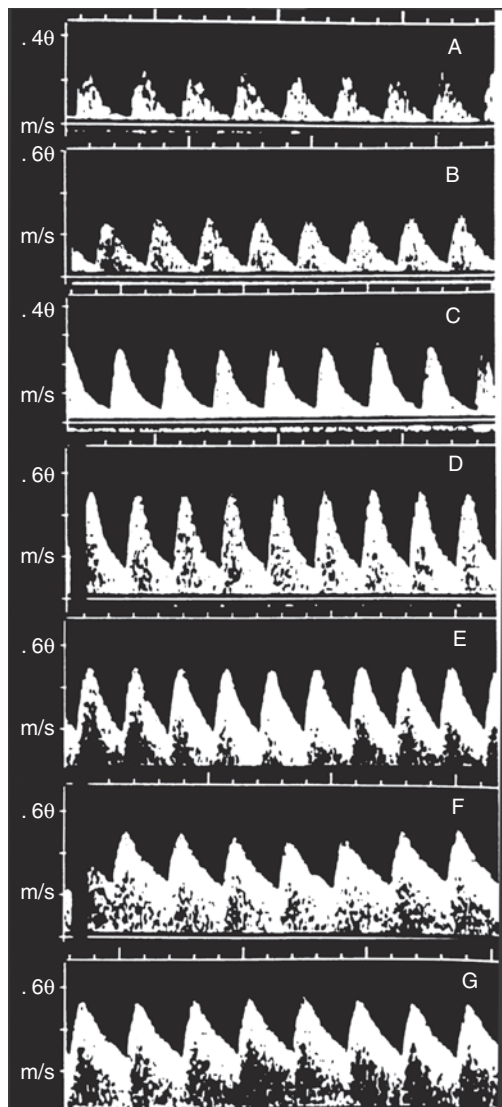

Figure 6 Gestational age effect on the umbilical arterial Doppler frequency shift waveforms. Panels are organized from the top to the bottom according to advancing gestation. Abbreviations: A, waveforms at 16 weeks; B, at 20 weeks; C, at 24 weeks; D, at 28 weeks; E, at 32 weeks; F, at 36 weeks; G, at 40 weeks. Note the progressive increase in the end-diastolic velocity and the concomitant fall in the pulsatility as gestation advances. Source: From Ref. 28.

Figure 7 Variation in the umbilical arterial resistance index (RI) at different stages of gestation. Source: From Ref. 30.

Fetal Breathing

Substantial changes in the intrathoracic pressure and central hemodynamics occur during fetal breathing, which produce dynamic variability in the umbilical arterial Doppler waveform and, therefore, in the Doppler indices. This severely compromises the utility of the Doppler indices during fetal breathing and provides the rationale for measuring the indices only during fetal apnea. However, the indices do not appear to be affected by fetal behavioral states (33).

Site of Doppler Interrogation

The location of the Doppler sampling site in the umbilical cord affects the Doppler waveform and therefore the Doppler indices, which are higher at the fetal than at the placental end of the cord (27).

Umbilical Arterial Doppler in FGR

FGR is associated with defective development of placental vascular systems. FGR and pre-eclampsia are associated with aberrant angiogenesis of fetoplacental arterial system. The efficacy of UA Doppler indices for detecting suboptimal fetal growth has shown to be variable and has been reviewed (Table 2) (34). This may be partly explained by the considerable amount of ambiguity that surrounds the use of the terms “FGR” and “small for gestational age (SGA).” It is well recognized that neither all growth-restricted fetuses are SGA, nor are all SGA infants growth compromised. Furthermore, being SGA does not necessarily mean a compromised outcome. It is apparent that not all FGR or SGA fetuses may suffer from in utero compromise in terms of asphyxia, which correlates better with absent end-diastolic velocity (AEDV) in the UA than with subnormal fetal abdominal circumference (<5th percentile) as measured by ultrasound (35). This issue, however, is apparently controversial and is further discussed in the next section. With regard to the various sonographic modalities for diagnosing FGR, the majority of studies have demonstrated that conventional fetal ultrasound biometry is more sensitive than umbilical arterial Doppler velocimetry (36). This should not be surprising as fetal size is expected to be better expressed by sonographic measurement of fetal dimensions than by Doppler velocimetry, which assesses the hemodynamic state; unless the latter is compromised, the Doppler indices will not change.

Umbilical Arterial Doppler Velocimetry and Antepartum Fetal Hypoxia-Asphyxia

The purpose of fetal surveillance is to detect fetal compromise from intrauterine hypoxia and asphyxia. Fetal homeostatic response to hypoxic and asphyxial challenge has been well described in animals (37). A central manifestation of this response is the flow redistribution that favors perfusion of the vital organs (the brain, the heart, and the adrenals) at the expense of less critical organs and tissues. This compensatory phenomenon provided the justification for investigating the efficacy of the Doppler velocimetry in identifying fetal hypoxia and asphyxia. Both clinical and animal experimental studies have been reported to address this issue.

Further insight may be obtained from experimental studies conducted in animal models. Many of the relevant findings in this area have been reviewed (38). It has been noted that in the

aorta of the fetal lamb, significant changes in the Doppler waveform occur only when the oxygen saturation declines to 10% to 15% or the fetal pH drops to <7.15 (39). Apparently, in an ovine fetus, hypoxia and acidosis may significantly affect umbilical and aortic velocity waveforms but only as a late phenomenon.

The association between the Doppler findings and fetal blood gases has been clinically investigated (35,40–47). These have been reviewed and are summarized in Table 3. Some investigators performed umbilical cord blood sampling at the time of elective cesarean section. Obviously, these studies are limited because blood gases measured in this manner may not reflect fetal acid–base status in utero. Others determined fetal blood gases by cordocentesis. Most studies used Doppler assessment of the UA, whereas one used aortic mean velocity and another added aortic and carotid Doppler assessment. All studies measured pH, most performed PO₂, and some also measured PCO₂ and lactate. Most investigators found a significant association between Doppler assessment of fetal circulation and fetal acid–base compromise. The response of fetal cerebral Doppler waveform presents another perspective on fetal hypoxia and acidosis. This is discussed later in the section dealing with fetal cerebral circulation.

Umbilical Arterial Doppler Velocimetry and Adverse Perinatal Outcome

The discriminatory efficacy of Doppler velocimetry for predicting perinatal outcome is briefly discussed in this

section. A fetal surveillance test may be used either as a diagnostic test for identifying the fetal compromise in high-risk pregnancies or as a screening test in a general obstetric population at low risk for fetal compromise. Both are presented below. In evaluating this information, we need to recognize the imprecision inherent in the available criteria for defining adverse perinatal outcome.

High-Risk Pregnancies

Several preliminary studies indicated that the Doppler indices might be powerful predictors of adverse perinatal outcome in complicated pregnancies. The diagnostic efficacy of umbilical arterial A/B (systolic, diastolic) ratio was investigated by Trudinger and coworkers in 170 high-risk patients (48). The parameters of fetal compromise included birth weight below the 10th percentile or an Apgar score of <7 at 5 minutes. The FHR was assessed in terms of reactivity and a modified Fischer score. The Doppler results revealed a sensitivity of 60%, a specificity of 85%, and a positive predictive value of 64%. For the FHR reactivity, the corresponding results were 17%, 97%, and 69%, respectively. The values for the Fischer score results were 36%, 88%, and 58%, respectively. In this study, the umbilical arterial S/D ratio appeared to be more sensitive but less specific than the electronic FHR monitoring techniques. Farmakides and others investigated the diagnostic efficacy of the nonstress test (NST) and of the umbilical arterial S/D ratio in 140 pregnancies (49). The measures of outcome included FGR, fetal distress, cesarean section for fetal distress, and

Table 2 Diagnostic Efficacy of Umbilical Arterial Doppler in Intrauterine Growth Retardation

Investigators	Doppler index	Prevalence rate (%)	Sensitivity (%)	Specificity (%)	Positive predictive value (%)

admission to the neonatal intensive care unit. Fetuses with a normal NST but abnormal S/D ratio had an outcome worse than those with an abnormal NST and a normal S/D ratio; however, those with both tests abnormal experienced the worst outcome.

Maulik and coworkers studied the diagnostic efficacy of the umbilical arterial S/D ratio for predicting adverse perinatal outcome in 350 high-risk pregnant patients utilizing the ROC technique and other traditional parameters of testing a test (50). The latter included sensitivity, specificity, and the predictive values. The kappa index was used to investigate the degree of agreement between the test and the outcome. The abnormal outcome parameters included SGA (<10th percentile), Apgar score at 5 minutes >7, fetal distress (late and severe variable decelerations, absent variability, fetal scalp pH <7.20), umbilical cord arterial pH <7.20, presence of thick meconium, and admission to neonatal intensive care unit for more than 48 hours. The study indicated that the ratio predicted the general adverse perinatal outcomes well; however, the diagnostic efficacy was better when the SGA infants were excluded (Table 4).

Low-Risk Pregnancies

Although the above findings are very encouraging, there are a few recent reports that demonstrate the inadequate efficacy of Doppler velocimetry of the UA as a screening test in a general obstetric population at a low risk for adverse perinatal outcome. In a large prospective study involving 2097 singleton pregnancies, Beattie and Dornan evaluated the capability of umbilical arterial Doppler indices (PI, A/B ratio, RI) to detect FGR and perinatal compromise (52). It was noted that the indices did not adequately predict any of the parameters of adverse perinatal outcome. The suboptimal efficacy of umbilical Doppler insonation in a low-risk population has been corroborated by others (53). Beattie and associates (54) performed Bayesian analysis of the above four studies to determine the posttest probability of an abnormal outcome for an individual patient. The posttest probabilities of an adverse

outcome was determined for an individual in terms of positive and negative likelihood ratios and are summarized in Table 5. It is evident that umbilical arterial Doppler velocimetry is of limited utility in a low-risk obstetric population. Clinical effectiveness of UA Doppler as a screening test in low-risk pregnancies is discussed later.

Significance of AEDV in the UA

Absence or reversal of end-diastolic flow velocity (Fig. 8) is associated with markedly adverse perinatal outcome including a high perinatal mortality rate with a higher prevalence of chromosomal abnormalities (especially trisomy 13, 18, and 21) and congenital anomalies. In the European multicenter study involving 245 cases with absent or reversed end-diastolic flow, the perinatal mortality was 28% and 96% to 98% of the infants required intensive care (55). In a review of 1126 cases of absent and reverse end-diastolic flow in the UA reported in the literature, it was observed that 170 per 1000 were stillborn and 280 per 1000 died during the neonatal period (Table 6) (56). Most deaths were due to obstetric complications such as growth restriction, prematurity, fetal anomalies, and aneuploidy. The perinatal mortality corrected for congenital malformations and chromosomal abnormalities was approximately 340 per 1000 births. This group demonstrates a high risk of chromosomal abnormalities with a predominance of trisomy 13, 18, and 21. There is also a high association between absent end-diastolic flow and a variety of congenital anomalies (Table 7). The frequency of absent end-diastolic flow is approximately 2% in well-defined high-risk pregnancies and may be as low as 0.3% in a general obstetric population.

In a prospective study involving pregnancies with FGR, Baschat and associates (58) investigated the relationship between fetal Doppler (UA, middle cerebral artery, and ductus venosus), biophysical profile score (BPP), and neurodevelopmental outcome at 2 years of age. Of the various fetal tests, only the UA reverse end-diastolic flow independently predicted poor neurodevelopment.

Table 4 Diagnostic Efficacy of Systolic/Diastolic Ratio Cutoff Point of 3.0 to Predict the Various Abnormal Outcomes

Category	Sensitivity	Specificity	Positive predictive value	Negative predictive value	Kappa index
General abnormal outcome	0.79	0.93	0.83	0.91	0.73
SGA only	0.75	0.77	0.32	0.95	0.33
Fetal distress, Apgar, pH, NICU	0.86	0.88	0.68	0.96	0.69

It has been observed that absent end-diastolic flow may improve, although often only transiently, and that weeks or more may elapse before the fetus may show additional evidence of compromise especially in preterm pregnancies. Thus, this finding is not necessarily an immediate indication for delivery in pregnancies before 34 weeks if fetal surveillance tests, such as the NST or biophysical profile, are reassuring (see “Guidelines for clinical practice” below).

OTHER FETAL SURVEILLANCE TESTS

Doppler sonography of ductus venosus, middle cerebral artery, and uterine artery has shown significant screening or diagnostic efficacy in high-risk pregnancies. However, their clinical effectiveness has not been adequately demonstrated by randomized trials. Ductus venosus Doppler does provide an additional tool for assessing serious fetal compromise (59).

The effectiveness of ductus venosus Doppler is under investigation at present in a multicenter randomized trial known as “Trial of Umbilical and Fetal Flow in Europe” (TRUFFLE), which is in the process of completion (60).

Current standard of practice for fetal monitoring includes antepartum FHR monitoring and fetal biophysical profile (BPP) or its modifications. The most common FHR monitoring technique is NST. The five-parameter BPP remains the main approach; however, modifications of this test have been proposed. Although diagnostic efficacy of NST and BPP has been demonstrated over the decades, there is insufficient evidence for their effectiveness in improving the outcome (61,62). Their usefulness has been shown in clinical experience and they remain an essential part of the standard of practice in fetal surveillance.

It may be more prudent to use multiple tests of fetal well-being in high-risk pregnancies. Fetal response to chronic stress progresses from compensation to decompensation and involves multiple systems. However, there is no consensus in clinical practice at present regarding the optimal choice or sequence of fetal testing.

CLINICAL EFFECTIVENESS OF DOPPLER VELOCIMETRY FOR FETAL SURVEILLANCE Randomized Trials

Introduction of a new diagnostic test involves sequential and often parallel developmental processes that transform the potential of a new technique into an effective diagnostic tool making a measurable improvement in the outcome. The steps include the demonstration of feasibility, association with disease processes, and diagnostic efficacy of the technique, but in the end it must be shown without bias that the technique improves the clinical outcome. This level of effectiveness can be demonstrated only by RCTs.

It is encouraging that at the time of the writing of this revised chapter, 20 RCTs on fetal Doppler ultrasound have

been published involving a total population of almost 25,000 women. A detailed review of these studies is available elsewhere (63) and summarized in Table 8. Additional trials were reported only in the abstract form or as presentations. As noted before, the multicenter randomized trial TRUFFLE study has completed the enrollment and is awaiting further analysis and eventual publication.

It is noteworthy that most trials performed in high-risk populations showed improved outcome. As observed previously, fetal Doppler ultrasound is the only fetal surveillance modality that is supported by this level of evidence of effectiveness. All the RCT studies evaluated umbilical arterial velocimetry; a few also used uterine arterial velocimetry. While most were conducted in high-risk patients, many were used in low-risk mothers. Considerable heterogeneity exists among the trials regarding the selection criteria, the study design, and the measures of pregnancy outcome. Most studies did not have any protocol of management based on the test results. Finally, none of the studies had adequate sample size and therefore lacked sufficient power. Depending on the choice of the outcome parameter and the effect size, it will probably require thousands of patients involving multiple centers to conduct such a study. It would be a tremendous

challenge to organize and obtain sufficient resources for a trial of this magnitude.

Several meta-analyses or systemic reviews of the Doppler trials have been conducted and are briefly summarized below.

Meta-analysis of Doppler Trials

Alfirevic and Neilson conducted a systematic review of 12 studies selected out of 20 identified studies and observed a 38% decline in the odds of perinatal mortality, which was significant (95% CI 15–55%) (65). Additional benefits of the Doppler usage included significant reductions in antenatal admissions, inductions of labor, and cesarean sections for fetal distress. Maulik briefly reported a meta-analysis that looked only at trials involving high-risk pregnancies where there were guidelines for the use of Doppler data in the clinical management (66). Only three studies were identified with a total of 1575 patients. An average of 80% reduction in fetal deaths without malformations was noted (odds ratio 0.19, 95% CI 0.06–0.63).

Westergaard and associates reported a meta-analysis that included only well-defined high-risk pregnancies complicated with FGR or hypertension. Of the 13 trials of Doppler in high-risk pregnancies, only six had defined FGR and/pregnancy hypertension as indications for surveillance. The analysis

showed that in the well-defined trials, there were significantly higher preventable perinatal deaths in the study than that in the control group (50% and 20% respectively) (67).

The most recent Cochrane review (68) included 18 completed trials encompassing over 10,000 patients. The review demonstrated a 29% decrease in perinatal mortality, which was significant with a risk ratio (RR) of 0.71 and a 95% CI of 0.53 to 0.98. This meant that 203 women needed to be treated for preventing one perinatal death. There were also less impressive but significant decreases in inductions of labor (RR 0.89, 95% CI 0.80–0.99) and cesarean deliveries (RR 0.90, 95% CI 0.84–0.97). No significant effects were noted in operative vaginal deliveries or Apgar scores <7 at 5 minutes.

In conclusion, most randomized trials of UA Doppler in high-risk pregnancies and their meta-analysis demonstrated a clinically and statistically significant improvement in the perinatal mortality. This constituted a level I evidence of effectiveness and that makes it unique among the other fetal surveillance tests.

Low-Risk Pregnancies

In contrast to high-risk pregnancies, trials of UA Doppler as a screening test in low-risk pregnancies did not show any improvement in pregnancy outcome. For example, a multicenter French randomized trial involving 4187 low-risk pregnant mothers failed to observe any improvements in the outcome with routine UA Doppler sonography between 28 and 34 weeks of gestation (69). Goffinet and coworkers conducted a systematic review of four trials selected out of seven studies and found no impact of UA Doppler on perinatal mortality in 11,451 low-risk pregnant mothers (odds ratio 0.51, 95% CI 0.20–1.29) (70). The Cochrane review of the topic in 2007 that included five trials with a total population of 14,338 women found no benefits of routine Doppler sonography in pregnancy (71). Moreover, the possibility of adverse outcome as suggested in two studies needs further investigation. In conclusion, routine Doppler ultrasound in low-risk pregnancies should be discouraged in clinical practice unless it is conducted under an approved experimental protocol.

Fetal Doppler in Multiple Pregnancy

The efficacy of Doppler velocimetry for identifying twin growth restriction has been variable with the sensitivity ranging from 29% to 82% (72). Fetal biometry remains the standard for the diagnosis of discordant twins. However, significant efficacy in predicting adverse perinatal outcome has been reported. Gaziano and associates (73) observed, in 94 twin pairs and 7 sets of triplets, that an abnormal pulsed Doppler velocimetry showed high correlation with adverse pregnancy events and that those with abnormal Doppler findings tended to be born 3 to 4 weeks earlier and to exhibit a greater number of stillbirths, malformations, and greater morbidity. Giles and coworkers (74) have suggested that the incorporation of the Doppler technique in the clinical management of twins may improve the perinatal outcome. A decline in corrected perinatal deaths from 42.1 in 1000 to 8.9 in 1000 was noted in their study. However, this was not a randomized trial.

A prospective randomized controlled multicenter trial of women with twin pregnancies was conducted that demonstrated

no improvement in the perinatal mortality with the addition of UA Doppler to the standard management (75). The perinatal mortality was 9/1000 live births in the Doppler group and 11/1000 live births in the control group. The study however was underpowered with a total of 526 women. The study did demonstrate that close monitoring in twin gestation is associated with a lower-than-expected fetal mortality in both the control and the Doppler groups.

Quintero and coworkers showed the prognostic value of Doppler of the UA, umbilical vein, and ductus venosus along with other ultrasound findings that constitute the staging of twin transfusion syndrome (76). The staging was proposed for individualizing the treatment options, especially the laser ablation procedure, and has become widely accepted in managing this complication.

In conclusion, fetal Doppler may be beneficial in managing multifetal gestations complicated with twin growth discordancy and those with twin transfusion syndrome. A comprehensive and relatively current review of the Doppler in multiple gestation is available elsewhere (72).

GUIDELINE FOR THE CLINICAL APPLICATION OF THE DOPPLER FETAL SURVEILLANCE

Based upon the above evidence of clinical efficacy of umbilical arterial Doppler indices, the following practical recommendations for its usage in managing high-risk pregnancy are suggested. These guidelines incorporate the existing modalities of fetal surveillance although some investigators advise the use of Doppler as the exclusive primary tool for fetal surveillance. Such a recommendation may not be pragmatic and pathophysiologic evidence suggests a more comprehensive approach for fetal surveillance.

Indications for Doppler Fetal Surveillance

Common indications for performing Doppler surveillance of the fetus at risk for chronic nutritive and respiratory stress are listed in Table 9 and are discussed below.

A variety of pregnancy complications such as FGR and pre-eclampsia can cause fetal stress. As discussed above, randomized trials have shown significant improvement in the rate of perinatal mortality in pregnancies complicated with clearly

Table 9 Indications for Umbilical Arterial Doppler Velocimetry

Primary indications
Fetal growth restriction by ultrasound fetal biometry (estimated fetal weight <10th centile)
Pre-eclampsia
Primary
Superimposed
Multiple gestation
Discordancy
Fetal growth restriction
Twin transfusion syndrome
Extended indications
Autoimmune vascular disease: SLE, APL syndrome
Pregestational diabetes: ≥ class C or vasculopathy
Sickle cell disease

Abbreviations: SLE, systemic lupus erythematosus; APL, antiphospholipid.
Source: From Ref. 77.

defined FGR and hypertension. Although umbilical arterial Doppler has been recommended in the past for prenatal diagnosis of FGR, sonographic biometry is a better predictor of fetal size. Although the indices may be helpful in distinguishing a growth-restricted fetus from a constitutionally SGA fetus, there is a dearth of evidence guiding how this should be translated into a clinical management policy.

UA Doppler is helpful in recognizing fetal compromise in multiple pregnancies, particularly in those with discordant growth and twin transfusion syndrome. Current recommendations include the use of UA and ductus venosus Doppler for classifying the severity of fetal compromise in twin transfusion syndrome, known as the Quintero staging system, which assists in guiding the management options. Doppler velocimetry may also be useful in managing pregnancies affected by autoimmune disorders including systemic lupus erythematosus and antiphospholipid syndrome; however, its effectiveness is uncertain in the absence of fetal growth compromise. Finally, the utility of umbilical arterial Doppler in managing postdated pregnancies remains unproven.

Technique of Umbilical Arterial Doppler Interrogation

Before Doppler examination, the mother is appropriately counseled regarding the reason for the test, the nature of the information generated by the device, its reliability and safety, and other relevant issues. Similar to the procedure in FHR monitoring, the mother lies in a semirecumbent position with a slight lateral tilt to minimize the risk of significant caval compression. Examination should be conducted only during fetal apnea and in the absence of fetal hiccup or excessive movement. Doppler insonation can be performed by either a

continuous-wave Doppler device or a pulsed Doppler duplex system; the latter is preferred for the UA.

With a pulsed-wave duplex Doppler system, an obstetric scan is initially performed to identify the loops of the cord (Fig. 9). Unlike the continuous-wave mode, the pulsed-wave Doppler insonation permits selection of the location in the umbilical cord for interrogation. Usually a free-floating loop of the cord is insonated. The cursor line representing the beam path is aligned to intersect the umbilical vessels at the selected location and the Doppler sample volume is placed in that location. The Doppler mode is then activated and the Doppler waveforms are recorded and analyzed.

Management of High-Risk Pregnancy Using Doppler Sonography

Principles of managing a high-risk pregnancy utilizing UA Doppler velocimetry in conjunction with other fetal surveillance test findings are described in this section. Management of high-risk pregnancies where fetal Doppler is indicated depends on several factors including the severity of fetal compromise as indicated by the Doppler and other fetal tests, and the underlying obstetric conditions such as pre-eclampsia, the gestational age, and the presence of fetal aneuploidy and malformations. These are further discussed below.

(i) Initial fetal assessment should rule out malformations. Such screening ultrasound is now in common practice and is typically performed at mid-pregnancy. If indicated, fetal karyotype should be determined especially in early-onset growth restriction with absent end-diastolic flow in the UA or with the presence of positive ultrasound or screening indicators. For those with FGR, appropriate follow-up growth

Figure 9 Duplex Doppler interrogation of the umbilical arterial flow. The upper panel shows gray scale and color (gray scale in the figure) depiction of the umbilical flow. The Doppler sample volume is placed in a free loop of the umbilical cord. The lower panel shows spectral Doppler waveforms from the umbilical artery. Cursors demonstrate the peak systolic and the end-diastolic velocity points in the wave. The inset shows the corresponding values and the Doppler indices.

scan should be performed according to the prevailing standard of practice (usually 3–4 weeks interval).

(ii) Fetal surveillance should be multimodal including UA Doppler and full or modified biophysical profile. FHR pattern should also be used using the traditional NST or the computerized cardiotocography (cCTG). The frequency of these should be usually once a week. Daily fetal movement assessment by the mother may be added to this list. Many would also advise the incorporation of the ductus venosus Doppler.

(iii) As abnormal elevation of the umbilical arterial Doppler indices usually precedes ominous changes in other tests, a high or increasing UA Doppler index (S/D, RI, or PI) warrants more intense fetal surveillance, which consists of biweekly umbilical Doppler, and FHR monitoring (NST or cCTG) or the BPP. There is considerable variability in the choice, frequency, and sequence of these tests. As the fetal compromise involves multiple systems, it is more prudent to use a combination of tests rather than sequence of single tests.

If these tests are assuring, fetal surveillance should continue unless intervention is indicated because of other complications. On the other hand, if these tests are ominous, delivery should be planned.

(iv) The development of AEDV in the UA indicates more urgent action as it is associated with an unusually adverse perinatal outcome.

Preterm pregnancies: In preterm pregnancies greater than 28 weeks but less than 34 weeks of gestation, when the risk of fetal lung immaturity is high, the management is conservative and further assurance of fetal well-being should be sought from daily surveillance by the UA Doppler and other fetal tests. Steroids should be administered for enhancing fetal lung maturity.

Delivery is recommended in the presence of ominous signs that include the reversal of UA end-diastolic flow by Doppler, non-reassuring FHR patterns (nonreactive NST, poor FHR baseline variability by NST or cCTG, persistent late decelerations), oligohydramnios, BPP score <4, and reversal or absence of the “a” wave of the ductus venosus Doppler. In many tertiary perinatal centers with the availability of advanced neonatal care, the threshold may be lowered to 32 weeks. A more conservative approach is advised in pregnancies less than 32 weeks.

There is controversy regarding conservative management versus immediate delivery in very preterm pregnancies. The growth restriction intervention trial project attempted to address this issue in a multicenter trial but failed to demonstrate any difference between immediate and delayed delivery groups (78). A follow-up study investigating the long-term outcome at 2 years showed a trend toward a higher rate of disability with immediate intervention but no differences in the median Griffiths test (79).

If the gestational age is less than 28 weeks, the management remains challenging. The validity of NST and BPP at this stage of gestation is not well established. Doppler of ductus may provide additional useful information, but there is no evidence of its effectiveness in this gestational group.

Term and near-term pregnancy: The development of AEDV should prompt consideration of delivery when fetal lung maturity is anticipated or proven. Although the prudence of

emergency delivery for this complication has been questioned, RCTs and their meta-analyses have shown improved outcome from obstetric interventions based on UA Doppler. It is recommended therefore that the mother should be delivered when this complication develops in a pregnancy at or near term (>34 weeks) when continuation of the pregnancy presents a greater threat to fetal safety and well-being.

Management of delivery: Standard guideline for intrapartum maternal and fetal monitoring in high-risk pregnancies should be followed. There is a higher risk of developing intrauterine asphyxia in fetuses with FGR or other associated complications arising from placental insufficiency. Close fetal surveillance during labor and delivery is therefore mandatory. The mode of delivery is determined by assessing relevant obstetric factors including cervical status, fetal presentation, and the severity of fetal compromise. If reversed end-diastolic velocity develops in the UA, the probability of impending fetal death is very high; therefore, it may be more prudent to deliver the infant promptly by cesarean section rather than to test its tolerance to the rigors of labor induction.

CONCLUSION

Development of Doppler ultrasound has allowed noninvasive assessment of the fetal circulatory state. Hemodynamic, angiomorphic, and pathophysiologic evidence affirms the rationale for using the method for fetal surveillance. Numerous studies, as reviewed in this chapter, have established the efficacy of abnormal Doppler indices for identifying adverse perinatal outcome in various pregnancy disorders, especially FGR. More importantly, the majority of clinical trials have demonstrated the effectiveness of UA Doppler in improving the perinatal outcome in high-risk pregnancies. The most promising benefit is a significant reduction in preventable perinatal deaths. Current evidence clearly indicates that Doppler velocimetry should be an essential component of antepartum fetal surveillance in high-risk pregnancies especially those with FGR. Clearly, no single testing modality should be regarded as the exclusive method for fetal monitoring as the various fetal monitoring tests reveal different aspects of fetal compromise, often in a complementary manner. The recommendations in this chapter do not provide a solution for every contingency that may develop in the course of a high-risk pregnancy. The physician must individualize the care in light of the myriad of variations in the clinical situation. The information presented in this chapter should be used as a pragmatic guideline that integrates the new modality with the existing standards of fetal surveillance. As new evidence accumulates and experience grows, evidence-based integration of the various modalities of fetal monitoring in appropriate sequence and frequency will add further refinement to this plan of management.

67 Assessment of fetal well-being: Fetal heart rate monitoring and the fetal biophysical profile

Yinka Oyelese, Martin Chavez, and Anthony M. Vintzileos

INTRODUCTION

The primary objective of antepartum fetal surveillance is the prevention of stillbirth. A second objective is the timely detection of fetal asphyxia that may result in long-term neurodevelopmental handicap. Antepartum fetal surveillance, for the most part, became possible only in the second half of the 20th century, mainly due to the advent of ultrasound and external continuous electronic fetal heart rate (FHR) monitoring (EFM). These technologies are now widely available and have become accepted as the mainstays of the evaluation of fetal well-being.

The use of any monitoring method to detect fetal compromise has, as a prerequisite, the clear understanding of the pathophysiology by which the particular condition results in adverse perinatal outcome. A test that is reliable for one condition may not be so valuable for predicting outcomes with another condition. Kontopoulos and Vintzileos (1) recently discussed how the efficacy of any antepartum screening test depends on the underlying pathophysiology of the condition and recommended condition-specific antenatal testing. Table 1A lists all the known pathophysiologic processes that can place the fetus at risk for in utero death or neurologic damage, whereas Table 1B lists some of the more common indications for antepartum fetal surveillance. Importantly, no single list of indications could ever cover all the reasons for fetal surveillance. Essentially, any condition that puts the fetus at risk for antepartum death may be considered as an indication for fetal surveillance.

Until late in the 20th century, the main methods of antepartum fetal monitoring were the measurement of fundal height and maternal kick counts. The introduction of the FHR monitor by Hon around 1960 (2) ushered in a new era in fetal well-being assessment. EFM was initially designed for intrapartum assessment of fetal well-being, but it eventually became a tool for antepartum fetal monitoring too. However, it soon became obvious that monitoring of the FHR alone had limitations, especially a high false-positive rate. In 1980, Manning and colleagues introduced the fetal biophysical profile (BPP) (3), which utilizes real-time ultrasound examination of the fetus. While there are numerous other forms of fetal monitoring, such as Doppler for hemodynamic fetal evaluation, this chapter will discuss the role of antepartum FHR monitoring and the BPP in fetal assessment, including the limitations of each technique.

EFM

About 1960, Hon introduced the EFM originally for the purpose of intrapartum assessment of the fetus (4,5). It was observed that certain FHR patterns were strongly predictive of

a non-asphyxiated fetus, while other patterns suggested intrapartum fetal oxygen deprivation (5). Fetuses suffering from intrapartum hypoxia frequently exhibited a slowing of the FHR following a contraction, termed late deceleration. Following the routine introduction of the EFM during labor, there was a remarkable reduction in intrapartum fetal deaths. Subsequently, it was suggested that EFM might play a role in assessing fetal well-being way before the onset of labor. Since the presence of intrapartum late decelerations indicated fetal hypoxia, it was believed that stimulating uterine contractions in patients who were not in labor might help identify fetuses that were at risk of hypoxia in the antepartum period. This led to the “oxytocin challenge test” (OCT), the original antepartum continuous electronic FHR assessment of the fetus, introduced in the early 1970s by Ray and colleagues (6). Using oxytocin, uterine contractions were stimulated, and the presence of FHR late decelerations were considered a positive test and predictive of fetal compromise (7).

The OCT was considered positive if greater than 50% of contractions were followed by late decelerations, and negative if there were no late or significant variable decelerations. An OCT was described as “suspicious” if there were intermittent late or variable decelerations, while the test was deemed “unsatisfactory” if there were fewer than three contractions over a 10-minute period, or if the fetal heart tracing quality was uninterpretable. In cases where there were prolonged contractions that led to decelerations, the term “hyperstimulation” was used. Later, it became apparent that these decelerations could also result from spontaneous uterine contractions, and therefore the test was renamed the “contraction stress test” (CST). Others used nipple stimulation instead of oxytocin to provoke uterine contractions and found similar results (8–13). A positive CST (or OCT) was indicative of uteroplacental insufficiency. During contractions, blood flow to the intervillous space is impeded. A bradycardic response develops due to a chemoreceptor response that is provoked by fetal hypoxia. These late decelerations in the antepartum period were shown to predict subsequent adverse outcomes before, during, and after labor. Several studies demonstrated that though the OCT had a high false-positive rate, the false-negative rate was low, about 1% or less (14). In other words, the risk of fetal death within 1 week after a negative test is negligible. However, the false-positive rate of the OCT is at least 20% to 45% (15,16). Importantly, conditions associated with fetal demise after a negative CST are often umbilical cord accidents and placental abruption, conditions that occur suddenly, and may not necessarily be expected to be predicted by any antepartum surveillance modality (14).

Table 1A Antepartum Maternal/Fetal Pathophysiologic Processes That Can Place the Fetus at Risk for In Utero Death or Neurologic Damage

Pathophysiologic process	Maternal/fetal condition
Decreased uteroplacental blood flow	Chronic hypertension Pre-eclampsia Collagen/renal/vascular disease Most cases of fetal growth restriction (i.e., <32–34 wk)
Decreased gas exchange	Postdate pregnancy, some fetal growth–restricted cases (i.e., >32–34 wk)
Metabolic aberrations	Fetal hyperglycemia Fetal hyperinsulinemia
Fetal sepsis	PROM Intra-amniotic infection Maternal fever, primary subclinical Intra-amniotic infection
Fetal anemia	Fetomaternal hemorrhage Erythroblastosis fetalis Parvovirus B19 infection
Fetal heart failure	Cardiac arrhythmia Nonimmune hydrops Placental chorioangioma Aneurysm of the vein of Galen
Umbilical cord accident	Umbilical cord entanglement (monoamniotic twins) Velamentous cord insertion/Funic presentation Noncoiled umbilical cord Oligohydramnios

Abbreviation: PROM, premature rupture of the membranes.

Table 1B Some Common Indications for Antepartum Fetal Surveillance

Intrauterine growth restriction
Prior stillbirth
Diabetes
Hypertension
Pre-eclampsia
Postdate pregnancies
Preterm premature rupture of the membranes
Oligohydramnios
Decreased fetal movements
Prior stillbirth
Maternal lupus
Multifetal pregnancies, particularly those with growth disturbances or discordance
Cholestasis of pregnancy

Needless to say, the OCT was cumbersome and difficult to perform. In the process of performing OCTs, it was often observed that the presence of FHR accelerations had good predictive value for a non-asphyxiated fetus (17). Consequently, the concept of the nonstress test (NST) was proposed. Since monitoring of fetal movements (including maternal kick counts) had previously been used to assess fetal well-being, the NST was considered an objective method of fetal monitoring. A “reactive” NST was initially defined as one with two to five or more accelerations in 20 minutes. An acceleration is defined

as a transient increase in FHR over the baseline of at least 15 beats/minute (bpm), lasting at least 15 seconds. For pregnancies less than 32 weeks of gestation, an acceleration is a transient increase over the baseline of at least 10bpm, lasting at least 10 seconds.

There are other variables in the heart rate pattern that may suggest fetal well-being or compromise. The normal fetal baseline heart rate is 110 to 160. The baseline heart rate decreases with gestational age, mainly as a consequence of vagal maturation. Fetal tachycardia (defined as a baseline FHR >160bpm) may occur in association with maternal fever, maternal ingestion of stimulants including beta-adrenergic agents. Uncomplicated fetal tachycardias (with accelerations and good variability) are generally associated with a good outcome. However, these require close and thorough evaluation. When there is a persistent complicated tachycardia (including a heart rate greater than 200bpm, where there is minimal or no variability, or where there are decelerations), delivery should be considered, especially at term or near term. Obviously, one must take the entire clinical picture into consideration. For instance, treating maternal fever or stopping stimulant medications may be enough to resolve the tachycardia.

Bradycardia is defined as a baseline FHR <110bpm. Again, this is generally benign if there are accelerations and good variability. However, FHRs of <100bpm may be associated with fetal heart block and require further evaluation. The absence of accelerations or reduced variability may be due to periodicity. However, if this persists for >45 minutes, further evaluation should be undertaken. A sinusoidal FHR pattern (Fig. 1) is considered an ominous pattern (18) and is often associated with fetal anemia or hypovolemia, including that resulting from such causes as isoimmunization, parvovirus infection, placental abruption, twin–twin transfusion syndrome (19–21), and ruptured vasa previa (22). Generally, prompt delivery is indicated, unless the cause of the sinusoidal FHR (such as fetal anemia) can be treated in utero (18,22).

The NST has several advantages over the CST—it is easy to perform and interpret, does not require oxytocin administration, and can be performed in shorter time than the CST. Furthermore, the CST has several absolute and relative contraindications, such as in patients with premature rupture of the membranes, prior classical cesarean delivery, multiple gestations, incompetent cervix, preterm labor, or vaginal bleeding. These important characteristics as well as the predictive reliability of the test made the NST the primary modality of fetal evaluation. Several studies have validated the role of the NST as a predictor of perinatal outcome (23,24). The presence of accelerations is associated with a low risk of fetal hypoxia, while the absence of accelerations carries a significantly higher rate of fetal hypoxia and acidosis. The FHR reactivity is controlled by the autonomic nervous system and the percentage of reactive NSTs increases with fetal maturation. By term, over 90% of fetuses demonstrate reactive NSTs. FHR accelerations are associated with fetal movements. An FHR tracing may be nonreactive due to fetal immaturity, fetal sleep state, maternally administered sedatives, fetal neurologic and cardiac anomalies, fetal hypoxia/acidosis, uteroplacental insufficiency, or fetal infection. Unfortunately, the NST also has a high false-positive rate of about 50%, while the

Figure 1 Fetal heart rate tracing demonstrating a sinusoidal fetal heart rate pattern.

false-negative rate is only about 0.3%. Translated differently, a reactive NST carries a very low risk of fetal hypoxia, while a nonreactive NST is only associated with adverse outcomes in less than one-half of cases. Phelan and colleagues reviewed 2226 patients who had undergone 4000 NSTs. Of these, 1564 women with a reactive NST were delivered within 1 week of the test. There were four fetal deaths giving a false-negative rate of 0.026%—these resulted from placental abruption and cord accidents, events that may not be necessarily expected to be predicted by an NST (25).

In the late 1980s, it was observed that fetal auditory stimulation would often lead to FHR accelerations in a fetus that had previously lacked accelerations (26–30). This reduced testing time and also reduced the nonreactive NST rate. An artificial larynx was developed that produced a vibroacoustic signal (VAS). A rapidly occurring acceleration following the stimulation is considered a positive response. A positive VAS was shown to have similar accuracy in predicting good perinatal outcomes as a spontaneously reactive NST, with the advantage of a reduced testing time.

The OCT/CST and NST are performed using an external FHR monitor and a tocodynamometer strapped to the maternal abdomen. The FHR monitor derives its signals ultrasonically or via phonocardiography. Ultrasound is the most widely used technique and provides an accurate tracing in the majority of cases. Perhaps obesity is the major factor that may be associated with an inability to obtain a satisfactory fetal heart tracing. Uterine contractions are monitored via the tocodynamometer. The tocodynamometer monitors the frequency and duration of the contractions, but cannot assess the strength of the contractions. The tocodynamometer may not adequately detect contractions in obese patients.

Antepartum FHR testing has undergone considerable evaluation in several studies. It has been shown to have good prediction of fetal well-being when accelerations are present

and decelerations are absent. However, the converse is not true; the absence of accelerations is not necessarily indicative of a compromised fetus. Thus, EFM was found to be associated with an exceedingly high false-positive rate, resulting in excessive unnecessary interventions such as inductions and cesarean deliveries. It became obvious that there was a need for some other form of surveillance that could reduce this false-positive rate.

THE FETAL BPP

In 1980, Manning and colleagues introduced the BPP (Table 2) (3). This test was based on a more thorough evaluation of the fetus; the main advantage of the BPP over EFM is that the BPP evaluates several different biophysical markers. The FHR allowed the assessment of only a single biophysical marker. Just as a heart rate alone in an adult cannot distinguish between sleep and coma, the FHR, when used alone, has significant limitations, especially in the absence of accelerations. The BPP is analogous to an intrauterine Apgar score with its dynamic variables (acute markers) reflecting fetal CNS function. In addition to FHR reactivity, other acute fetal markers such as fetal movements, fetal breathing movements and tone, as well as assessment of the intrauterine environment, that is, estimation of amniotic fluid volume and placental grading could be objectively evaluated. The fetal BPP was developed to decrease the false-positive results associated with FHR monitoring. The most important element of this testing method is the combination of acute and chronic markers of the fetal condition. The acute markers include FHR reactivity, fetal breathing, fetal movements, and fetal tone, while fetal amniotic fluid volume is a chronic marker of fetal well-being. The BPP avoids the high false-positive rates of the NST and the CST and therefore helps reduce unnecessary interventions.

The Physiologic Basis for the BPP

Acute Markers

The acute fetal biophysical markers—FHR reactivity, fetal movements, fetal breathing movements, and fetal tone—are not random events, but are initiated and regulated by the fetal central nervous system (CNS) (Table 3). The presence of any one of these markers implies that, at the time of testing, the CNS center that controls the particular activity is

Table 2 Fetal Biophysical Profile Scoring (Manning and Coworkers)

	Score 2	Score 0
Movements	Three or more gross body movements in a 30-min period. Simultaneous trunk and limb movements count as a single movement	Less than three gross body movements in a 30-min period
Tone	At least one movement of a limb from a position of flexion to one of extension, with a rapid return to flexion	Fetal limb in extension with no return to flexion with movement
Breathing	At least 30 sec of sustained fetal breathing movements observed over a 30-min period	Less than 30 sec of sustained fetal breathing movements observed over a 30-min period
Amniotic fluid	At least a single amniotic fluid pocket measuring 2cm × 2cm in two perpendicular planes	No amniotic fluid pocket that measures at least 2cm × 2cm in two perpendicular planes
Fetal heart rate	At least two accelerations (of >15 beats per minute, lasting at least 15 sec) in a 40-min period	Less than two accelerations in 40 min

Nonstress test	Posterior hypothalamus, medulla

intact, functional, and therefore non-hypoxic. The converse, however, is not necessarily true; the absence of a single fetal biophysical activity is not always due to hypoxia and acidosis. Fetal biophysical activities such as fetal breathing movements, fetal body movements, and FHR variability all undergo periodic changes. Thus, the absence of biophysical activities is more frequently the result of periodicity rather than a pathologic condition and needs to be interpreted with caution. The periodicity of these biophysical activities may be short term (20–40 minutes) or long term, similar to those diurnal rhythms of extrauterine life. Maternal administration of CNS depressants and sedatives, such as opiates, barbiturates, and benzodiazepines, may inhibit fetal biophysical activities, while factors that cause stimulation of the maternal CNS, for example, hyperglycemia or catecholamines, may result in increased biophysical activities. The effect of fetal hypoxia and acidosis, or fetal infection, on the fetal BPP depends on the severity, duration, chronicity, and frequency of the hypoxic insult(s). Fetal hypoxia may be transient without acidosis, or prolonged with associated metabolic or mixed acidosis, affecting multiple organs. Acute fetal hypoxia (or fetal infection) produces a definite decrease in FHR reactivity (nonreactive NST) and fetal breathing movements, and when severe hypoxia (or infection) abolishes fetal movements and tone (31–33).

The biophysical activities appear progressively in normal fetuses as gestation advances. The first biophysical activity to appear is tone; the fetal tone center begins functioning at 7½–8½ weeks of gestation. This is followed shortly thereafter by the fetal movement center, which begins functioning at approximately 9 weeks of gestation. The fetal breathing movement center starts operating at about 20 to 21 weeks of gestation, and finally the FHR reactivity center becomes functional by the end of the second trimester or early third trimester. These centers vary in their sensitivity to hypoxia and acidosis (31–33). It was first observed by Vintzileos and colleagues that the biophysical activities that become active first in fetal neurodevelopment are the last to become compromised in fetuses exposed to intrauterine asphyxia or intra-amniotic infection (31–33). Thus, the FHR reactivity and breathing centers, controlling the biophysical activities that appear latest in gestation, are the most sensitive and the first to become affected when the fetus is exposed to hypoxia or intra-amniotic infection (31). Data from our prior studies indicate that FHR reactivity and fetal breathing are abolished when the fetal pH is <7.20, whereas fetal movement and tone are abolished at pH values <7.10. Thus, according to the “gradual hypoxia concept,” the earliest biophysical manifestations of fetal compromise (fetal hypoxia or infection) are a loss of

variability in the NST and absence of fetal breathing. As fetal condition deteriorates, fetal movements and then tone become abolished. In our experience, poor fetal tone is associated with the highest perinatal death rate (42.8%) (32). An understanding of this progressive sensitivity of the biophysical activities to fetal hypoxia or infection of the fetal CNS centers is a prerequisite for the correct interpretation of the information derived from the biophysical assessment and allows for accurate assessment of the degree of fetal compromise in high-risk patients with intact as well as ruptured membranes.

Chronic Markers

The most important chronic marker of the BPP is the amniotic fluid volume, although placental grading was also included in the original studies by Vintzileos et al. (3,32). Chronic uteroplacental insufficiency that results in fetal hypoxia is frequently associated with redistribution of cardiac output away from non-vital to vital fetal organs. Thus, there is typically a reduction in renal perfusion, with consequent decreased urine production and, therefore, oligohydramnios. Oligohydramnios places the fetus at high risk for cord compression and in utero death. Several studies have demonstrated a strong correlation between oligohydramnios and increased incidence of adverse perinatal outcome. Chamberlain and colleagues demonstrated, in a study of 7582 referred high-risk patients, that in structurally normal fetuses, the perinatal mortality rates were 1.97 in 1000 in the presence of normal qualitative amniotic fluid volume (largest pocket >2cm and <8cm), whereas rates in fetuses with marginal (largest pocket 1–2cm) and decreased amniotic fluid (largest pocket <1cm) were 37.7 in 1000 and 109.4 in 1000, respectively (34). Another study of 147 pregnancies complicated by oligohydramnios in pregnancies at gestational ages >34 weeks found an increased risk of labor induction, non-reassuring FHR patterns, cesarean delivery, neonatal intensive care unit admission, meconium aspiration, stillbirth, and neonatal death (35). Amniotic fluid volume is not influenced by acute changes in fetal CNS function. Most investigators consider the finding of oligohydramnios, even when it occurs on its own, as an abnormal biophysical assessment even if when all the remaining biophysical parameters are normal and the presence of oligohydramnios is generally regarded as an indication for intensive surveillance (in preterm gestations) or delivery (term or near-term gestations) (3,33,36,37). When spontaneous severe FHR decelerations and oligohydramnios coexist, delivery may be indicated, regardless of gestational age. Vintzileos and colleagues had initially included placental grading in the fetal BPP (32). These investigators observed that patients with grade 3 placentas had an increased incidence of abnormal intrapartum FHR patterns (44.4%) and placental abruption (14.8%) (32). Thus, inclusion of grade 3 placentas in the BPP alerts the obstetrician to the significant risk of intrapartum complications.

Since the early 1980s, attempts have been made to give a score to each biophysical variable to produce a “fetal BPP score.” There are currently two types of scoring systems: one proposed by Manning and coworkers (Table 2) (3) and the other by Vintzileos and coworkers (Table 4) (32). In both scoring systems, a score of >8 is considered reassuring of fetal

Table 4 Criteria for Scoring Biophysical Variables According to Vintzileos and Coworkers

Nonstress test

Score 2 (NST 2): five or more FHR accelerations of at least 15bpm in amplitude and at least 15-sec duration associated with fetal movements in a 20-min period

Score 1 (NST 1): two to four accelerations of at least 15bpm in amplitude and at least 15-sec duration associated with fetal movements in a 20-min period

Score 0 (NST 0): one or fewer accelerations in a 20-min period

Fetal movements

Score 2 (FM 2): at least three gross (trunk and limbs) episodes of fetal movements within 30 min. Simultaneous limb and trunk movements were counted as a single movement

Score 1 (FM 1): one or two fetal movements within 30 min

Score 0 (FM 0): absence of fetal movements within 30 min

Fetal breathing movements

Score 2 (FBM 2): at least one episode of fetal breathing of at least 60-sec duration within a 30-min observation period

Score 1 (FBM 1): at least one episode of fetal breathing lasting 30–60 sec within 30 min

Score 0 (FBM 0): absence of fetal breathing or breathing lasting <30 sec within 30 min

Fetal tone

Score 2 (FT 2): at least one episode of extension of extremities with return to position of flexion, and also one episode of extension of spine with return to position of flexion

Score 1 (FT 1): at least one episode of extension of extremities with return to position of flexion or one episode of extension of spine with return to flexion

Score 0 (FT 0): extremities in extension. Fetal movements not followed by return to flexion. Open hand

Amniotic fluid volume

Score 2 (AF 2): fluid evident throughout the uterine cavity. A pocket that measures >2 cm in vertical diameter

Score 1 (AF 1): a pocket that measures <2 cm but more than vertical diameter

Score 0 (AF 0): crowding of fetal small parts. Largest pocket <1 cm in vertical diameter

Placental grading

Score 2 (PL 2): placental grading 0, 1, or 2

Score 1 (PL 1): placenta posterior difficult to evaluate

Score 0 (PL 0): placental grading 3

Abbreviations: NST, nonstress test; FHR, fetal heart rate; bpm, beats per minute; FM, fetal movements; FBM, fetal breathing movements; FT, fetal tone; AF, amniotic fluid; PL, placental grading. Maximal score 12; minimal score 0. *Source:* From Ref. 32.

The Fetal BPP and Fetal Acid–Base

The BPP aims at assessing fetal acid–base status at the time of testing. However, in order to assess the accuracy of the fetal BPP in assessing antepartum fetal acid–base status, it is crucial that the acid–base status be assessed shortly after the BPP is performed. Furthermore, labor has a profound effect on acid–base status measured at birth. A major disadvantage of several studies has been the long interval between performing the biophysical assessment and the birth of the infant, as well as the effects of labor and drugs on the fetus. In order to overcome these limitations, Vintzileos and coworkers studied 124 consecutive patients with singleton pregnancies at gestational ages between 26 and 43 weeks, limiting their study to patients undergoing cesarean section prior to the onset of labor (33,38). All patients had a BPP performed within 6 hours of the cesarean section. This BPP was correlated with fetal acid–base status as determined by umbilical cord blood pH measurements. Figure 2 illustrates the relationship between the fetal biophysical score and cord arterial pH. Importantly, all nine fetuses with scores of <4 were acidemic with umbilical cord arterial pH values of 6.99 ± 0.10 (mean \pm SD). Thirteen fetuses with scores of 5 to 7 had a cord artery pH of 7.19 ± 0.06 (mean \pm SD); 9/13 of fetuses (69%) were acidemic. One hundred and two fetuses had a score of >8; in this group of fetuses, the cord artery pH was 7.28 ± 0.04 (mean \pm SD); only two of these (2%) were acidemic. The three groups had statistically different cord arterial pH values. The relationship between the biophysical score and cord venous pH was similar.

As expected, based on the gradual hypoxia hypothesis, there was a relationship between the individual biophysical activities and the umbilical cord blood artery pH values (Fig. 3). When combined biophysical activities were considered, of the 96 fetuses with reactive NSTs and/or fetal breathing present (lasting >30s), none was acidemic. All the remaining fetuses had nonreactive NSTs and absent fetal breathing. However, 17 fetuses had normal (three or more) body movements and tone; the mean pH of this group was 7.20 and 10 (59%) of these fetuses were acidemic. Four fetuses had compromised movements (one to two body movements) or tone; the mean cord blood artery pH was 7.16, and three fetuses (75%) were acidemic. In the seven fetuses with all biophysical activities absent, the mean cord blood artery pH was 6.95, with 100% of them having cord blood artery pH values <7.20. Careful observation of the results suggests that there are different levels of sensitivity to hypoxia and acidosis at which the fetal biophysical activities become compromised. The FHR reactivity and fetal breathing seem to be compromised when the pH is lower than 7.20. At pH values of 7.10 to 7.20, fetal movements and tone are still present but not normal and at pH values <7.10, movements and tone are totally absent. The ability of the individual biophysical components alone and in combination to predict fetal acidemia is shown in Table 5. Of the individual biophysical components, FHR reactivity and fetal breathing had 100% sensitivities and negative predictive values, an observation that suggests that either test is a reasonable choice for primary fetal surveillance. The combination of nonreactive NST and absent fetal breathing movements (the “abnormal test”) improved the specificity and positive predictive values to 92%

well-being. A score of <8 is non-reassuring and repeat testing or delivery is suggested. A limitation of the original BPP scoring system of Manning et al. is that biophysical activities are given an “all or none” score (3). For instance, if there are movements detected that are insufficient to meet to score of 2, the fetus is assigned a “0” for that biophysical activity. However, most would agree that a fetus that demonstrates two movements over 30 minutes may be different from one that exhibits no movements at all. Thus, the initial assignment of intermediate scores, as proposed by Vintzileos et al. (32), had as its main purpose to identify the minimum requirements for each biophysical component to meet normalcy criteria.

Table 5 Efficacy of the Fetal Biophysical Variables to Predict Fetal acidemia

Biophysical variable(s)	Definition of the abnormal test	Sensitivity (%) (n)	Specificity (%) (n)	Positive predictive value (%) (n)	Negative predictive value (%) (n)
Biophysical score	<7	90% (18/20)	96% (100/104)	82% (18/22)	98% (100/102)
Nonstress test, fetal breathing movements	Nonreactive NST and no breathing	100% (20/20)	92% (96/104)	71% (20/28)	100% (96/96)
Nonstress test	Less than one acceleration in 20 min	100% (20/20)	76% (79/104)	44% (20/45)	100% (79/79)
Fetal breathing movements	<30 sec	100% (20/20)	64% (67/104)	35% (20/57)	100% (67/67)
Fetal movements	Less than three	50% (10/20)	96% (100/104)	71% (10/14)	91% (100/110)
Fetal tone	Compromised or absent	45% (9/20)	100% (104/104)	100% (9/9)	90% (104/115)
Amniotic fluid	<1 cm	35% (7/20)	93% (97/104)	50% (7/14)	88% (97/100)
Amniotic fluid	<2 cm	45% (9/20)	86% (89/104)	38% (9/24)	89% (89/100)
Placental grading n, number of fetuses	Grade 3	5% (1/20)	94% (98/104)	14% (1/7)	84% (98/117)

and 71%, respectively. Fetal tone has the highest positive predictive value (100%) for fetal acidemia, but low sensitivity (45%), an observation that suggests that fetal tone alone should not be used for primary fetal surveillance.

Cordocentesis is a technique that allows accurate assessment of relationship between the fetal BPP and fetal umbilical cord blood gas values. Ribbert and colleagues studied 14 severely growth-retarded fetuses, performing a BPP assessment prior to fetal blood sampling by cordocentesis (39). The fetal BPP was correlated with fetal blood pO₂, pH, oxygen saturation, and oxygen content. It was found that the fetal BPP was a good indicator of the degree of fetal acidemia. Of the individual fetal biophysical activities, FHR reactivity was compromised for ΔpH (observed pH subtracted from the appropriate mean for gestation) below -2 standard deviations (SD)s; fetal breathing movements were compromised for ΔpH values below -3 SDs; fetal body movements and fetal tone were compromised for ΔpH values below -4 SDs. These preliminary data using fetal blood gas values obtained at cordocentesis confirmed the observations of Vintzileos and coworkers in that the fetal BPP can predict the degree of fetal acidemia and that the FHR reactivity and fetal breathing movements are the first, whereas fetal gross body movements and tone are the last, biophysical activities to be compromised during acidemia. In another study of 62 patients undergoing cesarean section prior to the onset of labor, the relationship between fetal biophysical assessment performed within 3 hours of delivery and cord blood gases was investigated (31). It was observed that nonreactive NSTs and absent fetal breathing movements were both associated with lower pH, pO₂, bicarbonate, base excess and higher pCO₂ than that when the NST was reactive or fetal breathing was present. The absence of fetal movements and/or tone was associated with lower pH, pO₂, bicarbonate and base excess, and a higher pCO₂ than when fetal body movements and tone were present (Figs. 3-7). These blood gas differences were noted in both cord arterial and venous blood. Thus, the first manifestations of fetal hypoxemia and acidemia are

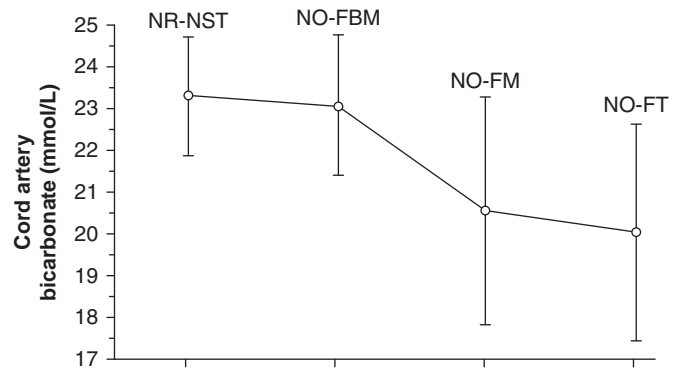

Figure 6 Relationship between cord artery bicarbonate level and absent fetal biophysical activities. The bicarbonate level tends to be lower in the absence of movements or tone compared with nonreactive nonstress test and absent fetal breathing. Results are means expressed in millimoles per liter (95% error bars). Abbreviations: No FM, absent fetal movements; No FT, absent fetal tone; No FBM, no fetal breathing movements; NR-NST, nonreactive nonstress test; Source: From Ref. 31.

Figure 7 Relationship between cord artery base excess and absent fetal biophysical activities. The base excess tends to be lower in the absence of movements or tone compared with nonreactive nonstress test and absent fetal breathing. Results are means expressed in millimoles per liter (95% error bars). Abbreviations: No FM, absent fetal movements; No FT, absent fetal tone; No FBM, no fetal breathing movements; NR-NST, nonreactive nonstress test. Source: From Ref. 31.

nonreactive NST and the absence of fetal breathing. As hypoxemia becomes more advanced, and hypercapnia and acidemia develop, fetal movements and tone become absent. A similar sequence of events in the deteriorating fetus also occurs in the presence of fetal infection (40).

The BPP: Impact on Perinatal Outcomes

In their initial study of the use of the BPP in clinical practice, Manning et al. (3) measured five biophysical activities (fetal movement, fetal tone, fetal breathing, amniotic fluid volume, and fetal NST) in 216 patients, all of whom delivered within a week of the last BPP. The patients were managed based on their NSTs, not based on the results of the BPPs. These investigators found that each of the five individual biophysical markers had a low false-negative rate, but that all five had a high false-positive rate. However, this false-positive rate varied widely among the different markers. The authors found that combining the markers led to a significant improvement in the false-positive and false-negative rates. There was a significant correlation between abnormal BPP scores and low 5-minute Apgar scores, fetal distress in labor, and perinatal death rate. These authors found a perinatal mortality rate of 0/1000 when all biophysical markers were normal (score 10), but that this rose to 600/1000 when all biophysical activities were abnormal (score 0). The fetal death rate with a score of 0 was 400/1000.

Based on the results of this initial study, Manning and colleagues suggested a management protocol based on BPP scoring that is outlined in Table 6. These investigators used this protocol for patient management in a subsequent prospective study involving 1184 consecutive referred high-risk patients who had 2238 fetal biophysical scores performed (40). The purpose of the study was to assess the impact of using the biophysical score on perinatal death rate in high-risk patients. There were six perinatal deaths, in the study group, giving a perinatal mortality of 5.06 per 1000. This was significantly lower than the predicted rate for a similar high-risk population (65 per 1000). Importantly, this perinatal death rate was also less than half of that in the general population in Manitoba (14.3 per 1000). Only one fetus died after a reassuring biophysical score, thus giving a true false-negative rate of 0.8 per 1000. As an added potential benefit, 13 of 19 (68.4%) fetuses with previously undiagnosed major congenital anomalies,

including 8 with lethal anomalies, were prenatally diagnosed as a result of real-time ultrasound. In two cases, the antepartum detection of the anomaly helped neonatal survival.

In 1983, Vintzileos and coworkers reported their initial experience using a BPP consisting of six variables in 150 patients with high-risk pregnancies during a 30-minute observation period (32). A total of 342 BPPs were performed. The patients were not managed based on the BPP results, but rather based on their nonstress or CSTs. There was a good correlation between the biophysical scores and adverse perinatal outcomes, including intrapartum fetal heart-rate pattern abnormalities, meconium during labor, fetal distress, and the perinatal mortality rate. Fetal biophysical scores (>8) were associated with good pregnancy outcome in all cases. Very abnormal scores (≤ 4) were almost always associated with fetal distress. The absence of fetal movements was the best predictor of abnormal intrapartum heart-rate patterns (80%), while a nonreactive NST was the best predictor of meconium-stained fluid (33.3%). Oligohydramnios was the best predictor of fetal distress (37.5%) and absent fetal tone was the best predictor of fetal death (42.8%). The 11 fetuses that were acidemic at birth (cord blood artery pH <7.20) all had nonreactive NSTs and absent fetal breathing. There were two fetuses with normal fetal movement and both survived. Of five fetuses with movement present but compromised (one or two body movements in 30 minutes), only one died. Three out of the four fetuses with absent fetal movement died; all three also had absent fetal tone. These observations suggested that the biophysical components do not contribute to the predictive accuracy in an equally proportionate manner.

Baskett et al., using the Manning scoring criteria, reported on 5618 BPP scores performed on 2400 high-risk pregnancies (41). The perinatal mortality in the study population was only 9.2 per 1000, compared with the overall perinatal mortality in the investigators' hospital over the study period of 14.5 per 1000. Structurally normal fetuses with a normal biophysical score had a perinatal mortality of only 1 per 1000. Fetuses with scores of 4 or less had a perinatal mortality rate of 292 per 1000. In this study, the positive predictive value of an abnormal biophysical score for abnormal perinatal outcome (defined as intrapartum fetal distress, 5-minute Apgar score <7 , intrauterine growth restriction, or perinatal death) was 79.2%. This predictive power was significantly better than that of the NST, fetal breathing movements, and fetal tone; however, it did not reach statistical significance when compared with fetal movement and amniotic fluid volume.

In the first prospective randomized blinded study of the BPP, Manning et al. randomized 735 women with high-risk pregnancies to BPPs or NSTs for fetal assessment (42). The results of the tests were used for management, but the physicians were not informed of which test had been used. The BPP was shown to have an improved predictive value over the NST for low Apgar scores. The negative predictive values were similar for both forms of fetal assessment. Sensitivity, specificity, and accuracy were not statistically different between the two methods of fetal assessment. In 1985, Platt and colleagues reported their results from a randomized prospective trial comparing the BPP with NST for the assessment of high-risk pregnancies, examining the ability of the tests to predict adverse perinatal outcomes (43).

Table 6 Management Scheme Based on Biophysical Profile Scoring

Score	Recommended management
8–10	Repeat in 1 week. In diabetic (insulin-dependent) and postdate patients, repeat twice weekly. No indication for active intervention
4–6	If fetal pulmonary maturity assured and cervix favorable, delivery, otherwise repeat in 24 hours. If there is persistent score of 4–6, deliver if fetal pulmonary maturity certain. Otherwise treat with steroids and deliver in 48 hours
0–2	Evaluate for immediate delivery. In cases of certain pulmonary immaturity, give steroids and deliver in 48 hours

A number of 1628 tests were performed on 652 women. The authors found that the diagnostic values for all outcome parameters (apart from the negative predictive value for low 5-minute Apgar scores) were consistently higher with the BPP than the NST. However, only the positive prediction of overall abnormal outcome and negative prediction of small-for-gestational-age infants achieved statistical significance.

Johnson and colleagues reviewed 307 consecutive post-term pregnancies assessed using twice-weekly BPPs and found that the BPP accurately differentiated fetuses with a normal outcome from those at risk for perinatal asphyxia (44). They proposed that conservative management of post-term pregnancies was made possible using the BPP for surveillance and that this had the potential to lead to a reduction in unnecessary inductions and cesarean deliveries. Meanwhile, Benacerraf and colleagues reported their observation on performing BPPs on 1000 women with high-risk pregnancies and found that four of five fetuses with oligohydramnios and absent or poor fetal tone and movements had evidence of fetal compromise at birth (45). Their finding reinforces the fact that oligohydramnios should be considered an ominous sign, regardless of the other variables, and generally should lead to intensive surveillance or delivery.

Vintzileos and coinvestigators described their experience using the BPP in 73 women with healthy pregnancies who had presented with preterm premature rupture of the membranes (PPROM) and were not in labor (46). They observed that PPROM did not affect the BPP. However, a low BPP (<7) predicted impending fetal infection. Subsequently, these investigators performed a retrospective study of 1151 pregnancies complicated by PPROM (47). They found that PPROM was associated with a higher rate of reactive NSTs, absent fetal breathing, and reduced amniotic fluid compared with those pregnancies without PPROM. However, they observed that the overall BPP score was not affected by PPROM in otherwise healthy pregnancies. In a further study, Vintzileos and colleagues compared the BPP with amniocentesis for the diagnosis of chorioamnionitis in patients with PPROM (48). They found that daily BPP assessment was superior to amniocentesis in predicting infection outcome in these women. The role of the BPP in the evaluation of patients with PPROM will be discussed further later in this chapter.

In another study, Manning and coworkers reported on 12,620 high-risk patients who had 26,257 BPP scores (37). There were 93 perinatal deaths of which 24 occurred in structurally normal, non-immunized fetuses (corrected perinatal mortality rate of 1.9 per 1000). Eight of these structurally normal fetuses died within one week of a normal BPP (corrected false-negative rate of 0.634 per 1000). The uncorrected stillbirth rate was 3.64 per 1000 and the uncorrected neonatal death rate was 3.72 per 1000. When the perinatal mortality was correlated with the biophysical score results, it was found that the overall mortality ranged from 0.652 per 1000 tests in pregnancies with a BPP score >8 to 187 per 1000 tests for pregnancies with a BPP score of 0. The overwhelming majority of the BPPs (97.5%) were normal and only 0.76% had a score of <4. The same authors subsequently reported their experience with 44,828 BPPs (49) performed in 19,221 high-risk pregnancies. The frequency of intrauterine

death among structurally normal fetuses after a reassuring BPP was 0.726 per 1000 (14 deaths). Four of those deaths resulted from cord prolapse, an outcome not likely to be predicted by a normal BPP score. Thus, the false-negative rate of a normal test, excluding cases that the BPP would not have been expected to predict, could have been as low as 0.518 per 1000 (10 deaths). Almost half of the antepartum fetal deaths occurred 5 to 7 days after a normal BPP. Therefore, it is possible that increasing the frequency of testing to twice a week may have prevented some of these deaths. The usefulness of the fetal BPP in predicting perinatal death has also been investigated by Baskett and coworkers (50) in 4184 fetuses. The overall perinatal mortality in the study population was 7.6 per 1000. Fetuses with a normal biophysical score (8–10) had a perinatal mortality rate of 1 per 1000, while fetuses with an equivocal score of 6 had a perinatal mortality rate of 31.3/1000. Finally, fetuses with a BPP score of 0 to 4 had a perinatal mortality of 200 per 1000. The false-negative rate of 0.7 per 1000 was very similar to the false-negative rate previously reported by Manning and coworkers.

Platt and coworkers (51) studied 283 patients who had a total of 1112 BPPs. Patients were managed on the basis of their NST results and not on their BPPs. The perinatal mortality rate for all patients delivered in their institution during the study period was 22.6 per 1000 as opposed to 14 per 1000 (corrected 7 per 1000) for the study population and 7.4 per 1000 for fetuses with a biophysical score of >8. The authors questioned the predictive accuracy of the biophysical score as compared with the NST alone.

Outcomes with Very Low BPP Scores

Manning and coworkers (52) reported on outcomes of pregnancies with BPP scores of zero. Twenty-nine of 28,655 fetuses (0.092%) had a last BPP score of 0 prior to delivery. The perinatal death rate in this group of 29 fetuses was 48.3% (14 of 29) and the majority (11 of 14) were stillborn. Death occurred as early as 30 minutes and as long as 11 days after the last test. Three asphyxia-related neonatal deaths occurred despite immediate and aggressive intervention. The positive predictive value of a BPP score of 0 for perinatal mortality or morbid perinatal outcome (defined as fetal distress in labor, 5-minute Apgar score <7, umbilical vein pH <7.20, or admission to a neonatal intensive care unit for over 24 hours for reasons unrelated to prematurity) was 100%. Thus, these authors argued that the very abnormal fetal BPP (score = 0) should be considered a perinatal emergency. Importantly, some fetuses will survive despite this extremely low biophysical score; thus, procrastination, when the BPP score is 0, based upon the belief that the outcome will be dismal, should be discouraged.

In another study of 26,780 fetuses, Manning and coworkers (53) studied the relationship between the last BPP score and various perinatal outcomes including mortality and morbidity. A highly significant inverse linear correlation was observed between the BPP score and fetal distress, admission to the neonatal intensive care unit, intrauterine growth restriction, low 5-minute Apgar score (<7), and umbilical cord pH <7.20. No correlation was found between the fetal BPP score and the incidence of meconium or major anomaly.

A highly significant inverse exponential relationship was observed between biophysical score and perinatal mortality. The authors interpreted the data as suggesting that the BPP scoring provides insight into the extent and degree of fetal compromise.

Several other investigators have subsequently found that the BPP, when used appropriately, leads to a reduction in perinatal mortality and adverse pregnancy outcomes in high-risk pregnancies. Furthermore, it has been useful in predicting those pregnancies at risk for an adverse outcome. The BPP was found to be an effective method of antepartum fetal surveillance in patients with diabetes mellitus, hypertension, multiple pregnancies, and other high-risk conditions. However, few years after its introduction into clinical practice, it became apparent that it was often used with inappropriate expectations or interpretation.

Factors Affecting the BPP

While the BPP is now widely used for fetal assessment, questions are often asked about how the BPP may be affected by several factors commonly encountered in obstetrics.

Gestational Age

Because the biophysical activities are gestational age dependent, it has been suggested that the BPP score would vary across gestation. Hence, Vintzileos and coworkers (47) performed 951 serial examinations from 25 to 44 weeks of gestation in 210 patients with intact membranes and normal pregnancy outcome. These investigators observed a significant increase in reactive NSTs after 32 weeks while both fetal breathing movements and amniotic fluid volume were decreased after 40 weeks. Fetal movements and fetal tone remained stable across these gestational ages. The incidence of grade 3 placentas increased significantly after 32 weeks. These variations in the frequencies of the fetal biophysical components from 25 to 44 weeks of gestation agree with the findings of several other investigators (54–57). It should be noted, however, that the frequency of reassuring biophysical scores (>8) did not change significantly from 25 to 44 weeks of gestation. Using the scoring criteria of Manning and coworkers, Baskett (58) had similar findings regarding the changes of the biophysical components throughout gestation. Their study involved pregnancies with normal perinatal outcome (5582 fetuses/11,012 BPPs). There were an increased number of reactive NSTs and fetal breathing movements at 34 to 41 weeks as compared with earlier gestations. The NST, fetal breathing movements, fetal tone, and amniotic fluid volume were more likely to be abnormal in prolonged gestations (42–44 weeks) as compared with term gestations (37–41 weeks). Although changes in the individual biophysical components were noted, the frequency of normal biophysical scores (>8) did not change significantly throughout gestation. The understanding of the gestational age–dependent changes of the biophysical components is mandatory for the proper clinical application of the BPP, especially when one manages very preterm gestations.

Magnesium sulfate is probably the most commonly used tocolytic in the United States. It is also used for seizure prophylaxis in pre-eclampsia. Peaceman and colleagues performed BPPs on 16 women who were treated with

magnesium sulfate tocolysis for preterm labor at gestational ages of 26 to 34 weeks of gestation (59). They found that magnesium sulfate did not affect fetal tone, gross body movements, or amniotic fluid volume. However, they found a reduction in fetal breathing movements and a higher proportion of nonreactive NSTs in fetuses exposed to magnesium sulfate. In another study, Carlan and colleagues (60) found that administration of magnesium sulfate for tocolysis was associated with a lowered score due to reduced fetal breathing movements. These investigators did not find that magnesium sulfate affected any other components of the BPP. Gray and colleagues evaluated the effect of magnesium sulfate on the BPP and failed to demonstrate any effect of magnesium sulfate on the BPP (61).

The corticosteroids betamethasone and dexamethasone are widely used to induce fetal lung maturation in fetuses at risk of preterm delivery. Rotmensch and colleagues found a transient but reversible suppression of fetal breathing movements, body movements, and FHR accelerations in pregnancies exposed to steroids for lung maturation (62). Jackson and colleagues similarly found a reduction in fetal breathing movements and gross body movements in fetuses in pregnancies where betamethasone was administered (63,64). These authors also observed a reduction in amniotic fluid volume. Deren and coworkers observed that fetuses exposed to betamethasone had reduced fetal movements, breathing movements, and a higher number of nonreactive NSTs (64). In a study of 84 pregnancies in whom betamethasone was administered, Kelly and colleagues found a reduction in BPP scores, mainly caused by a reduction in fetal movements, fetal breathing movements, and a greater proportion of nonreactive NSTs (65). In summary, most investigators have found that steroids affect the BPP mainly through a reduction in reactive NSTs, fetal body movements, and fetal breathing movements. However, this reduction in BPP scores is transient (48–72 hours) and has not been associated with worse perinatal outcomes. This transient reduction in FHR reactivity and fetal breathing movements should be taken into consideration in evaluating preterm fetuses, when the mother has been administered corticosteroids, so iatrogenic prematurity can be avoided.

Inappropriate Use of the BPP

Vintzileos and colleagues pointed out several of the reasons that the BPP may be used inappropriately (36). First, these investigators emphasized that the most frequent error among clinicians is to base the management of the patient on the biophysical score alone. They argued that it is crucial that the clinician should utilize the individual components of the score rather than the total score in making management decisions. For instance, a fetus with a reactive NST and a normal amount of amniotic fluid, but demonstrating no tone or movements during the examination is assigned a score of 4. However, both the acute marker, the most sensitive one (reactive NST), and the chronic marker (amniotic fluid volume) have indicated that this fetus is not hypoxemic. Unfortunately, such patients are often said to have failed their BPP and end up being delivered inappropriately and often prematurely. More than likely, the absence of fetal movements, tone, and/or breathing in such a case may be the result of periodicity. Conversely, a fetus with a BPP score of 8, but with severe

oligohydramnios, should be delivered if the gestational age is term or near term, despite the “favorable” BPP score of 8 because this fetus is a candidate for a cord accident and death in utero despite normal biophysical activities at the time of testing.

A second error that is often encountered, when using BPP to guide management, is failing to consider the overall clinical picture of the individual case. For instance, a fetus at term with severe growth restriction should be delivered, despite the presence of a reassuring BPP score.

Third, one should not use the same interval of testing (i.e., weekly) for all cases. Generally, a BPP score is considered reliable for 1 week. However, certain high-risk conditions, such as insulin-dependent diabetes, growth restriction, or postdate pregnancies may require more frequent testing. Manning and colleagues in evaluating 12,620 pregnancies with BPPs found that half of the fetal deaths after reassuring BPP results occur between 5 and 7 days after testing, suggesting that twice-weekly testing may reduce mortality. The interval between testing, therefore, should be individualized based on the circumstances of each particular case. When a test is non-reassuring, rather than repeat the test in 24 hours, as is widely advocated, it is appropriate to extend the period of testing beyond 30 minutes. Extending the testing duration will help differentiate between a compromised fetus and one where biophysical activities are absent due to periodicity, whereas just retesting in 24 hours, as is the usual advice, may result in fetal demise.

Next, some investigators advocate the use of BPP without performing an NST. However, the NST may detect FHR variable decelerations that may detect the fetuses at risk for cord accident. These fetuses may have a normal BPP score, and false reassurance may be provided if an NST is not performed.

Physicians may often delay delivery even with non-reassuring BPP testing due to such concerns as an unfavorable cervix or preterm gestation. This attitude may carry a significant risk of an adverse perinatal outcome. Clinicians should act based on the information derived from the biophysical assessment.

Finally, operator inexperience and faulty technique may lead to incorrect assessment of biophysical activities and inappropriate management decisions. Amniotic fluid measurements should occur in umbilical cord-free pockets. In addition, fetal breathing movements should be considered present only if they are continuous, lasting for more than 30 seconds. Fetal body movements should be considered present only if there are three or more rolling trunk movements observed in a 30-minute period.

Selective Use of the NST

The selective use of the NST was reported by Manning and coworkers (66), who omitted the NST from the initial biophysical evaluation and included only the other four biophysical components (fetal breathing movements, fetal movements, fetal tone, and amniotic fluid volume). The authors studied 2712 patients who had a total number of 7851 tests and showed that the test accuracy was not compromised. In addition, the need for NST was reduced to only 2.7% of the cases. The selective use of the NST improved the efficiency of the authors' testing unit, shortened the duration of the test,

and increased the number of patients who could be tested daily. Another study by Eden and coworkers, however (67), questioned the wisdom of omitting the NST from the initial biophysical evaluation, as fetuses with all normal biophysical components but variable decelerations during NST testing had an increased frequency of abnormal perinatal outcome. Mills and coworkers (68) proposed a two-tier approach to biophysical assessment of the fetus. They performed a retrospective review of 2038 biophysical assessments in 500 high-risk pregnancies. The authors compared the efficacy of the NST and BPP in predicting fetal asphyxia in fetuses with normal and abnormal growth. The sensitivity, specificity, positive predictive value, and negative predictive value of the NST to predict lethal fetal asphyxia were 100%, 77.5%, 0.4%, and 100%, whereas that of the fetal BPP were 100%, 99.7%, 33.3%, and 100%, respectively. The authors suggested that the appropriate biophysical evaluation of the fetus could be determined based on the clinical problem and the fetal growth. According to the authors, when fetal growth is normal, by ultrasound evaluations at every 4 weeks, no biophysical assessment is necessary. If the growth is abnormal, biweekly NSTs and fetal growth checks by ultrasound at every 2 weeks are indicated. The authors concluded that the fetal BPP should be reserved for those cases where the NST is non-reassuring or equivocal. By using this testing method, the authors speculated that they could theoretically reduce their workload of NSTs by >60% and BPPs by >75%.

The BPP in Diabetes and Postdate Pregnancies

Johnson and coworkers (44) managed 307 consecutive post-term pregnancies with twice-weekly BPPs and suggested that if the biophysical score was reassuring, waiting for spontaneous onset of labor was advisable, resulting in good perinatal outcomes with a much lower cesarean section rate (15% vs. 42% for induction patients). The same authors also reported on the use of the fetal BPP in managing 238 diabetic pregnancies who had a total number of 1028 profiles performed (69). In patients with an abnormal score, there was a high rate of intensive care nursery admissions and cesarean section rate (50%). Of the fetuses with normal BPP scores, 57.4% entered spontaneous labor, 31.3% were induced, and the remaining 11.3% were delivered by elective repeat or primary cesarean section. Stillbirths were prevented and 87% of the patients delivered at or near term with minimal maternal or neonatal morbidity. Abnormal BPP scoring was associated with a significantly higher rate of operative intervention and neonatal morbidity. According to the authors, the fetal BPP allows for a safe expectant management in the diabetic pregnancy.

The usefulness of the fetal BPP in twin gestations has been studied by Lodeiro and coworkers (70). Forty-nine twin gestations with additional high-risk factors such as suspected growth retardation of one or both twins, maternal chronic hypertension, or pregnancy-induced hypertension were followed with weekly BPPs. The sensitivity, specificity, positive predictive value, and negative predictive value of the biophysical assessment in predicting fetal distress were 83.3%, 100%, 100%, and 97.7%, respectively. The false-negative rate was 2.2%. However, the only false-negative death resulted from extreme prematurity in a set of twins delivered at

26 weeks of gestation. Four twin gestations had fetal distress in only one of the twins and all eight fetuses (four pairs) had nonreactive NSTs. The BPP accurately predicted the distressed twin of each of the four pairs, and it also correctly identified well-being for its counterpart twin. The authors concluded that the BPP is a safe and effective tool in the antepartum fetal surveillance of twin gestations.

The wisdom of arbitrary assignment of equal score weights for the various biophysical components was questioned by Manning and coworkers (71). In a study of 525 fetuses, they studied the relationship between the last abnormal BPP score, in total and by variable composition, and a variety of abnormal perinatal outcomes such as fetal distress in labor, low 5-minute Apgar score (<7), intrauterine growth restriction, and admission to the neonatal intensive care unit for >24 hours. It was found that all variable combinations for the same score subsets (scores 6, 4, and 2) are not equal in predictive accuracy. For a biophysical score of 6, the probability of fetal distress or death was significantly higher with either nonreactive NST/fetal tone absent or nonreactive NST/absent fetal breathing movements, whereas the probability of fetal distress was significantly lower when fetal breathing movements were absent in the presence of oligohydramnios. Significant variations in positive predictive accuracy also occurred within subsets of variable combinations yielding a BPP score of 4; these variations, however, disappeared with a BPP score of 2. Overall, the NST, amniotic fluid volume, and fetal breathing movements emerged as the most powerful variables for all perinatal outcome measures. Fetal tone seemed to play a lesser role, and fetal movement was found to be important only for predicting fetal distress.

A Rational Approach to Antepartum Fetal Biophysical Assessment

Considering the “gradual hypoxia concept,” and also the 100% sensitivity of the combination of the nonreactive NST and absence of fetal breathing movements for predicting the acidemic fetus, Vintzileos and coworkers recommended a modified fetal evaluation scheme for patients with intact membranes (Fig. 8). This scheme is based on the individual biophysical components rather than the score (32,36). It should be noted that this scheme is also supported by the data of Manning and coworkers (71), which suggest that the NST, amniotic fluid volume, and breathing movements are the most powerful predictors of fetal compromise.

This protocol includes assessment of an acute (NST or fetal breathing) and a chronic marker (amniotic fluid volume). A reactive NST or fetal breathing lasting >30 sec (even in the presence of a nonreactive NST) makes fetal acidemia at the time of testing highly unlikely. However, there is a caveat in patients with uncontrolled diabetes. Hyperglycemia may cause fetuses in diabetic pregnancies to exhibit fetal breathing even in the presence of (lactic) acidemia. Thus, the blood glucose should be checked in diabetic women at the time of the BPP assessment.

When the NST is nonreactive, it becomes crucial to make the differentiation between fetal sleep and fetal acidemia. If fetal breathing lasting greater than 30 seconds is detected, the examination is terminated and further management is based on the amniotic fluid volume assessment. If all biophysical activities (nonreactive NST, fetal breathing, fetal movements, and fetal tone) are absent after 30 minutes of continuous observation, the fetus should be delivered promptly. If the

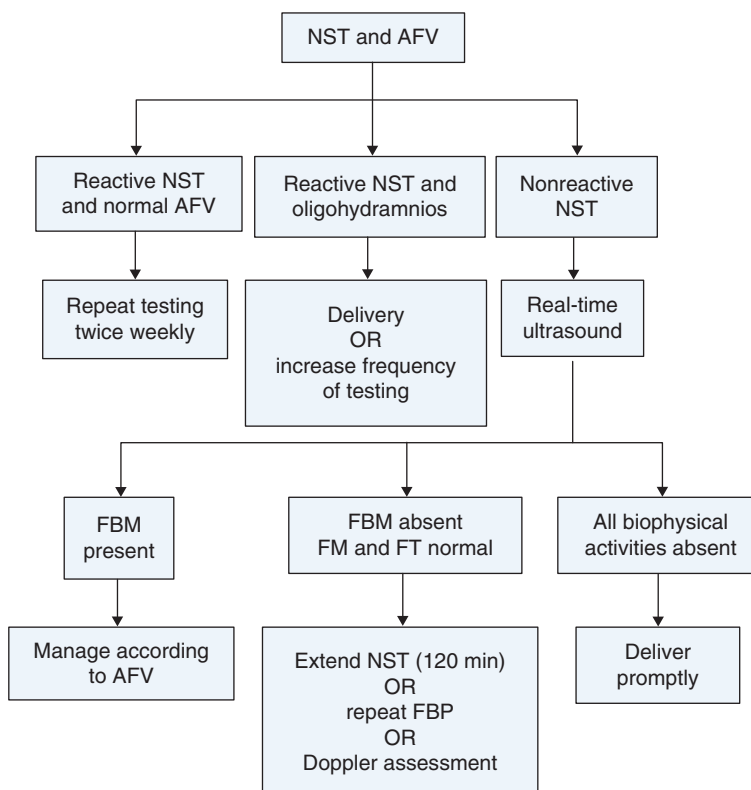

Figure 8 An algorithm for the use of the modified fetal biophysical profile in antepartum fetal surveillance. Abbreviations: AFV, amniotic fluid volume; FBM, fetal breathing movements; FM, fetal movements; FBP, fetal biophysical profile; FT, fetal tone; FHR, fetal heart rate; NST, nonstress test. Source: From Ref. 74.

fetus has a nonreactive NST and breathing is absent, while movements and tone are normal, testing duration should be extended to differentiate fetal sleep from fetal compromise. The NST is continued until a reactive pattern is observed or until 120 minutes have elapsed. If the NST is still nonreactive, the real-time ultrasound examination should be repeated. If no fetal breathing is observed, and the gestational age is >32 weeks, additional evaluation (i.e., Doppler velocimetry) or delivery may be considered. In very preterm gestations (<32 weeks) in the absence of FHR cyclicity, if there is a nonreactive NST and absent fetal breathing, additional evaluation or delivery should also be considered (72,73). If FHR cyclicity and body movements are both present and normal, then expectant management is indicated. The presence of oligohydramnios and/or variable decelerations during NST suggests that the fetus is at risk for umbilical cord accident, and the fetus should be delivered if the gestation is at or near term. The presence of a normal amount of amniotic fluid and the absence of variable decelerations is reassuring, and expectant management may be reasonable. In the presence of oligohydramnios in a term or a near-term gestation with intact membranes, delivery is indicated regardless of how reassuring the other biophysical components are. In our view, a largest amniotic fluid pocket less than 2 cm (or amniotic fluid index <5 cm) defines oligohydramnios. The combination of oligohydramnios and variable decelerations during the NST may indicate the need for delivery in viable, structurally normal fetuses with intact membranes, regardless of gestational age. In very preterm gestations (<32 weeks) in the presence of oligohydramnios and no identifiable fetal anomalies, pregnancies should be managed on a case-by-case basis taking into consideration the results of Doppler velocimetry (if the underlying pathophysiology is reduced uteroplacental blood flow). However, it is crucial to recognize that these fetuses are at increased risk of stillbirth and that while it may be necessary to attempt to prolong gestation to improve maturity at birth, these fetuses may die while being managed conservatively. If delivery is not undertaken, frequent testing (every 24 hours) is an alternative logical plan of management. In this group of fetuses, Doppler studies may assist in deciding management.

Computer-Assisted BPP

The biophysical methods currently used in clinical practice are arbitrary since they do not provide exact quantification of the biophysical activities over a long period, nor do they account for the occasionally long intervals of fetal inactivity, which are frequently observed in normal fetuses. To circumvent these drawbacks, an extended period of concurrent observation of the biophysical activities has been attempted by using computer-assisted systems or phonographic transducers (74,75). Devoe and coworkers (76) have reported their experience by using a computerized system that allowed analysis of the simultaneously acquired biophysical activities in 200 term high-risk fetuses. The biophysical activities obtained for each high-risk fetus were compared with previously established nomograms. The results correlated with the presence or absence of perinatal mortality, fetal distress, a low 5-minute Apgar score (<7), and intrauterine growth retardation. A test was considered abnormal if two or more

biophysical activities quantitatively fell >2 SD below the population mean. A decreased frequency of fetal body movements, decreased amniotic fluid volume, and decreased frequency of FHR accelerations were the most common abnormalities. When fetuses with normal or abnormal perinatal outcomes were classified by the last computerized biophysical test, the sensitivity was 86%, specificity 89%, positive predictive value 75%, negative predictive value 93%, and overall diagnostic accuracy 86.2%. This diagnostic accuracy was significantly better as compared with the arbitrary scoring system of Manning and coworkers. However, this comparison was not based on a randomized trial; in addition, it was not clear whether or not the computer-assisted BPP results influenced patient management.

THE FETAL BPP IN PATIENTS WITH PROM

The effect of PROM on the BPP has been studied extensively. Vintzileos and colleagues performed a retrospective analysis of 1151 fetal BPPs performed between 25 and 44 weeks of gestation in pregnancies with good outcomes (defined as those with no congenital anomalies, infection, fetal distress, or perinatal mortality/morbidity) (47). These investigators compared the fetal BPPs and scores of patients with intact membranes with those who had PPRM, but had good pregnancy outcomes. The frequency of reactive NSTs, fetal breathing, fetal movements, and fetal tone did not change across gestation from 25 to 44 weeks in patients with PROM. However, when compared with patients with intact membranes, those pregnancies with PROM had a higher frequency of reactive NSTs, absent fetal breathing, and reduced amniotic fluid volume. The frequency of nonreactive NST at less than 32 weeks of gestation was only 13.5% in the presence of ruptured membranes. The overall biophysical scoring was not altered by the presence of PROM. The changes in the fetal BPP caused by PROM are summarized in Table 7.

In a prospective study, Vintzileos et al. (46) performed frequent fetal biophysical assessments on 73 patients with PROM with no clinical signs of labor or infection and demonstrated that an abnormal BPP was an early indicator of intra-amniotic infection. A fetal BPP was performed on admission and was repeated every 24 to 48 hours. The last biophysical assessment before delivery was correlated with the development of clinical amnionitis, possible neonatal sepsis, and neonatal sepsis. The diagnosis of possible neonatal sepsis was made when there was strong clinical and laboratory evidence of neonatal infection but the cultures were negative. The diagnosis of neonatal sepsis was made in the presence of positive cultures of blood, urine, or cerebrospinal fluid. There

Table 7 Summary of Changes in the Fetal Biophysical Profile Associated with Premature Rupture of the Membranes

Increase in fetal heart rate reactivity
Decrease in fetal breathing movements

No change in fetal tone
No change in the overall biophysical score

was no correlation between the fetal biophysical assessment and intra-amniotic infection in the 20 of the 73 patients who delivered at greater than 24 hours following the last biophysical assessment. Fifty-three patients delivered within 24 hours of the last biophysical examination; in these patients, a biophysical score of >8 was associated with an infection rate of 2.7%, while an abnormal biophysical score (<8) was associated with an overall infection rate of 93.7% (46). The first manifestations of fetal intra-amniotic infection were nonreactive NST and absent fetal breathing. Loss of fetal movement and absent fetal tone occurred only in advanced infections. The best predictor of infection was the overall biophysical score. The fetal biophysical score range was <8 in all the 14 cases with possible neonatal sepsis or neonatal sepsis. No difference in the mean umbilical cord blood pH between the infected and non-infected cases was found, an observation that suggests that the low scores of the infected group were not mediated by hypoxia, but rather by infection. In patients with PROM, the degree of oligohydramnios, one of the components of the BPP, is strongly correlated with pregnancy prolongation, abnormal antepartum and intrapartum FHR patterns, cesarean section rates, fetal distress, infection, and perinatal mortality. Vintzileos and colleagues correlated the degree of oligohydramnios with pregnancy outcome in 90 patients with PROM and no signs of infection or labor (77). Patients with severe oligohydramnios (largest amniotic fluid pocket <1 cm) had the highest frequency of amnionitis (47.3%), possible neonatal sepsis (26.3%), and neonatal sepsis (31.5%), compared with 9.2%, 3.7%, and 1.8%, respectively, in patients with a largest amniotic fluid pocket >2 cm. Based on this finding, these investigators concluded that patients with PROM and severe oligohydramnios should have daily fetal BPPs performed. A retrospective analysis of 127 consecutive patients with PROM who had NSTs performed every 24 to 48 hours as part of the fetal BPP demonstrated that those who initially had a reactive NST and subsequently converted to a nonreactive NST developed clinical intra-amniotic infection in almost 90% of the cases (78). The last NST prior to delivery had sensitivity, specificity, positive, and negative predictive values to predict infection outcome of 78.1%, 86.3%, 67.7%, and 92.1%, respectively. Fetal breathing movements (lasting >30 s) have also been shown to predict intra-amniotic infection. In a study of 130 patients with PROM who were followed with BPP assessments every 24–48 hours, the sensitivity, specificity, positive, and negative predictive values of fetal breathing to predict intra-amniotic infection were 91.6%, 64.8%, 50%, and 95.3%, respectively (79). Of the individual biophysical components, the presence of fetal breathing has been the most reliable in ruling out fetal infection, if observed within 24 hours prior to delivery. Vintzileos and coworkers compared daily fetal BPPs with amniocentesis (for Gram stain and culture) in 58 patients who presented with preterm PROM and no apparent infection or labor (48). In addition to the usual indications for delivery, a positive Gram stain or culture of the amniotic fluid, obtained by amniocentesis, or a persistently abnormal biophysical score (<8) on two examinations, 2 hours apart, in the presence of a nonreactive NST and absent fetal breathing were also considered as the indications for delivery. The last BPP prior to delivery and amniocentesis results on admission were correlated with

infection outcome. All but one of the 13 cases with neonatal infection were associated with an abnormal biophysical assessment. There were two cases with amnionitis without neonatal infection; both cases had normal BPPs. The sensitivity, specificity, positive predictive value, and negative predictive value of the BPP for infection were 80%, 97.6%, 92.3%, and 93.3%, respectively. The sensitivity, specificity, positive predictive value, and negative predictive value of the Gram stain were 60%, 81.3%, 52.9%, and 85.3%, respectively, whereas those of the amniotic fluid cultures were 60%, 86%, 60%, and 86%, respectively. The authors concluded that in preterm PROM daily BPPs are more efficacious than amniocentesis on admission in selecting those patients who either have or will develop intra-amniotic infection and therefore require prompt delivery. Importantly, the fetal BPP is simple, noninvasive, can be repeated daily, or even more frequently and is applicable to all patients. Vintzileos and coworkers (80) managed 73 consecutive patients with PROM with daily BPPs in an attempt to determine whether daily BPPs improved pregnancy outcomes. The pregnancy outcome of this group was compared with the outcomes of two other historic groups: 73 consecutive patients with PROM in the first control group were managed conservatively while the 73 consecutive patients with PROM in the second control group were managed with amniocentesis on admission. Maternal and neonatal infection rates, as well as low 5-minute Apgar scores were significantly less in the study group than among controls. The percentage of mother–infant pairs who developed infection in the study group (10.9%) was significantly less than that in the control group (30.1%). Clinical amnionitis was reduced from 20.5% to 5.4%. The frequencies of possible neonatal sepsis and neonatal sepsis were also lower in the study group compared with the control group (5.4% vs. 13.6% and 1.3% vs. 9.5%, respectively). The study group also had significantly less neonatal sepsis (1.3% vs. 12.3%). The authors concluded that the use of amniocentesis may decrease the incidence of clinical amnionitis, but it does not improve the neonatal infection outcome. The neonatal infection outcome was, however, reduced by using daily biophysical assessment.

In order to investigate the role of fetal acidemia in causing diminished biophysical activities in the setting of subclinical infection and PROM, Vintzileos and coworkers (81) performed a prospective evaluation of 53 consecutive patients with preterm PROM who were delivered solely on the basis of an abnormal fetal biophysical assessment. Fetal acidemia at birth was defined as cord artery pH <7.20 . Of the 53 fetuses, 19 developed no maternal or neonatal infection and none was acidemic at birth. Seventeen fetuses developed possible neonatal sepsis and none was acidemic at birth. Fifteen fetuses developed neonatal sepsis and only five were acidemic at birth. Two fetuses developed clinical amnionitis and only one was acidemic at birth. While fetal acidemia could explain the diminished fetal biophysical activities in 5 of the 15 fetuses who developed neonatal sepsis and in 1 with clinical amnionitis, this mechanism could not explain the compromised biophysical activities in the remaining 10 fetuses with neonatal sepsis and in all 17 fetuses who developed possible neonatal sepsis. A possible explanation for the diminished biophysical activities of the infected non-acidemic fetus may be an increased production of prostaglandins, particularly interleukin-1. Interleukin-1, the main fever

mediator, induces changes in the electroencephalogram that may be responsible for the decreased motor activity during fever in both animals and humans (82). Since interleukin-1 is capable of stimulating prostaglandin production from macrophages and other cell types, it has been suggested that this may be responsible for the decrease in fetal breathing observed not only prior to labor but also in the setting of subclinical infection. This increased prostaglandin secretion may directly inhibit the fetal CNS centers or may indirectly lead to increased peripheral vascular resistance through vasoconstriction of the umbilical and chorionic vessels (83,84). Since there are experimental data to suggest that prostaglandins increase placental vascular resistance through vasoconstriction of umbilical and chorionic vessels, the relationships among umbilical artery velocimetry, the fetal BPP, and placental inflammation in patients with PROM have also been investigated (85). The study population involved 28 consecutive patients with preterm PROM who were followed with daily fetal BPPs and umbilical artery velocimetry. After delivery, placental pathologic examination for evidence of inflammation was performed in all cases. When only the last examination, within 24 hours of delivery, was considered, patients with placental inflammation (choriodecidualitis, umbilical and/or chorionic vasculitis) had higher mean umbilical artery Doppler systolic/diastolic (S:D) ratios (2.92 ± 0.62 vs. 2.29 ± 0.25) and lower biophysical scores (6.2 ± 2.3 vs. 9.1 ± 2.1) compared with those without evidence of placental inflammation. It should be noted that the mean S:D ratio value 24 hours prior to delivery in cases with placental inflammation was 2.92, which is not necessarily higher than the normal range. Fetuses with placental infection increased their S:D ratio during the last 24 hours prior to delivery approximately 30% (which was statistically significant) over the mean value of the preceding days. These data suggest that larger studies are needed to more accurately determine the value of the longitudinal trend in Doppler velocimetry indices in regard to being additional noninvasive means of identifying subclinical intra-amniotic infection. The increase in umbilical vascular resistance supports a role for vasoactive substances, such as prostaglandins, as mediators of infection causing vasoconstriction of umbilical and chorionic vessels. This increase in vascular resistance may compromise uteroplacental circulation and diminish biophysical activities prior to the development of fetal acidemia.

CONCLUSIONS

Antepartum fetal surveillance has led to a reduction in perinatal mortality. The techniques described in this chapter are now widely accepted and almost universally used. A clear understanding of the physiologic basis for these tests and of the pathophysiology of the conditions that can cause fetal death or intrauterine hypoxia is crucial to appropriate application of these surveillance methods. Unfortunately, there will still be some causes of death that cannot be predicted or prevented using these methods.

69 Amnioinfusion

James Kerns, Erol Amon, and Hung N. Winn

INTRODUCTION

Amnioinfusion is a technique in which a crystalloid solution, usually normal saline, is instilled into the amniotic cavity to replace amniotic fluid, which may be absent or low. This technique has been employed with increasing frequency and interest during the past three decades. It is used most often during the intrapartum period to prevent, decrease, or eliminate variable decelerations (1–5). During the antepartum period, amnioinfusion is used less frequently. It is mainly used in this setting to facilitate evaluation of fetal anatomy, less commonly in attempts to reduce fetal complications from prolonged oligohydramnios, and rarely to prevent infectious complications from preterm premature rupture of the membranes (PROM) (6–10).

PATHOGENESIS AND CLINICAL ASPECTS OF OLIGOHYDRAMNIOS

Near the end of the first trimester, the amnion and chorion fuse to create the amniotic cavity, which contains approximately 50 mL of amniotic fluid. In early pregnancy, the amniotic fluid is primarily the product of maternal transudate through the amniotic membranes. By the 16th week of gestation, the amniotic fluid volume is mainly regulated by the processes of fetal urination and fetal swallowing. As the pregnancy progresses, the normal amniotic fluid volume rapidly increases to a maximum (range 0.5–2.0 liters, 95% confidence interval) at about 34 weeks of gestation. The volume then normally decreases as a natural progression (11).

Oligohydramnios can result from

1. any condition that prevents the formation of urine or prevents the entry of urine into the amniotic sac, including bilateral renal agenesis, bilateral multicystic dysplastic kidneys, infantile polycystic kidney disease, and complete lower tract obstructive uropathies;
2. uteroplacental insufficiency, particularly in the setting of fetal growth restriction (FGR);
3. post-term pregnancies;
4. rupture of membranes (ROM);
5. prolonged maternal use of indomethacin or other nonsteroidal anti-inflammatory drugs;
6. abdominal pregnancy; and
7. reasons unknown, that is, idiopathic.

The amniotic fluid environment is necessary for normal fetal growth and development, as evidenced by fetal lung hypoplasia and deformations in the case of Potter's syndrome. Pulmonary hypoplasia may well develop if prolonged oligohydramnios (>2 weeks) secondary to preterm PROM occurs prior to 24 weeks of gestation. The earlier the

gestational age when the premature ROM occurs, the greater the incidence of lung hypoplasia (12). Oligohydramnios predisposes to umbilical cord compression, which can lead to fetal hypoxia if resultant interference with blood flow is severe, repetitive, and prolonged.

Clinical management involves obtaining a patient's history to determine:

1. leakage of amniotic fluid;
2. risk factors for FGR such as smoking, drug abuse, severe diabetes, or cardiovascular disorders;
3. medication history; and
4. family history of congenital anomalies, especially urinary tract abnormalities.

Physical examination may reveal the fundal height to be less than expected, leakage of amniotic fluid from the cervical canal, and/or positive tests for ROM. Fetal heart rate monitoring may reveal variable or prolonged decelerations.

Ultrasound evaluation is essential in assessing the amniotic fluid volume and fetal anatomy. Occasionally, amniocentesis with injection of indigo carmine dye may be necessary to diagnose ROM, especially when there is a history of leakage of fluid in the absence of confirmatory findings.

Ultrasound evaluation of the amniotic fluid includes the one largest vertical pocket and the amniotic fluid index (AFI). The latter is a summation of the highest vertical dimensions of the four quadrants of the uterine cavity. Oligohydramnios exists if the AFI is less than 5 cm. If the vertical dimension of the largest pocket of fluid is <1 cm, severe oligohydramnios is present.

The initial step in the clinical management of oligohydramnios is to determine the etiology. Management is then based on gestational age, maternal health, fetal diagnosis and prognosis, and the patient and family's concerns.

INDICATIONS FOR AMNIOINFUSION

General Overview

Amnioinfusion is generally classified according to the pregnancy status as antepartum or intrapartum. The procedure is performed either transcervically or transabdominally. Its purpose can be diagnostic, therapeutic, or prophylactic.

During the antepartum period, amnioinfusion may be used transabdominally to improve sonographic imaging, to obtain fluid for culture, to obtain fetal cells for karyotyping, and to restore adequate levels of fluid to reduce the likelihood of lung hypoplasia and arthrogyposis.

During the intrapartum period, amnioinfusion may be diagnostic (instilling and aspirating fluid to evaluate the microbiology of in utero infections), therapeutic (to alleviate cord compression), or prophylactic (selected cases to decrease the incidence of meconium aspiration syndrome).

Antepartum Indications: Diagnostic

Oligohydramnios poses a diagnostic challenge for the physician, as the differential diagnosis is broad. Etiologies may include urethral outflow obstruction, absent or diminished renal function, PROM, FGR, congenital malformations, or chromosome anomalies. Conventional sonographic imaging may prove inadequate to view the fetal anatomy, owing to the absence of a satisfactory acoustic window. Fetal positioning, including crowding of small parts, may also impair visualization. Therefore, diagnostic imaging is an important step prior to selecting a course of therapy.

In 1988, Grembruch and Hansamnn described transabdominal amnioinfusion to improve ultrasound imaging (13). Quetel et al. used amnioinfusion in patients with oligohydramnios and were able to provide an adequate acoustic window and perform a comprehensive ultrasound evaluation (10). They confirmed the diagnosis of ruptured membranes by transabdominal instillation of indigo carmine and observed the passage of blue dye into the vagina. Fluid could be aspirated during the amnioinfusion procedure for evaluation and the cells cultured for karyotyping.

Antepartum Indications: Therapeutic

Fisk and colleagues (8) performed serial amnioinfusion in a few selected cases and found that they could avert lung hypoplasia. Serial infusions were initiated as soon as feasible after the diagnosis of oligohydramnios was made and terminated after the canalicular phase of lung development was complete. In the setting of PROM, some investigators demonstrated that successful amnioinfusion resulted in prolonged gestation, improved neonatal outcome, reduced incidence for pulmonary hypoplasia, and fewer abnormal neurologic sequelae compared with those patients with persistent oligohydramnios (14,15). However, the Cochrane Collaboration review concluded that there was too little evidence to show the beneficial effects of amnioinfusion to the fetus following PROM (16). Since pulmonary hypoplasia remains the most common cause of neonatal death following vesico-amniotic shunting for obstructive uropathy, serial amnioinfusion may improve the neonatal outcomes for this condition.

Antepartum amnioinfusion has been proposed to improve the success rate of external cephalic version. Benifla et al. instilled about 800 mL of solution transabdominally into the amniotic cavity of the patients who had failed standard attempts at external version. In each case, ($n = 6$), a successful external version resulted after the amnioinfusion (17). However, others found that transabdominal amnioinfusion of 1000 mL of solution into the amniotic cavity did not improve the successful external version ($n = 7$) (18). The Cochrane Collaboration review concluded that there was too little evidence to show the benefit of transabdominal amnioinfusion in external cephalic version (19).

Intrapartum Indications: Diagnostic

An indwelling, intrauterine, fluid-filled pressure catheter was initially introduced to monitor uterine tone and uterine activity. The diagnostic use of this medical device has been expanded. In the clinical setting of chorioamnionitis, fluid may be aspirated from a catheter port for Gram-stain evaluation

with or without culture and sensitivity, as clinically indicated. A paucity of amniotic fluid may be detected at the time of amniotomy. This could signify thick meconium or oligohydramnios.

Intrapartum Indications: Therapeutic

Using pregnant monkeys, Gabbe and coworkers demonstrated that removal of amniotic fluid produced variable decelerations, which were subsequently eliminated when the fluid volume was restored (20). Many have reported that a similar mechanism of using fluid as an umbilical cord cushion, via transcervical amnioinfusion in the setting of oligohydramnios, results in a significant improvement in variable and prolonged decelerations, which do not otherwise respond to conventional methods (intravenous fluids, repositioning, O₂ administration, and manipulation of the presenting fetal part).

Accurate measurement of the amount of fluid retained is difficult, because unknown quantities of fluid may leak out during transcervical therapy. Serial ultrasound evaluation of the AFI may be useful in assessing the change as a guide for further infusion therapy including avoiding polyhydramnios (2,3,10,21). It is important to define the end point of the amnioinfusion such as AFI of 8 cm, total volume of solution infused, total rate infused, or the resting tone of the uterus.

Intrapartum Indication: Prophylactic

Oligohydramnios in the setting of structurally normal fetuses occurring in the intrapartum period may be caused by membrane rupture, FGR, or postdates. With the loss of the amniotic fluid cushion, there is an increased risk of cord compression, which may lead to variable or prolonged decelerations. These decelerations may be associated with hypoxia and acidosis. Using amnioinfusion, variable decelerations have been eliminated or reduced in frequency or severity during the first and second stages of labor, thereby reducing the associated hypoxia and acidosis and leading to an improved fetal acid-base status at delivery (2,4,5,20).

With prophylactic restoration of amniotic fluid volume at term, Strong and colleagues (3,21) reported a decreased incidence of meconium aspiration syndrome, severe variable decelerations, end-stage bradycardia, operative delivery for fetal distress, and low umbilical artery pH values. Other investigators (21–24) concluded that amnioinfusion prophylaxis at 36 weeks or greater in patients with membrane rupture and oligohydramnios (AFI <5 cm) resulted in reduced intrapartum morbidity, decreased rates of cesarean delivery, and decreased episodes of fetal intolerance to labor. They also concluded that there were improved umbilical cord gas values, neonatal outcomes, and improved Apgar scores.

The presence of meconium may be the natural response of the gastrointestinal system to maturation. It may also be the response of the fetus to a stressful condition such as hypoxia, acidosis, or vagal stimulation. Generally, these etiologies are distinguished by the normality of the fetal heart rate pattern, with completely normal patterns being indicative of normal maturation.

Meconium has been associated with increased perinatal morbidity and mortality, especially due to aspiration of meconium-stained amniotic fluid. Meconium aspiration syndrome, defined as respiratory distress requiring mechanical

ventilation in a neonate with meconium aspiration, carries a mortality rate of approximately 25% and accounts for about 2% of all perinatal deaths. The passage of meconium in utero occurs in 8% to 16% of all deliveries; however, meconium aspiration syndrome occurs in only 1% to 3% of all cases of meconium-stained fluid (25). Meconium aspiration may occur before or during labor, or during the process of delivery. When meconium is aspirated into the lower respiratory tract, mechanical obstruction and chemical inflammation may occur.

Prior to the use of amnioinfusion, combined obstetric and pediatric suctioning of the neonate's airway during and after delivery was the mainstay of preventing meconium aspiration syndrome. This technique, as described by Carson and colleagues (26), was reported to decrease the frequency of meconium aspiration syndrome, assuming the aspiration occurred during the delivery process.

Some investigators reported amnioinfusion's beneficial effects in laboring patients who had meconium and oligohydramnios. Amnioinfusion resulted in a decreased incidence of:

1. 1- and 5-minute Apgar scores <7;
2. meconium visualized below the cords and in the oropharynx;
3. the presence of thick meconium in selected clinical settings;
4. umbilical arterial cord pH values <7.20;
5. intrapartum fetal distress;
6. operative delivery for fetal distress;
7. cesarean delivery rates; and
8. need for positive pressure ventilation of the newborn (27–29).

It was noted that the rates of cesarean delivery for arrest disorders were similar in the amnioinfusion and the control groups.

The Cochrane Collaboration recent review concluded that amnioinfusion during labor for meconium-stained amniotic fluid showed (i) no improvement in the perinatal outcomes if the labor and delivery unit has adequate monitoring of fetal condition and (ii) a significant improvement in the perinatal outcomes if the labor and delivery unit has limited capacity in monitoring fetal conditions during labor (27).

In summary, amnioinfusion provides an additional therapeutic option in labor to treat patients experiencing variable and prolonged decelerations that are unresponsive to conventional methods. Amnioinfusion also allows for prevention of fetal heart rate-related complications when used prophylactically in the intrapartum setting of oligohydramnios (30).

CONTRAINDICATIONS

In general, absolute contraindications to vaginal delivery are also absolute contraindications to intrapartum transcervical amnioinfusion. These include placenta previa and prior ruptured uterus. Other contraindications include conditions in which there would be no fetal benefit, such as lethal fetal anomalies and fetal death. The relative contraindications are listed in Table 1.

Clear evidence of impending fetal hypoxia or acidosis generally requires expedient delivery rather than temporization with amnioinfusion. Maternal exclusions include maternal

Table 1 Relative Contraindications to Amnioinfusion

Uterine anomalies
Chorioamnionitis
Maternal heart disease class II, III, IV
Fetal growth restriction
Fetal malformations
Malpresentation
Classical or unknown cesarean section scar
Abruptio placentae
Multi-fetal gestation

heart disease (New York Heart Association functional classification II or greater), as noted by Sadosky and colleagues due to potential fluid overload from absorption (29). Abnormal uterus such as septate uterus may be less distensible and less pliable to amnioinfusion, thus less timely change in the pressure–volume curve. Whether chorioamnionitis is a contraindication is controversial, since some consider this condition to be an indication.

PROTOCOLS

A variety of protocols for amnioinfusion have emerged, all of which have common elements and guidelines. The common elements can be divided into pre-infusion preparation and evaluation, infusion equipment and monitoring, and post-infusion evaluation. The common guidelines are patient education and nursing in-service, evaluation of equipment, defining eligibility for infusion, and delineating the limits of the infusion. The ideal protocol defining the recommended infusion technique and rate has not been established. Various protocols are available, with variations defined by different authors for their own purposes. No controlled study has demonstrated the superiority of any given protocol.

In general, an eligible patient, during labor, has one or more of the following indications:

1. Variable deceleration with or without oligohydramnios;
2. Meconium amniotic fluid at term with limited monitoring capability;
3. Oligohydramnios either at term or preterm as a result of ROM; and/or
4. Oligohydramnios with intact membranes.

Variable decelerations, as previously discussed, are attributed to cord compression, with multiple studies showing that relieving the cord compression and improving the oxygen delivery to the fetus improve the intrauterine environment and the neonatal outcome.

The recommended protocol may include the following:

1. Informed consent concerning the clinical setting, risks and benefits, and alternatives. Oral consent may be legally sufficient, but it is best followed by written consent for amnioinfusion and cesarean delivery, if indicated.
2. A pelvic examination is performed to verify presentation, absence of cord prolapse, cervical dilatation and effacement, and fetal station.
3. Membrane rupture should be confirmed prior to transcervical amnioinfusion. An internal fetal heart

rate electrode and an intrauterine pressure catheter, the latter ready for amnioinfusion, should be placed appropriately.

4. Some authors perform ultrasound for amniotic fluid volume index at the start as well as serially, but this may be unnecessary. Strong and coworkers (21) showed that 250 mL of infusion into a relatively closed system increases the amniotic fluid volume index by 4 to 4.3 cm (range 0–7.7 cm).
5. The intrauterine catheter system chosen should be able to monitor intrauterine pressure and instill amniotic fluid.
6. The fluid chosen for infusion is either normal saline or lactated Ringer's.
7. Consider warming the infusion to 37°C for the preterm fetus or rapid infusion.
8. Infuse normal saline at a rate of 10 to 14 mL/min. If a faster rate is carried out (e.g., 15–25 mL/min by gravity), then warming the fluid to 37°C is recommended. The initial infusion volume is generally 500 to 600 mL. Some recommend stopping the infusion after a bolus, while others recommend continuous infusion at a lower rate (2–3 mL/min).
9. End points for the infusion are individualized, based on experience and the purpose to be achieved. These include:
 - (a) a predetermined volume of 600 to 1000 mL;
 - (b) resolution of variable decelerations;
 - (c) an AFI of 8 to 10 cm; and
 - (d) a slow continuous irrigation and lavage at 2 to 3 mL/min, as long as fluid is continually draining out of the uterus.
10. If sonographic monitoring is available, the following guidelines are recommended:
 - (a) If AFI >10 cm, no additional bolus is recommended.
 - (b) If AFI is 5 to 10 cm, a second bolus of 250 mL is added and reassessment by sonogram is conducted.
 - (c) If AFI <5 cm, a second bolus of 500 mL is added and reassessment by sonogram is conducted.
11. Periodic re-bolus with 500 to 600 mL of fluid every 6 hours or a constant low infusion rate of 2 to 3 mL/min may be used, depending on uterine tone and AFI.
12. Periodic assessment of the fetal heart rate pattern, uterine tone and activity, volume infused, vaginal leaking, and progress of labor is necessary.
13. Evaluation for complications.

Meconium-staining amniotic fluid presents potential meconium aspiration and the meconium aspiration syndrome. Amnioinfusion is effective in diluting meconium but may not reduce the incidence of the neonatal sequelae.

Preterm PROM presents two major concerns, namely, potential cord compression with its sequelae and intrauterine infection. There should be a low threshold to initiate therapeutic amnioinfusion and systemic chemoprophylaxis in the appropriate clinical setting.

Oligohydramnios at term, with membrane rupture occurring during labor, subjects the fetus to the potential of cord compression and its sequelae. The protocol recommended is the same as that for variable decelerations.

COMPLICATIONS

The adverse effects and potential complications of amnioinfusion are summarized in Table 2.

In a survey, 26% of centers reported at least one associated complication. The most frequent complication was uterine hypertonus (14%), followed by fetal heart rate abnormalities (9%) (30).

Although Posner and colleagues (31) found no change in uterine tone with controlled volumes of amnioinfusion and monitoring, they did report polyhydramnios with over-infusion. Two cases of polyhydramnios with uterine tenderness, one initially thought to be placental abruption (32) and the other with elevated uterine tone and fetal bradycardia from the amnioinfusion (33), were reported. In both cases, when the excess fluid was removed, the elevated uterine tone and uterine tenderness were relieved. In the case reported by Tabor and Maier, the bradycardia resolved after the excess fluid was removed (33). Over-distension and elevated uterine tone from amnioinfusion could disrupt a previous cesarean section scar. One case of a disrupted uterine scar was noted during a repeat cesarean delivery in which there was no resolution of the variable decelerations with amnioinfusion (1). Strong and colleagues (34) reported no change in the incidence of uterine scar disruption.

One case of cord prolapse was reported, but it was the same case in which the delivery was assisted by mid-forceps. No difference in the incidence of nuchal cords was demonstrated (31).

Miyazaki and Taylor (1) noted one case of fetal bradycardia, which occurred during rapid infusion of room temperature fluid (400 mL over 8 minutes). The proposed mechanism was sudden chilling, leading to vasoconstriction, hypertension, and reflex bradycardia in the fetus. They noted no episodes of bradycardia when the infusate was warmed to 37°C, regardless of the infusion rate. Thus, warming of the fluid appears unnecessary if the infusion rates are limited to 10 to 15 mL/min or less.

The rate of amnionitis as a result of amnioinfusion is variable (10,21). Patients with a higher rate of amnionitis also had more vaginal examinations. When this element was corrected, the rate was not significantly different from that of the control (non-infused) group (29). The majority of investigations reported no significant change in the rates of amnionitis associated with amnioinfusion.

Table 2 Complications of Amnioinfusion

Potential neonatal electrolyte imbalance
Potential neonatal hypothermia
Umbilical cord prolapse
Acute polyhydramnios
Fetal bradycardia
Elevated uterine tone
Previous cesarean section scar disruption
Amnionitis/endometritis
Amniotic fluid embolus

Nageotte and coworkers (4) noted that there were no significant differences in the basic electrolytes (Na, K, Cl, and CO₂) in newborns delivered following amnioinfusion as compared with those not subjected to amnioinfusion. The infusate used in this study was normal saline.

No conclusive evidence of the effect of amnioinfusion on the length of labor is available. The evidence presented by Strong and colleagues (3) suggested that there was a significant increase in the length of labor from 10.1 ± 6.5 to 16.8 ± 12.1 hours in their group, whereas Schrimmer and coworkers (5) reported a shorter duration of labor in their group of patients. Macri and colleagues (35) noted no significant change in the lengths of labor between the control group and the amnioinfusion group.

Dibble and Elliott (36) reported possible amniotic fluid embolus in two cases following amnioinfusion. No direct association was made to this rare pregnancy complication and amnioinfusion. They proposed that these two cases were mild because of the dilutional effect of the infusate on the particulate matter in the amniotic fluid. Other authors have also reported maternal respiratory distress in association with amnioinfusion (37,38).

CONCLUSIONS

Amnioinfusion is useful during the intrapartum period for relief of variable and prolonged decelerations, and obtaining fluid for evaluation of meconium staining and microbiology.

Amnioinfusion in the antepartum period may be useful in improving the ultrasound image, obtaining fluid for karyotype or culture and restoring fluid volume to decrease the likelihood of lung hypoplasia, arthrogyposis, or other fetal compression disorders in the setting of oligohydramnios.

Amnioinfusion has been an established part of the clinical management of complicated obstetric patients.

71 The maternal immune system during pregnancy

Breton F. Barrier

INTRODUCTION

The effects of pregnancy on the immune system are intriguing and clinically recognizable. A viral pharyngitis in pregnancy may persist for weeks on end while fulminate vulvar condyloma may suddenly regress in the postpartum period. At first glance, these changes seem to defy logic. Why does multiple sclerosis improve in pregnancy (1), while an active lupus flare is fueled? (2). Why does ankylosing spondylitis worsen (3), yet rheumatoid arthritis improves (4)?

Deepening the mystery is the remarkable coexistence of the fetus—a semi-allograft recognized by the maternal immune system—living freely within the maternal host without rejection. This phenomenon first caught the attention of Nobel laureate Sir Peter Medawar over 50 years ago, prompting him to advance his now-famous four nonexclusive postulates about maternal–fetal tolerance: (i) the fetus may not be immunogenic, (ii) the uterus may be immunoprivileged, (iii) the placenta may be an immunologic barrier, and (iv) the mother may be immunosuppressed (5). From the time that Medawar first enunciated these postulates, rapid advances in maternal–fetal immunology have evolved, giving great hope for an approaching era of practical clinical application.

The immune system is an exceptionally complex and elegant network of cells, cytokines, chemokines, antibodies, and regulatory proteins. Because of this complexity, it is useful to artificially partition the immune system to facilitate study and dialog. The broadest categories have been classically described as the immune system's innate and adaptive arms. The cellular constituents of these arms are summarized in Table 1.

THE INNATE ARM OF THE IMMUNE SYSTEM

The innate arm of the immune system is the first line of defense and includes (i) epithelial cells, (ii) macrophages, (iii) neutrophils, (iv) natural killer (NK) cells, and (v) complement. Innate sentinel cells include epithelial cells and macrophages that sample the local environment and rapidly respond when pathogens are detected. Neutrophils and NK cells are the primary effector cells of the innate immune system. Eosinophils and basophils play an important role in allergic and parasitic infections and will not be discussed in detail in this chapter. Serum complement does just that—“complement” immune processes by weakening or marking pathogens for destruction.

Epithelia

The epithelial barrier to the environment provides the first line of defense against the intrusion of pathogens. Some epithelia, such as endometrium, possess the ability to synthesize and secrete cytokines, and to process and present antigens to adaptive immune cells, driving proliferation of autologous

lymphocytes (6). Endometrial epithelial cells possess special pattern recognition receptors (PRRs) called Toll-like receptors (TLRs) that recognize “pathogen-associated molecular patterns” (PAMPs) (7). Different TLRs recognize various PAMPs, and their expression is highly tissue specific. TLRs are found in epithelial urogenital tissues, professional antigen-presenting cells (such as macrophages and dendritic cells), and trophoblast-derived tissues such as placenta and amnion (8).

Complement

Complement is a collection of serum proteins that bind pathogens, leading to immediate destruction, opsonization, or chemotaxis. Once activated, factors remain bound to the pathogen (i.e., factor C3b) or released locally for neutrophil chemotaxis (i.e., factor C3a). Complement is activated through multiple mechanisms resulting in the formation of a “C3 convertase” (Fig. 1): (i) it is activated by antibodies present on pathogens through factor C1q (the “classical” pathway); (ii) it binds directly to the pathogen through factor C3b (the “alternative” pathway), or (iii) it is activated by the terminal mannose of bacterial N-acetyl glucosamine through mannose-binding protein (the “lectin” pathway). The presence of C3b then opsonizes organisms for phagocytosis by neutrophils and macrophages. In some cases, such as with *Neisseria* sp., complement also forms a multicomponent membrane attack complex (MAC) that leads to direct perforation and lysis of the organism (9,10).

Maternal complement levels in pregnancy are similar or greater than those of nonpregnant controls (11). Because of the potential of activation of complement by maternal antibodies toward paternal antigens, the trophoblast must have a mechanism in place to inhibit this process. At least three important complement regulatory proteins are expressed by the trophoblast as early as 6 weeks of gestation: decay-accelerating factor (DAF, CD55) (12), membrane cofactor protein (MCP, CD46), and CD59.

DAF inhibits formation and accelerates decay of C3/C5 convertase, which inhibits the alternative pathway. MCP is an intrinsic-acting protein that binds efficiently to C3b attached to other molecules on the cell surface (13). MCP then cleaves the C3b or C4b components of complement to their inactive derivatives, which inhibits the classical complement pathway. Finally, CD59 inhibits the final common component of both complement pathways—the MAC. CD59 is expressed in greater amounts than either DAF or MCP, although the absence of CD59 is compatible with successful pregnancy, indicating that MCP and DAF are able to compensate for a lack of CD59.

Expression of all three proteins occurs on the terminally differentiated syncytiotrophoblast that is in direct contact with maternal blood. Villous cytotrophoblast cells express CD59

Table 1 Commonly Encountered Cytokines

Cytokine	Origin	Function
IL-1 β	Epithelium, macrophages, neutrophils	Stimulates T- and B-lymphocytes; makes B-cells responsive to IL-5 and T-cells responsive to IL-2
IL-2	T-cells	Autocrine stimulation of T-cells
IL-4	T-cells (Th ₂)	Differentiation of naive T-helper cells into Th ₂ cells
IL-5	T-cells (Th ₂)	Stimulates B-cell growth and increases immunoglobulin secretion
IL-6	Epithelium, macrophages, T-cells	Stimulates acute phase response; differentiation of B-cells (IgG1 antibody) and T-cells (cytotoxic and Th ₁₇ types)
IL-10	Activated T-cells and monocytes	Downregulates function of Th ₁ and Th ₂ cells
IL-12	Macrophages and dendritic cells	Induces synthesis of IFN γ , IL-2, and TNF by Th ₁ cells; reduces synthesis of IL-4, IL-5, and IL-10 by Th ₂ cells
IL-13	T-cells (Th ₂)	Induces IgG4 and IgE isotype switching in human B-cells
IL-17A	T-cells (Th ₁₇)	Induces epithelia and macrophages to produce IL-6, IL-8, TNF, and TGF β
TGF β	T-cells (Treg)	Inhibits activation of lymphocytes and monocytes, promotes differentiation of Treg cells and Th ₁ cells, causes IgA isotype switching
IFN γ	T-cells (Th ₁), NK cells	Increases MHC class I expression, promotes Th ₁ differentiation, stimulates NK cells
TNF	Epithelium, macrophages, T-cells	Stimulates acute-phase inflammatory response, is neutrophil chemoattractant, is synergistic with IL-6 and IL-1 β
Chemokine		
IL-8 (CXCL8)	Epithelium, endothelia, macrophages	Attracts neutrophils
RANTES (CCL5)	Epithelium, T-lymphocytes	Attracts T-cells, eosinophils, basophils
MCP-1 (CCL2)	Macrophages, monocytes, endothelium	Attracts monocytes/macrophages

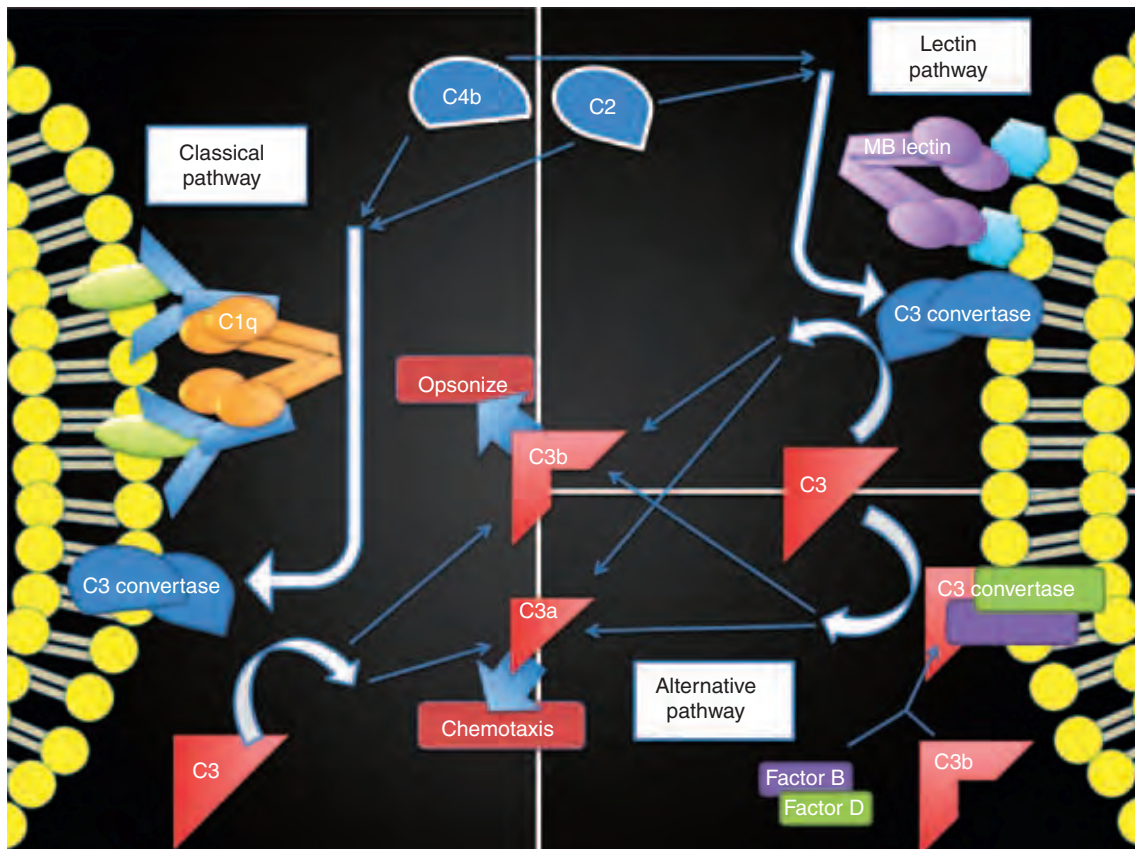

Figure 1 Complement pathways. All three pathways result in the formation of C3 convertase, which catalyzes C3 to split into C3b (binds pathogens) and C3a (chemotactic for neutrophils). Through the *classical pathway*, component C1q binds to antibodies on the bacterial cell surface, catalyzing C4b and C2 to combine into C3 convertase. Through the *lectin pathway*, mannose-binding lectin (MB lectin) binds mannose on the bacterial surface, catalyzing C4b and C2 to combine into C3 convertase. Through the *alternative pathway*, free factor C3b combines with factor B and factor D to form a C3 convertase.

Table 2 Cells of the Innate and Adaptive Arms of the Immune System

Innate immune system	
Epithelium	Initial barrier to pathogens; present antigen; contain PRRs
Macrophages	Immune sentinel; kill pathogens; present antigen; contain PRRs
Neutrophils	Immune foot soldiers; kill opsonized pathogens
NK cells	Cytotoxic; kills infected cells in similar manner to cytotoxic T-cell
B-1 cells	Hybrid innate/adaptive B-cells; produce poly-reactive antibodies
$\gamma\delta$ T-cells	Hybrid innate/adaptive T-cells; T-cell receptors act like PRRs
Adaptive immune system	
Cytotoxic T-cell	Cytotoxic lymphocyte; directly kills infected cells
T-helper (Th) cells	Cytokine-secreting lymphocytes; direct immune processes
Th ₁	Promotes inflammation; produces IFN γ and IL-2
Th ₂	Promotes antibody responses; produces IL-4, IL-5, and IL-13
Treg	Suppresses inflammation; produces IL-10 and TGF β
Th ₁₇	Promotes inflammation; produces IL-17; recruits neutrophils
B-cell	Antibody-secreting lymphocyte; directed by Th ₂ cells
Dendritic cell	Professional antigen-presenting cell; programs T-lymphocytes
<i>Abbreviations:</i> PRR, pattern recognition receptors; NK, natural killer.	

but are largely devoid of MCP and DAF after 8 weeks of gestation. Proliferation of this population to generate invasive cytotrophoblast cell columns is associated with continued expression of CD59 and an increased expression of DAF and MCP (14,15). MCP is also expressed on the preimplantation embryo (16).

Cytokines

Cytokines are intracellular messengers of the immune response, triggering receptors on immune cells and local tissues that lead to downstream events such as cell differentiation, activation, and cytokine secretion. Chemokines—derived from the words *chemotactic cytokines*—are cytokines that play a primary role in chemotaxis. They summon specific immune cell populations into a tissue to engage a pathogenic threat. Cytokines form the communication network for the immune system and are produced and utilized by cells in both arms. A list of commonly encountered cytokines, their cell of origin, and their common function is listed in Table 2.

Macrophages

Macrophages are innate sentinel cells that function as effector cells against certain pathogens. As an innate sentinel, the macrophage detects pathogens using surface receptors such as the mannose receptor, scavenger receptors (which bind many charged ligands), TLRs, and CD14, a TLR-4 co-receptor that recognizes bacterial lipopolysaccharide (LPS). Once activated, macrophages generate large cytoplasmic granules containing oxygen free radicals, antimicrobial peptides, and lysozyme that destroy phagocytized pathogens. They also secrete many important index cytokines and chemokines, such as interleukin (IL)-6, TNF, and IL-8.

The recognition of molecular patterns by sentinel cells should not be confused with antigen-initiated adaptive immune processes. The activation of the innate immune system does not directly lead to the development of immunologic memory. Activated sentinel cells release cytokines and chemokines. These cytokines and chemokines primarily recruit and activate innate effector cells, but they may also influence the process of antigen presentation to initiate adaptive processes (17).

Macrophages increase rapidly in number during early pregnancy, then remain relatively stable throughout gestation, representing 20% to 25% of CD45+ leukocytes and 10% of total decidual cells at the implantation site (18,19). Villous macrophages have been demonstrated to secrete substances that promote the development of multinucleated syncytia from cytotrophoblast cells, which subsequently secrete human placental lactogen and human chorionic gonadotropin (hCG) (20).

Uterine macrophages are capable of presenting alloantigen and have a suppressive effect on mixed lymphocyte reactions and may contribute to protection of the fetus against immunologic rejection (21,22). This may be at least in part due to expression of indoleamine 2,3-dioxygenase (IDO), which is suggested to have an immunosuppressive role in pregnancy. They exhibit lower IL-1 expression when compared with their peripheral counterparts, are capable of inducing interferon (IFN)- γ expression by NK cells, and secrete IL-10 (23,24).

Uterine macrophages may also regulate the population of uterine NK (uNK) cells, influencing differentiation and activation status through the production of IL-15, which is secreted by uterine macrophages isolated from both early and term gestations (24,25).

Neutrophils

Innate effector cells include neutrophils, which are of myelocytic lineage. Neutrophils are hailed by activated macrophages using chemokines such as IL-8 or indirectly by a population of “helper” T-cells through IL-17 secretion (26). Once neutrophils arrive, they rely on antibody binding and/or complement activation on the pathogen surface to direct chemotaxis and bind and phagocytose pathogens. Antibodies produced by B-lymphocytes tag (opsonize) pathogens for destruction. Neutrophils then use CD16, the Fc antibody receptor, to adhere to the opsonized pathogen.

The number of leukocytes in the peripheral blood increases during pregnancy, primarily due to an absolute increase in neutrophils (27). Peripheral neutrophils exhibit decreased lobularity index and myeloperoxidase activity at midgestation of normal pregnancy, suggesting a relative immaturity of the population as numbers increase (28).

Both neutrophils (29,30) and monocytes (31) display reduced chemotaxis, adherence, reactive oxygen metabolite release, phagocytosis, and microbial killing in pregnant compared with nonpregnant women. In seeming contradiction to this, neutrophils in pregnancy circulate in a chronically active state. Although pregnancy neutrophils cannot be fully activated for oxidant production (29), their basal rate of unstimulated oxidant production is the same as that of LPS-treated nonpregnancy neutrophils (30). Thus, while the maximum potential for activation of resting pregnancy neutrophils is suppressed, they circulate in a baseline-activated state.

Neutrophils have also been implicated in the process of cervical ripening and parturition (32,33). Chemotaxis to the cervix and lower uterine segment are actively promoted by myometrial and cervical factors, chiefly by liberation of IL-8 and expression of cell adhesion molecules (34,35). The resulting infiltration of neutrophils leads to a release of local inflammatory cytokines (36,37) and proteolytic enzymes (38) that ripen the cervix and initiate parturition.

NK Cells

Innate effector cells include NK cells, which are of lymphocytic lineage. In contrast to other lymphocytes, NK cells do not possess the CD3 complex or clonally expand in response to antigen stimulation. NK cells do possess many activating and inhibitory receptors of two major structural classes, those of the immunoglobulin superfamily [killer immunoglobulin-like receptors (KIRs) and LIRs] and of the C-type lectin-like family

(Ly49, NKG2D, and CD94/NKG2) (39). These receptors recognize cell surface molecules, such as major histocompatibility complex (MHC)-1 glycoproteins and their structural relatives. The balance between activating and inhibiting signals determines the behavior of the NK cell. If the balance favors activation, the NK cell kills the target cell in much the same way as a cytotoxic T-lymphocyte, by forming an immunologic synapse, perforating the target cell membrane, and infusing granzyme into the cell, which initiates apoptosis of the target cell.

NK cell populations undergo marked changes in pregnancy and can be divided into two distinct subsets (Fig. 2). The majority (90%) have low-density expression of CD56 (CD56 dim) and express high levels of CD16, the immunoglobulin receptor that is responsible for antibody-dependent cellular cytotoxicity. These are considered “peripheral” NK cells. The rest of NK cells (10%), so-called uterine NK cells or large granular lymphocytes, have high-density expression of CD56 (CD56 bright) with low levels of CD16 (CD16 (-)) (40).

Peripheral NK cells are notably decreased in number in the decidua during normal pregnancy (41). Classic circulating CD57+/CD16+ NK cells have a 25% to 30% decrease in cytotoxicity during normal pregnancy (42–48). The decrease can be measured not only by decreases in cytotoxicity assays but also by a decrease in the expression of activation markers CD69, CD25, CD71, and HLA-DR (49). Though baseline cytotoxicity is lower, these peripheral NK cells are able to respond to infection with similar efficacy to nonpregnant controls (50).

Figure 2 Differences between the CD56 dim peripheral NK cell and the CD56 bright uterine NK cell. The CD56 dim peripheral NK cell retains its cytotoxic ability through expression of CD16, a receptor that binds to the antibody heavy chain. By contrast, fewer than 15% of uterine NK cells express this receptor. Uterine NK cells are also highly granulated and produce more cytokines than their peripheral counterparts, suggesting a regulatory function.

Interestingly, peripheral NK cells maintain a nonpregnant phenotype during anembryonic gestations, ectopic pregnancies, and recurrent spontaneous abortions, all of which have been associated with increased NK activity (42,51,52). Thus, classic NK appear to have a differing phenotype in normal versus abnormal pregnancies and could serve as potential effector cells during the elimination of abnormal pregnancy.

uNK cells with the phenotype CD56 bright/CD57-/CD16- are actively recruited to the endometrium and decidua during the late secretory phase of menstruation and early normal pregnancy (53–56) and remain in the decidua if implantation is successful (57). These cells comprise 70% to 80% of decidual leukocytes, but less than 1% of peripheral blood leukocytes, existing side by side at the trophoblast margin with macrophages (20% of leukocytes) and CD3+ T-cells (10% of leukocytes) (58,59). uNK cells possess the receptor for IL-15, which serves to activate them and promote their survival by increasing their expression of *bcl-2* (60–63). IL-15 is expressed predominantly by the perivascular stromal cells surrounding spiral arteries during the mid to late secretory phase of the menstrual cycle and in early pregnancy (64).

uNK cells are considered to be poorly cytotoxic, yet potent cytokine producers, in contrast to classic NK cells that display higher levels of cytotoxicity but are poor cytokine producers. A small fraction of uNK cells (10–15%) contain surface CD16 detectable by flow cytometry (65). CD16 is an antibody receptor, and only CD16+ cells exhibit cytotoxicity, and thus most uNK cells lack cytotoxic capability (66). All uNK cells remain at the implantation site in high numbers during early gestation, decrease after 20 weeks of gestation, and are practically absent in term decidua (67–69).

uNK cells are found in association with extravillous trophoblast in the placental bed (70). It has been suspected by some investigators that interactions between uNK cells and invading endovascular or perivascular trophoblast might promote spiral artery remodeling during human pregnancy. This suspicion is based on the close proximity of these uNK cells with spiral arteries and bolstered by placentation data from murine studies (71). However, in the human, trophoblast invasion along spiral arteries extends deeply into the inner myometrium, where uNK cells do not reside (72), and murine evidence that uNK cell production of IFN γ promotes vascular remodeling remains to be established in the human (73). Thus, the role of uNK cells in the establishment of human hemochorial placentation is unclear.

ADAPTIVE ARM OF THE IMMUNE SYSTEM

The adaptive arm is the immune system's "intelligent" response to specific pathogens. This response is antigen dependent, occurring over weeks rather than minutes as in the innate response. The advantage of this more slowly evolving process is that it has time to "learn" through experience, developing a highly specialized, targeted response to specific antigens that results in the development of immunologic memory. The adaptive immune system consists of antigen-presenting cells, antibody-producing B-lymphocytes, "cytotoxic" CD8+ T-lymphocytes, and a variety of "helper" CD4+ T-lymphocytes. The primary factors determining the developmental fate of naive T- and B-lymphocytes include the type of antigen-presenting cell

and the assortment of cytokines present in the local microenvironment. Cytokines that direct the specific adaptive response are primarily (but not exclusively) produced by T-helper (Th) lymphocytes and referred to as "Th" cytokines.

A core assortment of T-helper cells have been identified based on their cytokine secretion profiles, each "Th" type serving a different immunologic function. The four most commonly described types of T-helper cells are the Th₁, Th₂, Treg, and Th₁₇ lymphocytes (Table 1).

Th₁ lymphocytes promote cytotoxic cellular and antibody-mediated responses through secretion of the Th₁ cytokine IFN γ . IFN γ activates effector cells such as "cytotoxic" T-lymphocytes, NK cells, and macrophages. It also promotes the production of dendritic cell IL-12, which in turn stimulates Th₁ cells to auto-produce IFN γ , reinforcing the phenotype. IFN γ inhibits the Th₂ phenotype by downregulating IL-4 production. IFN γ upregulates MHC class I antigen on target cell surfaces and activates CD8+ cytotoxic T-cells and NK cells, the sum of which promotes the recognition and clearance of intracellular pathogens.

Th₂ lymphocytes promote humoral responses by B-cells through secretion of Th₂ cytokines such as IL-4 and IL-5. These humoral responses result in the development of antibodies that target humoral factors for removal rather than cells for destruction. The presence of other local cytokines promotes antibody isotype switching. For example, IL-13 promotes switching to the IgE antibody class, TGF β promotes switching to the IgA class, and the Th₁ cytokine IFN γ promotes switching to the IgG class.

Regulatory T-lymphocytes (Tregs) have been one of the more recently characterized helper-T-cell subsets. These cells are identified by the presence of a nuclear transcription factor called Forkhead box P3 (FoxP3) and characterized by their suppressive effect on effector T-cells, in part due to secretion of cytokines IL-10 and TGF β . IL-10 antagonizes Th₁ cells and macrophages, while TGF β is a potent suppressor of all other Th responses (Th₁/Th₂/Th₁₇) in the human. Tregs secrete TGF β and/or IL-10 in response to specific antigen and are believed to be an important resident of the maternal–fetal interface necessary for suppressing any adaptive immune responses against the fetus.

Th₁₇ lymphocytes are the most recently characterized class of T-helper cells. Th₁₇ cells secrete cytokines including IL-17A, important for recruiting neutrophils to sites of inflammation, which makes them appear to function similarly to Th₁ cells. Both IFN γ and IL-4 have been shown to negatively regulate Th₁₇ differentiation, while the presence of TGF β and IL-6 together appear to promote this differentiation. Th₁₇ cells appear to play an important role in autoimmune diseases, but if they play a role in inflammatory states during pregnancy, such as preterm labor and pre-eclampsia, this has not yet been defined.

T-Helper (Th) Shift in Pregnancy

Pregnancy has classically been described as having a "Th₂ shift" (74,75). In general terms, the systemic maternal immune response is noted to shift from a cytotoxic (Th₁) to a humoral (Th₂) T-helper paradigm of function. In light of evolving knowledge of T-helper-cell subsets, the Th₁/Th₂ balance paradigm has been recognized as an oversimplification (76,77).

It has become clear that additional regulatory mechanisms play an important role, including those mediated by the regulatory T-cell (Treg). As potent suppressors of inflammation, Tregs appear to be important for the maintenance of normal pregnancy (78).

If the shifting of immune cell subsets to a regulatory phenotype contributes to fetal protection, this may aid in our understanding of the observed maternal tolerance acquired against paternal antigens (79,80). Innate processes also appear to promote local blunting of the adaptive immune system at the maternal fetal interface, including such factors as depletion of tryptophan at the maternal–fetal interface by IDO (81), and the expression of nonclassical placental MHC antigens such as HLA-G. It has been suggested that HLA-G might be an important determinant in the development of Tregs (82,83,84).

Peripheral T-Cells

Pregnancy is accompanied by several unique changes in peripheral and decidual T-cells. Peripheral T-cells demonstrate decreased proliferative responses in serum from pregnant women, detected as a decreased T-cell response to mitogens (85). This may be due to a general state of suppression during pregnancy, as evidenced by a decrease in memory CD4+ T-cells and an increase in naive CD4+ T-cells, decreased expression of activation markers HLA-DR and CD25, and a decrease in precytotoxic CD8+/S6F1+ cells with a concomitant increase in regulatory CD8+/S6F1-cells (86).

Peripheral blood CD4+/CD25+ lymphocytes, the putative regulatory T-cell subset, are increased during the first and second trimesters (87).

Uterine T-Cells

Uterine T-cell changes are unique. T-cells comprise only about 10% of decidual lymphocytes (88,89) and decrease in decidua by >60% during pregnancy. This is due primarily to a decrease in CD8+ T-cells thereby increasing the CD4+/CD8+ ratio (90). Of the CD8+ T-cells in the decidua only a few express perforin, a suppressive phenotype among CD8+ T-cells (91).

Uterine decidual T-cells have been reported to express multiple KIRs including both inhibitory and activating types. When both are expressed in a single T-cell, the inhibitory receptor has been suggested to be preferentially active and may contribute a level of immunosuppression (92).

Uterine decidual T-cells have been characterized as expressing CD25, a chief phenotypic characteristic shared by activated lymphocytes and Treg cells (93,94). Up to 14% of uterine T-cells in the decidua possess a classic Treg phenotype (87). There is evidence for local expansion of decidual Treg cells and a low occurrence of Th₁₇ cells in normal first-trimester decidua (95,96). Furthermore, local moderate Th₁ activity is reported, evidenced by a population of IFN γ -secreting T-cells. Local IFN γ could serve the important purpose of upregulating MHC class II proteins on decidual stromal cells. Decidual stromal cells express ligands (B7-H1 and B7-DC) for the programmed death (PD)-1 receptor, which may play a crucial role by decreasing decidual T-helper cell production of IFN γ , TNF, and IL-2 (97).

During normal and anembryonic pregnancy, but not ectopic pregnancy, CD71 and CD25 increase, signifying

activation of T-cells in response to successful implantation. The response may be augmented by the trophoblast production of IL-2, which, because of the lack of change in ectopic pregnancy, is probably decidua dependent (98,99). Further evidence that T-cells are specifically involved with implantation and placental proliferation is derived from experiments with monoclonal antibodies against CD4 and CD8, which stimulates or inhibits placental proliferation, respectively (100).

$\gamma\delta$ T-Cells

$\gamma\delta$ T-cells are an interesting intermediate cell type that appear to have both innate and adaptive function. They rearrange T-cell receptor (TCR) genes to produce diversity and can develop a memory phenotype. However, various subsets contain a restricted TCR that appears to be used as a PRR (101). These cells recognize not only nonclassical MHC class I molecules (102) but also heat shock proteins, soluble antigen, and carbohydrates (103).

$\gamma\delta$ T-cells appear in the first-trimester decidua (104,105) and increase in the peripheral blood during pregnancy (106). They are also present in second-trimester placental villi (107). $\gamma\delta$ T-cells increase 2.4-fold in the decidua compared with peripheral blood, which is indicative of selective migration (105), and are twice as common as all other T-cells there (108), although the specific mechanism for their selection is unknown.

The specific function of $\gamma\delta$ T-cells is not clearly known. Because of their population kinetics and location, several roles have been proposed. They may protect the mother and fetus from infection, trophoblast from rejection, or limit passage of fetal leukocytes to the maternal circulation (105).

B-Cells

Maternal serum has been found to inhibit priming of B-cells in vitro via a molecule in the IgG fraction of serum, which reduces IL-2 receptor density. This inhibitory action is even more pronounced with retroplacental serum suggesting that it may be concentrated at the maternofetal interface (109).

Peripheral B-cells in pregnancy exhibit decreased synthesis of IgM with increases in IgA and IgE. As IgA and IgE do not cross the placenta, these changes may be a protective mechanism for the fetus. The increase of IgE and IgA (with concomitant decrease in IgM) may be explained, at least in part, by an increase in CD23 (low-affinity IgE receptor) expression on B-cells, which serves as an autocrine growth factor for pre-activated B-cells and is enhanced in the presence of maternal IgG (109).

The importance of these changes is illustrated by the fact that B-cell antibody synthesis can be implicated in pregnancy complications and spontaneous abortions. Antitrophoblastic IgG and IgM, which were better able to fix complement and lyse target cells than in controls, have been demonstrated in significantly higher numbers in patients with recurrent spontaneous abortions (110). Antibodies against fetal endothelial cells have also been demonstrated in patients with recurrent spontaneous abortion (111).

Modulation of B-cells also occurs with regard to B-cell subsets. B-1 (CD5+) cells are downregulated during pregnancy while numbers of conventional B-cells (CD5-) remain constant. B-1 cells are the main producers of polyreactive

autoantibodies (112) and this antibody production can be enhanced in the presence of estrogen (in mice) (113). This downregulation may thus represent a protective mechanism for the fetus and the mother. During pregnancy, B-cells are generally either absent from or inactive in the uterus and decidua (114,115).

EFFECT OF PREGNANCY ON MATERNAL CELL-MEDIATED IMMUNITY

Cell-mediated immunity is promoted by IFN γ , is carried out by CD8+ T-lymphocytes and NK cells, and results in the programmed cell death (apoptosis) of the foreign cell or infected host cell. Decreased cell-mediated immune function in pregnancy is manifested by a tendency toward reactivation of chronic viral infections, such as cytomegalovirus (116), human papillomavirus (117), and herpes simplex virus (HSV) (118), and by an increased frequency in acquiring new viral infections (119). Circulating NK cells maintain their population size (120), and though they express a general decrease in cytotoxic activity (121–127), they can still respond appropriately to pathogens (128).

Pregnant women are more prone to contract HSV (129), have a longer course of infection (130), and suffer increased morbidity (131,132). Prior to polio vaccine, the risk of paralytic polio was increased in pregnancy (133). Malaria has been shown to have a prolonged course as well as increased morbidity and mortality during pregnancy (134). Varicella pneumonia has also been noted to occur almost exclusively in pregnant females or those otherwise immunosuppressed (135).

Impairment in cell-mediated immune function in pregnancy is associated with improvement in autoimmune diseases such as multiple sclerosis (136,137), rheumatoid arthritis (138), and psoriasis (139).

EFFECT OF PREGNANCY ON MATERNAL HUMORAL IMMUNITY

In contrast to cell-mediated immunity, humoral immunity, promoted by Th₂ cytokines such as IL-4 and IL-5, is preserved in pregnancy. Circulating B-cell numbers are unchanged (140,141). T-cell-independent B-cell functions remain intact as manifested by normal IgG stimulation with *Staphylococcus aureus* (142). There is an appropriate antibody response to vaccines (143). Serum complement concentrations remain normal or slightly elevated (11). T-helper cell activity is intact, evidenced by the maintenance of PPD positivity during normal pregnancy (144).

The shift favoring antibody production may help explain the persistence or worsening of immune-complex-mediated autoimmune disease in pregnancy. While the development of a de novo lupus flare during pregnancy may not frequently occur, exacerbation of existing lupus nephritis can be problematic. Grave's disease, seasonal allergies, myasthenia gravis, idiopathic thrombocytopenic purpura, and IgA nephropathy—antibody-dependent diseases—worsen.

The key difference between the pregnant and nonpregnant states is in the development and function of the maternal-placental-fetal unit. Trophoblast-immune cell interactions result in the differentiation of specialized subpopulations of lymphocytes. Moreover, peptide and steroid hormones generated by the placenta have demonstrable effects on immune cells.

INFLUENCE OF PLACENTAL HORMONES ON IMMUNITY

Placental hormones appear to play a role in immune function during pregnancy. The hCG can inhibit mitogen-induced T-cell and T-cell-dependent B-cell responses (145–149). These actions appear to be accomplished directly through T-cell hCG receptors (150), but further delineation of this mechanism is still the subject of ongoing investigation.

Pregnancy induces thymic cortical involution, possibly contributing a mechanistic explanation for altered T-cell function (151,152). The view that such involution represents a quiescence of the gland is in conflict with the data that the medullary portion of the gland actually appears to become more active (153). Murine thymic epithelial cells express the progesterone receptor, and this receptor is necessary for thymic involution to occur in pregnancy in mice (154).

Progesterone appears to be a very important immunoregulatory hormone of pregnancy, but the pathways by which it mediates its effect are still unclear. It is unlikely that specific progesterone receptors on lymphocytes and NK cells exist, as they have not yet been identified (155,156). However, decidual stromal cells have progesterone receptors, and a mechanistic link between these cells and various leukocytes has been suggested (157).

Despite lack of evidence of classic progesterone receptors in these cells, T-lymphocytes and decidual NK cells are reported to produce a peptide called progesterone-induced blocking factor (PIBF) in response to this hormone (158–160). PIBF has been reported to decrease activated lymphocyte production of IL-12 and TNF-alpha and cause a concomitant increase in IL-10 (161). PIBF is also reported to inhibit perforin liberation from the granules of stimulated NK cells (162), thereby limiting their cytotoxicity. The PIBF receptor has been characterized as joining with the IL-4 receptor alpha chain to form a novel type of IL-4 receptor (163).

Decreased levels of PIBF have been associated with recurrent spontaneous abortion (164), and monoclonal antibodies against PIBF have been demonstrated to cause decreased IL-10 levels with an associated immune-mediated resorption of pregnancies in mice (165).

Administration of the progesterone receptor antagonist RU486 has been reported to cause a decrease in the production of PIBF (166) and to be associated with at least a threefold increase in NK cytotoxicity (167,168).

TROPHOBLAST DEFENSE: ALTERED MHC EXPRESSION

An interesting mechanism of protection of the fetal allograft from maternal defenses appears to be the altered expression of MHC class I molecules by both syncytiotrophoblast and cytotrophoblast. All trophoblast cells are devoid of "classical" MHC class I molecules, except for the transient expression of HLA-C during early pregnancy. This inhibition of expression of HLA-A and HLA-B is apparently not affected by genomic imprinting, since both maternal and paternal alleles are inducible by IFN γ treatment in vitro (169).

In addition, there is an absence of expression of MHC class II antigens, which appears to be caused by hypermethylation of the IFN γ -responsive promoter that regulates expression of the class II transactivator (CIITA) gene. In vitro introduction of exogenous CIITA can induce cell surface expression of HLA-

DR, -DP, and -DQ, leading to an acquired capacity to present antigen to antigen-specific T-helper cells (170).

Once formation of the cytotrophoblastic shell is complete, the syncytiotrophoblasts and villous cytotrophoblasts remain free of classical MHC class I molecules and downregulate the expression of the nonclassical MHC class I molecules. The invasive cytotrophoblasts, on the other hand, provide the primary contact point for maternal blood and continue to express an assortment of nonclassical MHC class I antigens, which may be helpful in deterring a maternal immune response toward paternal antigens.

Nonclassical MHC molecules that are present throughout pregnancy include HLA-E and HLA-G. Like classical MHC antigens, these molecules appear to be involved in the abrogation of NK-cell-mediated lysis of trophoblast via interactions with inhibitory NK cell receptors (171–173).

Many studies have focused on HLA-G, first discovered in 1987 (174). It is an inhibitory nonclassical MHC class I molecule that is found on both invasive cytotrophoblastic and amniotic epithelial cells (175). Like the classical MHC class I molecules, it comprises an alpha chain associated with β 2 microglobulin. Unlike the classical MHC class I molecules, HLA-G contains limited polymorphism and a truncated cytoplasmic tail as a result of a stop codon in exon 5/6. It can appear in 6 isoforms: two soluble and four membrane bound.

The membrane-bound isoforms have been shown to inhibit NK cell migration and NK-mediated cell lysis through interactions with various lectin family and immunoglobulin-like receptors on NK cells and macrophages (176–178). HLA-G binds the CD94/NKG2A and p49 receptors, one or both of which are found on all NK cells isolated from maternal decidua during the first trimester (179). It may also bind the ILT2 and ILT4 (immunoglobulin-like transcript) inhibitory receptor on macrophages (180).

Soluble isoforms of HLA-G may serve an immunoregulatory role during pregnancy. Soluble HLA-G appears to induce apoptosis of CD8+ T-cells through the Fas/FasL pathways (181), and a low concentration is detectable in the serum of pregnant women throughout gestation. Although soluble HLA-G is present only in small amounts, it is more than twice as abundant in the serum of pregnant women as in nonpregnant and is likely in even greater concentration at the maternal–fetal interface (182).

HLA-E is not found on the cell surface unless HLA-G is also present. It is co-expressed with HLA-G due to a specific nonapeptide transcribed from the leader sequence of HLA-G, which serves as a ligand for HLA-E to induce its surface expression (183,184). HLA-E appears to have similar characteristics to HLA-G, for example, binding CD94/NKG2A (185,186).

HLA-G and HLA-E have both been demonstrated to influence cytokine production by decidual NK cells. Decidual NK cells cocultured with K-562 leukemia cells lacking classical and nonclassical MHC molecules expressed TNF-alpha, IL-10, and GM-CSF. When the K-562 cells were transfected with HLA-G, these concentrations of these three cytokines were significantly decreased in culture supernatants. When this same cell line was transfected with HLA-E, only IL-10 was significantly decreased (187).

HLA-C has been shown to exist only transiently on trophoblasts in the first trimester. It is recognized by KIRs (killer immunoglobulin-like or inhibitory receptors) on NK cells. Decidual NK cells have a higher expression of KIRs specific for HLA-C than do peripheral NKs. HLA-C is also upregulated in the presence of IFN γ , which may serve as a protective mechanism for trophoblastic cells (188). Expression of HLA-C apart from the pregnant state has been shown to be deleterious in some circumstances, as expression of HLA-Cw4 has been associated with poor prognosis in HIV infection and rapid development of AIDS, suggesting potential immunosuppressive functions (189).

Because of these functional differences from other “classical” MHC class I molecules, some investigators have suggested that, from a conceptual standpoint, HLA-C may be better grouped with the “nonclassical” MHC class I molecules (190).

TROPHOBLAST DEFENSE: OTHER MECHANISMS

In addition to the nonclassical MHC molecules, the trophoblast expresses other antigens that may counter maternal immunosurveillance. The Fas ligand (FasL) binds to Fas expressed on target cells and results in the initiation of the target cell apoptosis pathway. Trophoblast constitutively expresses the FasL, while decidual NK cells express Fas. IFN γ and TNF promote Fas expression and sensitivity, whereas IL-6 and IL-10 increase the resistance of trophoblast cells to Fas-mediated apoptosis (191).

RCAS1 (receptor-binding cancer antigen expressed on SiSo cells), a membrane-associated homodimer, has been recognized to play a role in immune evasion of the tumor cells in a manner similar to the FasL (192). Both RCAS1 and the FasL appear to be expressed concomitantly in uterine endometrial glands and extravillous cytotrophoblasts (193).

IDO is an enzyme that catabolizes tryptophan and is expressed by syncytiotrophoblast in mice (194). In the murine model, it is released by macrophages in response to IFN γ , inhibits T-cell proliferation, and is able to prevent T-cell-mediated rejection of normal pregnancies (194,195). IDO has also been demonstrated in human placental trophoblast cells and decidual macrophages, where its expression is stimulated by IFN γ (196,197). The expression of IDO by syncytiotrophoblast is a likely contributor to decreased serum levels of tryptophan found during pregnancy (198).

THE PLACENTAL SINK

The apical surface of the syncytiotrophoblast contains specialized Fc(γ) receptors (Fc γ R) (199,200). Significant transport of the four classes of maternal IgG begins around 20 weeks of gestation. The placenta may also serve as an immunosorbent tissue to protect the fetus from antibodies directed toward paternal antigens (201).

CONCLUSION

In conclusion, research over the past three decades has identified a host of changes in the maternal immune system and fetal tissues that promote the initiation and maintenance of normal pregnancy. It is daunting to think that what is now known is probably the tip of the iceberg. However, through further study, the immunology of the maternal–fetal interface may hold the secrets of successful and healthy pregnancy.

72 Placental transport and metabolism

Jeffrey M. Dicke

As a fetal organ, the placenta not only is obligated to the fetus but also answers to the mother. More than merely a conduit for the provision of oxygen and nutrients to the fetus, the placenta actively regulates the passage of substrates necessary for fetal growth and development. The importance of placental function and dysfunction is manifest in a variety of adult chronic illnesses that are now felt to be a consequence of in utero insults. This phenomenon is known as fetal origins of adult disease and includes cardiovascular disease and features of the metabolic syndrome, including dyslipidemia, type 2 diabetes, insulin resistance, and obesity. The finding that the placenta is capable of influencing an individual's general health years following its relatively brief service is a testament to its critical effect on intra- as well as extrauterine survival. Preventative care and overall health begin in utero and require a healthy placenta. This realization has implications not only for an individual's quality of life but also for societal approaches to public health.

Placental nutrient transport potential involves multiple variables including placental size, architecture, blood flow, nutrient production and consumption, and transporters for glucose, lipids, and amino acids.

The placenta grows continuously throughout gestation. This benefits the fetus in a number of ways and is one determinate of fetal growth. The larger the placenta, the larger the surface area available for nutrient exchange. There is also a decrease in trophoblast thickness, decreasing the diffusion distance between maternal and fetal circulations. These changes support the observations that placental growth in the midtrimester is associated with fetal weight in the third trimester and that overall there is a positive correlation of placental size with fetal size (1–3).

Environmental insults, which reduce placental weight, such as nutritional conditions and glucocorticoid administration, can also have an effect on placental morphology. Changes in barrier thickness, surface area available for exchange, vascularity, and rates of proliferation and demise of certain cell types are ways in which placental efficiency may be diminished or enhanced (4,5). For example, hypoxia has been associated with a reduction in barrier thickness between maternal and fetal capillaries in the human placenta, presumably encouraging diffusional change (6). Maternal food restriction in guinea pigs, whose hemomonochorionic placenta is more like the human placenta than other non-primates, alters placental size and structure. Undernutrition is associated with reduced placental weight, decreased surface area available for exchange, and increase in membrane thickness. The placenta under these circumstances not only is small but also has diminished substrate transport capacity (4).

Placental growth and function also depend upon adequate blood flow. This requires normal trophoblast invasion and

remodeling of the spiral arteries, achieved by vasculogenesis, new blood vessel formation from endothelial precursor cells, and angiogenesis, new vessel formation from those already present. Deficient conversion of the spiral arteries leads to impaired villous perfusion and hypoxia, which itself can have a pejorative effect on vascular remodeling by limiting proliferation and growth of fetal vessels (7,8). This results in increased resistance to blood flow in the umbilical arteries, which is reflected in abnormal flow velocity waveforms using Doppler ultrasound. Growth of the placenta, its blood vessels, and its blood supply are intertwined such that, under normal circumstances, fetoplacental growth correlates with the ability to provide oxygen and nutrients to the placenta for subsequent transfer to the fetus.

The consumption and production of nutrients by placental tissues impact the availability of nutrients for transport to the fetus. In humans, 40% to 70% of the glucose and oxygen taken up by the uterus is utilized by uteroplacental tissues, which also produce lactate and metabolize amino acids for fetal use (9,10). Just as placental growth, morphology, and blood supply are subject to exogenous factors, uteroplacental management of carbohydrates and amino acids is influenced by a host of variables including placental size, nutrient availability, and concentrations of hormones such as glucocorticoids, growth hormone, and insulin growth factors in maternal and fetal blood (11–13). In sheep, hypoglycemia is associated with decreased placental glucose consumption (14) while preterm exposure to cortisol has the opposite effect (15). Similarly, placental disposition of essential amino acids is influenced by undernutrition, heat stress, and treatment with IGF-1 (14,15), which enhances fetal and placental amino acid uptake (16). These are ways in which placental utilization of nutrients is influenced by environmental factors with subsequent effects on nutrient availability to the fetus.

Hormones are produced by the placenta and released to the mother and fetus. These include peptides, steroids, glycoproteins, and cytokines. Progesterone and placental lactogen have effects on the mother, which promote glucose delivery to the fetus (2). The placental variant of growth hormone (GHv) and IGF-1 and IGF-2 may influence nutrient provision by endocrine effects on maternal metabolism and/or paracrine effects on placental potential for simple and facilitated diffusion (16,17). Binding of these hormones to placental receptors can change placental clearance of analogs of glucose and amino acids in vivo and in vitro (18). Maternal levels and placental expression of GHv are decreased in pregnancies with growth-restricted fetuses, implicating changes in placental endocrine function as a cause rather than a result of abnormal fetal growth (19).

Placental prostaglandins (PG) PGE₂ and PGF₂α affect fetal nutrient and oxygen provision indirectly by their effects on

regional blood flow, uterine contractility, and fetal endocrine function (20,21). In vitro studies using murine placenta subjected to oxidative stress through a process of hypoxia/reoxygenation have demonstrated significant increases in the concentrations of cyclooxygenase, enzymes that stimulates PG production (22). In nonhuman primates, undernutrition increases activity of placental PGH synthase and levels of PGE₂ and PGF₂α. These increases correlate with reduced uteroplacental glucose consumption and are reversible by restoration of normoglycemia (20). PG dehydrogenase (PGDH), an enzyme that converts active prostaglandins into their inactive metabolites, has also been demonstrated in placental tissue (23). Changes in PG synthesis and metabolism have been associated with cortisol concentrations as glucocorticoids enhance PGH synthase activity and reduce PGDH activity, which increases intrauterine production of PGE₂ and PGF₂α (21,23). These changes increase with advancing gestation, a time of rising fetal cortisol concentrations and myometrial contractility.

11-β-hydroxysteroid dehydrogenase type-2 (11-β-HSD-2) is a placental enzyme that inactivates glucocorticoids, compounds produced by the trophoblast that regulate organ growth and maturation. Fetal exposure to glucocorticoids is associated with growth restriction in both animals and humans. By converting cortisol to cortisone, 11-β-HSD-2 forms a placental barrier by limiting transfer of free cortisol from mother to fetus. Decreased 11-β-HSD-2 activity and increased levels of cortisol in the fetus have been associated with fetal growth restriction (24). It is presumed that the placenta mitigates the effects of steroids on fetal growth as experimental studies have shown that repeated doses of corticosteroids given to pregnant ewes resulted in reduced birth weight while direct administration to the fetus did not interfere with fetal growth (25,26). In humans, placental activity of 11-β-HSD-2 correlates with birth weight (27). Additionally, gene expression of 11-β-HSD-2 is sensitive to environmental and nutritional stressors. Hypoxia (in vitro) and infection decrease activity, which may lead to increased cortisol levels and suboptimal growth (28). While in vitro data derived using a variety of cell models are inconclusive, evidence to date suggests that glucocorticoids may decrease glucose transfer and increase amino acid transport (29). Glucocorticoids also influence fetal growth via their effects on placental production and activity of other hormones, including prostaglandins, progesterone, and estrogens (28). This is another way in which the placenta adapts to conditions in utero in an attempt to maintain optimal fetal growth.

Insulin-like growth factors, especially IGF-1, are presumptive regulators of placental transport based on the observations that IGF receptors are expressed in the syncytiotrophoblast, which in vitro studies have demonstrated increased glucose uptake and system A activity following treatment with IGF-1 (30) and that reduced fetal levels of IGF-1 (31) and expression of the IGF receptor were associated with intrauterine growth restriction (IUGR) (32). Based on the above, it has been proposed that reduced levels of IGF-1 in the maternal circulation could result in diminished transplacental transport of glucose and amino acids while increased levels of IGF-1, as occurs in diabetes, would have the opposite effect.

A relatively recent addition to the armamentarium regulating placental transport activity (maternal nutritional status, placental blood flow, maternal/placental hormone production, hypoxia) is mammalian target of rapamycin (mTOR). A serine/threonine kinase, mTOR protein is expressed in the cytosol of the syncytiotrophoblast and is thought to regulate cell growth by its influence on translation and transcription through a mechanism of “nutrient sensing” (33). This refers to a proposed process whereby mTOR regulates production of proteins related to cell growth in response to the placental environment, including nutrient availability, oxygenation, and growth factors. These proteins regulate nutrient transporters and thereby affect fetal growth. In vitro data supporting the proposed role of mTOR in fetal growth include the finding that the activity of the mTOR signaling pathway is down-regulated in IUGR and that inhibition of mTOR resulted in nearly complete inhibition of leucine uptake by the system L amino acid transporter (34).

In addition to the aforementioned influences on placental transport and fetal growth, the organization of the placental plasma membrane interface between the maternal and fetal circulations is considered to be a critical component of placental function. This interface is the syncytiotrophoblast that consists of a microvillous membrane (MVM), exposed to maternal venous blood and a basal membrane (BM), which is in contact with the fetal circulation. Available and accumulating evidence indicate that the placenta employs multiple nutrient transporters to provide the sustenance necessary for fetal growth. The MVM and BM contain specific receptors and proteins that regulate the supply of glucose, lipids, and amino acids available to the fetus. Following is a review of the cellular mechanisms responsible for fetal nutrition.

GLUCOSE

Glucose transport is facilitated by a family of isoforms with the prefix GLUT. In human placenta, six GLUT isoforms have been identified at the mRNA level (35,36). The major placental GLUTs are GLUT1 and GLUT3 (37–39), whose abundance and activity differ in response to a variety of environmental factors, including diabetes, maternal nutritional status, hypoxia, and reduced uterine blood flow (28). These GLUTs have different kinetic activity and are differentially expressed within the placental membranes. GLUT3 occurs in the MVM at the maternal–fetal interface and is presumed to be responsible for the rate of glucose delivery to the fetus. GLUT1 tends to be located in the plasma BM and may modulate placental glucose consumption as well as being the rate-limiting step in transplacental glucose transport (39,40).

FATTY ACIDS

Long-chain polyunsaturated fatty acids (LC-PUFA) are important not only for maternal health but also for fetal growth and central nervous system development. The LC-PUFA arachidonic acid (AA) and docosahexaenoic acid (DHA) are present in high concentrations in the fetal brain and regulate the structure and function of neural membranes (41). Diminished DHA in brain lipids is associated with learning impairment in various species. Eicosanoids, which are derived from AA, are integral to cell division and other important physiological processes (41).

The observation that LC-PUFA are higher in plasma lipids of the cord than in maternal plasma lipids at birth supports the notion of active maternal–fetal transfer, which is a complex, incompletely understood process. Human placental receptors to very-low-density lipoprotein, low-density lipoprotein, and high-density lipoprotein facilitate uptake of maternal plasma lipoproteins (42).

In addition, placental lipoprotein lipase, which is localized in the MVM, hydrolyzes lipoproteins (43). The free fatty acids (FFA) released diffuse across the plasma membrane. Fatty acid transport proteins, fatty acid translocase, and plasma membrane fatty acid-binding proteins (FABPpm) facilitate unesterified fatty acid uptake into the placental cells (44). An isoform of FABPpm unique to the placenta occurs only in the MVM of the syncytiotrophoblast, suggesting that it may be important in placental FFA uptake (45). While they are thought to encourage transmembrane passage of FFA, the manner in which this is accomplished by FABP is uncertain. Once transported into the syncytial cytoplasm, FFA bind to FABP and are presented to the BM through which they are presumed to be transported to the fetus via either diffusion or facilitation by FABPs (46).

AMINO ACIDS

While glucose is the primary fuel for the fetus, amino acids are critical as they are precursors for protein synthesis as well as nonprotein compounds, such as nitric oxide, neurotransmitters, and polyamines. The types and balance of essential and nonessential amino acids supplied to the fetus are important determinates of fetal growth. Amino acid concentrations in the fetal plasma exceed those in the mother (47). The uptake and transport of amino acids across the trophoblast membrane is an active process regulated by at least 15 different transport proteins with different structures, overlapping substrate specificity, expression, and activity. Sodium-dependent transport systems and their substrates include systems A (alanine, serine, proline, glycine), ASC (alanine, serine, cystine), N (histidine, asparagine, glutamine), β (taurine), X_{AG}^- (glutamate and aspartate), and GLY (glycine, sarcosine). Cationic amino acids are transported via system γ^+ . Small neutral amino acids are handled by system ASC. System L transports neutral and branched-chain amino acids while aromatic amino acids are the substrate for system T (48).

There are two main types of amino acid transporters, both of which are present in the placenta: accumulative transporters and amino acid exchangers (49). The former regulate influx of amino acids and lead to increased concentrations within the cell. Amino acid exchangers swap amino acids from outside the cell with those inside the cell. This allows the composition of amino acids within the cell to be altered to meet fetal metabolic requirements, with no change in total concentration. Exchangers are one potential means by which nonessential amino acids in the fetal circulation can be exchanged for less readily available essential amino acids within the placenta. Such a process is one way in which the placenta meets the unique growth and energy demands of the fetus.

Net amino acid transfer across the placenta is necessary to sustain fetal growth. There is active transport of amino acids across the MVM into the syncytiotrophoblast via accumulative

transporters (47). These include subtypes of system A, a sodium-dependent transporter, which transports small neutral amino acids (SNAT1, SNAT2, and SNAT4), such as alanine, serine, glycine, and proline and system X_{AG}^- , which regulate uptake of glutamate and aspartate. System A transporters are notable among MVM accumulative transporters in that their substrate amino acids are also subject to exchange transport (50).

Although the mechanisms of amino acid uptake by the maternal-facing MVM have been delineated, the means by which amino acids traverse the BM to the fetus are less well understood. In studies of isolated perfused placenta, exchange and nonexchange transport systems have been demonstrated. The activity of the exchange systems was suggestive of system ASC and isoforms of system L (LAT1, LAT2). Possible nonexchange transporters include system N, system T (TAT1), and the system L isoform LAT4 (51).

In summary, the appropriate quantity and balance of amino acids are essential for fetal and placental health. Provision of amino acids from the maternal circulation into and through the placenta to the fetus requires the coordinated activity of multiple transport proteins, which function differentially in the MVM and BM to provide and maintain the appropriate levels of specific amino acids required for protein synthesis and energy metabolism.

CHANGES ASSOCIATED WITH ABNORMAL FETAL GROWTH

Fetal growth restriction connotes changes in the demonstrated and proposed mechanisms of nutrient transport sufficient to preclude normal fetal growth.

Using vesicles prepared from the MVM and BM of the syncytiotrophoblast from placentas of IUGR pregnancies, changes in amino acid transport systems have been demonstrated including both decreased volume and transport capacity for amino acids. Downregulation of systems A, L, and TAU in the MVM results in reduced provision of taurine, lysine, and leucine (52,53). Additionally, reduced activity of lipoprotein lipase, necessary for placental transport of FFA, has been reported in MVM from IUGR pregnancies (54). Diminished transport of leucine and lysine has been detected in BM vesicles (55). The expression and activity of glucose transport proteins is unaltered in IUGR (56).

In vitro studies demonstrating alterations in amino acid transport have served as a prelude to a variety of in vivo investigations attempting to extend in vitro findings. While the numbers of patients in these studies is small, the results to date support the notion of the placenta as an arbiter of amino acid availability.

Fetal blood sampling of 4 AGA and 14 IUGR human pregnancies coincident with a constant infusion of a leucine isotope revealed that the change in steady-state fetal/maternal leucine enrichment was significantly lower for IUGR pregnancies than appropriate-size-for-gestational-age (AGA) pregnancies. Additionally, the magnitude of the decrease in IUGR pregnancies correlated with the clinical severity of IUGR. The conclusion from this work was that the decrease in the fetal/maternal leucine ratio may be due to reduced placental leucine flux and/or increased protein catabolism in the fetal and placental tissues (57).

In a different study of seven AGA and seven IUGR human pregnancies, fetal blood sampling was performed shortly following maternal intravenous bolus administration of a solution containing isotopes of leucine, phenylalanine, glycine, and proline. Leucine and phenylalanine use exchange transporters and are transferred transplacentally more rapidly than amino acids that do not use exchange transporters, such as glycine and proline. Following maternal administration, the fetal/maternal enrichment ratio for the essential amino acids leucine and phenylalanine was significantly reduced in IUGR versus AGA pregnancies, consistent with inhibited transplacental flux. The fetal/maternal enrichment ratio of the nonessential amino acids glycine and proline was not significantly different (58).

Intravenous infusion of a solution of amino acids in 10 patients with uncomplicated pregnancies prior to cesarean section revealed a significant increase in the maternal concentration of all amino acids versus 16 control patients. Umbilical venoarterial differences were measured as an index of placental amino acid provision to the fetus. For most amino acids, the fetal concentration and the venoarterial concentration difference per micromole of oxygen increased, indicating amino acids cross the placenta rapidly. However, the umbilical uptakes of three essential amino acids, threonine, histidine, and lysine, did not change significantly despite increases in the maternal concentration. Thus, increasing maternal concentrations led to an increase in the delivery of most, but not all, amino acids to the fetus (59).

A similar protocol was used to study whether maternal infusion of amino acids could increase umbilical uptake and fetal amino acid concentrations in 18 pregnancies complicated by IUGR. Eight patients received a pre-cesarean section intravenous infusion of a solution of multiple amino acids. The remaining 10 patients were controls. Similar to what was described in uncomplicated pregnancies, the maternal concentration of all amino acids was significantly increased in the infusion group versus the controls. The umbilical uptake in the infusion group was significantly higher for leucine, isoleucine, methionine, arginine, serine, proline, and glycine. By contrast, there was no increase in the uptake of three essential amino acids, lysine, histidine, and threonine, in these IUGR pregnancies (60).

In contradistinction to the attention afforded placental changes in IUGR pregnancies, alterations associated with accelerated fetal growth have been less extensively studied. Evidence to date suggests that surplus substrate alone incompletely explains the pathology of large-for-gestational-age (LGA) fetal growth patterns. Strict glucose control does not necessarily prevent LGA newborns in diabetic pregnancies (61), implicating altered placental transport capacity as another mechanism of abnormal growth. Increased expression and activity of glucose transporters in the BM of pregnancies complicated by type 1 diabetes have been demonstrated (62). Given the fact that glucose delivery to the fetus is mediated by the BM, this is one potential means by which excess glucose is made available to the fetus in spite of maternal normoglycemia. Similar changes have not been reported in LGA pregnancies with gestational diabetes mellitus (GDM) (63). This implicates insulin as a factor in increased glucose transport. BM amino acid transport systems are reportedly unaltered in LGA diabetic pregnancies (64). There are conflicting reports on system A and

system L activity in the MVM of these pregnancies (65). However, these studies involved different populations in one of which the placental weight was increased in proportion to the fetal weight (64), which was not the case in the other study (65). In vivo studies have revealed increased umbilical levels of amino acids in GDM pregnancies with good control (66) and increased umbilical vein and artery glucose levels in fetuses of GDM mothers with normal glucose levels (67).

In summary, as the purveyor of nutrient provision to the fetus, the placenta is a vital organ, not only in the sense of its necessity for fetal survival but also as an entity capable of regulating its own response to maternal and fetal conditions. In considering the maternal-placental-fetal trinity, evidence continues to accumulate delineating the active role of the placenta in adjusting nutrient provision based on a host of ever-changing influences that are normally balanced to sustain equilibrium between maternal supply and fetal demand. Under normal circumstances, the placenta provides the appropriate balance and quantity of glucose, amino acids, and lipids to support optimum or at least adequate fetal growth. Disturbances on either side of the placenta are known to stimulate changes within the MVM and BM of the syncytiotrophoblast intended to compensate so as to protect its charge, the fetus. The response of the placenta to an unfriendly environment is typically to autoregulate as much as possible to best promote fetal survival. This is accomplished via multiple transporters, hormones, and growth factors that coordinate fetal nutrient demands with maternal supply. In so doing, changes may be initiated which, while necessary to maintain fetal viability, result in signaling and long-term changes in nutrient metabolism sufficient to increase the postnatal risks for cardiovascular and metabolic disorders.

73 Fertilization and normal embryonic and early fetal development

Asim Kurjak, Ritsuko K. Pooh, Aida Salihagic-Kadic, Iva Lausin, and Lara Spalldi-Barisic

The anatomy and physiology of placental and embryonic development is a field where medicine exerts its greatest impact on early pregnancy at present time, and it opens fascinating aspects of embryonic differentiation. Clinical assessment of those stages of growth relies heavily on three-dimensional (3D) and four-dimensional (4D) sonography, one of the most promising forms of noninvasive diagnostics today. The embryologic phenomenon, once matters for textbooks, is now routinely recorded with outstanding clarity.

It is clear that with the use of 3D and 4D ultrasound, both structural and functional developments in the first 12 weeks of gestation can be assessed more objectively and reliably. New technology moved embryology from postmortem studies to the in vivo environment. It is the purpose of this chapter to illustrate the potential of 3D/4D sonography in the study of structural and functional early human development (1–11).

FROM FERTILIZATION TO IMPLANTATION— THE FIRST 4 WEEKS

Introduction of the color Doppler made it possible to visualize blood vessels that enabled detailed examination of small vessels such as arteries supplying preovulatory follicle, corpus luteum, or endometrium (Figs. 1–5). Perifollicular vascularization can help in the identification of follicles that are containing high-quality oocytes with a high probability of recuperating, fertilizing, cleaving, and implanting. The 3D ultrasound makes it also possible to visualize cumulus oophorus (Fig. 6).

Fertilization is the end of the complicated process of conjunction of gametes by entering one spermatozoon into the oocyte. The gametes, ovum and sperm, contain half of the number of the chromosomes (haploid) compared with the number present in somatic cells (diploid). They obtain haploid number of chromosomes through the process of meiosis during the gametogenesis (4). The oocyte is approximately 120 μm in diameter and has a thick membrane known as zona pellucida. The spermatozoon moves using the flagellum or tail, and the total length of the spermatozoon including the tail is 60 μm . Both oocyte and spermatozoon are highly specialized sex cells. Oocytes are produced in the ovary and expelled from it during the ovulation after which fimbriae of the fallopian tube sweep the oocyte into the ampulla where it can be fertilized. Sperms are produced in seminiferous tubules of the testes and stored in epididymis and ductus deferens. Ejaculation of semen results in the deposit of million sperms in the vagina around the external uterine os. They pass through the uterus and tubes and in the ampulla they surround the

secondary oocyte if it is present. When the sperm enters the oocyte, the nucleus of the mature oocyte consists of the female pronucleus and the head of the sperm separates from the tail and enlarges to become male pronucleus. Fertilization is complete when the pronuclei unite and the maternal and paternal chromosomes intermingle during metaphase of the first mitotic division of the zygote. That cell is the primordium of the human being. The inification of the pronuclei restores a haploid number of chromosomes and completes the fertilization. Therefore, fertilization is a distinct moment when the diploid cell is formed and the development of an individual human begins (3).

Transfer of the oocyte is facilitated by the changing endocrine milieu of the early luteal phase with its rising ratio of progesterone to estrogen, which affects the oviductal and uterine musculature and relaxes the isthmic sphincter. It is probable, however, that the cilia, rather than the musculature, are the primary active transporters of the conceptus. Thus, pharmacologic inhibition of oviductal muscles does not prevent transfer of the conceptus. Furthermore, if a segment of oviduct is excised, turned around, and replaced such that cilia beat away from the uterus, the conceptus moves to that part of the oviduct and then it stops (Figs. 7–9) (4).

Already few minutes after the ovulation, oocyte is located in the ampullar part of the fallopian tube. It is surrounded by the *zona pellucida*. On the surface of the zona pellucida, there are few rows of the granulosa cells that make *corona radiata*. At the periphery of the corona radiata are left cells of *cumulus oophorus*. Often, these three units are called *oocyte–corona–cumulus complex*. Capability for the fertilization is limited: oocyte can be fertilized only 6 to 12 hours after the ovulation. Sperms are capable for fertilization 48 to 72 hours, until they are movable. Fertilization occurs in the ampullar part of the fallopian tube. The process of fertilization begins with conditioning of the spermatozoon in the male and female reproductive tracts. Thereafter, fertilization involves not only the egg itself but also the various investments that surround the egg at the time it is released from the ovary follicle. Fertilization, therefore, is not an event; it is a complex biochemical process requiring a minimum of 24 hours to complete syngamy (formation of a diploid set of chromosomes). During that process, there is no commingling of maternal and paternal chromosomes within a single nuclear membrane (pre-zygote); after this process, the paternal chromosome material is commingled (zygote). The most important activity of this new cell is the recognition of the new genome that presents the principal information center for the development of the human being and for all its further activities.

Figure 1 Visualization of morphology and vascularity of preovulatory ovarian follicle on the 10th and 11th day of menstrual cycle.

Figure 2 Developmental stages of fresh corpus luteum displayed by transvaginal color Doppler.

Early Development of the Embryo

After syngamy, the zygote undergoes mitotic cell division as it moves down the fallopian tube toward the uterus. Shortly after gene activation, conceptus shows marked quantitative increase in its biosynthetic capacity. Net synthesis of mRNA and protein increases, transport of amino acids and nucleotides into the cells rises, and changes occur in the synthetic patterns of phospholipids and cholesterol. The growth and metabolic activity of the preimplantation conceptus in vitro has been shown to be stimulated by a number of growth factors that vary between species and include insulin-like growth factors (IGF-1 and 2), transforming growth factors alpha (TGF-alpha) and beta (TGF beta 1 and 2), epidermal growth factor (EGF), and platelet-derived factor A. Receptors of those factors have been identified on human conceptus. Synthesis of many of

those factors has been detected in early conceptus itself or in maternal tissues; therefore, it is reasonable to conclude that these factors act as *autocrine* or *paracrine* agents that promote the early development (3–5).

A series of mitotic divisions lead to the development of the *pre-embryo*. The newly divided cells are called blastomeres. 24 hours after fertilization from single-cell zygote two-celled embryo is developed. 2 days after the fertilization embryo consists of 6 to 8 blastomeres. Blastomeres form cellular aggregates of distinct, totipotent, undifferentiated cells that retain the capacity to develop independently into normal pre-embryos. After every division, blastomeres become half of their previous size keeping the total size the same as in the beginning when it was just one cell. All up to eight-cell phase, blastomeres are cluster of cells inside the zona pellucida.

Figure 3 Improved visualization of perfollicular blood flow by three-dimensional power Doppler.

Figure 4 Vascularization of nonpregnant uterus.

Figure 5 Richly vascularized thickened endometrium at the day of embryo transfer.

Figure 6 Surface of ovary of a young patient. Follicular cyst and follicle with intrafollicular structure visualized by three-dimensional sonography.

But after the third division, they lose their round shape and they impact one to the other making compact round cluster of cells that are tightly connected by tight junctions. With that change, which is called *compaction*, cells from the outside start to differentiate from those inside. Third day after the fertilization, cells of the compact embryo divide again and *morula* arises. It contains 16 cells, outer part from which trophoblast will appear and inner cells from which embryo will appear.

Blastocyst enters the uterine cavity. In most species, it appears at the 32- to 64-cell stage. Inner part of cells is then called embryoblast and it is located on one side of the blastocyst. Outer part of cells is trophoblast and it makes epithelial surface of the blastocyst. The expansion of the blastocele is stimulated by growth factors EGF and TGF-alpha (4). Throughout the development, from fertilization to the blastocyst, conceptus remains enclosed in zona pellucida. Zona pellucida has two functions. First, it prevents blastomeres of the conceptus from falling apart during early cleavage period prior to compaction. If conceptus does divide into two distinct groups of cells at this time, monozygotic twins result. Second, it prevents two genetically distinct conceptuses from sticking together to make a single chimeric conceptus (4). Free-living

blastocyst is bathed in uterine secretions from which it draws the oxygen and metabolic substrates important for growth and survival. There is a limit of the size that free-living conceptus can attain before such exchanges become inadequate. Before that critical stage is reached, conceptus grows its own blood vascular system. It also grows highly vascularized zones at its extraembryonic surface through which the interchange of materials with maternal tissues is particularly facilitated. During the pre-, peri-, and postimplantation stages of pregnancy, conceptus utilizes maternal juices almost exclusively. That sort of nutrition is called *histiotropic*. However, this source becomes progressively inadequate and so with the successful conclusion of implantation, in maternal endometrial tissue, develops a corresponding specialized and vascularized region. That region will become a placenta, and this sort of nutrition is called *hemotropic*.

When zona pellucida disappears, it makes it possible for blastocyst to implant into the endometrium (Fig. 10).

Once entering the uterus, the conceptus engages in an elaborate interaction with the mother in which several messages are transmitted in both directions. First, conceptus establishes physical and nutritional contact with the maternal endometrium at the implantation. Failure to do so would

Classification of perfollicular vascularity according to the percentage of color by power doppler:

- A) Grade I, when color mapping takes up less than 25% of the follicular circumference;
- B) Grade II, when color mapping covers between 25 and 50%;
- C) Grade III, if color signal appears between 50 and 75%; and
- D) Grade IV, color mapping between 75 and 100% of the follicular perimeter.

Figure 7 Power Doppler display of vascularization of periofollicular follicle.

deprive the conceptus of essential nutritional substrates and arrest in growth. Second, conceptus signals its presence to maternal pituitary-ovarian axis; somehow it must convert the whole female reproductive system from cyclic pattern to a noncyclic in which progesterone dominates.

At the time when blastocyst is prepared for implantation, in the middle of the luteal phase of cycle, endometrium is about 10 to 14mm thick. It is prepared for the implantation by various factors: EGF, IGF-I, and local paracrine and autocrine factors. From day 16 to 22, the receptivity of the endometrium is the highest, which is called "implantation window." At that time, a large number of pinopodes (outgrowth of cytoplasm of endometrial cells) occur, and help blastocyst to implant. When zona pellucida disappears, it makes it possible for conceptus to make contact with decidual endometrium. Implantation consists of three phases: apposition, adhesion, and invasion. Apposition and adhesion are assisted with adhesive molecules of endometrium like laminin, fibronectin, and receptors like integrins. Conceptus produces signals that make change in mother's blood flow. It produces early pregnancy factor, which has immunosuppressive effect. By the beginning of the implantation, proteases and matrix metalloproteinases are activated. Conceptus that is stuck to the surface of the endometrium begins its invasion.

Enzymes of the trophoblast invade mother's circulation and build hemochorial placentation.

In some species, implantation is invasive (humans) in difference to some where it is noninvasive. Invasive conceptus tends to be smaller at attachment and only a few trophoblast cells are involved in making contact with the maternal endometrium. Within few hours, increased vascular permeability is observed. This is associated with edema and a progressive sprouting and ingrowth of capillaries. The stromal reaction is particularly marked in primates where it is called *primary decidualization reaction*. The uterine glandular and decidual tissue adjacent to the invading trophoblast of the conceptus is destroyed. It releases primary metabolic substrates: lipids, carbohydrates, nucleic acids, and proteins, which are taken by the growing conceptus. Decidual tissue thus functions like a large yolk reservoir.

The invasiveness of the conceptus is influenced by the effectiveness of the decidual response. The depth of the invasion varies between species. Those species in which the conceptus invades the stroma so deeply that the surface epithelium becomes restored over it are called to be implanted *interstitially*.

Endometrium that occurs in the attachment process involves leukemia inhibitory factor (LIF). It is produced by

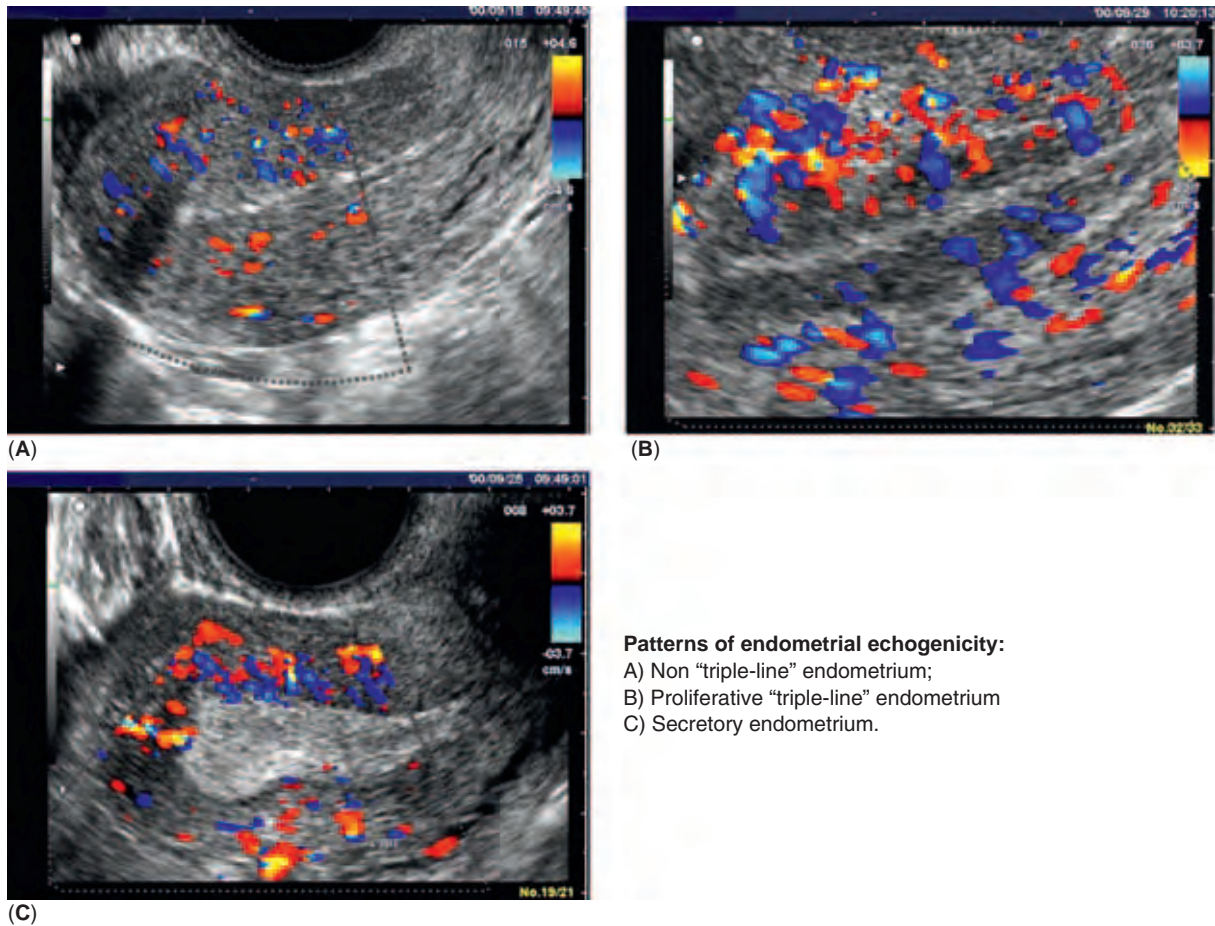

Figure 8 Endometrial thickness and rich vascularization indicating good uterine receptivity.

the cells of the endometrial glands under the influence of estrogen. Receptors for LIF also appear in both the epithelium and the stroma of the endometrium around the time of implantation. Seems like LIF promotes endometrial receptivity to attachment and/or subsequent decidualization.

In the presence of the estrogen, either the conceptus produces the signal or the local endometrium becomes sensitive to a signal being already sent. The nature of this putative signal is unknown, but it induces the HB-EGF production locally and the conceptus in turn responds in shedding its zona, attaching and invading (4).

The invasiveness of the trophoblast depends of the expression and regulation of the different proteolytic enzymes. TGF-beta promotes decidualization and controls trophoblastic invasion. Histamine and prostaglandins are involved in the stromal response: inhibition of either one of them reduces the decidualization.

An important feature of decidual response is increase in vascular permeability and growth of new capillaries (*angiogenesis*).

As implantation proceeds, trophoblast differentiates into two layers: inner cytotrophoblast and outer syncytiotrophoblast. Around day 9, syncytiotrophoblast cells begin to produce human chorionic gonadotropin (hCG). It maintains the thick endometrium and can be detected in maternal blood or urine, which is used for early pregnancy testing (3).

A small intradecidual gestation sac can be seen by transvaginal sonography between 32 and 34 days (Figs. 11 and 12). The

secondary yolk sac is the earliest extraembryonic structure normally seen within the gestational sac at the beginning of the 5th gestational week (Fig. 13). Yolk sac volume increases from week 5 to 10. When it reaches its maximum at week 10, it would have already started to degenerate, which can be seen by the significant reduction in visualization rates of the yolk sac vascularity. The start of embryo-chorionic circulation changes the source of nourishment to all intraembryonic tissues. Development of the embryo becomes dependent on the circulation of embryonic blood. In the embryo, there are three distinct blood vascular systems: vitelline circulation (from yolk sac to embryo), intraembryonic circulation, and feto-placental circulation. It is possible to visualize and assess them virtually from conception.

At 5 weeks it is possible to obtain a 3D image of the developing intervillous circulation in the maternal site of the placenta (Fig.14). Doppler shows intense vascular activity surrounding the chorionic shell. At 7 weeks 3D power Doppler images depict aortic and umbilical blood flow.

DEVELOPMENT OF EMBRYO THROUGH FIRST 4 WEEKS

Along with the implantation process, changes occur in the embryoblast to produce a bilaminar embryonic disc, composed of the epiblast and the hypoblast. Early in the 2nd week, the amniotic cavity appears as a space lined with amnioblasts derived from the epiblast. By the end of the 2nd week, the embryonic disc becomes oval in shape. Along the median line

Echographic characteristics of implantation and early placentation

Endometrium - secretory phase (3–4 weeks)

- The “triple – line” disappears and is replaced by an **echogenic pattern**. At this stage the endometrium is at the maximum thickness as it reaches upto **14mm**.

Figure 9 Vascularization is very obvious in the secretory phase of menstrual cycle.

in the posterior region of the embryonic disc, a thickening of the epiblast called the *primitive streak* appears, and it defines the longitudinal axis of the embryo. During the 3rd week, lateral epiblast cells migrate medially, enter the primitive streak, and then converge to form the primitive groove.

During the latter half of the 3rd week, drastic changes for morphogenesis (development of the body form) begin. The embryonic disc elongates craniocaudally to become pear-shaped and then slipper like. Cranial to the primitive node, a thickening of the ectoderm appears bilaterally and is called the neural plate because it will eventually develop into the neural tissue. Between the bilateral neural plates, a longitudinal neural groove develops in the midline, flanked by the neural folds bilaterally. Around day 20, the bilateral neural folds begin to fuse with each other to form the neural tube, which is the primordium of the central nervous system (CNS; brain and spinal cord). The rostral (anterior) neuropore normally closes on days 24 to 26, and the caudal (posterior) neuropore closes by 28 days. When the neuropores close completely, three brain vesicles (forebrain or prosencephalon, mesencephalon or midbrain, and rhombencephalon) have already appeared. Rarely the neural tube fails to close completely, resulting in a variety of neural tube closure defects such as anencephaly, encephalocele, myeloschisis, and myelomeningocele.

By the end of the 3rd week, the paraxial mesoderm condenses segmentally along the midline to form somite pairs. First the somites are recognized as conspicuous surface elevations and gradually increase in number craniocaudally. The somites give rise to most of the axial skeleton, trunk and limb musculature, and dermis of the skin. The formation and specification of somite segments are controlled by a unique combination of Hox genes (Hox code). Concurrent with somite differentiation, the intraembryonic coelom arises as isolated spaces between the layers of the lateral plate mesoderm, which is the primordium of body cavities. The coelomic cavities subsequently coalesce to form a single, horseshoe-shaped cavity that eventually gives rise to the pericardial, pleural, and peritoneal cavities.

At the beginning of the 4th week, the embryo is almost straight. During the 4th and 5th weeks, the embryo body undergoes a drastic shape change as a result of embryonic folding. Embryonic folding occurs in both the longitudinal and the horizontal planes, resulting from the rapid growth of the embryo, especially the brain and spinal cord, as well as the expansion of the amniotic cavity. Folding of the embryo in the horizontal plane rolls the lateral parts of the embryonic disc ventrally and forms a cylindrical embryo.

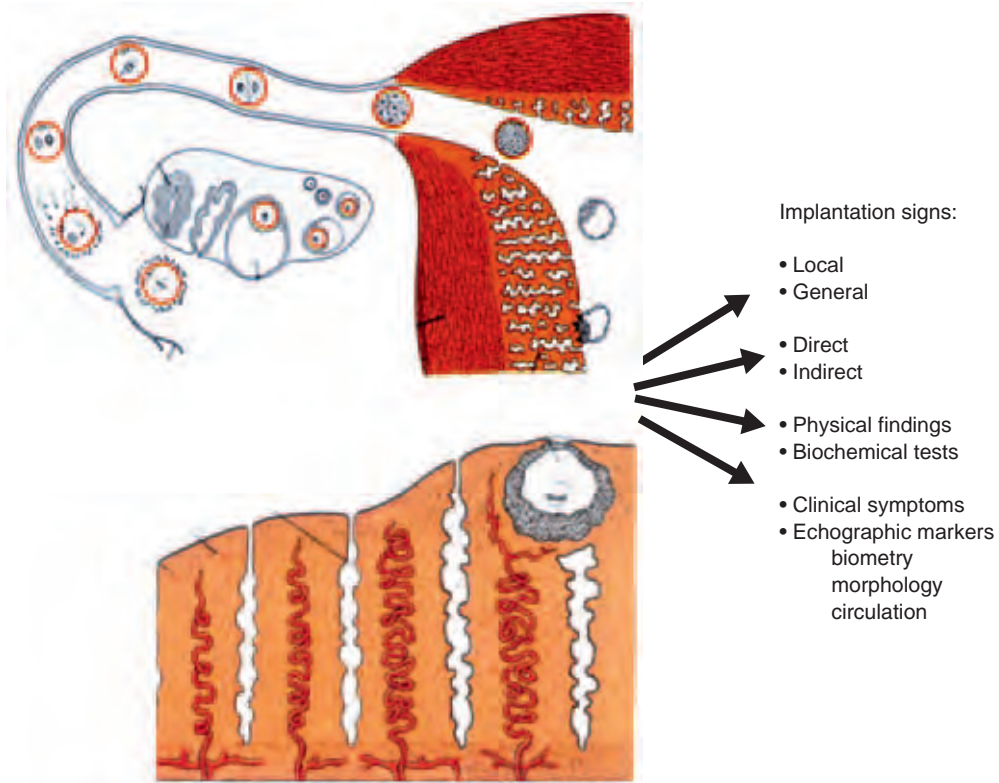

Figure 10 Schematic illustration of the process of implantation.

Echographic characteristics of implantation and early placentation

Gestational sac (5th week)

Figure 11 Gestational sac at 5 weeks visualized by two-dimensional sonography.

Another important developmental event that occurs during the 4th week is the emergence of limb buds. Forelimb buds appear by 28 days and hindlimb buds about 2 days later. By the end of the 4th week, the embryo is in a C-shape.

During the 5th week, limb buds elongate and their distal ends become paddle shaped. The second pharyngeal arch overgrows the third and fourth arches and forms an ectodermal depression known as the cervical sinus. Ultrasonography reveals some primitive spontaneous movements of the embryo, such as twitching of the trunk, in the 7th week.

During the 6th week, the upper limbs undergo rapid morphologic differentiation, and digital rays, indicating that the future digits are recognizable. By the end of this week, the elbow and wrist regions become clearly identifiable. Retinal pigment is visible in the eyes. On the first and second pharyngeal arches, six swellings develop as the primordia of the auricle of the external ear. As a result of the rapid growth of the brain, the head is larger relative to the trunk and starts to lie over the cardiac prominence (1-6).

ULTRASONIC VISUALIZATION OF EARLY HUMAN DEVELOPMENT

Gestational sac can be visualized from the middle of the 5th week of amenorrhea as a small spherical anechoic structure placed inside one of the endometrial leaves (7). Planar mode tomograms are helpful in distinguishing early intraendometrial gestational sac from collection of free fluid between the endometrial leaves (pseudogestational sac). The 3D sonography enables precise measurement of exponentially expanding gestational sac volume during the first trimester. At the beginning of the 5th week, small secondary yolk sac is visible as the earliest sign of the developing embryo (Fig. 15). Adjacent to the yolk sac, embryo can be seen as a small straight line when it reaches 2 to 3 mm in length at the end of the 5th week.

Six Weeks

Typical characteristics of the 6th week embryo include a rounded bulky head and a thinner body. The head is prominent due to the developing forebrain. Limb buds are rarely visible in this stage of pregnancy. However, umbilical cord and vitelline duct are always clearly visible. At this stage of pregnancy, the planar mode will allow for more accurate assessment of multiple pregnancies.

Seven Weeks

During the 7th week, fast development of rhombencephalon (hindbrain) takes place. This process gives even more prominence to the head. By the use of planar mode developing vesicles of the brain can be depicted as anechoic structure inside the head. The biggest and usually the only visible part is rhombencephalon placed on the top of the head (vertex). Diencephalon and its cavity become visible few days later. The head is strongly flexed anteriorly being in the contact with the chest. Limb buds are often visible laterally to the body.

Eight Weeks

During the 8th week of pregnancy, there is expansion of the ventricular system of the brain (lateral, third, and midbrain ventricles). The shape of the face is becoming apparent, but the flexion of the cranial pole still makes it difficult to view the face entirely (Fig. 15). The vertex is now located over the position of the midbrain. Structures of the viscerocranium are not visible due to the small size. Arms and feet are clearly visible. Insertion of the umbilical cord is visible on the anterior abdominal wall. During the 8th and 9th weeks, developing intestine is being herniated into the proximal umbilical cord. The amnion can be clearly seen and the extraembryonic coelom is still larger in volume than the amniotic sac.

Figure 15 Normal morphologic development from 5 to 10 weeks of gestation.

The extraembryonic space will appear more echogenic than the amniotic sac. The ventricular cavities are characteristically cystic, particularly the rhombencephalon. This should not be confused with an early diagnosis of Dandy Walker cyst.

Nine to Ten Weeks

Cerebral hemispheres continue with development during the 9th and 10th weeks of pregnancy. Visible are lateral ventricles containing hyperechoic choroid plexuses. The head is clearly divided from the body by the neck. External ear is sometimes depicted in the 3D surface image. Herniation of the midgut is present. Dorsal column, the early spine, can be examined in its whole length. The arms with elbow and legs with knee are now visible. Feet can be seen approaching the midline (Fig. 15).

Eleven to Twelve Weeks

During the last phases of the end of the first trimester, striking changes in the development of the head and neck continue. Details of the face such as the nose, orbits, maxilla, and mandible are visible. Herniated midgut returns to the abdominal cavity.

Planar mode enables detailed analysis of embryonic body with visualization of the stomach and urinary bladder. Kidneys are also often visible. Arms and legs continue with development. Long bones can be visualized as hyperechoic elongated structures inside upper and lower extremities. Fingers and toes are visible (Fig. 16). Detailed 3D analysis of fetal spine, chest, and limbs is obtainable by using the transparent X-ray-like mode.

Figure 16 Fetus at 11 weeks showing movement of upper and lower extremities (A–D).

Excellent visualization has been achieved by the 3D and 4D ultrasound combined with the transvaginal approach (1,6,8,10,11). Demonstration of small embryo less than 10mm is still difficult. Figure 17 shows 18.3mm-CRL (crown-rump length) embryo at 8 weeks of gestation and macrographic pictures of an aborted specimen at the same gestational age.

Maximum mode of 3D ultrasound can clearly demonstrate fetal bony structure. Rapid ossification of craniofacial bones dramatically occurs during the first trimester. Craniofacial bony structure can be demonstrated from 10 weeks of gestation by ultrasound. Figures 18 and 19 show premature structure of craniofacial bony structure visualized by using maximum mode of 3D ultrasound at 11 and 14 weeks of gestation respectively.

Difference of frontal bone appearance between 11 and 14 weeks indicates membranous ossification of cranium in this stage. Figure 20 demonstrates bony structure of the occipital region of head at 13 weeks of gestation.

During early embryonal period, the CNS structure rapidly changes its appearance. The 3D ultrasound produced

high-resolitional images of embryos in early stage by tomographic ultrasound imaging and three-orthogonal imaging technologies (Figs. 21–26).

Indeed, advances described deserve the adjective “breath-taking,” in particular 4D parallel study of the structural and functional early human development (12–23).

Those 3D neuron-sono-embryologic imaging in utero may change embryonal staging in vivo in future, from “gestational age based on menstrual period or measurement of CRL” into “morphologic staging system” such as Carnegie staging in embryology. Indeed, improvements in the visualization deserve the adjective “breath-taking” in the better inside into the early human development (1,6,24–29).

THE ASSESSMENT OF VASCULARITY BY 3D POWER AND COLOR DOPPLER SONOGRAPHY

By adding colored blood flow signals to the gray scale image or extracting just the color-coded signals, it is possible to depict 3D image of vascular features of early pregnancy (Fig. 27).

This enables research of longitudinal changes in embryonic and early uteroplacental circulation. It has been found

that 3D power Doppler can clearly depict the full 3D continuation of early embryonic and umbilico-placental circulation. By adding the pulsed Doppler, pulsations from the embryonic aorta and umbilical artery can be identified as early as the 6th week of gestation. Umbilical artery is characterized by pulsations with absent end-diastolic

velocities. Between the 11th and 14th weeks, diastolic velocities gradually emerge (24). Placental branches of umbilical artery are easily depicted by 3D power Doppler (12,30–39).

Intracranial circulation becomes visible from the 8th week of gestation (Fig. 28).

The 3D power Doppler image presents early vascular anatomy on the base of the skull with branches evolving laterally to the mesencephalon and cephalic flexure. Pulsed Doppler signals are initially characterized by the absent end-diastolic velocities. Continuous pan-diastolic flow emerges at the gestational age of 9 to 10 weeks. A significant decrease in impedance was observed in intracranial vessels with advancing gestational age, being more pronounced than that in the other parts of the fetal circulation (12,22).

From the maternal side of placenta, it is possible to obtain the simultaneous 3D imaging of the developing intervillous circulation during the first trimester of pregnancy (Fig. 32A and 32B).

The 3D power Doppler reveals intensive vascular activity surrounding the chorionic shell starting from the first

sonographic evidence of the developing pregnancy during the 5th week of gestation.

Hyperchoic chorionic ring is interrupted by color-coded sprouts that penetrate its limits. These are areas of developing intervillous circulation. Pulsed Doppler reveals blood flow of two types in these areas: a pulsatile arterial like and a continuous venous like (27–29). All were in concordance with clear histomorphology evidence that spiral arteries began to open directly into the intervillous space during the second month of gestation (29).

FUNCTIONAL DEVELOPMENT OF CNS

The structural and functional development of the human CNS begins in the early embryonic period and proceeds through a sequence of very complicated processes long

Figure 27 On 4th and 5th weeks of the normal pregnancy, endometrium more (A) or less (B) vascularized, but it is always possible to distinguish a three-dimensional color signal penetrating to gestational sac. We named this finding the “comet sign” and it indicates the implantation site.

8 Weeks

after delivery (40). It is important to point out that the caudal region of the neural tube gives rise to the spinal cord and the rostral region becomes the brain. The initial development is completed at 7 weeks of gestation (5 weeks after conception), when all five major subdivisions of the brain are clearly visible: the telencephalon, diencephalon, mesencephalon, metencephalon, and myelencephalon (Fig. 33) (41).

The earliest interneuronal connections, the synapses, can be detected in the spinal cord shortly before the onset of embryonic motility, at 6 to 7 weeks of gestation (42). Therefore, the neural activity leading to the first detectable movements is considered to originate from the spinal motoneurons (43). Another important prerequisite for the motility is the development and innervation of muscular fibers. It is well known that primitive muscle fibers (myotubes) are able to

Figure 33 The main events in the development of the central nervous system (CNS) and motor development during the first 8 weeks of pregnancy. Source: From Ref. 40.

contract as soon as they are innervated by motoneurons (44). Between 6 and 8 weeks of gestation, muscle fibers have formed by fusion of myoblasts, efferent and afferent neuromuscular connections have developed, and spontaneous neural activity causing motility can begin.

The main events in the development of the CNS and motor development during the first 8 weeks of pregnancy are presented in Figure 33. The first spontaneous embryonic movements are gross body movements and they can be observed at the 7 to 7.5th weeks of gestation. They consist of slow flexion and extension of the fetal trunk, accompanied by the passive displacement of arms and legs (45). These, so-called vermicular movements appear in irregular sequences (46). Simultaneous with the onset of spontaneous movements, at the 7.5th week of gestation, the earliest motor reflex activity can be observed, indicating the existence of the first afferent–efferent circuits in the spinal cord (47). The first reflex movements are massive and indicate a limited number of synapses in a reflex pathway. General movements are the first complex, well-organized movement pattern, which involve head, trunk, and limb movements. This pattern has been interpreted as the first sign of a supraspinal control on motor activity (48,49) and can be recognized from 8 to 9 weeks of gestation onward (49,50).

It is very important to note that even at this early stage of development, embryonic and fetal movements appear in recognizable temporal sequences, without any amorphous or random movement. The explanation for this fascinating phenomenon lies in the intrinsic properties of neurons. That means that neural cells begin to generate and propagate action potentials as soon as they interconnect (51). The interconnected neurons generate patterned activity because of

endogenous properties of the neurons (52). Recent investigations have shown that neurons are able to communicate through non-synaptic mechanisms even before the onset of synaptogenesis (53–55).

The brain stem is fashioned around the 7th week of gestation (48) and basic structures of the diencephalon and cerebral hemispheres are formed by the end of the 8th gestational week (56). The remarkable expansion of the cerebral hemispheres follows during the remainder of gestation. The development of synapses in the human cerebral cortex begins after the formation of the cortical plate, at the end of the 10th week of gestation (53,57).

The brain stem consists of the medulla oblongata, pons, and midbrain (Fig. 34).

It forms and matures in a caudal to rostral direction. That means that the phylogenetically older structures, such as the medulla oblongata, will form and mature earlier in the gestation. The major structures of the medulla oblongata are fashioned by 7th to 8th week of gestation and are completely matured by 7 months of gestation (48). In addition to its many subnuclei, the medulla gives rise to a variety of descending spinal motor tracts that reflexively trigger limb and body movements. It also hosts the five cranial nerves (VIII–XII), which exert tremendous influences on gross body movements, heart rate, respiration, and the head turning. As the medulla matures in advance of more rostral structures of the brain stem, reflexive movements of the head, body, extremities, as well as breathing movements (Fig. 34) and alterations in heart rate, appear in advance of other functions. The formation of pons begins almost simultaneously, but its maturation is more prolonged. The

Figure 35 Image of the fetus recorded by three-dimensional/four-dimensional sonography, showing isolated finger movements.

10 Weeks

Figure 36 Fetal movement at 10 weeks and 6 days. Active arm movements (A–E) are associated with active body and lower limb movements. Despite active movements of glenohumeral and elbow joints at this stage, wrist and finger movements were not visualized in most cases.

11 Weeks

Figure 37 Fetus at 11 weeks still opens the palms but five digits are no longer on the same layer (A). Mild adduction of the thumb and atonic fingers were observed and the palm appearance was clearly different from that in 9 and 10 weeks (B).

12 Weeks

Figure 38 Clench (A) and unclench (B) of the fist at 12 weeks. At this stage, fetuses start to clench and unclench their fists.

structures of the pons include the V to VIII cranial nerves (vestibular nuclei of the nerve VIII) and the medial longitudinal fasciculus, pontine tegmentum, raphe nucleus, and locus coeruleus, which exert widespread influences on arousal, including the sleep–wake cycles. Facial movements, which are also controlled by V and VII cranial nerve, appear around 10 to 11 weeks.

At 10 weeks of gestation, lateralized behavior may be observed, and the fetus begins to show the earliest signs of right- or left-handedness. Stimulation of the brain is known to influence brain organization and it is argued that fetal motor activity may eventually stimulate the brain to develop “handedness” and subsequent lateralization of the function (58,59). From 10 weeks onward, the number and frequency of fetal movements increase and the repertoire of movements begins to expand. Qualitative changes in general movements can also be observed. These movements, which are slow and of limited amplitude during 8 and 9 weeks, become more forceful at 10 to 12 weeks. After the 12th week, they become more variable in speed and amplitude (60). The isolated limb movements seen at the 9th week of gestation are followed by the appearance of the movements in the elbow joint at 10 weeks, changes in finger position at the 11th week, and easily recognizable clenching and unclenching of the fist at 12 to 13 weeks. Finally, at 13 to 14 weeks, isolated finger movements can be observed, as well as increases in the activity and strength of the hand/finger movements (61) (Fig. 35). Using 4D sonography, Kurjak and collaborators have found that from 13 gestational weeks onward, a “goal orientation” of hand movements appears and a target point can be recognized for each hand movement (62).

According to the spatial orientation, they classified the hand movements into several subtypes: hand to head, hand to mouth, hand near mouth, hand to face, hand near face, hand to eye, and hand to ear. Our recent longitudinal study, performed by 4D ultrasound in 100 fetuses from all trimesters of normal pregnancies, has shown increasing frequency of various movement patterns, such as general movements, isolated arm and leg movements, stretching, as well as head movements, during the first trimester. Only the startle movement pattern seemed to occur stagnantly in this period of gestation (63). Using 4D sonography, general movements were found to be the most frequent movement pattern between 9 and 14 weeks of gestation (64). Furthermore, the advanced ultrasonic techniques, 3D and 4D sonography, significantly improve the assessment of structural and functional development of embryonic and fetal CNS (65–67). Some illustrative examples are shown on Figures 36, 37, and 38.

The development of CNS begins rather early in the embryonic period and proceeds throughout the gestation and continues long after birth.

Although some histogenetic processes are not finished until puberty, the neurodevelopmental events are very active in the early pregnancy (56). The earliest signs of functional development of CNS, such as motility, can be registered as early as the late embryonic period (62,68).

The sequential appearance of specific movement patterns, first described by de Vries et al., is presented in Table 1 (68).

Despite the rapid development and a fascinating variety of movements during this early period of gestation, dynamic

Table 1 Developmental Sequence of Fetal Behavioral Patterns in the First Trimester of Pregnancy (68)

pattern of neuronal production and migration, as well as the immature cerebral circuits, is considered too immature for the cerebral involvement in the motor behavior (69).

74 Group B streptococcus infection

Jessica Winn and Hung N. Winn

Group B streptococcus (GBS) (*Streptococcus agalactiae*), a Gram-positive coccus, is one of the major causes of maternal or neonatal severe infection and sepsis. Maternal infection associated with GBS includes acute chorioamnionitis, endometritis, and urinary tract infection. Neonatal GBS infection is characterized as early onset if occurring within 7 days of age or late onset otherwise and involves bacteremia, pneumonia, or meningitis (1,2).

EPIDEMIOLOGY

Of all pregnant women in the United States, 10% to 30% have recto-vaginal colonization with GBS (3–5). In patients with preterm labor or preterm premature rupture of membranes (PPROM), the incidence of genital colonization of GBS is 15% (6). Of urinary tract infections during pregnancy, 2% to 7% result from GBS colonization (7). The incidence of neonatal GBS infection (number of cases per 1000 live births) was gradually decreased between 1990 and 2008. It was 1.8, 0.5, and 0.28 in 1990, 2000, and 2008, respectively (8–13). This decline can be attributed to screening of pregnant woman for GBS colonization and use of intrapartum antibiotic prophylaxis (14–17). Neonatal colonization of GBS may occur as a result of in utero ascending infection from the maternal genital tract or direct contact during delivery. Vertical transmission from the mother to the neonate by either method accounts for up to 50% (13) of cases of neonatal GBS colonization, and 1% to 2% of these infants will develop early-onset GBS infection (14,18–22). The case fatality of early-onset GBS neonatal infection varies from 2% to 3% for term infants without meningitis to 20% for preterm infants (13,23). Maternal risk factors that predispose a neonate to early-onset GBS infection include preterm delivery, prolonged rupture of membranes (>18 h), PPRM, chorioamnionitis, sustained intrapartum fetal tachycardia, GBS bacteriuria during the current pregnancy (>10⁴ cfu/mL), intrapartum fever (temperature of at least 38°C or 100.4°F), or prior infant with GBS infection (15,16,24,25). The risk of having an infant with early-onset GBS is 6.5 times higher in a pregnant woman with maternal fever, prolonged rupture of membranes, or preterm birth when compared with women who displayed none of the above findings (18,26,27). Late-onset GBS neonatal infection may occur from maternal–neonatal transmission, or nosocomial or community contacts (28,29).

DIAGNOSIS

Group B streptococcal colonization can be detected by either culture or rapid diagnostic tests. Currently, culture remains the gold standard for diagnosing GBS colonization. The yield of positive GBS culture is increased by sampling the anorectum in addition to the vagina, since the gastrointestinal tract is a major reservoir of GBS (5,30). This can be done in a

single swab. Inhibition of competing organisms by using a selective medium such as Todd–Hewitt broth, which contains gentamicin, polymyxin B, and nalidixic acid or colistin (24), also increases the yield of the GBS culture. The main limitation of culture is time. Since culture results are not available for 24 to 48 hours, management may be problematic if delivery is imminent.

Rapid diagnostic tests of GBS directly detect the extracted specific polysaccharide antigen. The available tests use either latex particle agglutination or enzyme immunoassay. These tests are relatively easy to perform, are generally less expensive than a culture, and produce results within a short period of time (usually within 1 hour). Although rapid detection tests are highly sensitive in patients who are heavily colonized with GBS, their overall rates of sensitivity and high false-negative results compared with those of cultures prevent their widespread clinical application (31–35). These drawbacks for the rapid diagnostic tests also exist in the setting of preterm labor or PPRM, demonstrating that the rapid latex agglutination test fails to identify GBS neonatal infection in (i) heavily, (ii) moderately, and (iii) lightly GBS-colonized mothers. More importantly, the overall sensitivity of the latex agglutination test in identifying maternal–neonatal pairs at risk for GBS neonatal infection is only 25% (6).

TREATMENT

Intrapartum chemoprophylaxis is effective in reducing the attack rate of early-onset neonatal GBS (26). In 2002, the Centers for Disease Control and Prevention (CDC) established new guidelines for GBS prevention. It recommended screening all pregnant women with culture of anogenital specimen at 35 to 37 weeks of gestation and providing intrapartum chemoprophylaxis for those with positive GBS culture. Specimen should be collected with swabbing the lower vagina and the lower rectum to obtain the best yield of GBS culture (36–39). Women with GBS bacteria during their current pregnancy and those with a prior history of having a neonate with invasive GBS infection do not need to be screened and should be given intrapartum chemoprophylaxis routinely (40). In 2010, the CDC maintained the same recommendations (24). Women with unknown GBS status at the time of delivery should be managed based on the presence of intrapartum risk factors [delivery at <37 weeks, rupture of membranes >18 hours, fever of ≥100.4°F (38°C)] (24).

Currently, prenatal treatment of asymptotically colonized pregnant patients with oral antibiotics is not recommended, since this approach is unlikely to eradicate maternal genital GBS colonization at the time of labor and delivery. Of pregnant patients who received antenatal ampicillin or aqueous penicillin for genital colonization of GBS, 30% to 70% remained colonized at delivery (41,42).

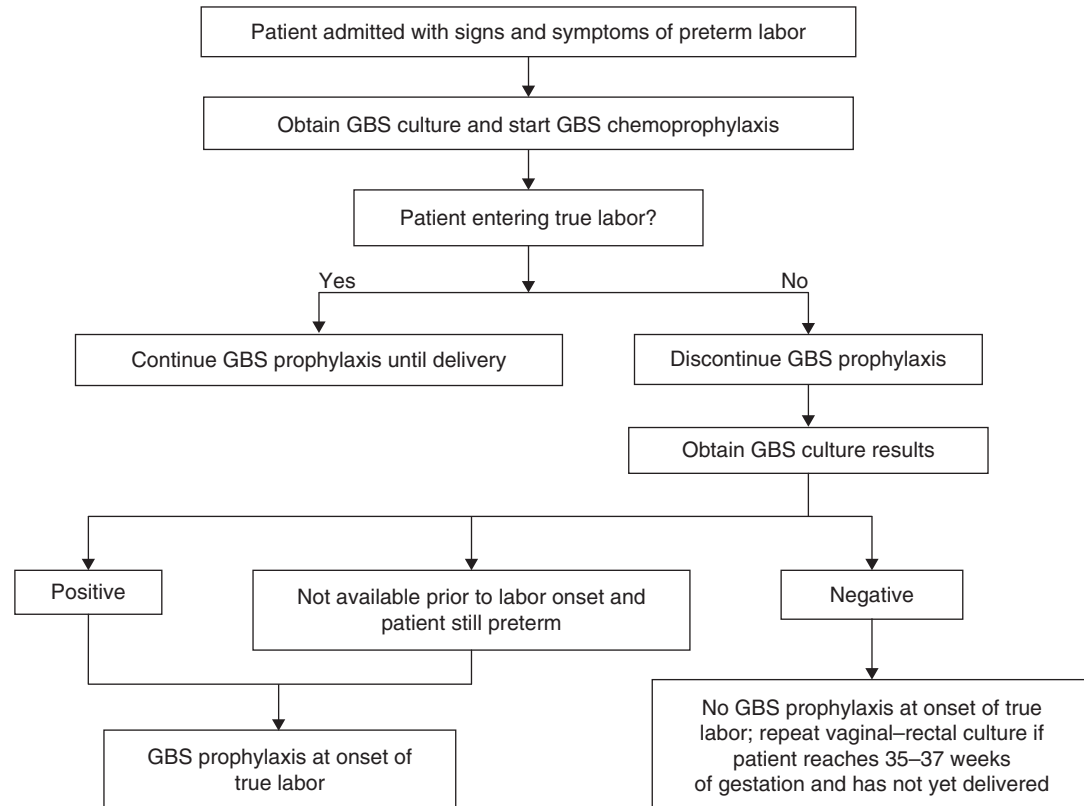

Figure 1 Algorithm for screening of group B streptococcal colonization and use of intrapartum prophylaxis in women with preterm labor. Abbreviation: GBS, group B streptococcus. Ref. 24.

In 2010, the CDC made recommendations regarding the prevention of early-onset neonatal GBS infection in the setting of preterm (less than 37 weeks) labor or PPRM (24). Patients who develop preterm labor without prior GBS screening during the preceding 5 weeks of admission should be screened for GBS colonization and provided GBS chemoprophylaxis. The latter should be stopped when the GBS screen is negative or preterm labor is resolved. GBS screening should be repeated at 35 to 37 weeks of gestation or when preterm labor recurs more than 5 weeks since the last GBS screening. Figure 1 summarizes the above process for management of patients with preterm labor.

Patients who develop PPRM should be screened for GBS colonization and provided antibiotics for prolonging latency period with adequate GBS coverage (ampicillin 2g initially, then 1g every 6 hours for 48 hours given intravenously) or GBS chemoprophylaxis otherwise. The GBS chemoprophylaxis can be discontinued when the GBS vaginal-rectal screening obtained on admission turns out to be negative. The patient with PPRM may not need GBS chemoprophylaxis on admission if her GBS screening was negative within 5 weeks of PPRM. Group B streptococcus (GBS) screening should be repeated at 35 to 37 weeks of gestation if she remains pregnant at that time. Figure 2 summarizes the above process. The patient should receive intrapartum chemoprophylaxis if she ever had genital GBS colonization during her pregnancy, regardless of the results of intervening GBS cultures and/or treatments in both situations of preterm labor and PPRM.

INTRAPARTUM CHEMOPROPHYLAXIS

Aqueous penicillin G is the drug of choice with the initial dose of 5 million units and maintenance dose of 2.5–3.0 million

units every 4 hours. Ampicillin is the alternative with the initial dosage of 2g and the maintenance dose of 1g every 4 hours. Penicillin G is preferable to ampicillin because of its narrower spectrum of bacterial sensitivity, thus being less likely to cause the selective emergence of other pathogenic bacteria (15). Women who are penicillin allergic but do not have a high risk of anaphylaxis (defined as a history of anaphylaxis, angioedema, respiratory distress, or urticaria after administration of a penicillin or cephalosporin) should receive cefazolin 2g IV initially then 1g every 8 hours. Cefazolin crosses the placenta and attains effective amniotic concentrations. Women who are allergic to penicillin and at a high risk of anaphylaxis should receive clindamycin IV 900mg every 8 hours if (i) the GBS is susceptible to both clindamycin and erythromycin or (ii) GBS is susceptible to clindamycin, resistant to erythromycin but without inducible resistance to clindamycin. Women who are allergic to penicillin and at a high risk of anaphylaxis but do not meet the above conditions for clindamycin should receive vancomycin 1g IV every 12 hours otherwise. Erythromycin is no longer used in women who are allergic to penicillin and are at high risk for anaphylaxis. Intrapartum chemoprophylaxis should be given intravenously until delivery. Figure 3 summarizes the GBS chemoprophylaxis (24).

SUMMARY

Although controversy exists regarding screening and treatments of GBS colonization in pregnant women, there is a consensus that chemoprophylaxis in the intrapartum period dramatically reduces the rate of infection in both the mother and the neonate. At present, the most cost-effective strategy of reducing early-onset GBS infection is universal screening of

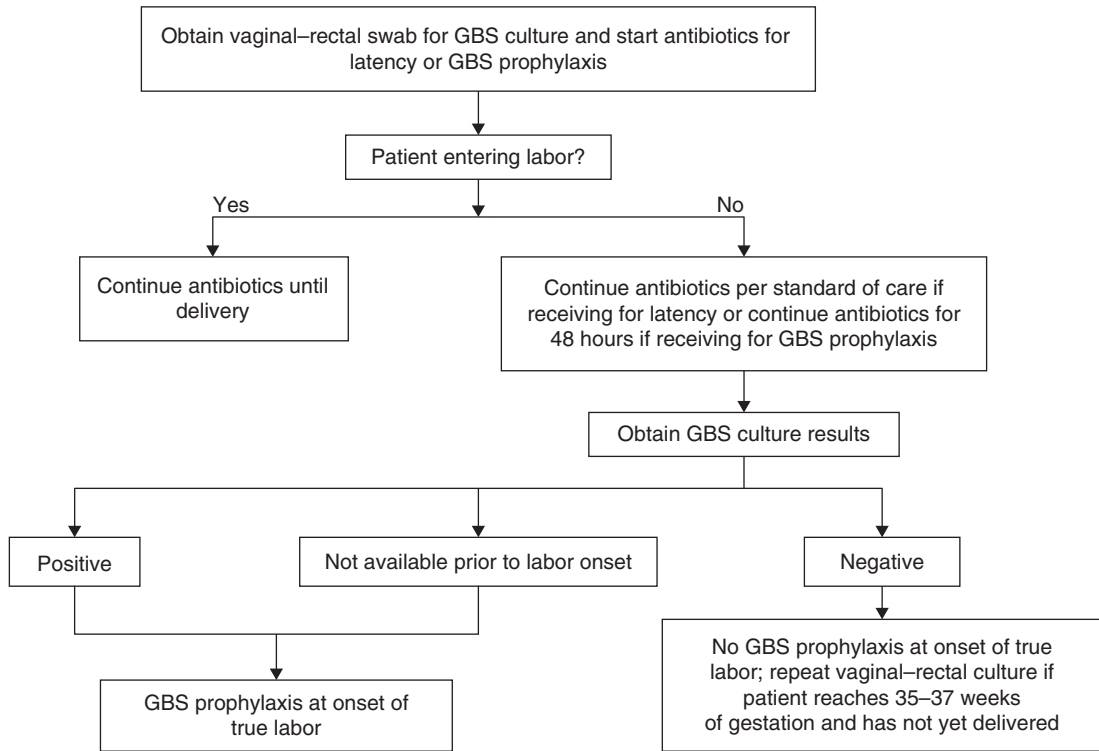

Figure 2 Algorithm for screening of group B streptococcal colonization and use of intrapartum prophylaxis in women with preterm premature rupture of membranes. Abbreviation: GBS, group B streptococcus. Ref. 24.

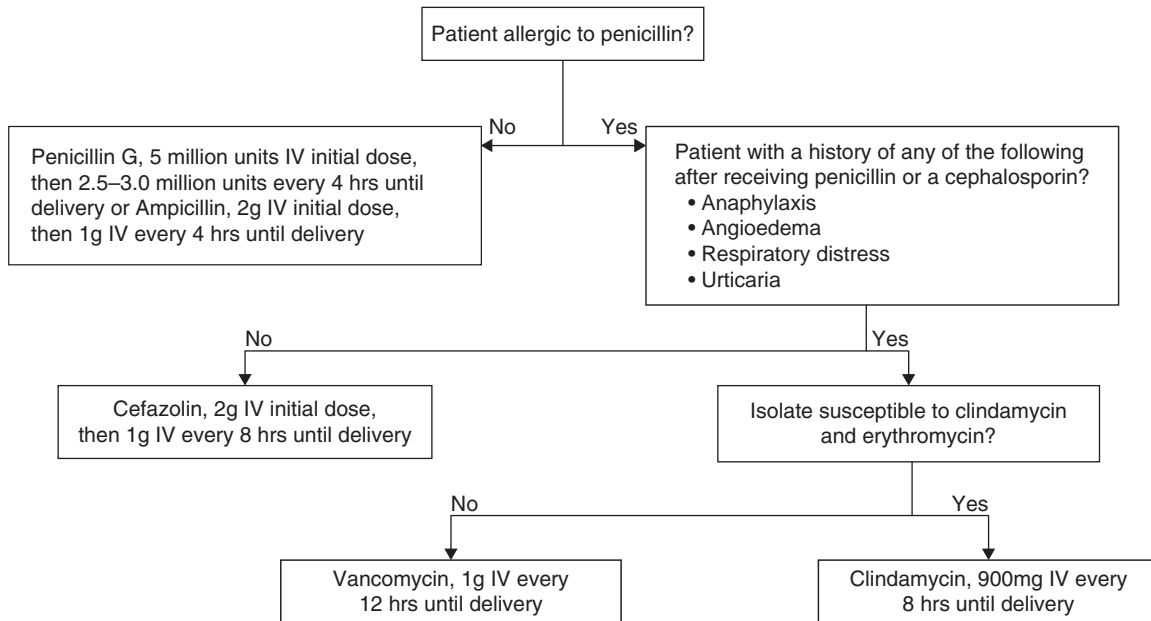

Figure 3 Recommended regimens for intrapartum antibiotic prophylaxis for prevention of early-onset group B streptococcal disease. Abbreviation: GBS, group B streptococcus. Ref. 24.

maternal GBS vaginal-rectal colonization at 35-37 weeks of gestation. Intrapartum GBS chemoprophylaxis should be given to patients without antenatal screening who have one of the following risk factors: preterm delivery, prolonged rupture of membranes (>18 h), intrapartum fever, or prior infant with GBS infection. Penicillin G is the drug of choice for

this purpose and ampicillin is the alternative. Cefazolin may be used in patients who are allergic to penicillin or cephalosporin without a high risk for anaphylaxis. Patients who have allergy to penicillin with a high risk of anaphylaxis should receive clindamycin if the bacterium is susceptible to both clindamycin and erythromycin or vancomycin otherwise. Maternal

vaccination, being developed, appears to be the most cost-effective measure in preventing early-onset GBS neonatal infection.

76 Postpartum infections

Dorothea Mostello

Serious postpartum infections remain a significant cause of maternal morbidity and mortality. Some factors that may predispose the puerpera to infection include rapid colonization of the postpartum endometrial surface by vaginal flora (1), contamination of the perineal area by vaginal and fecal flora, introduction of bacteria through manipulations or instrumentation employed to effect delivery, as well as the physiologic adaptation of the breasts for lactation. Despite these risks, the overall incidence of clinical infection in the postpartum period is relatively low (less than 10%). Because postpartum women are generally young and healthy, their general resilience may impede prompt diagnosis if the patient or physician underestimates the risks of infection. Identification and close surveillance of patients at risk allow for timely diagnosis and prompt treatment, which may minimize serious sequelae of infection.

The standard definition of “puerperal fever” as an oral temperature of 38.0°C or more in any 2 of the first 10 days postpartum, exclusive of the first 24 hours, is impractical and may not be a valid indicator of infection. While transient elevations in temperature occur commonly and resolve spontaneously, a temperature greater than 38.4°C or persistent low-grade fever during the first 24 hours postpartum is highly predictive of ensuing infection (2). Disregarding temperature elevations that do not fit into a standard definition or ignoring signs and symptoms of infection not accompanied by fever may delay proper evaluation and therapy.

Time of onset of symptoms may provide a clue to etiology. Infections occurring within 48 hours of delivery commonly involve the uterus and peritoneum following cesarean section, the urinary tract following catheterization, or the respiratory tract. The microorganisms responsible for early infection were frequently present or introduced at the time of delivery, and the rate of bacteremia is high. Abdominal and episiotomy wound infections, breast infections, complications of uterine infection, and uterine infection that follows vaginal delivery usually present later in the postpartum period. The rate of bacteremia is low and the organisms associated with late infection may be anaerobic, chlamydial, endogenous, or introduced after delivery (3).

ENDOMETRITIS

Endometritis, or infection arising from the uterine cavity, is the most common postpartum infection. The diagnosis, classically heralded by a tender uterus and foul lochia, is usually one of exclusion in the febrile postpartum woman without signs of infection from another source.

The pathophysiology of endometritis is similar to that of other pelvic infections—polymicrobial and ascending from the colonized lower genital tract. No risk factor is absolutely predictive; however, when more than one factor is present, risk

is cumulative (4). Endometritis following vaginal delivery occurs in 1% to 3% of patients. Delivery by cesarean section increases the incidence 3 to 30 times when compared with the vaginal route (5,6). Thus, cesarean delivery is the greatest risk factor for endometritis, with baseline rates of 9% following elective and 29% following nonelective procedures (7). Microorganisms from amniotic fluid or vagina directly inoculate the myometrium and peritoneal cavity at the time of surgery. The presence of suture material and surgically devitalized tissue, along with postoperative exudation and fluid collections, creates a favorable environment for subsequent bacterial growth (8). Placement of the uterine incision, however, has no effect on the incidence of postpartum infection (9).

Frank chorioamnionitis is an obvious antecedent of postpartum intrauterine infection, often despite intrapartum antibiotic therapy (10). Risk is compounded by the frequency of dysfunctional labor and failure to progress in women with chorioamnionitis, necessitating delivery by cesarean section (11). A positive amniotic fluid culture, even in the absence of overt signs of infection, is also highly predictive of subsequent endometritis, especially following cesarean section (12,13). Bacterial contamination of amniotic fluid, rare when fetal membranes are intact, is almost always present after 6 hours of ruptured membranes (14). The quantity and virulence of the organisms that colonize the amniotic fluid following membrane rupture are primary determinants of subsequent infection (6,15).

Major risk factors include prolonged duration of ruptured membranes (16), long labor with multiple vaginal exams, low socioeconomic status (17), obesity (17,18), and the presence of bacterial vaginosis (19). Untreated carriers of group B streptococci are also more likely to develop endometritis (20). Administration of glucocorticoids for acceleration of fetal lung maturation does not increase the risk of endometritis or other postpartum infections (21).

The diagnosis of endometritis is usually based upon clinical findings. Fever is the most useful sign and should prompt a physical examination even within the first 24 hours postpartum. In the absence of other signs of infection, continued observation may be appropriate, but further evaluation is indicated if fever persists. Endometritis after cesarean section typically presents within 48 hours of surgery. When endometritis follows vaginal delivery, the diagnosis is made within 7 days in 84% and within 14 days in 98% (6).

The patient may complain of malaise, chills, abdominal pain, or foul-smelling discharge. On physical examination, tachycardia, decreased bowel sounds, lower abdominal tenderness, uterine and adnexal tenderness to bimanual palpation, and purulent or foul lochia may be found, although physical findings may be minimal. A pelvic mass on initial

examination is unusual. Because the differential diagnosis for fever in the immediate postpartum period includes atelectasis, pneumonia, pyelonephritis, viral syndrome, mastitis, and appendicitis, the physical examination should be conducted to exclude these conditions.

If infection is suspected, laboratory evaluation should include complete blood count, urinalysis and urine culture from a catheterized specimen, and blood cultures in most cases. Routine endometrial cultures are rarely useful, as well-chosen antibiotic therapy results in a rapid recovery in most patients despite culture isolates. An endometrial culture may be helpful when hemolytic streptococci or clostridia are suspected or when endometritis develops in patients who are at risk for infection with unusual or resistant organisms (22). Prior to obtaining specimens transcervically, preparation by cervical cleansing is recommended to minimize contamination with lower genital tract flora (8).

With the aim of minimizing infectious morbidity, prevention of endometritis is paramount. Even though instrumental delivery is a risk factor for endometritis following vaginal delivery (23), data are too few and of insufficient quality to recommend routine use of prophylactic antibiotics for operative vaginal delivery (24). Antibiotic prophylaxis for cesarean section, however, reduces the rate of subsequent endometrial infection by more than half after both elective [relative risk (RR) 0.38, absolute risk reduction 4%] and nonelective procedures (RR 0.39, absolute risk reduction 18%) (25,26). The effect is evident even in nonlaboring patients with intact membranes (RR 0.05) (27) with significant cost savings per case (28).

Many antibiotics provide effective prophylaxis. The most recent systematic review (29) showed no benefit in efficacy of either single broad-spectrum agents over ampicillin or first-generation cephalosporins or multiple doses of antibiotics over a single dose. Clindamycin was recommended for penicillin-allergic women. Recent concerns over the rising resistance of Gram-negative organisms have prompted a trend away from ampicillin toward first- and second-generation cephalosporins and ampicillin/sulbactam, although data supporting their superiority are lacking. Adding aztreonam to the clindamycin has been proposed in cases of penicillin allergy.

While delaying administration of the antibiotic until cord clamping was originally touted to avoid clouding the evaluation of the newborn, recent evidence shows significant maternal benefit to administration of the antibiotic 15 to 60 minutes preoperatively. Attaining therapeutic tissue levels of antibiotic before bacterial contamination decreases the risk of endometritis compared with dosing after cord clamping [adjusted odds ratio (aOR) 0.22] without increasing the neonatal length of stay or incidences of sepsis or septic workup in the newborn (30–32). The practice of giving intrapartum prophylaxis to women colonized with group B beta-hemolytic streptococci has also resulted in fewer cases of subsequent endometritis (33).

Other measures of prevention have been studied and warrant consideration. Delivery of the placenta at cesarean section by external uterine massage and gentle traction rather than manually has been shown to reduce the rate of endometritis in several randomized controlled trials (34–36). Administration of methylergonovine 0.2 mg q6h following

cesarean section until discharge from the hospital (37) can decrease the rate of endometritis as well as minimize blood loss. A promising measure in the prevention of endometritis is extended spectrum antibiotic prophylaxis. The addition of an antibiotic (doxycycline or azithromycin) targeting *Ureaplasma urealyticum*, which has been shown to be a significant predictor of endometritis despite typical antibiotic prophylaxis and intact membranes, significantly reduced both endometritis and wound infection (38–40). Preoperative intravaginal treatments, such as intravaginal metronidazole gel (41) or a vaginal scrub with povidone-iodine (42), aimed at decreasing the inoculum of vaginal bacteria that may ascend, also show reduced rates of subsequent endometritis in controlled studies. Interventions with no effect on the rate of post-cesarean endometritis include in situ versus exteriorized repair of the uterine incision, glove change after delivery of the fetus before proceeding with the operation, and removal of uterine debris with tissue forceps versus uterine wiping with a laparotomy pad after placental delivery (35,36,43).

Choice of antibiotic therapy for acute endometritis is directed by the bacteriology of the infection. Aerobic organisms are found in about 70% of cultures and anaerobic organisms in about 80% (44). Typically, more than one isolate per culture are identified (45). Gram-negative bacilli, particularly *Escherichia coli*, are the most common aerobes, followed by Gram-positive aerobes such as groups B and D streptococci. Group A streptococci and *Staphylococcus aureus* are recovered in less than 5% of cases. The most common anaerobic isolates are *Bacteroides bivius* and *B. fragilis* as well as the anaerobic streptococci peptococcus and peptostreptococcus. Genital mycoplasmas and chlamydia also may be recovered from patients with acute endometritis (3).

Empirical therapy with parenteral antibiotics should be initiated as soon as the diagnosis of endometritis has been made and cultures have been taken (Table 1). Most patients will show a clear response to treatment within 48 to 72 hours. Following vaginal delivery, 95% respond to initial administration of a penicillin plus an aminoglycoside, despite incomplete anaerobic coverage. With additional antibiotics in those who fail initial therapy, less than 2% develop major infectious complications such as abscess or septic pelvic thrombophlebitis (6). The most recent systematic review (46) did not specifically address endometritis following vaginal delivery due to insufficient data. Recommendations for treatment of endometritis following cesarean delivery are clear: regimens with poor activity against penicillin-resistant

Table 1 First-Line Therapy for Endometritis

After cesarean delivery

Clindamycin 900mg intravenously every 8 h plus

Gentamicin 4mg/kg intravenously once daily^a,
(plus ampicillin 2g intravenously every 6 h)^b

Clindamycin (as above) plus aztreonam 2g

Intravenously every 6–8 h^a

Metronidazole 500mg intravenously every 6 h

Plus gentamicin (as above), plus ampicillin (as above)

After vaginal delivery

Ampicillin (as above), plus gentamicin (as above)

^aFor penicillin-allergic patients. ^bDepending on the agent used for prophylaxis.

anaerobes (e.g., *Bacteroides fragilis* group) are more likely to fail. The combination of clindamycin and an aminoglycoside remains the gold standard. Although small studies comparing clindamycin/gentamicin with single broad-spectrum agents (such as second- or third-generation cephalosporins, ureidopenicillins, or penicillins combined with a beta-lactamase inhibitor) show them to be equally effective, meta-analysis shows that only 20 women would need to be treated with clindamycin and gentamicin to prevent one failure with other regimens (46). Metronidazole–penicillin–aminoglycoside and clindamycin–aztreonam may be appropriate choices for post-cesarean infection as well (8).

Fewer failures occur with once-daily gentamicin dosing (46). Advantages of once-daily dosing include a superior bactericidal effect with higher peak serum concentrations, time for recovery of bacterial sensitivity between doses (post-antibiotic effect), lower trough levels resulting in less accumulation of the drug in the cochlear system, and cost savings (47,48). Typical formulas for calculating the daily dose may be inadequate in the postpartum woman due to greater renal clearance, increased volume of distribution, and obesity. The pharmacokinetics has been investigated with the following recommendations: 4 mg/kg actual body weight, or 5 mg/kg adjusted body weight, or substituting a volume of distribution of 0.4 to 0.43 L/kg in the formula pharmacies usually use to calculate the dose (49).

Changes in endometrial flora have been demonstrated following administration of prophylactic antibiotics and may affect treatment of subsequent infection. The use of cefazolin and other cephalosporins is associated with increases in infections with enterococci (17,22,50,51), and the use of penicillin or ampicillin has resulted in an increased risk of infections caused by Gram-negative organisms (50,52) and mycoplasmas (50). Unfortunately, no evidenced-based recommendations exist for treatment of women who develop endometritis after receiving antibiotic prophylaxis for cesarean section. In one study (53), only 54% of women, who had received cephalosporin prophylaxis and developed post-cesarean endometritis, responded to clindamycin and gentamicin within 48 hours. An additional 40% responded to the addition of ampicillin or vancomycin. Thus, it seems prudent and pragmatic to consider initial treatment with clindamycin and once-daily gentamicin if a penicillin has been used for prophylaxis, but treatment with ampicillin, clindamycin, or metronidazole, and once-daily gentamicin if a cephalosporin has been used for prophylaxis.

Common sense guidelines and important caveats warrant mentioning. When the diagnosis of endometritis is suspected, it is unwise to extend the prophylactic agent for a longer time as the causative organism is likely resistant. In general, do not use an antibiotic for treatment to which the patient has been recently exposed (52). When high fever but no localizing signs are present, consider group A streptococcus infection (52) as two-thirds of patients present with a fever only (54). Similarly, group B streptococcal cultures are not 100% predictive; if a patient has an early-onset endometritis with high-spiking fever, group B streptococcus may be the causative organism even if her culture within 5 weeks was negative (33).

The appropriate duration of therapy has not been well established. Typically, parenteral antibiotics have been

continued until the patient has been afebrile for 48 hours and the physical examination is benign. Discontinuation of treatment in a nonbacteremic patient when the patient's temperature has been $\leq 37.5^{\circ}\text{C}$ for at least 24 hours has been shown to be safe and cost-effective in both private and indigent populations (55,56). After treatment of uncomplicated endometritis, follow-up oral antibiotics, except in patients with known chlamydial infection, are generally unnecessary (3,17,46,57).

Failure to respond within 48 to 72 hours warrants reevaluation of the patient. Common causes of failure include wound infection and resistant microorganisms. Culture results should be reviewed, if available, and cultures of blood, endometrium, and wound collected. Antibiotic therapy should be assessed. Increases in dose or frequency of administration may be required, as pregnancy-related changes in renal function, blood volume, and total body water affect elimination and volume of distribution of drugs, usually toward lower serum levels (58). In patients receiving clindamycin plus an aminoglycoside, aminoglycoside levels should be drawn and ampicillin added to provide coverage against enterococci (22). Anaerobic coverage should be added if lacking. Single-agent therapy may be changed to clindamycin plus an aminoglycoside plus a penicillin. For proven staphylococcal infection, specific therapy should be added (e.g., nafcillin 1–2 g intravenously every 4–6 hours, cefazolin 2 g intravenously every 8 hours, or vancomycin 1 g intravenously every 12 hours). Wound infection, of course, warrants drainage.

If antibiotic therapy requires no modification, or if changes fail to produce response (80% respond) within another 48 to 72 hours, the case should be scrutinized for sources of continued fever. The differential diagnosis must be broadened to include wound infection, pelvic cellulitis, pelvic abscess, venous thromboembolism, drug fever, septic pelvic thrombophlebitis, enterocolitis, retained placental fragments, as well as viral or connective tissue disorders. Pelvic ultrasound may be helpful in visualizing retained placenta or a fluid collection. A computed tomographic (CT) scan may identify ovarian vein thrombosis, abscess, hematoma, or other masses.

The incidence of documented bacteremia following cesarean section is 3% to 4%, compared with 0.1% to 0.4% in patients who have delivered vaginally. Endometritis accounts for the majority of cases, but wound, respiratory and urinary infections, as well as endocarditis may be responsible (59,60). Bacteremia is more commonly found in post-cesarean endometritis (8–30%) compared with endometritis following vaginal delivery (5%) (5,6). Risk for positive blood cultures is correlated with length of labor, number of vaginal exams, duration of ruptured membranes, estimated blood loss, and intra-amniotic infection (61). Bacteremia is rare ($<1\%$) in the postpartum woman with a temperature peak $<38.8^{\circ}\text{C}$, but occurs in more than 20% of those with higher fevers (61). Organisms isolated from the blood reflect organisms infecting the endometrium and are found in similar proportions (57). While blood culture results may guide antibiotic therapy for endometritis, failure to respond to initial therapy does not correlate with a resistant organism in blood culture (59). Identification of a pathogenic organism resistant to the antibiotics administered warrants broadening the antibiotic coverage despite apparent clinical response. Prolonged therapy may be indicated when *S. aureus* is isolated from the blood to

avoid metastatic infection (8,44). Mortality among obstetric bacteremic patients is extremely low (<1%) compared with other medical or surgical populations (60).

Late postpartum endometritis, with onset from 7 to 42 days after delivery, is a clinically mild disease, which typically occurs in women who have delivered vaginally. Lower abdominal pain and an increasing vaginal discharge with odor are the presenting symptoms; systemic signs are rare. *Chlamydia trachomatis*, uncommon in acute endometritis (45), is isolated from the cervix or endometrium in 30% to 67% of cases (62). In women with chlamydial infection detected in the antepartum period, late postpartum endometritis develops in 30% to 60% if untreated (62). When late-onset infection is suspected, a cervical or endometrial culture for chlamydia should be obtained. Azithromycin (1 g orally in a single dose), tetracycline (doxycycline 100 mg orally twice a day for 7 days), or erythromycin (500 mg orally four times a day for 7 days) therapy is clinically effective. Treatment in the antepartum period may prevent late postpartum infection.

WOUND INFECTIONS

Abdominal wound infections occur in 1.6% to 10% of women delivered by cesarean section (4,63,64). Antibiotic prophylaxis has been shown to reduce the rate of wound infection after both nonelective (RR 0.36) and elective (RR 0.73) cases (25). Extended spectrum prophylaxis with doxycycline and/or azithromycin (covering for *Ureaplasma*) reduces the risk even further (38,40). Other basic measures, such as preoperative showering with chlorhexidine, clipping hair rather than shaving the area for incision, and preparation of the skin with an alcohol-based agent, are also advocated (65). Risk factors identified by prospective surveillance include skin closure with staples rather than subcuticular suture and maternal obesity (66), particularly in women with subcutaneous tissue thickness greater than 3 cm (67). One randomized trial showed a reduction in wound infections using the Joel-Cohen rather than Pfannenstiel incision (68). No effect on rate of infection has been demonstrated with prophylactic subcutaneous drainage (69).

The diagnosis of wound infection is based on the findings of local advancing erythema, induration, and/or drainage from the wound. Fever is not always present. Clinical signs typically manifest 4 to 8 days following delivery; 71% occur after discharge from the hospital (66). Many patients have had endometritis and present with recurrent fever after the initial response to treatment for the uterine infection. The majority of wound infections result from extension of polymicrobial contamination of the endometrium and amniotic fluid to the incision site (70), but the skin may also be the source of bacteria (65). Staphylococcal wound infections, accordingly, typically develop in women without obstetric risk factors. If wound infection presents with fever and spreading cellulitis within the first 48 hours after operation, a single bacterial pathogen, such as group A or B beta-hemolytic streptococci or *Clostridium perfringens*, may be responsible. A Gram stain of material aspirated from the active margin of infection may identify the causative organism.

Treatment for early-onset infection consists of antibiotic therapy such as penicillin 4 million units intravenously every 4 hours or cefazolin 2 g intravenously every 6 hours, and

prompt debridement of necrotic tissue (71). Later infections usually respond to simple incision and drainage. Antibiotics are required only if there is extensive cellulitis, bacteremia, or failure to defervesce within 12 to 24 hours of opening the wound (71). Debridement under anesthesia is sometimes required (70). Fascial dehiscence of the wound occurs in 0.5% of post-cesarean patients and may be more common when wound infection is present (64,70). Fascial repair under anesthesia may be necessary. Modern management of open wounds, including secondary closure within 1 to 4 days of disruption, negative pressure wound therapy (vacuum-assisted closure), or healing by secondary intention with dressings that keep the wound moist and absorb drainage, has been shown to be superior to frequently changed, traditional "wet-to-dry" dressings and cleansers that disrupt wound healing (65).

Complications of wound infection such as necrotizing fasciitis, synergistic bacterial gangrene, and clostridial gas gangrene are extremely rare after cesarean section but should be suspected if the patient fails to respond following incision and drainage of the wound. Early recognition is essential to prevent mortality from these life-threatening conditions. Necrotizing fasciitis should be suspected if the patient appears critically ill or if the edema and induration surrounding the wound worsen rapidly despite treatment or are accompanied by local anesthesia or crepitus. At surgical exploration, there is undermining of the involved skin surrounding the wound and the superficial fascia lacks resistance to a blunt instrument. Synergistic bacterial gangrene is recognized by a central ulcer, a surrounding deep red zone, and peripheral erythema. The process is slowly progressive and is often marked by inordinate pain. Clostridial gangrene presents with sudden onset of severe pain, mild local edema, thin watery drainage from the wound, and systemic toxicity. In advanced stages, the skin appears bronzed with bullae, gangrene, and crepitation. Gas may be evident on X-ray (71). These destructive processes require extensive surgical debridement. Aerobic and anaerobic cultures and broad-spectrum parenteral antibiotics are appropriate in the management of these polymicrobial infections. Delays in treatment may lead to maternal mortality.

SEPTIC PELVIC THROMBOPHLEBITIS

Septic pelvic thrombophlebitis is a potentially life-threatening complication that occurs most commonly after obstetric procedures. The diagnosis is typically suspected in a woman with persistent fever after several days of adequate antibiotic therapy for presumed endometritis with no wound infection apparent (72). This persistent fever occurs in about 1 in 650 deliveries (72) or 0.5% to 2% of patients with postpartum endometritis (73).

The pathogenesis of pelvic thrombophlebitis rests on Virchow's triad of venous stasis, endothelial damage, and alterations in coagulation factors. Damage to the intima of pelvic veins may result from direct surgical trauma or from the inflammatory response to an infected uterus. The velocity of blood flow through the dilated ovarian veins declines sharply postpartum. The long veins have multiple valves, which are major sites of venous pooling and their thin walls make them subject to external compression. Pregnancy-related increases in levels of clotting factors and platelet adhesiveness, along

with possible thromboplastin release from placental fragments and necrotic tissue, may generate a thrombotic process (73).

Pelvic thrombophlebitis encompasses two fairly distinct forms—ovarian vein thrombosis and thrombosis of multiple small pelvic vessels. In the acute ovarian vein syndrome, onset is usually within 2 to 4 days postoperatively, but may be weeks after delivery. The patient usually appears ill with a low-grade fever, tachycardia, flank or lower abdominal pain with guarding, and ileus with abdominal distention. Nausea and vomiting may be present. A tender, rope-like, abdominal mass originating near the uterine cornu and extending cephalad and laterally, palpable in one-half to two-thirds of patients, represents the thrombosed ovarian vein. Ovarian vein thrombosis commonly occurs in association with pelvic infection, but the patient's symptoms worsen, rather than improve, with continued antibiotic therapy. The syndrome may present in the absence of clinical infection, sometimes prompting laparotomy to exclude other disorders. The differential diagnosis includes acute appendicitis, broad ligament hematoma, degenerating fibroid, adnexal torsion, pyelonephritis, ureterolithiasis, and abscess.

Postpartum ovarian vein thrombosis is predominantly right sided (80%), with bilateral and left-sided lesions unusual (14 and 6%, respectively) (74,75). The preponderance of right-sided involvement is explained by venous drainage, which, in the upright position, flows from the left ovarian vein and uterine venous plexus into the right ovarian vein, increasing venous stasis and the inoculum of pathogens on the right (3). Incidence is approximately 1 in 3000 deliveries, following 1 in 800 cesarean and 1 in 9000 vaginal deliveries (72). Although, when studied, 50% of women who had postpartum ovarian vein thrombosis were found to have inherited prothrombotic factors (76), no clinical risk profile could be established—prior thrombosis was rare, many had taken oral contraceptives without complication, and none had a family history of clots.

Septic pelvic thrombophlebitis with diffuse thrombosis of multiple small pelvic vessels usually presents with enigmatic fever and typically follows the diagnosis of endometritis or other pelvic infection. After several days of antibiotic therapy, recurrent high-spiking fevers occur despite resolution of other signs and symptoms of infection. The patient generally feels well when not febrile and may need to be convinced that she has a serious complication. Imaging techniques do not demonstrate the small uterine and vaginal veins, which have been shown at laparotomy to be involved (77). The diagnosis is usually presumptive, based on defervescence within 48 to 96 hours (average 37 hours) after addition of heparin to the antibiotic regimen (78). The incidence is estimated at 1 in 2000 deliveries, following 1 in 400 cesarean and 1 in 10,000 vaginal deliveries (79).

Diagnostic imaging may be helpful in evaluating patients with suspected septic pelvic thrombophlebitis as thrombus in ovarian and larger veins may be visualized by CT scan, ultrasound, or magnetic resonance imaging (MRI). Sonography has been suggested as a screening examination for postpartum ovarian vein thrombosis, but sensitivity is only 56%, with imaging hampered by intervening bowel gas or obesity (80). CT and MRI are also superior to sonography at evaluating for other conditions in the differential diagnosis. CT remains the imaging procedure of choice (sensitivity

78–100%), as MRI (sensitivity 92–100%) offers no clinical advantages to balance its increased cost (80,81). All imaging techniques are helpful only if positive and are inadequate in excluding the diagnosis.

Serious complications of pelvic thrombophlebitis are mainly due to extension of thrombus or embolization. About 45% of ovarian vein thromboses imaged are seen to extend to the inferior vena cava (76); extension to femoral, iliac, mesenteric veins, and even the right atrium is possible. Extension of clot from the ovarian to the renal vein may result in renal vein thrombosis with subsequent nephrotic syndrome and renal insufficiency. Clots in pelvic vessels may fragment, possibly owing to the presence of bacteria, and embolize. Showers of small infected emboli are characteristic with resulting septicemia and metastatic abscesses (82) (Fig. 1). Massive involvement of ovarian veins or the vena cava may precipitate large pulmonary emboli with symptoms of venous occlusion; in fact, respiratory distress from pulmonary embolism may be the presenting symptom (75). Mortality from pulmonary embolism or metastatic abscesses is estimated at 18 deaths per million (80). Ventilation–perfusion or CT scanning of the lung may be indicated to determine whether pulmonary embolization has occurred. Classic papers report evidence of emboli in one-third or more of patients tested (73,82,83), even though symptomatic pulmonary embolism was rare (84). No modern reports contain a systematic assessment for emboli.

The diagnosis of pelvic thrombophlebitis, in either form, may not be confirmed by radiographic study. Clinical response to heparin may secure the diagnosis in both the acute and the enigmatic syndromes. Full anticoagulation should be instituted along with broad-spectrum antibiotics (Table 2) as microorganisms have been isolated from resected venous specimens and require treatment to promote resolution of the thrombus (73,85). Resolution of the fever does not imply resolution of the clot, so a full course of anticoagulation is necessary. Substitution of low molecular weight for unfractionated heparin seems reasonable, but has not been systematically studied. Primary surgical ligation of ovarian veins and vena cava, employed 50 years ago, decreased mortality from 50% to 10% (86), but is fraught with risks of significant hemorrhage, embolization, and death (74). Today, a surgical approach should be reserved for patients who do not respond to anticoagulation plus antibiotics, who experience pulmonary

Figure 1 Septic emboli are seen as multiple peripheral and hilar infiltrates on the computed tomographic scan without contrast.

Table 2 Treatment of Septic Pelvic Thrombophlebitis

Continuation of antibiotic therapy
Until the patient is afebrile for 48–72 h
Full anticoagulation with heparin
5000–10,000 units loading dose, followed by 800–2000
Units/h to maintain the PTT at 1.5–2.5 × baseline value
Duration of anticoagulation therapy
Ovarian vein thrombosis
6 weeks to 6 months (no fewer than 3 weeks)
May change to oral anticoagulation after the first 5–7 days
Suspected thrombosis of smaller pelvic vessels (enigmatic fever)
7–10 days

Abbreviation: PTT, partial thromboplastin time.

embolism while on therapeutic anticoagulation, or in whom the diagnosis is uncertain. If pelvic vein thrombosis is found unexpectedly at postpartum laparotomy, closure of the abdomen without vein ligation and institution of medical therapy is probably the treatment of choice. Need for anticoagulation during or after subsequent pregnancy is probably not required.

The subject of anticoagulation has recently become controversial. The observation that some fevers eventually resolve without heparin has led some to argue that the superior efficacy of today's antibiotics may obviate the need for heparin. One trial in 14 women with CT-proven ovarian vein thromboses, randomized to receive either antibiotics and heparin or antibiotics alone, showed no difference in durations of fever or hospitalization and no evidence of symptomatic emboli (72). Unfortunately, the numbers were too small to preclude possible protection from embolization by heparin.

EPISIOTOMY INFECTIONS

Postpartum infection arising from an episiotomy site is a rare but potentially fatal condition. An episiotomy is a contaminated wound; yet clinical infection manifests in only 0.035% to 3% of patients (63,87). In a randomized controlled trial, use of prophylactic antibiotics (second-generation cephalosporin) for repair of third- and fourth-degree tears was shown to decrease the rate of infectious complications (88). Life-threatening infection associated with episiotomy has occurred in 0.5 to 2 per 100,000 live births, accounting for 20% of maternal mortality. Perineal infection has been classified according to the depth of soft-tissue involvement (89). Successful management depends on accurate assessment of the infected tissues.

Infection limited to the skin and superficial fascia along the episiotomy incision may be managed conservatively. Episiotomy dehiscence or perineal pain may be the presenting complaint, with edema and erythema confined to the area immediately adjacent to the episiotomy (89). The previous repair should be taken down to allow careful inspection of the wound to exclude hematoma, abscess, or unsuspected rectovaginal communication. Following cleansing and debridement, the wound may be allowed to heal secondarily. With surrounding cellulitis, a course of broad-spectrum parenteral antibiotics (such as suggested in Table 1), in addition to local wound care, may be required. Early repair of episiotomy dehiscence, while contrary to traditional practice, has produced excellent anatomical and functional results (90).

Superficial fascial infection presents with erythema and edema, which extend beyond the area of episiotomy to the thigh, buttock, or abdominal wall. Appropriate therapy is dependent upon determination of associated necrotizing fasciitis. Diagnosis by inspection is unreliable, thus surgical exploration may be necessary to rule out fascial necrosis. In the absence of obvious signs of necrotic fascia, frozen-section biopsy has been employed to expedite diagnosis and avoid a possible lethal delay in treatment (91). In the absence of fascial necrosis, severe systemic involvement is uncommon and response to broad-spectrum antibiotics should occur within 24 to 48 hours. Lack of response or progression of the infection during antibiotic therapy may indicate a more severe infection.

When necrotizing fasciitis is present, aggressive management is necessary to avert mortality. Both Camper's and Colles' fascial layers become necrotic with this infection, which spreads along these fascial planes, undermining the skin, and eventually involves all tissues external to the deep fascia (92). The onset is acute with a rapidly progressive clinical course, systemic toxicity, and a fatality rate of 21% to 76% (89). Although the condition is classically described in patients with diabetes or atherosclerosis, affected obstetric patients are usually otherwise healthy (93). The patients appear severely ill, usually with fever and leukocytosis. Erythema with indistinct margins that gradually fade into normal areas may be present. As the disease progresses, skin color becomes blue or brown, with subsequent formation of bullae and gangrene. Progressive brawny edema and induration are evident; vulvar edema, especially unilateral, is characteristic (93). Marked local tenderness is common initially, but the lesions become hypesthetic or anesthetic as cutaneous nerves become ischemic (92). Crepitation may be detected. Exudate is serosanguinous "dirty dishwater" rather than purulent. Anemia due to hemolysis is common (92), but may be masked by massive fluid shifts into the extravascular compartment with resultant hemoconcentration (89). Hypocalcemia may develop due to saponification of liquified subcutaneous fat (92). At surgical exploration, the superficial fascia does not bleed and lacks resistance to blunt probing; the skin is easily separated from the underlying deep fascia.

Prompt surgical resection of the involved tissues is essential for effective management of necrotizing fasciitis. Mortality is 100% in patients treated with antibiotics alone or with incision and drainage only (94). Debridement should extend to where the subcutaneous tissues cannot be separated from the underlying deep fascia or from normal skin. Any tissue that is indurated, edematous, or crepitant, or that does not bleed readily when incised, should be removed (92). More than one surgical debridement may be necessary if subcutaneous necrosis is not arrested. Hyperbaric oxygen is an adjunctive measure and should not substitute for surgical debridement.

Similar to most pelvic infections, necrotizing fasciitis is a polymicrobial disorder. The pathophysiology involves bacterial synergism among various combinations of aerobic and anaerobic organisms (92,94). Comprehensive antibiotic coverage with a penicillin, clindamycin, and an aminoglycoside is recommended as an adjunct to operative intervention until a healthy bed of granulation tissue is apparent. After extensive debridement, these patients resemble those with severe burns.

Management in an intensive care setting with invasive monitoring, aggressive fluid management, and hemodynamic support may be required (92). The wound may be allowed to heal secondarily.

Infection beneath the deep fascia produces myonecrosis. A clostridial infection is the most common cause, although myonecrosis can occur from a neglected necrotizing fasciitis, which invades deep fascia. Clostridial infection may present early in the postpartum period with severe pain disproportionate to the physical findings. A wound or blood culture positive for clostridia should raise the index of suspicion for myonecrosis. Crepitation or clinical deterioration in the presence of an episiotomy infection warrants surgical exploration and radical excision of involved tissues, supplemented with antibiotic therapy. For clostridial infection, high-dose penicillin (4 million units intravenously every 4 hours) is indicated. Polyvalent gas gangrene antitoxin is thought to be ineffective (89). *C. perfringens* is the most notorious organism associated with myonecrosis. *Clostridium sordellii* has also been identified in serious episiotomy infections, but presents with massive malignant vulvar edema thought to be caused by toxin production and results in death from cardiovascular collapse (95).

MASTITIS

Lactation mastitis is a cellulitis of the interlobular connective tissue within the mammary gland that usually occurs within the first 6 weeks postpartum (96). Mastitis occurs in up to 9.5% of breastfeeding women (96,97), but may rarely occur in women who are not nursing. Most cases are sporadic, presenting commonly in the second or third week following delivery (98,99). The onset of symptoms is usually abrupt with chills, malaise, generalized achiness, and fever as high as 39 to 40°C. The affected breast is tender, hot, swollen, and erythematous in a wedge-shaped segment (96) with its apex at the nipple and its base toward the periphery, demarcated by the divisions between the lobes of the breast. Decreased milk secretion may be noted (100), but expression of pus from the ducts is uncommon (99). Poor breastfeeding technique with attachment difficulties, injury to the nipple, nipple fissuring, and milk stasis (101) is considered to be the primary etiologic factor, along with lowered immune status from stress or sleep deprivation (96), but the cause of most cases is unclear (97). One study found fewer than 10 feedings/day to be protective (96), contrary to common belief. Mastitis is no more common among women who are nursing for the first time than among women who have previously nursed. Previous mastitis is a risk factor for recurrence in successive pregnancies (96), perhaps due to persistence of poor practices (102).

Breast infections should be distinguished from segmental breast inflammation due to milk stasis or focal engorgement. Milk contains pro-inflammatory cytokines, which may leak into the circulation when not drained and elicit a systemic response in the absence of infection (101). Fever and erythema are less marked in the absence of infection and will resolve with rest, frequent, complete emptying of the breast, and without antibiotics (101,103). Local hot wet compresses or prone soaks in a hot tub may soften the indurated breast and allow drainage (99). Change in feeding position may permit drainage of blocked ducts. Antibiotics are indicated if

symptoms do not resolve. Patients with obvious signs and symptoms of mastitis should be treated immediately with antibiotics, as delay in institution of antibiotic therapy is associated with abscess formation (98,104). Diagnostic criteria based on leukocyte counts from the milk and quantitative bacterial cultures, helpful in differentiating mastitis in dairy cows, are not always valid in women, as bacterial counts have not been reliable (101).

Appropriate therapy for mastitis includes routine emptying of the breast and administration of antibiotics. Breastfeeding from both breasts should continue. If the infected breast is too sore for nursing, gentle pumping may be employed to reduce congestion. Weaning may increase the risk of abscess formation (97,99,105). Choice of antibiotic may be empirical or based on culture of expressed breast milk. *S. aureus* is the organism isolated in 35% to 50% of breast infections, and 50% to 70% show penicillin resistance in vitro (97,100,104,106). Other common pathogens include coagulase-negative staphylococci, streptococci, *E. coli*, *Klebsiella pneumoniae*, and *Bacteroides fragilis* (100). Cultures of breast milk may be prudent, since methicillin-resistant *S. aureus*, primarily community-acquired, is emerging as a pathogen in mastitis (107), even in those without predisposing factors (108).

Therapy with a penicillinase-resistant penicillin, such as dicloxacillin (250–500 mg orally four times a day) or amoxicillin/clavulanic acid (500/125 mg three times a day), or a first-generation cephalosporin (cephalexin 500 mg orally four times a day) should be started immediately after cultures are obtained. Erythromycin or azithromycin is the alternative in penicillin-allergic patients. In most cases, antibiotics may be given orally, and hospitalization is not required. Therapy should be continued for at least 10 days. Most patients become afebrile and asymptomatic within 36 to 48 hours of beginning treatment (97). If the patient is not improved within 48 hours, examination for abscess formation is warranted.

Breast abscesses develop in 4% to 11% of patients despite appropriate treatment (96,97,106). An indurated, fluctuant area may be palpable, usually peripherally, and should be aspirated for culture if suspected. Axillary lymphadenitis is not typical, but the patient may be febrile and tachycardic, with leukocytosis. Bacteremia may occur (109). *S. aureus* is recovered from 38% of abscesses (104). Ultrasound is a useful adjunct when there is clinical suspicion of abscess or in cases of mastitis that do not promptly respond to appropriate therapy (110). Ultrasound imaging excludes abscess in one-third to one-half of suspected cases (104) and may allow guided aspiration of those that are confirmed (110). Serial aspiration has emerged as first-line therapy for abscesses, with a 91% cure rate. Aspiration and irrigation are performed with follow-up every 2 to 3 days for re-aspiration until the abscess is no longer visible by ultrasound (110). Incision and drainage have been the standard treatment, but risks ductal damage and a poor cosmetic result (110). If incision and drainage are required, radial or circumferential incision is made over the site of maximum tenderness and loculi are broken down, followed by insertion of a dependent drain or pack. Rapid resolution is invariable.

Antibiotic coverage is recommended preoperatively and susceptibility-directed antibiotic therapy is continued

postoperatively (109). Milk stasis should be prevented by complete emptying of the breast with pumping to avoid secondary abscess formation. Continuation of breastfeeding from the affected breast is controversial. In the past, the presence of a staphylococcal breast abscess has been associated with infant deaths from lung abscesses, presumably due to aspiration of a large inoculum (3). Certainly, breastfeeding may continue from the unaffected breast and resume from the affected breast once the abscess has resolved.

Epidemic mastitis is a hospital-acquired infection caused by *S. aureus*. During the 1940s and 1950s, when lengthy postpartum hospitalization was practiced, up to 20% of women became infected (3). The infection involves the lactiferous glands and ducts of the breast, in contrast to the interlobular connective tissue in the sporadic form, and may affect multiple lobes. Abscess formation is common. Epidemic mastitis usually originated in hospital nurseries and was traceable to attendant carriers of the specific phage type that caused the infection (3,98). Infants suffered significant mortality from staphylococcal pneumonia, meningitis, osteomyelitis, and pyoderma during these outbreaks (98). Fortunately, infection control measures and superior antibiotics have made epidemic mastitis an unlikely occurrence today.

URINARY TRACT INFECTION

Immediately postpartum, bacteriuria is found in up to 40% of women (111), but resolves spontaneously in most (112). By the third postpartum day, bacteriuria is found in 1.7% to 4% by suprapubic aspiration. Only one-fourth of women with bacteriuria complain of dysuria, but the symptom is more common following catheterization. Conditions and procedures that are associated with bladder catheterization—cesarean section, vaginal operative delivery, epidural anesthesia, tocolysis, pre-eclampsia, abruption, renal disease—significantly increase the risk of bacteriuria (113,114). Antibiotic prophylaxis decreases the incidence of post-cesarean bacteriuria (115).

Treatment for urinary tract infection is similar to that for the nonpregnant woman. High rates of cure are achieved even with a short (3 days) course of therapy (113). The causative organism is *E. coli* in 80% to 90% of infections, but may be another coliform or staphylococcal or enterococcal species (3,113). Culture and susceptibility testing may guide therapy, especially in patients who have recently received antibiotics. Suprapubic aspiration from a full bladder or urethral catheterization may be necessary to obtain samples of urine, as clean-catch midstream collections are frequently (46–69%) contaminated (113).

Treatment of persistent asymptomatic bacteriuria, perhaps unwarranted in the nonpregnant patient, is recommended in the postpartum period (111). Decreased bladder tone, increased capacity, and incomplete emptying, along with a dilated collecting system and an enlarged uterus, capable of mechanical obstruction, may be present for weeks to months postpartum. These pregnancy-related changes predispose to vesicoureteric reflux and development of pyelonephritis. Infection of the urinary tract can be minimized by avoiding routine urethral catheterization of laboring or postpartum women. High-risk patients, who have received antibiotic suppression during the antepartum period to prevent

pyelonephritis, should probably continue the regimen for at least 2 weeks postpartum.

UNUSUAL INFECTIONS

Infections resulting from spinal or epidural anesthesia occur following less than 1 in 10,000 blocks (116). The diagnosis should be considered in the febrile patient with backache and pain radiating from the spinal area. Evaluation may include neurologic examination, cerebrospinal fluid analysis, and myelography. Weakness, numbness, and finally paralysis will develop if the infection goes untreated (117).

Subgluteal or retrosoal infections have been reported following paracervical or pudendal block (116,118). Patients presented with poorly localized severe hip pain and limited range of motion. Associated organisms were normal vaginal or bowel flora. Gas in the soft tissues was seen in half the cases, and abscess formation was common. Treatment may be delayed, owing to failure to suspect the diagnosis. In addition to antibiotic therapy, surgical drainage, debridement, and diverting colostomy may be necessary for appropriate treatment. Sequelae from these serious infections include persistent discomfort, impaired ambulation, and death.

Toxic shock syndrome has been reported in women with puerperal mastitis (119), postpartum endometritis (120), and abdominal wound infections (3) and may occur from several days to weeks after delivery. The organism responsible is typically *S. aureus* producing toxic shock syndrome toxin-1, but may alternatively be group A *Streptococcus* producing pyrogenic exotoxin A. Toxic shock syndrome presents with high fever, hypotension, rash, and multiorgan dysfunction. With proper antibiotic treatment and aggressive supportive care, most cases resolve in 48 to 72 hours, but mortality is 10% in cases of persistent hypotension, renal failure, or adult respiratory distress syndrome (ARDS) (120).

SEPTIC SHOCK

Rarely, septic shock may complicate a postpartum infection. Septic shock is characterized by hypotension and inadequate tissue perfusion, owing to overwhelming infection. The hypotension may be preceded by chills and fever and associated tachycardia, tachypnea, oliguria, or mental obtundation. Theories of pathogenesis and treatment of septic shock are reviewed elsewhere (121) (see further discussion in Chapter 11).

Microorganisms causing sepsis incite the formation or release of vasoactive and inflammatory mediators that lead to peripheral vasodilatation, regional microembolization, and endothelial cell injury. Severe multiorgan dysfunction involving the lungs, kidneys, liver, heart, and central nervous system may result from inadequate perfusion. Aggressive management strategies incorporate broad-spectrum antibiotic coverage, volume replacement, invasive hemodynamic monitoring, inotropic agents, and peripheral vasoconstrictors to maintain afterload. Rapid reversal of organ hypoperfusion, improvement in oxygen delivery, and correction of acidosis must be achieved for successful stabilization of the patient. A careful search for infected or necrotic foci that may be responsible for persistent bacteremia is warranted. Surgical intervention is sometimes required to remove the underlying cause of sepsis.

Associated complications include ARDS, pulmonary edema, disseminated intravascular coagulation, thromboemboli, and cardiac arrest. The risk of maternal mortality increases as associated complications become superimposed on the septic hypotension. Fortunately, mortality due to septic shock is thought to be considerably lower than that in the nonobstetric population. Early identification of sepsis, prompt institution of antibiotic therapy, volume administration, and cardiopulmonary support when needed are essential to prevent complications and minimize mortality.

77 Urinary tract infections in pregnancy

Steven R. Allen

Urinary tract infections (UTIs) commonly complicate pregnancy, present in approximately 10% of gestations. Asymptomatic bacteriuria (ASB) is encountered most frequently. Symptomatic infections, cystitis and pyelonephritis, complicate pregnancy less frequently. Of these three infections, the primary impact on pregnancy outcome derives from acute pyelonephritis, which is commonly preceded by ASB rather than acute cystitis (1). Clinical presentation, risk factors, common complications, and treatment for these three forms of UTI are summarized in Table 1.

PATHOGENESIS

Female anatomy and the physiologic changes of normal pregnancy impart risk factors for UTIs. Because of the short length (approximately 4cm) of female urethra and its termination beneath the labia and relatively near the anus, it is at increased risk of colonization by Gram-negative colonic bacteria. Urethral and periurethral bacteria may intermittently enter the bladder, typically after intercourse (2). Once within the urinary tract, attachment of bacterial pili or fimbriae to carbohydrate components of urothelial cell surface glycolipids and glycoproteins enhances virulence (3).

Half of women with UTIs during pregnancy have an enlarged bladder capacity, and 15% have a significant post-void residual volume (50–150 mL) (4). Normal physiologic changes of pregnancy include a mild hydronephrosis and hydroureter, potentially created by both the mechanical compression of the ureter by the enlarging uterus and pelvic blood vessels at the pelvic brim (right greater than left), and the relaxant effect of progesterone on ureteral smooth muscles. In combination, these factors account for the increased rate of both bladder and ascending infections during pregnancy.

Population-specific risk factors for UTIs in pregnancy include nonwhite race, younger maternal age, and antepartum genital tract infection (5).

The bacterial spectra responsible for all three types of UTIs in pregnancy are similar and also are similar to the spectra of bacteria causing UTIs in nonpregnant females. *Escherichia coli* is the most common isolate, present in 70% to 90% of positive urine cultures. Bacteria from other genera of Enterobacteriaceae are the next most common: *Klebsiella*, *Enterobacter*, *Citrobacter* and *Proteus*. Gram-positive organisms cause <10% of UTIs in pregnancy, with group B streptococcus the most common member of this group (1,6–9).

Beyond the fetal risks discussed below in relation to antibiotic exposure and the potential complications of pyelonephritis, maternal UTIs may also increase the risk of fetal anomalies. Analyses of data from the U.S. National Birth Defects Prevention Study show associations between the first-trimester maternal UTI and gastroschisis plus at least one other major anomaly (OR 3.1, 95% CI 1.4–6.7) (10) and

cardiovascular malformations (left ventricular outflow tract obstruction, OR 1.48, 95% CI 1.02, 2.14; atrioventricular septal defect, OR 2.55, 95% CI 1.19, 5.48) (11). For both of these noted associations, the risk appears to exist regardless of fever or antibiotic exposure.

ANTIBACTERIAL CONSIDERATIONS

Because of the similarity of bacterial spectra responsible for each of the three types of UTIs discussed within this chapter, similar antibacterial selection strategies can be applied for treating each. An understanding of the changing resistance pattern for *E. coli* is critical in selecting an appropriate antibiotic, since it is the predominant cause of UTIs. *E. coli* isolates from women with acute cystitis during an observation period ending in 1996 showed progressive resistance to ampicillin (34%), cephalothin (28%), trimethoprim (18%), and trimethoprim–sulfamethoxazole (18%). *E. coli* resistance to trimethoprim–sulfamethoxazole (TMP–SMX) had increased to over 20% in some regions of the United States (12). Results from a single institution in 2000 showed *E. coli* to be unacceptably resistant to ampicillin (75% incidence of sensitivity) and marginally more likely to be sensitive to TMP–SMX. In that study population, nitrofurantoin had the highest likelihood of success for treating uropathogens (100% susceptibility for *E. coli* and 89% overall) (13).

Several antibiotics have proven to be effective for treating UTIs. When treating UTIs in pregnancy, the safety considerations must obviously include potential fetal effects. The following drugs may be considered during pregnancy.

Penicillins and Cephalosporins

High likelihood of resistance prevents these agents from being ideal empiric choices.

Trimethoprim–Sulfamethoxazole

Although TMP–SMX has been recommended as a primary treatment for uncomplicated UTIs (14), progressive bacterial resistance to it now potentially limits its effectiveness as an empiric therapy (13). The best predictor of resistance to TMP–SMX in urinary coliform bacteria is recent use of TMP–SMX (OR 5.9; 95% CI 2.4, 14.3); other predictors include diabetes, recent hospitalization, and current use of antibiotics (15). In addition to declining efficacy, safety features should also be considered before using TMP–SMX to treat UTIs during pregnancy. Both trimethoprim and sulfonamide antibiotics inhibit nucleic acid synthesis by interfering with bacterial production of folic acid. A case-control study of birth defects in the United States and Canada reported an increased likelihood of first-trimester exposure to dihydrofolate reductase inhibitors (including TMP–SMX) among women giving birth to babies with cardiovascular

Table 1 Summary of Urinary Tract Infections During Pregnancy

	Acute cystitis	Asymptomatic bacteriuria	Pyelonephritis
Symptoms	Urgency Frequency Dysuria	No symptoms	Back or flank pain Fever Chills
Unique risk factors	History of recurrent cystitis	Parity Nonwhite race Lower socioeconomic status Diabetes Prior UTI	Asymptomatic bacteriuria Younger age Nulliparity Sickle cell trait or disease
Complications	Recurrent acute cystitis	Pyelonephritis	Bacteremia Septic shock Pulmonary edema
Treatment	Oral broad-spectrum antibiotic, 3–7 days	Oral broad-spectrum antibiotic, 3–7 days	Broad-spectrum antibiotic, parenteral until clinically improved, then oral to complete 10- to 14-day course, followed by oral broad-spectrum antibiotic prophylaxis until 6 weeks postpartum

defects (OR 3.4; 95% CI 1.8–6.4) and oral clefts (OR 2.6; 95% CI 1.1–6.1) (16). The increased risk of cardiovascular defect associated with dihydrofolate reductase inhibitor consumption was offset in women who also took supplemental folic acid (400 µg/day). Although neonatal jaundice has occasionally been reported after fetal exposure to sulfonamides, a contemporary literature review shows no reported cases of kernicterus after such exposure (17). These findings support a recommendation to avoid TMP–SMX in both the first and late third trimesters, and to recommend a higher folic acid supplement dose (4mg/day) if TMP–SMX is prescribed in the first trimester (18).

Nitrofurantoin

This agent's primary benefit is its continued effectiveness against most strains of *E. coli*. It is also effective against many other gram-positive and gram-negative urinary pathogens, but has limited effectiveness against *Klebsiella*, *Enterobacter*, *Pseudomonas*, and *Proteus*. It reaches a high concentration in urine, but not in renal tissue, thus should not be used as primary treatment for pyelonephritis. Rare maternal complications include reversible sensory neuropathy (19) and reversible pneumonitis (occurring in fewer than 1/100,000 exposures) (20). Nitrofurantoin is not teratogenic and does not need to be avoided in the first trimester (21). The extremely low risk for fetal or neonatal hemolytic anemia due to impaired glutathione reductase activity or glucose-6-phosphate dehydrogenase deficiency (with an estimated risk of 0.001%) (22) need not prohibit its use near term. However, these concerns still prompt some recommendations against its use near anticipated delivery (23).

Gentamicin

Aminoglycosides attain high renal tissue levels, thus may be particularly beneficial in the treatment of pyelonephritis. Although ototoxicity has been reported with other aminoglycosides, there are no clear human data supporting fetal ototoxicity (24,25).

Fluoroquinolones

Although arthropathy may develop after fetal exposure in animals, limited human data have not shown arthropathy or other defects following fetal exposure (26). However, concerns about the potential development of drug resistance if this effective family of antimicrobials is overused logically keep fluoroquinolones from being first-line agents for the treatment of UTI in pregnancy.

Fosfomycin

Limited data for this agent in pregnancy preclude a specific recommendation for its use (27,28).

CYSTITIS

Acute cystitis in pregnancy has a clinical presentation not unlike that of symptomatic bladder infection outside of pregnancy. The diagnosis should be suspected in a woman with urgency, frequency, dysuria, or hematuria, and without evidence of upper UTI or systemic illness. A culture of catheterized or midstream urine positive for a single organism confirms the diagnosis. Although the traditional diagnosis of UTI is based upon a quantitative culture containing $\geq 10^5$ bacteria/mL, a lower threshold may be appropriate in the presence of bladder symptoms. Comparing cultures of urine obtained directly from the bladder via suprapubic aspiration or urethral catheterization with those of midstream specimens in acutely dysuric (nonpregnant) women, midstream samples with $\geq 10^2$ bacteria/mL have a sensitivity of 95% and a specificity of 85% for the detection of coliform bacteria (29).

Acute cystitis occurs much less frequently in pregnancy than asymptomatic UTIs. Harris and Gilstrap (6) found the incidence of cystitis to be 1.3% among a population of military dependents. Two-thirds developed their symptomatic infection after the initial clinic visit, and of these, 95% had negative urine cultures at their first prenatal visit. Although half of the patients with cystitis had a history of UTIs, after a 10-day course of antibiotic only 17% had recurrence, and no patients developed pyelonephritis.

The usual treatment for acute cystitis in pregnancy is with a short (3–7 days) course of broad-spectrum antibiotic. In nonpregnant women, without the cited physiologic genitourinary tract changes that predispose to UTI during pregnancy, multiple-dose regimens provide better treatment than a single dose of a broad-spectrum antibiotic (30). Logic predicts that multiple-dose regimens also will be more efficacious in pregnant women. Before the more common antimicrobial resistance patterns currently seen, a 10-day oral course of any one of the following—ampicillin 250mg four times a day, nitrofurantoin macrocrystals 100mg three times a day, sulfisoxazole 500mg four times a day, or cefazolin 250mg four times a day—demonstrated equal efficacy in pregnant women (6).

Taking into account the considerations listed in the prior section, any one of the typically effective drugs may be started empirically for the clinical diagnosis of cystitis, with appropriate changes in selection if directed by urine culture sensitivity results. Limited published data are available to specifically direct the best therapy for acute cystitis in pregnancy. Five days of twice-daily oral therapy with nitrofurantoin 100mg or ampicillin 500mg had similar cure rates (87% and 90%) in 1989 (31), before recent increases in ampicillin resistance, and similar cure rates have also been shown in a small study comparing a single 3-g dose of fosfomycin trometamol and a 3-day course of 400-mg ceftibuten per day (95% and 90%) (28). Given the predominance of *E. coli* as a uropathogen and its ongoing susceptibility to nitrofurantoin, that agent is likely to be the best primary therapy in most cases (13).

A follow-up urine culture may be obtained after initial treatment to confirm appropriate therapy for cystitis, but because of the low rate of recurrence and its typical symptomatic presentation, serial screening urine cultures are not recommended.

Sexual intercourse is a risk factor for recurrent cystitis in some women. Pfau and Sacks (32) showed a 99% reduction from the baseline (pre-pregnant) rate of recurrent cystitis among 33 pregnant women using post-coital cephalixin 250mg or nitrofurantoin 50mg. As compared with daily prophylaxis, this form of therapy provides most at-risk women with the convenience and cost benefit of less frequent antibiotic administration.

ASB

ASB, silent bacterial colonization of the urinary tract, is the most common UTI in pregnancy, with an incidence of 2% to 10% (7,33,34). Lower socioeconomic status, nonwhite race, increased parity (33), diabetes, and prior UTIs increase the risk (35).

For asymptomatic women, bacteriuria is diagnosed by quantitative urine culture: two consecutive voided specimens with isolation of the same bacterial strain in quantitative counts $\geq 10^5$ bacteria/mL or a single catheterized urine specimen containing $\geq 10^2$ bacteria/mL (36). Although only approximately 80% of women with a positive initial screening culture would have that confirmed on subsequent sampling, the detection of $\geq 10^5$ bacteria/mL in a single voided midstream urine is generally accepted as an adequate and more practical alternative to the requirement for serial positive samples (37).

The bacteria identified in ASB are generally similar to those of other UTIs, except that group B streptococcus is more common in this UTI, present in approximately one-quarter of positive screening cultures (8,38).

The significance of ASB during pregnancy lies not in the primary infection but rather in the potential secondary complications. Although ASB is no more common in pregnant women, the physiologic changes of pregnancy that lead to urinary stasis increase the likelihood of ASB progressing into an ascending infection. Subsequent pyelonephritis occurs in approximately 40% of untreated women with ASB (39). Fortunately, the risk of pyelonephritis is reduced to approximately 3% following the treatment for ASB (40). A meta-analysis evaluating the relationship between ASB and pregnancy outcomes showed low birth weight to be 3.4% more likely following ASB and preterm birth to be 3.8% more likely after untreated ASB (41). The same analysis showed a reversal of ASB's impact upon the risk of low birth weight with antibiotic treatment (OR for low birth weight if given antibiotics = 0.52, 95% CI 0.38–0.7).

The risks of untreated ASB and the inability to identify it clinically prompt recommendations for routine screening in pregnancy (36,42,43). As no rapid screening techniques have adequate sensitivity or predictive values, urine culture remains the recommended standard for detecting ASB (42,44).

Current published guidelines for ASB screening recommend that a urine culture be obtained at least once in early pregnancy (36), such as at 12 to 16 weeks of gestation (or at the first prenatal visit, if later) (42). Screening on that schedule will not identify all cases of ASB. A prospective cohort study in which participants had serial urine cultures performed showed that only 43% of the overall positives occurred at <20 weeks of gestation (38). However, early studies showing a great reduction in risk for pyelonephritis following primary antimicrobial therapy for ASB and an average risk for subsequent pyelonephritis in initially nonbacteriuric women of only 1.4% (40) together suggest that serial screening to identify ASB later in pregnancy would have a relatively low yield and not be cost effective.

To accurately interpret the results of a quantitative urine culture, it must have been obtained under conditions that minimize contamination. Vulval cleansing with chlorhexidine may reduce the bacterial colony counts of a midstream urine sample, and cleansing with water provides more representative results. Additionally, the quantity of bacteriuria correlates with the time interval between episodes of voiding; although a first morning void is not necessary, the practice of having patients drink fluid to speed diuresis should be avoided (45).

Although early protocols used continuous treatment until delivery, by 1977 Whalley and Cunningham (46) had shown that short-term treatment (14 days) combined with surveillance for recurrent bacteriuria provided similar results. In 2000, a Cochrane systematic review concluded that published data are insufficient to determine the optimal duration of therapy for ASB in pregnancy (47). In 2005, the Infectious Diseases Society of America recommended 3 to 7 days of antimicrobial therapy for ASB, but did not identify an optimal drug for therapy (36).

A Cochrane systematic review of antibiotic treatments for ASB in pregnancy published in 2007, which included

randomized controlled trials of a variety of antibiotics (sulfonamides, nitrofurantoin, penicillin, and ampicillin), concluded that antibiotic treatment is effective in reducing the risk of pyelonephritis, but no single antibiotic choice is superior (48). According to that review, the number of women needed to treat to prevent one case of pyelonephritis is seven.

Since the diagnosis of bacteriuria is made by urine culture and no optimal drug choice had been identified, antimicrobial selection for the treatment of ASB in pregnancy may be guided by susceptibility results and fetal safety considerations.

In response to the potential silent recurrence of ASB, the Infectious Diseases Society of America recommends periodic screening after initial therapy in pregnancy (36). Urine cultures obtained 1 to 2 weeks after initiation of therapy and additional screening per trimester would meet these guidelines.

Following a recurrent UTI, broad-spectrum antibiotic suppression for the remainder of the pregnancy may be helpful, such as with nitrofurantoin 100mg every day. For women with recurrent infections, urologic examination should be scheduled for 3 to 6 months postpartum, as up to half of these women will have a urinary tract structural abnormality (4). Although pyelographic abnormalities are more common in women with a history of ASB, it is unclear whether these are primarily or secondarily associated.

PYELONEPHRITIS

Affecting 1% to 2% of all pregnancies, pyelonephritis is one of the most common serious medical problems encountered during pregnancy. It will develop in 36% to 42% of untreated women with ASB; this risk falls to $\leq 3\%$ with the treatment for bacteriuria (39,49). Only approximately 1.4% of women without bacteriuria early in a pregnancy will subsequently develop pyelonephritis before delivery (40). Pyelonephritis occurs most commonly during the second or third trimester, although up to one-quarter of infections are diagnosed intrapartum or postpartum (1,50,51). In addition to other risk factors for UTIs in general, younger age, nulliparity (51), and sickle cell trait (52) or disease (OR 1.3, 95% CI 1.0–1.8) (53) make pyelonephritis more likely. It is usually an ascending infection, more likely to occur during pregnancy because of the physiologic changes predisposing to urinary stasis. Conditions unique to the renal medulla make the kidney particularly vulnerable to infection in the presence of stasis: high urine osmolarity, high urea and sodium concentrations, and low pH impair chemotaxis and inhibit polymorphonuclear leukocyte phagocytosis.

Unlike its usual precursor ASB, pyelonephritis is nearly always diagnosed clinically. Patients typically present with the symptoms of back pain and chills (82%); approximately one-quarter have nausea and vomiting. An elevated temperature is uniformly present, with a temperature of $\geq 40^\circ\text{C}$ in 12% of patients. The majority of patients have costovertebral angle tenderness (predominantly right sided or bilateral) (1). Because none of these signs or symptoms is pathognomonic for pyelonephritis, the final diagnosis should depend on a urine culture positive for a known uropathogen.

To speed up diagnosis and treatment while awaiting the urine culture results, microscopic examination of uncentrifuged urine can be performed. One bacterium per high power

field indicates a bacterial concentration of at least $10^5/\text{mL}$. One or more white blood cells per high power field will also usually be seen in pyelonephritis. Although indicative of a UTI, none of these findings are specific for pyelonephritis. If the diagnosis of pyelonephritis is suspected, blood cultures may also be obtained before antibiotic treatment is begun. However, the additional cost of blood cultures may not be substantiated by clinical benefit, as the blood culture results of the patients with pyelonephritis who develop bacteremia usually parallel the urine culture results; MacMillan and Grimes changed antibiotic treatment based on blood cultures in only 2% of pregnant patients with pyelonephritis (54).

Traditional management recommendations for acute pyelonephritis in pregnancy include hospitalization and intravenous antibiotic administration until significant clinical improvement allows conversion to oral antibiotics, completing a 10- to 14-day course of therapy (55). Van Dorsten and associates showed the importance of appropriate initial antibiotic selection, demonstrating a 67% rate of successful treatment with an antibiotic proven effective by routine sensitivity methods, as compared with a 42% rate of successful treatment with an antibiotic to which the isolated bacteria were resistant (56). Although ampicillin has been used for primary therapy, the increasing resistance of *E. coli* to ampicillin compromises its status as the drug of choice. Gentamicin is nearly uniformly effective but because of associated costs for monitoring serum levels and the lack of an oral equivalent, it is not most commonly used for primary therapy. Gentamicin and ampicillin may be combined for efficacious empiric therapy of pyelonephritis in pregnancy; the half of women with ampicillin-resistant uropathogens have no higher rate of complications (anemia, renal dysfunction, respiratory insufficiency, or preterm birth) than the half with ampicillin-sensitive uropathogens (57). A variety of successful protocols may be used to treat pyelonephritis in pregnancy (Table 2).

Sanchez-Ramos and coworkers reported the single-daily intravenous administration of ceftriaxone 1g to be equally effective and less costly than three-daily 2-g doses of cefazolin intravenously (58). Wing and colleagues randomized gravidas with pyelonephritis to receive initial parenteral treatment with ampicillin (2g IV every 4 hours) plus gentamicin (2mg/kg IV loading then 1.75 mg IV every 8 hours), cefazolin (2g IV every 8 hours), or ceftriaxone (1g IM every 24 hours) and identified no difference in the duration of fever, time to resolution of costovertebral angle tenderness, duration of hospitalization, or birth outcomes (59).

Table 2 Pyelonephritis Antibiotic Protocol Options

Antimicrobial agent	Suggested regimen
Cefazolin \pm gentamicin (dose as below)	1–2g IV q6–8h
Cefuroxime	0.75–1.5g IV q8h
Ceftriaxone	1–2g IV or IM q24h
Ampicillin \pm gentamicin (dose as below)	2g IV q4h
Gentamicin	2mg/kg IV loading dose, then 1.75mg/kg q8h or per pharmacokinetic dosing
Cephadrine	1g IV q6h

In addition to parenteral antibiotics, some gravidas with pyelonephritis also will initially require hydration to correct intravascular volume deficits and electrolyte imbalances, antipyretic treatment, and tocolysis.

Recognizing that outpatient oral treatment of acute pyelonephritis in nonpregnant patients has been proven safe and effective (60), successful trials of outpatient treatment for pregnant women with uncomplicated pyelonephritis also have been published (61–63). Angel and colleagues compared oral and intravenous cephalosporin treatments of pyelonephritis in pregnancy, reporting excellent results for both forms of administration (91% and 93% success rates, respectively) (61). Millar and colleagues demonstrated the efficacy of outpatient treatment for pyelonephritis in women with pregnancies of gestational age both less than 24 weeks and after 24 weeks (62,63). Their protocol at less than 24 weeks compared initial parenteral ceftriaxone for outpatient treatment with cefazolin for inpatient treatment (both followed by oral cephalexin 500mg four times daily for 10 days), with similar culture-negative success rates (78–80%) at follow-up 2 weeks after completion of therapy. However, inpatients receiving initial cefazolin were more likely to remain febrile for more than 3 days or require a change in antibiotic. Millar's subsequent study of women with pyelonephritis after 24 weeks of gestational age treated all participants with ceftriaxone 1g IM twice (24 hours apart), then cephalexin 500mg orally four times daily for 10 days, and led to 91% culture-negative success at 2-week follow-up. The majority of the women randomized to outpatient treatment were discharged with follow-up within 2 to 3 days, but 28% remained hospitalized for complications including sepsis or preterm labor. The cited studies comparing inpatient and outpatient therapy for pyelonephritis in pregnancy share comparable success rates and lack of complications for both strategies. Furthermore, the published outpatient strategies, limiting the outpatient option to otherwise uncomplicated patients, share a conservative approach of initial hospital observation and prompt outpatient follow-up.

A meta-analysis of randomized control studies of treatments for symptomatic UTIs during pregnancy reviewed six pyelonephritis studies and concluded that data are insufficient to recommend any specific best strategy among the study protocols (64). Factors to consider in selecting an empiric regimen may then include local resistance patterns and costs.

The benefit of chronic antibiotic prophylaxis after primary treatment for pyelonephritis has been demonstrated by Harris and Gilstrap (9), who reduced the 60% risk of recurrent pyelonephritis in their population to 3% by continuing broad-spectrum antibiotic prophylaxis after primary therapy throughout the duration of pregnancy. Nitrofurantoin macrocrystals 50mg every day is an excellent choice for prophylaxis. Note, however, that such prophylaxis is effective only if the primary antibiotic therapy is appropriate for the etiologic organism (56). Although most early studies on the potential benefit of prophylactic antibiotics following acute pyelonephritis in pregnancy ended prophylaxis at the time of delivery (9,65), Sandberg extended the prophylaxis for a month postpartum (66), and many subsequent studies have extended prophylaxis until 6 weeks postpartum (62,63).

Frequent follow-up urine cultures may suffice as an alternative to chronic antibiotic prophylaxis following pyelonephritis in pregnancy. In a study tracking urine cultures every 2 weeks and comparing the option of chronic nitrofurantoin following treated pyelonephritis, gravidas not receiving prophylaxis were no more likely to get recurrent symptomatic UTI (14% vs. 8%); however, they were nearly twice as likely to have a subsequent positive urine culture (59% vs. 33%, $p < 0.02$) (66). The cost of multiple urine cultures will probably exceed the cost of prophylactic nitrofurantoin.

Following appropriate parenteral antimicrobial therapy, clinical improvement occurs quickly, with resolution of fever anticipated within 48 hours in 85% of patients (67). In the uncommon event of no improvement after 48 to 72 hours of appropriate antibiotic therapy, consideration should be given to complicating factors such as obstruction, cortical abscess, papillary necrosis, or perinephric abscess. A renal ultrasound scan will detect many of the treatable complications that could delay response to therapy. However, ultrasonography has only one-quarter of the sensitivity of non-enhanced helical computed tomography for the detection of renal calculi (68).

Transient renal dysfunction has been demonstrated during acute pyelonephritis, with a reduction of endogenous creatinine clearance to ≤ 80 mL/min in 27% of patients, and an incidence of approximately 20% for elevated blood urea nitrogen (>11 mg/dL) and serum creatinine (>1 mg/dL) (1,69). The urinary tract is the most common site of origin for gram-negative sepsis, and bacteremia occurs in up to 17% of patients with pyelonephritis. Bacteremia in the presence of pyelonephritis is usually an incidental finding, but it may also present as septic shock. Cunningham and co-workers reported a 3% incidence of septic shock among gravidas with acute pyelonephritis (67). Septic shock occurs secondary to endotoxemia or exotoxemia, and may lead to diffuse organ failure. Acute renal failure secondary to acute tubular necrosis may further compromise the transient renal dysfunction commonly seen with pyelonephritis. Pulmonary insufficiency, including dyspnea, tachypnea, hypoxemia, and pulmonary infiltrates, complicates 7% of gravidas with pyelonephritis (51). Septic shock complicating pyelonephritis may also cause hemolysis, thrombocytopenia, hepatic dysfunction, and adult respiratory distress syndrome. A syndrome of noncardiogenic pulmonary edema, with or without renal, hepatic, or hematopoietic dysfunction, has been reported in 2% of pregnant patients with pyelonephritis (70). This syndrome typically appears within 30 hours of admission and manifests as dyspnea, tachypnea, hypoxemia, and pulmonary effusions and consolidation; 20% of patients require mechanical ventilation, and most recover within 2 to 3 days.

An association between pyelonephritis and both preterm delivery and increased perinatal mortality was recognized in the pre-antibiotic era; however, appropriate antibiotic therapy appears nearly to eliminate these risks. Gilstrap and co-workers reported a higher rate of low birth weight for women with pyelonephritis (<2500 g, 15% incidence vs. 10% in controls) (71), but no increase in perinatal mortality rate, and Fan and associates found no increase in low birth weight, size small for gestational age, or preterm delivery (50).

79 Bacterial vaginosis in pregnancy: Evidence-based approaches

James A. McGregor and Michael W. McCullough

INTRODUCTION

Bacterial vaginosis is the most common cause of vaginal discharge and malodor among women of reproductive age (1,2). This condition has also been termed *Gardnerella* vaginitis, nonspecific vaginitis, and anaerobic colpitis. Studies have shown an association with early and late pregnancy loss, preterm birth, preterm labor, premature rupture of membranes, chorioamnionitis, amniotic fluid infection, postpartum endometritis, and cesarean section infectious morbidity (3–18). These associated complications have resulted in the recommendation for screening all pregnancies as a way to prevent adverse events. Unfortunately, studies have often been conflicting as to the exact relationship between bacterial vaginosis and poor pregnancy outcomes. Recent large-scale analysis has shown screening in the asymptomatic general population to be ineffective. Many organizations including the U.S. Preventive Services Task Force (19), American College of Obstetrics and Gynecology (19), British Association for Sexual Health and HIV/Clinical Effectiveness Group (20), and the Society of Obstetricians and Gynaecologists of Canada do not recommend screening of bacterial vaginosis in low-risk pregnant populations (21). This chapter will review bacterial vaginosis in pregnancy, the pathophysiology involved in associated adverse pregnancy outcomes, and the screening recommendations based on the current literature.

MICROBIOLOGY AND PATHOGENESIS OF BACTERIAL VAGINOSIS

Bacterial vaginosis consists of microecologic alterations in which a characteristic set of bacterial species greatly expand their populations within the vagina. This causes dramatic shifts in the biochemical make-up of vaginal fluid (Table 1) (22,23).

In the healthy vagina, between 5 and 15 microbial species are usually recoverable. High concentrations (10^5 – 10^6 /g of fluid) of lactic acid-producing acidophilic facultative lactobacilli are normally the predominant microflora found throughout the menstrual cycle (23,24). *Lactobacillus crispatus*, *Lactobacillus jensenii*, *Lactobacillus fermentum*, and *Lactobacillus gasseri* represent the predominant vaginal species (24). Many of these produce H_2O_2 along with lactic acid. Other bacteria account for the remaining 10% of bacteria recovered (23–25).

The acidic environment in the healthy vagina is maintained by microbial metabolism of glucose, produced by vaginal epithelial cells from glycogen, to lactic acid (25). In addition to maintaining an acidic vaginal environment, H_2O_2 -producing lactobacilli contribute to the maintenance of a healthy, self-sustaining vaginal ecosystem (26,27). In vitro experiments demonstrate that *Lactobacillus* species inhibit growth of bacteria by producing antimicrobial factors, including acidolin and lactacin B, in addition to H_2O_2 (26–29). The microbicidal

action of H_2O_2 is further enhanced in the presence of a halide ion, such as chloride, from cervical mucus, and peroxidase enzymes, such as myeloperoxidase, produced by neutrophils and monocytes (28).

Each of these factors is present in the vaginal fluid of healthy women in sufficient concentrations to produce in vitro bactericidal effects (28). In a longitudinal study, Hillier and colleagues (30) found that women without H_2O_2 -producing lactobacilli more often developed bacterial vaginosis and more frequently relapsed after successful treatment. These findings support the hypothesis that an absence of H_2O_2 -producing lactobacilli precedes the shift in the vaginal ecosystem toward development of bacterial vaginosis (31). This increase in pH tends to displace lactobacilli from receptor sites on vaginal epithelial cells and maximizes adherence of *Gardnerella vaginalis* and other bacterial vaginosis-associated microorganisms (31,32).

The condition of bacterial vaginosis is characterized by this dramatic decrease in normal lactobacilli and subsequent high concentrations of aerobic and anaerobic bacteria, most notably *Prevotella*, *Peptostreptococcus*, *Porphyromonas*, and *Mobiluncus* species, along with *G. vaginalis*, *Mycoplasma hominis*, and *Ureaplasma urealyticum* (23,24).

Biophysical changes associated with bacterial vaginosis include elevated pH (>4.5), reduced redox potential, increased fluid concentrations of diamines, polyamines, and organic acids, as well as increased concentrations of enzymes, including mucinases, sialidases, IgA proteases, collagenases, nonspecific proteases, and phospholipases A₂ and C (24,33–39). Endotoxin (lipopolysaccharide), cytokine interleukin-1 α , and prostaglandins E₂ and F_{2a} are also increased in the vaginal fluid of women with bacterial vaginosis (40,41). Amines, primarily trimethylamine, putrescine, and cadaverine, are produced during amino acid metabolism by bacterial vaginosis-associated anaerobic bacteria (37,42). These volatile amines are released as pH increases and are responsible for the “sharp” or “fishy” odor sometimes noticed in the presence of bacterial vaginosis (37,43). Several short-chain fatty acids, including succinate, acetate, propionate, isobutyrate, butyrate, and isovalerate, are also increased in bacterial vaginosis (24). In vitro studies demonstrate that increased succinic acid dramatically impairs neutrophil phagocytic killing, response to chemotactic stimuli, and generation of respiratory bursts required for bacterial killing (44). Butyrate inhibits lymphocyte activation by release of an endotoxin (45,46).

These virulence factors promote tissue attachment, overcome host defense mechanisms, and facilitate entrance of microorganisms and associated factors into the upper reproductive tract. Vaginal fluid protease and phospholipases probably play roles in bacterial vaginosis pathogenesis and ascent of microbes and into the uterus during pregnancy.

Mucinases and sialidases lyse protective mucin and promote bacterial attachment, allowing invasion and spread to underlying epithelial cells. These enzymes may also play a role in disruption of cervical mucus, leading to upper genital tract spread of bacterial vaginosis-associated microflora (38). During pregnancy, bacterial phospholipases A₂ and C, as well as nonspecific proteases, may act on cervical and amniochorion tissues to promote cervical ripening and amniochorion weakening (40). In addition, phospholipases A₂ and C may promote the release of arachidonic acid and prostaglandins, furthering the processes leading to preterm birth (40). Thus, these bacterial substances directly contribute to the initiation of a number of bacterial vaginosis-associated obstetric complications (38–42).

EPIDEMIOLOGY AND NATURAL HISTORY OF BACTERIAL VAGINOSIS

Numerous studies have prospectively examined bacterial vaginosis among populations of pregnant women and demonstrated prevalence ranging from 6% to 32% (Table 2) (5,7,9–13,43,46,58). Studies from Canada, Sweden, and Denmark report bacterial vaginosis among 14% of pregnant women (56,59,60), which is similar to the 16% prevalence

reported in the United States (13). Epidemiologic factors showing increased prevalence in the United States are African-American race, smoking, and multiple sexual partners and are the lowest among women with no history of heterosexual contact (5,56,57,61,62). Among nonpregnant women of reproductive age, bacterial vaginosis is detected more often among those not using any method of contraception and among women using an intrauterine contraceptive device (36,63).

Studies in pregnancy show that most women who test negative stay negative while women with bacterial vaginosis remain positive unless treated (12,61,63,64). Among pregnant women initially tested negative for bacterial vaginosis in the first trimester, 2.9% of British women and no Swedish women developed bacterial vaginosis by the follow-up examination at 28 weeks of gestation, and 47% to 55% of initially positive women continued to have findings of bacterial vaginosis at the third-trimester follow-up visit. A further 2.4% of women without bacterial vaginosis in the first trimester had developed bacterial vaginosis by term (61,65). In 31% of untreated women with bacterial vaginosis, the condition resolved by 28 weeks of gestation (63). Importantly, Joesoef and coworkers (12) determined that women with bacterial vaginosis at 16 to 20 weeks of gestation suffered

Table 1 Biochemical Factors in Bacterial Vaginosis and Their Potential Pathophysiologic Effects

Vaginal fluid constituent	Known or potential actions	Potential effects in pregnancy
pH	Attachment of anaerobic bacteria and <i>Lactobacillus</i> species attachment	Numbers of pathogenic anaerobic bacteria
Succinic acid	Impairs neutrophil phagocytic killing and response to chemotactic stimuli	Vaginal fluid host defenses
Butyrate	Toxic to fibroblasts in cell culture	effects on cervical connective tissue and amniochorion
Sialidase/Mucinase	Degrades protective surface mucin, bacterial attachment to epithelial cells	Cervical mucus barrier
IgA protease	Degrades IgA proteins	Cervical IgA
Collagenase	Degrades collagen types	Cervical ripening, amniochorion weakening
Nonspecific proteases		
Phospholipase A ₂	Induces matrix metalloproteinases, induces prostaglandins	Cervical ripening, amniochorion weakening, and uterine contractions

Table 2 Prevalence of Bacterial Vaginosis in Pregnant Women Followed Prospectively

Study population	Diagnostic method	Prevalence
USA Seattle, Washington (10,47–49)	Gas-liquid chromatography	14–28%
	Clinical	6–21%
	Gram stain	12–21%
Denver, Colorado (13,38)	Gram stain	18.7–23%
	Clinical	32%
	Gram stain and pH > 4.5	16%
Vaginal Infections and Prematurity Study (50) Maternal-Fetal Medicine Network Centers (51)	Gram stain and pH > 4.5	23.4%
	Clinical	23%
Halifax, Nova Scotia, Canada (52)	Clinical	23%
Finland (16)	Quantitative cultures	21.4%
Göteborg, Sweden (53)	Papanicolaou's smear and pH>4.5	14.3%
Harrow, UK (54,55)	Gram stain	12–14%
Adelaide, Australia (15)	<i>Gardnerella vaginalis</i> culture (heavy growth)	28%
Jakarta, Indonesia (56)	Gram stain	17%
Canada (57)	Gram stain	14%

increased risk for preterm birth, even if they no longer had findings of bacterial vaginosis at the later follow-up visit (28–32 weeks of gestation). Prospective treatment studies show that bacterial vaginosis recurs between 20% and 80% in pregnancy, regardless of initial successful treatment (38,66). The individual factors that predispose to acquisition, persistence, resolution, and/or recurrence of bacterial vaginosis probably involve failure of H₂O₂-producing lactobacilli to recolonize and reestablish a normal, protective vaginal ecosystem following treatment (26,31,67).

DIAGNOSIS OF BACTERIAL VAGINOSIS

Clinical Diagnosis

The clinical “gold standard” established in 1983 by Amsel and colleagues (36) is based upon the presence of three of four clinical criteria:

1. homogeneous, thin vaginal fluid that adheres to the vaginal walls;
2. vaginal fluid pH > 4.5;
3. release of amine odor with alkalinization of vaginal fluid, the “whiff test”; and
4. presence of vaginal epithelial cells with borders obscured by adherent, small bacteria called “clue cells.”

Of the four Amsel’s criteria, the presence of clue cells on saline wet-mount examination is the most specific and sensitive indicator of bacterial vaginosis. Identification of clue cells accurately predicts 85% to 90% of women with clinical bacterial vaginosis (positive predictive value). Identification of clue cells may be hindered by adherence of normal bacteria, cellular debris, and availability and quality of the microscopy (65,68).

Clue cells can be microscopically distinguished from normal vaginal epithelial cells by their characteristic stippled and ragged appearance (Fig. 1). The cell borders are obscured by adherent small coccobacilli-type bacteria, in contrast to normal vaginal epithelial cells where the cell borders are distinct and clearly seen (Fig. 2). In addition to the presence of clue cells, the characteristic long rods, of *Lactobacillus* morphotypes, are absent or rare. Background bacterial flora appears greatly increased and short rods and coccobacillary forms predominate. *Mobiluncus* species may be identified by their characteristic spiral or serpent-like motility (69).

The “whiff test” is similarly sensitive for the diagnosis of bacterial vaginosis, but may also be positive in trichomoniasis. Alkalinization of vaginal fluid releases volatile amines, putrescine, cadaverine, and trimethylamine, which give off a characteristically “fishy” or sharp odor. This odor may be noticed by a woman as amines are released spontaneously during activities that raise the vaginal pH, such as sexual intercourse, douching, or menses (37,43).

Normal vaginal pH from menarche to menopause ranges between 3.8 and 4.2. Amsel and colleagues (36) determined that a vaginal fluid pH over 4.5 discriminated between bacterial vaginosis and normal vaginal fluid. Identification of pH over 4.5 is highly sensitive for the diagnosis of bacterial vaginosis, but it is not specific (2,36,70).

Other factors may raise vaginal pH, including semen, cervical mucus, menses, trichomoniasis, and possibly recent

douching. Samples for examination of vaginal fluid pH must be obtained from the lateral vaginal side wall or posterior fornices in order to reflect accurately vaginal, and not cervical, pH. Similarly, the pH indicator paper must allow distinction between the normal vaginal pH (3.8–4.2) and a pH over 4.5. The characteristic thin, homogeneous, and adherent vaginal fluid is the most subjective indicator of bacterial vaginosis.

Laboratory Diagnosis

Gram stains of vaginal fluid are used in research settings to identify the shift from predominance of *Lactobacillus* morphotypes to predominance of coccobacillary morphotypes and gram-negative rods characteristic of bacterial vaginosis. The Gram-stain diagnosis involves quantitative estimations of

Figure 1 “Clue cells” identified on microscopic examination of saline preparation.

these types of bacteria in the vaginal fluid (70–72). Normal vaginal fluid is described by a predominance of large gram-positive rods, considered *Lactobacillus* morphotypes, with or without smaller gram-variable bacilli, considered *Gardnerella* morphotypes (Fig. 2) (73). A pattern of mixed vaginal flora, which includes *Gardnerella* morphotypes, gram-negative rods, fusiforms, curved rods, gram-positive cocci, and absent or reduced numbers of *Lactobacillus* morphotypes (less than five per high-power field), is consistent with bacterial vaginosis (Fig. 3) (73). The current laboratory “gold standard” incorporates Gram stain using a scoring system, the most prevalent being the “Nugent scoring” system with a sensitivity of 89% and a specificity of 83% when compared with Amsel’s criteria (Fig. 4).

The technique of Nugent and coworkers (74) examines four bacterial morphotypes and assigns a summary score to the vaginal specimen based on the semiquantitative assessment for *Lactobacillus* morphotypes, *G. vaginalis*, *Prevotella* morphotypes, and *Mobiluncus* morphotypes. A score of 7 to 10 is considered to indicate bacterial vaginosis (74). Compared

with other diagnostic methods, this standardized scheme has superior reproducibility (73).

This reproducibility has made the “Nugent score” the standard used in the majority of recent research. The required laboratory to perform the test and time delay prevent Gram-stain scoring systems from widespread clinical settings.

Nonquantitative microbial culture for *G. vaginalis* is both an inaccurate and expensive way to diagnose bacterial vaginosis. Clinical cultures should not be used to diagnose bacterial vaginosis. Since organisms such as *G. vaginalis* can be recovered from up to 60% of women with and without bacterial vaginosis, this leads to unacceptable false-positive rates (2,59). Quantitative aerobic and anaerobic vaginal cultures have been used in clinical research studies to evaluate bacterial vaginosis, but this technique is costly and impractical for clinical use (9,10).

Newer diagnostic techniques, including nucleic acid probes to detect high concentrations of *G. vaginalis*, have become available (71,75). Such tests as the Affirm VP III Microbial Identification Test (Becton Dickinson and Company, Sparks, MD) may provide a less subjective test for bacterial vaginosis than other current methods. Briselden, Hillier, and Sheiness reported accurate detection (sensitivity) of 95% to 97% of women with clinical criteria for bacterial vaginosis using the Affirm VP III test. Specificity for this test ranged from 71% to 98% (71,75). Identification of several different vaginal fluid biochemicals associated with bacterial vaginosis such as amines (FemExam) and sialidase activity (BV Blue) have recently become available commercially. (5,6,24,37,76).

OBSTETRIC COMPLICATIONS ASSOCIATED WITH BACTERIAL VAGINOSIS

Preterm Birth

Associations between bacterial vaginosis and increased risk for adverse pregnancy outcomes have been investigated through case-control, cross-sectional, prospective cohort studies and randomized controlled treatment trials (Table 3) (4–13,38,50,54,56,60,74–76). Despite differences in study design, definitions of preterm birth, and the techniques used to identify bacterial vaginosis, research from around the world supports the association between bacterial vaginosis and increased risk of preterm labor, preterm birth, and preterm premature rupture of the membranes (Table 3) (5–13,38,56,78). Crucially, bacterial vaginosis and associated microorganisms appear to increase the risk of preterm birth at the lowest viable gestational ages (8). Two published studies report an association between previsible second-trimester pregnancy loss and bacterial vaginosis, suggesting that pathophysiologic processes associated with bacterial vaginosis cause a continuum of both previsible loss and birth of severely premature newborns (11,56).

Multiple prospective studies indicate that bacterial vaginosis may be detected months prior to the onset of preterm labor or preterm birth (5,7,9–13). Eschenbach and colleagues (4) and Gravett and coworkers (5,6) were the first to implicate bacterial vaginosis as a risk factor for preterm labor and low birth weight. Bacterial vaginosis was identified using gas-liquid chromatography among 19% of 534 pregnant women studied (5). The presence of bacterial vaginosis in the mid-third trimester (mean 32.6 weeks) was associated with

Figure 3 Normal vaginal fluid Gram stain.

Figure 4 Gram stain of bacterial vaginosis.

increased risk for preterm labor [odds ratio (OR) 2.0, 95% confidence interval (CI) 1.1–3.5] and preterm premature rupture of the membranes (OR 2.0, 95% CI 1.1–3.7) (5). McDonald and colleagues (9) examined bacterial vaginosis (culture for heavy colonization with *G. vaginalis*) earlier in gestation (22–28 weeks) and demonstrated similar risks for preterm birth following labor (OR 1.8) and preterm premature rupture of the membranes (OR 2.7).

Studies that examine for bacterial vaginosis at the earliest gestational ages and carefully control for intervening antimicrobial treatment demonstrate the strongest association between bacterial vaginosis and preterm birth (Table 3) (10,11). The highest relative risks (sevenfold increase) between bacterial vaginosis and preterm birth and premature rupture of the membranes were noted in a Finnish study involving women who were initially examined in the first trimester (10). In an insightful analysis, Joesoef and colleagues (12) examined the risk of preterm birth for women

found to have bacterial vaginosis between 16 and 20 weeks of gestation and/or between 28 and 32 weeks of gestation (12). Women with bacterial vaginosis in the early second trimester experienced a twofold increase in premature birth compared with women without bacterial vaginosis (12). Women with bacterial vaginosis at 28 to 32 weeks of gestation experienced somewhat less increased risk for premature birth (OR 1.5, 95% CI 0.7–3.0). Women who developed bacterial vaginosis between the screening intervals (i.e., those negative at 16–20 weeks of gestation and positive at 28–32 weeks of gestation) were not at increased risk for preterm birth (10.7% preterm birth among women developing bacterial vaginosis vs. 11.8% among women never positive for bacterial vaginosis; calculated OR 0.9) (12). As discussed, women with findings of bacterial vaginosis at 16 to 20 weeks of gestation were at increased risk for preterm birth, even if they no longer had findings of bacterial vaginosis at the later follow-up visit (20.5% preterm birth among women with bacterial

vaginosis at both visits and 20.5% preterm birth among women with bacterial vaginosis only at the first visit vs. 11.8% preterm birth among women without bacterial vaginosis) (12). These findings suggest that physiologic processes present or initiated at, or prior to, 16 to 20 weeks of gestation are important for the subsequent development of preterm birth. These authors concluded that “only bacterial vaginosis in early pregnancy plays a major role as a risk factor for preterm delivery” (12). Results of a large prospective cohort study from the National Institute of Child Health and Human Development-sponsored Vaginal Infections and Prematurity Study Group demonstrated a 40% increase in risk of delivering a preterm low-birth weight infant and a 10% increase in risk of preterm premature rupture of the membranes among women with bacterial vaginosis detected between 23 and 26 weeks of gestation (13). These authors calculated a 9% attributable risk for prematurity in this study of over 10,000 subjects (13). Other populations could receive more or less benefits, depending on the prevalence of bacterial vaginosis.

Intrapartum and Postpartum Infections

Bacterial vaginosis has been linked to clinical chorioamnionitis, amniotic fluid infection, as well as postpartum endometritis and cesarean section infection. These associations were first suggested by observations that the microorganisms frequently recovered from women with these complications often include the common constituents of bacterial vaginosis, i.e., *Prevotella bivia*, *G. vaginalis*, *M. hominis*, *U. urealyticum*, and *Peptostreptococcus* species (6,14–16). Clinical studies have examined bacterial vaginosis, identified by either Gram stain or gas-liquid chromatography, and shown that women with clinical amniotic fluid infection more commonly have findings of bacterial vaginosis compared with women without clinical infection. (6,15,16) Among the 286 (2.4%) women from the Vaginal Infections and Prematurity Study who developed amniotic fluid infection, antenatal carriage (23–26 weeks of gestation) of bacterial vaginosis (relative risk 1.5, 95% CI 1.2–2.2) and bacterial vaginosis-associated microorganisms were significantly associated with amniotic fluid infection (78). This increase in risk for amniotic fluid infection associated with bacterial vaginosis was independent of duration of labor, duration of rupture of membranes, concurrent infection with *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, *Trichomonas vaginalis*, group B streptococcus, and effective antimicrobial treatment (77). Postpartum endometritis occurs following 2% to 5% of vaginal births and 10% to 20% of cesarean deliveries (79). These infections are polymicrobial in nature for over 80% of affected women (80). In a series of 161 women with postpartum endometritis described by Watts and colleagues (81), the common constituents of bacterial vaginosis (i.e., *G. vaginalis*, *P. bivia*, *Peptostreptococcus* species, and *Bacteroides* species) were recovered from endometrial cultures in up to 60% of women (81). Wound infections developed among 18% (16/79) of women with endometrial bacterial vaginosis-associated flora and among 8% (4/53) of women with other bacteria recovered from the endometrium (81). Subsequent work by Watts demonstrated a 5.8-fold increased risk for post-cesarean section endometritis among women with bacterial vaginosis (14).

BACTERIAL VAGINOSIS TREATMENT IN PREGNANCY

Oral (systemic) treatment with either metronidazole or clindamycin is preferred for the treatment of bacterial vaginosis during pregnancy. Only oral treatments provide adequate antimicrobial levels in both uterine and vaginal tissues and are associated with improved pregnancy outcome in published studies. Cure rates are similar to those obtained among nonpregnant women (56,77). Initial cure rates within 1 to 2 weeks following completion of treatment are generally 25% to 35% higher than those among women examined 4 to 5 weeks posttreatment (82,83).

Oral metronidazole, 500mg two times daily for 7 days, is the standard therapy recommended by the Centers for Disease Control in the United States for treatment of bacterial vaginosis (81). Resolution of bacterial vaginosis occurs among 85% to 100% of studied women examined approximately 1 week following completion of oral metronidazole treatment (84). The percentage of women without bacterial vaginosis 4 to 5 weeks following completion of treatment ranges from 60% to 95% and averages approximately 80% (82,84). Similarly, cure rates of 70% have been seen with the use of metronidazole and erythromycin (82). Different regimens of oral metronidazole have been examined in trials and observational reports; in general, cure rates at 4 weeks post-dosing with a single 2-g dose of metronidazole range from 45% to 69% (84).

Clindamycin is also an effective treatment for bacterial vaginitis, as well as its associated microflora, including some genital mycoplasmas. Greaves and coworkers (69) examined 49 women 7 to 10 days following completion of a 7-day course of oral clindamycin, 300mg twice daily, and demonstrated a cure rate of 94% for bacterial vaginosis. McGregor and associates (56) examined 194 pregnant women and found a 92% cure rate 2 to 4 weeks post-treatment (56). Oral treatment with clindamycin may be used throughout pregnancy, including the first trimester; it provides resolution of bacterial vaginosis equivalent to that of oral metronidazole.

Intravaginal treatments for bacterial vaginosis are similarly effective at eradication of bacterial vaginosis but have not been shown to improve pregnancy outcomes (38,80,82,84). Metronidazole gel 0.75% one 5-g applicator intravaginally once a day for 5 days or clindamycin 2% one 5-g applicator for 7 days is recommended. Other treatments for bacterial vaginosis have been evaluated: ampicillin, augmentin, ofloxacin, erythromycin, triple sulfa cream, and vaginal acidification (60,84). These treatments are less effective than both oral and vaginal preparations of metronidazole or clindamycin and are not recommended. Similarly, probiotic therapy with microbial products, such as lactobacillus powders and capsules, should be avoided; many of the nondairy products are contaminated with potentially harmful bacteria such as *Clostridium sporogenes* and *Enterococcus* species (85). Therapy with yogurt or acidophilus milk is also likely to be of little benefit, since the *L. acidophilus* strains are not easily established in the vagina (86).

Treatment of sexual partners of women with bacterial vaginosis is unnecessary: randomized controlled trials that examined co-treatment of male partners failed to demonstrate reduced recurrence rates of bacterial vaginosis for women (87,88).

SCREENING IN PREGNANCY

In 2001, the U.S. Preventive Services Task Force published recommendations after review of seven randomized control trials. Screening in asymptomatic low-risk pregnancies was not recommended, and there was insufficient evidence to recommend screening for the high-risk population. In 2008, Nygren (52) and associates reviewed literature that was published following the 2001 task force findings. Seven randomized, controlled trials were included in their analysis and the results pooled with the 2001 report data. No evidence was found supporting screening in the asymptomatic low-to-moderate-risk patients. Screening in high-risk patients varied with three of five studies showing a benefit, one showing no benefit, and one showing harm with treatment (52).

Considering the current literature, there seems to be no benefit to screening the asymptomatic low-risk general population. Screening high-risk patients may provide benefit; however, there is no current consensus. The following are general guidelines that use current clinical evidence:

1. Test and treat all symptomatic patients.
2. Asymptomatic low-risk patients do not appear to benefit from universal screening.
3. Asymptomatic women at high risk for adverse pregnancy outcomes may benefit from screening and treatment. If screening is preformed, it should be done prior to 16 weeks of estimated gestational age.
4. Oral or vaginal preparations have similar organism eradication rates; however, vaginal treatments do not affect the preterm labor and delivery rates. Therefore, all patients at high risk for adverse outcomes should be treated with oral clindamycin 300mg twice a day for 7 days or metronidazole 500 mg two times a day for 7 days.
5. Test for cure should be done in 3 to 4 weeks after treatment.

CONCLUSION

Bacterial vaginosis is the most common cause of vaginal discharge in pregnant and nonpregnant women. This condition represents massive microbial and biochemical perturbations of the lower reproductive tract microecology. Diagnostic tests (Amsel's criteria) are easily performed. Treatments include oral or vaginal treatment with metronidazole or clindamycin. Descriptive and intervention studies carried out worldwide demonstrate increased risks of preterm birth and other adverse pregnancy outcomes associated with bacterial vaginosis; however, conclusive epidemiologic evidence to support screening in the general population has not been found. One explanation that has been proposed by Simhan et al. (89) involves molecular epidemiology looking at the individual patient's inflammatory response to a bacterial vaginosis infection based on genotypes. In the hypothesis by Simhan et al. (89), patients may be "hyperresponders" at risk for an overresponse of local immune factors resulting in pregnancy loss or preterm delivery, "normo-responders" with enough inflammatory mediators to promote clearing of the infection, or "hypo-responders" putting these patients at risk for ascending infection, preterm delivery, chorioamnionitis,

and postsurgical infections (89,90). These new ideas and technology may provide future researchers the tools in which to discover the contributing factors to the ongoing problem of being born "too soon."

80 Viral hepatitis in pregnancy

Dennis Ng

This chapter reviews two of the most common hepatitis affecting pregnancy, hepatitis B and C. It is catered toward a mixed audience of practicing obstetricians, obstetrics and gynecology residents, maternal–fetal medicine fellows, and health-care providers for pregnant patients. There has been an explosion of knowledge in disease pathophysiology and treatment options for hepatitis B and C in the last 10 years. Guidelines for treatment and management for hepatitis B and C are changing every 2 to 3 years. To the uninitiated, this can be a daunting subject.

My intention is to provide you with an easy-to-understand review of the subject, emphasizing on the main concepts and principles in the management of hepatitis B and C, in the context of pregnancy and delivery. As such, no attempt has been made nor is it possible to be all-inclusive in the minute details of the subject. Instead, I attempt to provide you with an insight into the pertinent questions at hand related to pregnancy and delivery that may arise in your consultation. Particular emphasis will be placed on counseling and public health issues, a subject often forgotten by practitioners, but of utmost importance.

Interested readers may refer to the several excellent textbooks on hepatology, review articles, and guidelines published by American Association for the Study of Liver Diseases (AASLD). This chapter will focus only on hepatitis B and C. Brief mention of hepatitis E will be made. Other viral hepatitis like herpes simplex virus hepatitis will not be covered.

PRESENTATION OF HEPATITIS B AND C AND GENERAL APPROACH

The pregnant female may acquire hepatitis A, B, and C acutely. If symptomatic, they usually complain of flu-like symptoms, general aches and pains, fatigue, nausea, and vomiting. Physical exam may reveal icterus, jaundice, right upper quadrant tenderness, and change in the color of urine. Labs may reveal high levels of aspartate aminotransferase (AST) and alanine aminotransferase (ALT) in the thousand range. alkaline phosphatase is usually only slightly elevated. Bilirubin may be elevated. These pregnant patients are best admitted to the hospital, particularly if symptomatic with nausea, vomiting, dehydration, where an expedited workup can be performed to rule out other causes of liver diseases unique to pregnancy like acute fatty liver of pregnancy and hemolysis, elevated liver enzymes, and low platelet count (HELLP) syndrome.

More commonly, hepatitis B comes to the attention of the clinician from the adoption of the universal hepatitis B screening during prenatal visit in the United States. Hepatitis C should be tested in high-risk patients. If found to be positive, they should be referred to the hepatologist/gastroenterologist to determine the status of hepatitis B or C, severity of liver

disease, and to help with management of liver disease postdelivery. It is important to screen for these diseases because many times, for a young healthy female patient, the obstetrician may be the only doctor they will see. Once diagnosed, it allows the clinician the golden opportunity to talk about public health issues, mode of transmission of hepatitis, ways to prevent progression of liver disease (e.g., quit drugs and alcohol), referral to a hepatologist for possible treatment options, and cancer screening for the liver (if relevant).

HEPATITIS B IN PREGNANCY

Epidemiology

Worldwide more than 350 million individuals are chronic hepatitis B carriers [1]. The prevalence of hepatitis B varies from region to region. Hepatitis B prevalence can be divided into low-prevalence (e.g., North America, Western Europe), intermediate-prevalence, and high-prevalence areas (e.g., sub-Saharan Africa, Asia excluding Japan, the Pacific basin, parts of the Middle East, and the Amazon basin).

It is important to note that there is a recent increase in immigrants from highly prevalent countries over the last few decades into the United States. Between 1994 and 2003, the United States admitted about 40,000 individuals with chronic hepatitis B infection annually [2]. Hence, areas of high concentration of these immigrants will have a higher prevalence rate. For example, a recent study in 2009 examined the seroprevalence of HepBsAg among the Asian Chinese in an urban Chinatown internal medicine practice in Chicago [3]. The number was 11.1%, suggesting that we should be even more vigilant about screening high-risk patients, because treatment where indicated has been shown to improve prognosis and decrease morbidity and mortality from hepatitis B in the long run.

Acute hepatitis B occurs in 1 to 2 out of 1000 pregnancies in the United States. Chronic carrier state occurs in 6 to 10 of 1000 pregnancies.

Importance of Hepatitis B on a Global Scheme

It is generally accepted that at least 50% of the hepatitis B carriers acquire infection either perinatally or during early childhood. Studies suggest that most of the infections occur around the time of delivery. This gives us the unique opportunity of intervening by providing active and passive hepatitis B vaccination. The goal is to prevent infection in the newborn, hence decreasing the burden of hepatitis B infection worldwide.

When you acquire hepatitis B as an adult, you have a 90% to 95% chance of clearing this virus (resolved hepatitis B infection). But when you acquire this as an infant, you have only a 5% to 10% chance of clearing this virus, that is, most of

the infants will be chronic carriers of hepatitis B, with its disease-related morbidity and mortality. Therefore, it makes sense for us to intervene to decrease the rate of perinatal and childhood infection. Taiwan has implemented a mandatory hepatitis B vaccination program 20 years ago, with a significant impact on perinatal, childhood, and adolescent infection. Chronic liver disease and hepatocellular carcinoma attributed to hepatitis B have decreased since implementation [4].

In the United States, we have a mandatory screening for all pregnant females, and if positive for hepatitis B surface antigen, the infants are to get active and passive immunization.

Even in the best of hands, when vaccinations have been carried out appropriately, there is still about 10% of infants who will get hepatitis B infection, suggesting that perhaps they acquired this virus in utero [5,6].

Effect of Acute Hepatitis B Infection During Pregnancy

Acute hepatitis B can occur during pregnancy; they present the same way as in the general population. Acute hepatitis B must be differentiated from hepatitis A and C, and other causes of hepatitis unique to pregnancy (HELLP syndrome, acute fatty liver of pregnancy, etc.). It appears that acute hepatitis B does not increase mortality and has no teratogenic side effects. However, a higher incidence of low birth weight and prematurity has been reported [7].

Effect of Pregnancy on Chronic Hepatitis B

In general, patients do well during pregnancy. Patients have been known to have a flare of hepatitis B during or after delivery (one theory is that the high levels of adrenocorticosteroids in the body have now decreased significantly postpartum, just like abruptly removing steroids from the patient). Therefore, it is important to monitor patients for symptoms of hepatitis and also to test for liver function tests, during and also after delivery.

Diagnosing Hepatitis B in the Mother

Over the years, we have developed better tests for hepatitis B, including the ability to measure HBV DNA PCR quantitatively down to the most minute level, for example, 5 IU/mL.

The most common mistake that I see clinicians make is to order an acute hepatitis panel. Usually this consists of HepBsAg, HepBcIgM, HepCAb, and HepAIgM. These are acute hepatitis markers, meaning good for diagnosing acute hepatitis infections, but tell you nothing about the chronic state of hepatitis B, which is what we are interested in, to determine treatment and management for the pregnant patient.

Below Are Some Typical Hepatitis B Serology You Might Encounter in Clinical Practice

Case 1

A 20-year-old Vietnamese pregnant college student, sent to you because tested positive for hepatitis B. Further workup reveals liver function tests (LFTs) normal, HepBsAg positive, HepBsAb negative, HepBcTotal positive, HepBcIgM negative, HepBeAg positive, HepBeAb negative, and HBV DNA >2,000,000,000. The ultrasound (US) of liver unremarkable.

Impression: She is in the immunotolerant phase of hepatitis B.

Case 2

A 30-year-old Malaysian female, pregnant, family history positive for hepatitis B in mother and father. Further workup reveals LFTs elevated, AST 60, ALT 70, HepBsAg positive, HepBsAb negative, HepBcTotal positive, HepBcIgM negative, HepBeAg positive, HepBeAb negative, HBV DNA 200,000. The US of liver with echogenic liver.

Impression: She is in immunoclearance phase of hepatitis B.

Case 3

A 38-year-old Chinese female, pregnant, family history positive of liver cancer in her dad. Further workup reveals LFTs normal, HepBsAg negative, HepBsAb positive, HepBcTotal positive, HepBcIgM negative, HepBeAg negative, HepBeAb positive, and HBV DNA undetectable. The US of liver unremarkable.

Impression: She has resolved hepatitis B infection.

Case 4

A 22-year-old white American female with the following labs: LFTs normal, HepBsAb positive, and every other marker for hepatitis B negative.

Impression: She has been vaccinated in the past and has shown immunity as evidenced by antibody formation.

Vaccinations for Hepatitis B for the Mother and Baby

The Centers for Disease Control and Prevention (CDC) recommends that all mothers be tested for hepatitis B during the initial prenatal visit [8]. This applies even if the patient has been vaccinated in the past or tested in the previous pregnancy.

If negative, the pregnant mother who is at risk for hepatitis B infection (unsafe sex, multiple sexual partners, health-care workers, active intravenous drug user, etc.) should be vaccinated. The limited data we have indicate that there is no apparent risk for adverse events to developing fetuses. Current vaccines contain noninfectious HBsAg and should cause no risk to the fetus.

If HepBsAg is found to be negative, and the high-risk patient refuses vaccination, or is unable or unwilling to get vaccinated, then HepBsAg should be rechecked closer to the time of delivery because this will change management if found to be positive.

If HepBsAg positive, the patient is a carrier for hepatitis B. She should be referred to a gastroenterologist/hepatologist for further characterization of her liver disease and the need for treatment. Counseling should be provided regarding the risk of transmission to the newborn and sexual partners, and prevention of HBV transmission to newborns and sexual partners. They should be evaluated for other concomitant liver diseases including hepatitis A and hepatitis C. All sexual contacts and family members should be tested for hepatitis B. If the patient is not immune to hepatitis A and is at high risk of acquiring it, then vaccines for hepatitis A should be given, because of the risk of severe hepatitis with hepatitis A on top of hepatitis B infection [9].

A patient who is not a hepatitis B treatment candidate during pregnancy may be a candidate for treatment at a later point in time. Therefore, it should be emphasized to the patient that she should continue to follow up with the

gastroenterologist/hepatologist after delivery. Hepatitis B is a chronic disease that requires regular monitoring and liver cancer screening in at risk patients. The clinicians caring for these pregnant patients have the golden opportunity of providing education regarding hepatitis B and also to ensure that patients continue to follow up with specialists.

The pregnant patient with hepatitis B should be enrolled into a special program that ensures that active and passive vaccinations not only happen, but also happen in a timely manner. This includes making sure that there is ready access to the vaccines when needed, including at 3:00 in the morning or the weekend. We have heard of horror stories in smaller hospitals where the vaccines is available but locked up in the central pharmacy in the weekend. This program should also ensure that the hepatitis B vaccines are completed in a timely fashion postdelivery.

Treatments Available for Hepatitis B in 2010

The last 10 years have seen tremendous progress in the treatment of hepatitis B. We now have five FDA-approved nucleoside and nucleotide analogs and two interferon-based regimen:

Interferonalpha-2b recombinant (1992), lamivudine (1998), adefovir dipivoxil (2002), entecavir (2005), peginterferon alpha-2a (2005), telbivudine (2006), and tenofovir (2008).

It is beyond the scope of this chapter to discuss selection of hepatitis B drugs and the rationale behind this. For the interested readers, please refer to AASLD 2009 updated guidelines.

Tenofovir and telbivudine are pregnancy category class B, while the rests are class C.

Prevention of Hepatitis B Transmission to Newborns

Active and Passive Vaccination

CDC recommendation for hepatitis B in infants is stated below [8]:

At Birth

- Administer monovalent hep B to all newborns before hospital discharge.
- If mother is HBsAg positive, administer HepB and 0.5 mL of hepatitis B immunoglobulin (HBIG) within 12 hours of birth.
- If mother is HBsAg unknown, administer HepB within 12 hours of birth. Determine mother's HBsAg status as soon as possible and, if HBsAg positive, administer HBIG no later than age 1 week.

After the Birth Dose

- The HepB series should be completed with either monovalent HepB or a combination vaccine containing HepB. The second dose should be administered at age 1 or 2 months. Monovalent HepB vaccine should be used for doses administered before age 6 weeks. The final dose should be administered no earlier than age 24 weeks.
- Infants born to HBsAg-positive mothers should be tested for HBsAg and antibody to HBsAg 1 to

2 months after completion of at least three doses of the HepB series, at age 9 through 18 months.

- Administration of four doses of HepB to infants is permissible when a combination vaccine containing HepB is administered after the birth dose. The fourth dose should be administered no earlier than age 24 weeks.

Breast-Feeding in Hepatitis B Patients

Even though HepBsAg can be detected in breast milk in a large proportion of infected women, several studies fail to demonstrate increased risk of infection due to breast-feeding as opposed to infants who are formula-fed in hepatitis B-infected mother.

Breast-feeding is not considered a contraindication to breast-feeding by the CDC or American Academy of Pediatrics in infants who receive HBIG and active vaccination as indicated.

The nipples should be cared for properly, and mothers should not breast-feed if there are signs of cracked or bleeding nipple.

Mode of Delivery

Despite the attractive idea of decreasing the risk of perinatal transmission, studies have so far shown that the mode of delivery does not appear to have a significant effect on decreasing the risk of hepatitis B transmission [10]. The CDC or American College of Obstetricians and Gynecologists does not currently recommend caesarian section as the preferred mode of delivery purely for the purpose of reducing perinatal transmission.

Role of Antiviral

There is emerging evidence that patients who are put on antiviral therapy during the last trimester, to reduce hepatitis B viral load, could potentially reduce the risk of perinatal transmission. There are many factors to be taken into consideration, including compliance with therapy, severity of liver disease, history of prior treatment, resistance issues, the risk of flare of hepatitis B should the antiviral be stopped postpartum, mothers' preference, and so on. The major concern is that three of the medications we have for hepatitis B are in pregnancy category C and two in category B. There is no category A medication for hepatitis at this point in time. These decisions are best made by the hepatologist and patient together.

Summary for Hepatitis B

Hepatitis B when diagnosed in mother prior to delivery affords us the opportunity to make a difference in reducing the risk of mother-to-infant transmission. Besides vaccination of the newborn, other important aspects of care of the young pregnant patients include counseling regarding their liver disease and mode of transmission and ways to reduce the risk of progression of liver disease. Patients who are not candidates for treatment now may become candidates in the future. Hepatitis B is not a disease to be diagnosed at a single point in time and be forgotten about. It requires lifelong follow-up with a clinician who is familiar with this disease.

HEPATITIS C

Background

Hepatitis C is a major public health problem in the United States. It is estimated that 170 million people are infected worldwide [11]. This is the number one cause for liver transplantation in the United States today. The top three diagnoses in my liver clinic are hepatitis C, nonalcoholic steatohepatitis, and alcoholic liver disease. The sad part is that the majority of the patients who are diagnosed with hepatitis C are unaware of their liver disease, because hepatitis C mostly do not present with any specific symptoms. In fact, most patients will tell you that they do not feel any different from their normal healthy self. Therefore, it is even more important to screen high-risk patients for active disease.

Why Do We Worry About Testing for Hepatitis C in High-Risk Patients?

We worry because about 80% to 90% of patients who acquire acute hepatitis C infection fail to clear the virus. After 6 months from the time of exposure, if they still have virus in their system, they are considered to have chronic hepatitis C with active disease. Over time, this may lead to increase in fibrosis of the liver, progression of liver disease to cirrhosis, and finally, decompensated cirrhosis (ascites, edema, hepatic encephalopathy, etc.), and death. This is in contradistinction to hepatitis B, where if they get infected as an adult, about 90% to 95% of patients successfully clear the virus (resolved hepatitis B infection).

Practicing obstetricians and health-care providers during and after pregnancy have a unique opportunity to screen high-risk patients for hepatitis C. Many times, this may be the only time when young ladies touch base with the health-care system. They may not have a primary care provider. This is even more true in patients who are poor, have no insurance, and where drug and alcohol usage is a daily occurrence.

Who Are High-Risk Patients?

The AASLD 2009 guidelines suggest that the following people are high risk for having hepatitis C infection and should be screened for hepatitis C [12]:

1. persons who have injected illicit drugs in the recent and remote past, including those who injected only once and do not consider themselves to be drug users,
2. persons with conditions associated with a high prevalence of HCV infection including
 - persons with HIV infection, persons with hemophilia who received clotting factor concentrates prior to 1987, persons who have ever been on hemodialysis, and persons with unexplained abnormal LFTs,
3. prior recipients of transfusions or organ transplants prior to July 1992 including
 - persons who were notified that they had received blood from a donor who later tested positive for HCV infection, persons who received a transfusion of blood or blood products, and persons who received an organ transplant,
4. children born to HCV-infected mothers,

5. health-care, emergency medical, and public safety workers after a needlestick injury or mucosal exposure to HCV-positive blood, and
6. current sexual partners of HCV-infected persons

How Do We Make the Diagnosis?

Over the last 10 years, we have made a remarkable improvement in the diagnostic sensitivity of assays to detect hepatitis C RNA virus. We can now detect virus level as low as 5IU/mL.

For high-risk patients, screening for chronic hepatitis C should begin with anti-HCV ELISA test (using the latest generation). A positive result suggests exposure to the virus in the past. The next test that should be done is HCV RNA PCR and a genotype. If PCR is positive, this implies that the patient has active chronic hepatitis C and should be referred to the appropriate specialist for consideration of treatment and education.

What Treatments Are Available Now?

Hepatitis C treatment has come a long way since it was discovered. The perception in the past was that you cannot cure hepatitis C. Now we have effective treatments, but unfortunately, cure rate is not 100%. On average, the quoted sustained virologic response (SVR; we think of this as cure) rate is about 50%, but this is an oversimplistic view. Many factors affect the SVR, including gender, race, obesity, concurrent liver disease, severity of liver disease, coinfection with HIV, on-treatment viral kinetics, genotype, compliance with therapy, and so on. The latest STAT-C drugs that are projected to come out in 2011 look promising in increasing the SVR.

What Does the Treatment Entail?

It involves a subcutaneous shot (peginterferon) every week and ribavirin pills twice a day. Treatment duration depends on prior treatment response, genotype of virus, viral kinetics during response, and so on and can range anywhere from 6 months to 12 months to 18 months. This will be determined by the specialist based on prior treatment response, on-treatment response, and other factors. Treatment may also be terminated early because of development of intolerable side effects, or development of life-threatening side effects, or if the patient is deemed a nonresponder to interferon therapy.

Who Are Good Candidates for Treatment?

The AASLD guidelines suggest that every patient who has chronic hepatitis C should be considered treatment candidates, unless there is contraindication. This includes patients in prisons and those who are on methadone therapy. We know that treatment can lead to SVR (i.e., the HCV RNA remains undetectable at 6 months after stopping therapy, i.e., cured). This will prevent the progression of liver disease to cirrhosis, translating into a decrease in morbidity and mortality.

Unfortunately, this therapy is neither suitable nor possible for everyone because of the severe and sometimes life-threatening side effects of interferon and ribavirin therapy. In addition, patients with certain preexisting medical conditions are not suitable candidates for treatment. Cost can be an issue. Also treatment requires the ability and willingness to take the medications faithfully, because SVR will be affected by

lack of compliance. They need to be able to show up regularly for appointments for monitoring.

Treatment with Regard to Pregnant Patients?

Hepatitis C treatment is contraindicated during pregnancy. Pegylated interferon is a pregnancy category C drug, and ribavirin is a pregnancy category X drug. It is important that the patient be referred to see a specialist so that they can be followed up postpartum for possible treatment in the future.

In addition, she should be educated on the mode of transmission for hepatitis C and abstinence from alcohol, tested for other sexually transmitted diseases, and advised to get her partners tested [12].

During hepatitis C treatment, patients are not allowed to get pregnant. It is recommended that they use two forms of contraception. I do not treat any patients who are unable or unwilling to comply with this. The package insert for pegylated interferon recommends that patients do not get pregnant until 6 months post therapy. Practically speaking, if patients are very worried about their hepatitis C, and would like to get treated first before getting pregnant, this will usually mean a delay of 1 to 2 years depending on how they respond to therapy.

Another frequently asked question is whether they should get treated first before pregnancy? This will depend on the age of the patient, the severity of liver disease, patient's preference, and urgency of getting pregnant and is best discussed with the specialist.

It is important to note that treatment with interferon can cause or exacerbate preexisting depression. In addition, treatment is contraindicated when she develops postpartum depression.

Please bear in mind that patients who are not treatment candidates now may become suitable candidates later in time and, therefore, the importance of referring to specialists for follow-up.

Transmission of Hepatitis C to Infants

Hepatitis C is primarily transmitted by parenteral exposure to blood and blood products from HCV-infected persons. This used to be the most common cause of hepatitis C infection in infants and children, until we developed ways to screen for hepatitis C in blood. Now, vertical transmission is mainly responsible for infection in newborn infants. It is important to identify these infants because the majority of these patients will remain chronically infected with hepatitis C, hence the potential to develop chronic liver disease.

The rate of vertical transmission of hepatitis C is estimated to be 5%. This number is reported to be higher in the 10% to 15% range in HIV–hepatitis C coinfecting patients [13].

Numerous studies have suggested that the vertical risk of transmission for hepatitis C is increased in the following setting:

1. HIV–hepatitis C coinfection.
2. HCV viremia—mothers with positive virus load have increased risk of transmission, compared with mothers with undetectable viral load (suggesting resolved infection). The overwhelming majority of infants with HCV infection have mothers with positive hepatitis C virus in the blood.

3. Prolonged rupture of membrane for more than 6 hours has been associated with increased risk of perinatal transmission.
4. Obstetric procedures and intrapartum exposure to maternal blood infected by HCV—Steininger et al. have shown that invasive monitoring of fetus with scalp electrode increases the risk of transmission [14].

What Can We Do to Decrease the Risk of Transmission to the Infant?

Unlike hepatitis B, no effective intervention has been identified so far to decrease the risk of transmission of HCV to infants. There have been many studies looking to see if C-section will decrease the risk compared with vaginal delivery. Most of the studies suggest that the risk of perinatal transmission is not altered. The Cochrane Collaboration (Issue 2 2009) has published a review on this topic [15]. The authors suggest that there is no good evidence to support using C-section for reducing mother-to-baby transmission of hepatitis C during labor and birth.

To the mother-to-be who is absolutely horrified by the idea of hepatitis C transmission to their newborn, a case could be made to treat their hepatitis C first prior to getting pregnant, because we know that the risk of hepatitis C transmission is much less in a patient who has no detectable virus in the blood versus active hepatitis C infection with high viral load. They must be made to understand that this will delay pregnancy anywhere from 1 to 2 years (see above discussion).

Testing for Hepatitis C in Infants

The antibodies from the mother have been found to be in the infants even though the infants are not infected; therefore, finding positive HCV antibodies in the newly born infant means very little. Antibodies have been tested positive in infants as late as 15 months old [16].

The NIH consensus statement in 2002 suggested the following for diagnosis of perinatal infections [17]:

1. infants born to HCV-positive mothers should be tested for HCV infection by HCV RNA tests on two occasions between the ages of 2 and 6 months and/or
2. have tests for anti-HCV after 15 months of age.

Breast-Feeding in Hepatitis C Patients

Hepatitis C has been found in low levels in breast milk of HCV RNA–positive mothers. Multiple studies have not shown an increased risk of vertical transmission via breast-feeding.

Large cohorts of mothers infected with HCV suggest that in the absence of damaged, cracked, or bleeding nipples, breast-feeding can be performed safely without increasing the risk of transmission to the infant.

CDC currently (October 2009) suggests that it is safe for mother infected with HCV to breast-feed unless she has a cracked or bleeding nipple.

Summary

Hepatitis C is a common disease in high-risk patients. They should be screened for hepatitis C, even though there is no

known intervention to decrease the risk of hepatitis C from mother to infant. Pregnant patients are not candidates for treatment with interferon and ribavirin. They should be referred to specialist to determine whether they may be candidates for hepatitis C treatment in the future. Education should be provided regarding public health–related issues, including mode of transmission of hepatitis C, avoidance of alcohol, vaccinations for hepatitis A and B if appropriate, and testing of sexual partners. It is fine to breast-feed the infant unless the nipples are cracked or bleeding.

HEPATITIS E

Clinically apparent acute hepatitis E is uncommon in the United States. A brief mention will be made here, because of its severity when acquired during pregnancy.

Hepatitis E causes acute hepatitis, just like hepatitis A. It is predominantly transmitted via the fecal–oral route, but less frequent mode of transmission has also been reported (ingestion of raw or undercooked shellfish, infrequently by blood products or blood transfusion).

Hepatitis E usually causes a self-limited acute hepatitis in men and nonpregnant females. However, HEV in pregnant females can result in fulminant hepatic failure, especially in the last trimester, resulting in death in as high as 25% of patients [18]. This is especially prominent in particular geographic areas in India.

This infection should be in the differential diagnosis of any female patient with a travel history to endemic areas, who presents with acute hepatitis. Vaccines for hepatitis E are not yet commercially available. Treatment remains supportive. It is best to educate pregnant patients who will travel to endemic areas (i.e., Asia, Africa, Middle East, and Central America) to avoid uncooked shellfish, avoid water that is not boiled, and avoid uncooked fruits and vegetables.

ADDENDUM

Since the writing of this chapter, 2 new drugs (telaprevir and boceprevir) have been approved by the FDA for the treatment of hepatitis C genotype 1. They significantly improve the cure rate for hepatitis C treatment. However, these protease inhibitors must be used together with peg-interferon and ribavirin, which means that they cannot be used for pregnant patients. All the discussion for the treatment of hepatitis C in pregnant patients still applies. Those interested to read more may refer to the AASLD 2011 Hepatitis C Treatment Guidelines.

ACKNOWLEDGMENTS

I would like to acknowledge the help of Jessica Wynn, MD, Internal Medicine Resident PGY2, University of Missouri, Columbia, Missouri, in preparing the section on *hepatitis E* in this chapter.

81 Toxoplasmosis

Edward R. Newton

INTRODUCTION

Although toxoplasma encephalitis (1) has gained worldwide recognition as a major cause of death and morbidity in immunodeficient individuals, especially those with acquired immunodeficiency syndrome (AIDS), the fetus and child remain the major victims of toxoplasmic infection. Approximately 4000 pregnant women per year in the United States are infected with *Toxoplasma gondii* and 10% to 60% of their fetuses will be infected. Although the majority (>90%) appear asymptomatic at birth, long-term studies suggest that a significant proportion (20–40%) will demonstrate defects consistent with chronic toxoplasmosis. These defects include chorioretinitis (most common), hydrocephalus, deafness, and mental retardation. Unfortunately, problems in primary prevention, diagnosis, treatment, and follow-up limit the effectiveness of intervention programs.

Biology

T. gondii is an ubiquitous coccidian whose effects are felt in many animals in addition to humans (Table 1) (2). Toxoplasmosis is a member of the phylum Apicomplexa, similar to malaria and cryptosporidia. Much of its life cycle is spent as an obligate intracellular parasite. There appear to be three distinct clonal genotypes with different human virulence; type II accounts for the majority of maternal to fetal infections (85–95%); 5% to 15% are caused by clonal type I.

The organism has three distinct forms: sporozoites within an oocyst, and tachyzoites (also called endozoites or trophozoites) and bradyzoites (or cystozoites) within a tissue cyst. The life cycle of *T. gondii* is outlined in Figure 1. Members of the cat family, Felidae, are the only known definitive hosts. The sexual reproductive cycle occurs in the villi of the cat ileum. The time from primary inoculation to oocyst appearance in the feces varies by the mode of primary infection: ingestion of tissue cysts (chronic infection in prey animals), 3 to 5 days; ingestion of fecal oocysts, 20 to 24 days; or ingestion of tachyzoites, 7 to 10 days. Oocysts are shed for 1 to 3 weeks with peak production between 5 and 8 days (4,5). Millions of oocysts are shed in a single day. Most cats are infected primarily between 6 and 12 weeks of age (6), corresponding to weaning and the development of hunting skills. Once a cat has been infected, its immune system severely curtails or eliminates future oocyst production. The previously infected cat may be a safer pet than curtailing the behavior of a seronegative cat.

After excretion with feces, the zygote within the oocysts ($13 \times 11 \mu\text{m}$) undergoes sporulation. The zygote divides into two sporoblasts that form two sporocysts within the larger oocyst. Each sporoblast undergoes two divisions to produce four sporozoites ($8 \times 3 \mu\text{m}$). Ultimately each oocyst contains eight infectious sporozoites. Sporulation takes 1 to 21 days

(average, 3–4 days), depending upon temperature, moisture, and oxygenation. The oocysts can remain infectious for months (4,5).

After elimination and within the 2 to 4 days prior to sporulation, the fecal oocysts are not infectious (4,5,7). As a result, human infection from direct contact with a shedding cat is unusual. The major role of cats in human toxoplasmosis is to pollute transiently the environment with massive numbers of oocysts that may remain infectious for months or years. A small coastal community in California contained 7284 owned cats and 2046 feral cats. Forty-four percent of the owned cats defecated outside >75% of the time. The annual fecal deposition of owned cats amounted to 76.4 tons (wet weight); the feral cats contributed about 29.5 tons of feces annually to the environment (8). In one estuarine in Northern California, degradation of the wetlands and runoff from nearby communities may have played a major role in the die-off of sea otters from a toxoplasmosis epidemic (9). Global warming and environmental degradation may increase the incidence of human infections with toxoplasmosis in northern Europe (10, 11). In northern Poland, about 18% of sand pits or sand heaps in three cities contained toxoplasma DNA, which was identified by PCR (12).

The potential public health implications are concerning. The likelihood of human toxoplasmosis is related to environmental conditions that enhance or reduce oocyst survival, the prevalence of feline toxoplasmosis within that region, and culinary habits of the at-risk population. There have been several studies looking at sources of toxoplasma infection in pregnant women (13–15). All three studies demonstrated the same risk factors for toxoplasmosis infection: consumption of under-cooked meat or game, contact with soil (poor hand hygiene), consumption of poorly cleansed raw vegetables (poor kitchen hygiene), poor cleansing of meat preparation utensils or surfaces (poor kitchen hygiene), and changing the litter box of the pet cat. The odds ratio exceeded 3.0 with all risk factors. Consumption of undercooked meats (50%), soil exposure (18%), and work with animals (5%) accounted for the major of maternal to fetal transmission of toxoplasma.

Higher rates of seropositivity to toxoplasmosis among pregnant women are associated with warm, moist climates: central Africa, 81%; Lisbon Portugal, 64%; Riyadh and Saudi Arabia, 30%; western Scotland, 13%; and Norway, 10% (16). In the United States, the age-adjusted seroprevalence rate was northeast, 29%; south, 23%; Midwest, 21%; and West, 18% (3). These observations are supported by experimental data concerning oocyst survival related to humidity and temperature. Oocysts remain infectious for at least 17 months in water, at least 32 days in 100% relative humidity (at 22–26°C), and 11 days at 37% relative humidity and lose their ability to infect at less than 19% relative humidity and when the moisture content of feces drops to 0% to 1% (17,18). Ambient

temperatures affect both sporulation (infectivity) and survival of the oocysts. Unless combined with low relative humidity (<20%), extremes in environmental temperature will not completely eliminate *T. gondii* from contaminated soil.

Survival and infectivity of sporulated oocysts after application of various cleaning agents have been examined experimentally by Frenkel and Dubey (5). High concentrations of ammonia (33%) and iodine (7%) killed all oocysts within 30 minutes, whereas ammonia (1.7%) and iodine (20%) were

no more effective than drying alone. Household ammonia (4–6%) requires more than 60 minutes of exposure to sterilize cat feces. Smaller particles of fecal matter (empty, uncleaned litter pan) exposed to water heated to boiling and poured into the pan (75–80°C) are sterilized rapidly.

Despite strong experimental evidence, a direct relationship between oocyst shedding and human toxoplasmosis is not clear from epidemiologic studies. Although 14% to 50% of cats in the United States are seropositive, oocysts are found in the feces of less than 1% of cats examined, perhaps due to the limited age range and short duration (1–3 weeks) of oocyst shedding (19,20). Likewise, the presence of oocysts in the soil correlates poorly with seropositivity in humans (19,20). Additionally, serologic studies of veterinarians and cat owners do not support a strong relationship between a long, intensive exposure to cats and a greater risk of acute toxoplasmosis (21–23). Indeed, persons who report no contact with cats have seropositivity rates of 5% to 40% (21–23).

The latter discrepant information raises questions concerning the role of direct contact with cats and acute toxoplasmosis and our present methods of ascertaining the association. The correlation between seropositivity and house cats may be too crude to reveal a relationship. Studies limited to exposure to sick, young, or feral cats may identify a relationship.

On the other hand, oocysts may be so widely distributed in the environment and direct contact with a cat that is shedding oocysts is so rare that the risk of acute toxoplasmosis through oocysts is a function of age and nonspecific contact, such as outdoor gardening, culinary habits, food preparation, presence of insect vectors, and personal hygiene.

Table 1 Seroprevalences of *Toxoplasma gondii* Among Various Animals in Developed Countries (2)

Animal	Seroprevalence
Cattle	15–50%
Fattening pigs (intensive farming)	1–31%
Pigs	1–21%
Chickens	6–9%
Sheep	16–40%
Goats	19–47%
Horses	1–17%
Dogs	25–40%
Rabbits	6–20%
Pet cats	22–68%
Feral or stray cats	33–68%
Wild turkeys (United States)	17%
Wild horses	16–37%
Deer	30–70%
Moose	15%
Bears (United States)	30–80%
Human (United States) (3)	18–29%

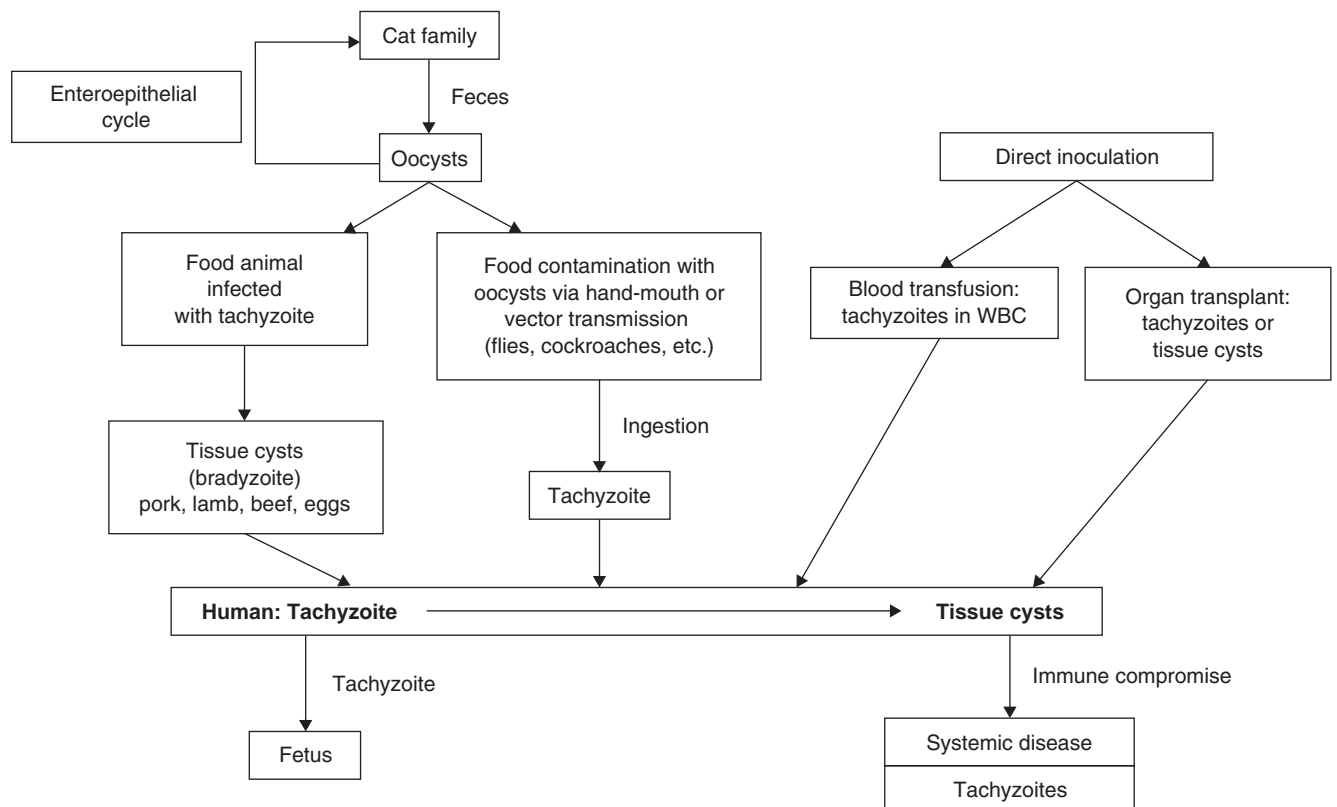

Figure 1 Life cycle of *Toxoplasma gondii*.

The tachyzoite form of the parasite is seen in the acute stage of the infection. Tachyzoites result from ingestion of oocysts, that is, food contamination or tissue cysts (brachyzoites/cystozoites), that is, infected food source. The liberated parasites can survive for 1 to 3 hours in pepsin–hydrochloric acid (stomach fluid) and 4 to 6 hours in trypsin (intestinal fluid)—enough time for transmural migration into the host. The tachyzoites are spread hematogenously and can be identified by Wright's or Giemsa's stains. Every cell type is susceptible to penetration.

The tachyzoite requires an intracellular habitat to survive. The intracellular, intravascular tachyzoite undergoes multiplication, endodyogeny, every 4 to 6 hours to form rosettes. These intracellular collections (tissue cysts) vary in size, but may contain as many as 3000 organisms and are 200 μm in size. Rupture of the host cell results in continuing infection and tissue destruction. As the host develops an immune response to the parasite, parasitemia and systemic infection with tachyzoites decrease. In their "protected" intracellular cysts, the tachyzoites evolve into brachyzoites (cystozoites).

The latent or chronic stage is manifested by tissue cysts in most organs. The brain, skeletal muscle, cardiac muscle, and placenta are the most common sites for tissue cysts, which may be identified by periodic acid-Schiff stain. Recurrent parasitemia is rare in immunocompetent individuals. However, under immunodepressed states, especially AIDS, the cysts may reactivate and cause parasitemia and tissue destruction.

The ingestion of tissue cysts in undercooked or uncooked meat is an important source of infection in the United States. Serologic evidence of past infection and potential for tissue cyst inoculation (2,24,25) is present in 15% of cattle, 15% of sheep, 30% of pigs, and 43% of goats. The reported frequency of tissue cysts in common cuts of meat is less frequent: fresh beef, less than 1%; lamb, 5%; mutton, 10%; and pork, 30% (2,24,25). However, these studies are based on older studies and may underestimate the risk. The selected samples used were too few and too small to estimate the prevalence accurately. It is also probable that modern farming techniques, intensive pen raising, and processed commercial feed reduce the risk. However, the recent movement back to local sources of meat, "reducing your carbon footprint," may lead to more beef, pork, lamb, or chicken that has been exposed to the barnyard cat and its feces.

There is clear evidence to support the relationship between infected meat ingestion and acute toxoplasmosis. Butchers and meat handlers have a higher seropositivity rate than does the general population, through oral ingestion or inoculation of open wounds. In 1965, Desmonts (26) reported a definitive study supporting the meat-to-human hypothesis. Seroconversion rates rose in response to adding undercooked mutton (as a part of therapy) to the diets of children in a French sanitarium. More recently, acute toxoplasmosis was associated with ingestion of undercooked hamburger (27).

Experimental data suggest that attention to food preparation will reduce transmission of tissue cysts. Cleansing food preparation surfaces and utensils with warm soapy water after meat preparation will limit contamination of other foodstuffs. Salting (2% NaCl/liter for 24 hours), drying (24 hours at 18–20°C), freezing (–15°C for 12–24 hours), or heating (to 60°C for 15–20 minutes) sterilizes the meat (28).

Clinical Presentations

Acute Infection

Toxoplasmosis is asymptomatic or very mild (lymphadenopathy and/or fatigue) in 80% of immunocompetent individuals. Cervical, suboccipital, supraclavicular, axillary, or inquired lymph nodes are commonly enlarged. An enlarged single posterior cervical node is highly suspicious. In cases associated with a virulent strain of *T. gondii* or in cases associated with immunosuppressive therapy, AIDS or congenital immunodeficiency syndromes or an immature fetus, clinical signs, or symptoms are present in 30% to 100% of infections.

The clinical syndrome in presumably immunocompetent individuals is best described by an epidemic related to oocyst exposure in a riding stable (29). Of 37 patients with serologically proven toxoplasmosis, 80% had fever, headache, and lymphadenopathy (flu-like syndrome). Myalgia, stiff neck, and anorexia were associated with 50% to 70% of patients. Additionally, arthralgia, rash, mental confusion, and hepatitis were more common than controls. Interestingly, only 3/25 (12%) of patients were correctly diagnosed by their physicians. The combination of lymphadenopathy, fatigue, malaise, atypical lymphocytosis, and/or occasional liver/spleen involvement is similar to mononucleosis or Epstein–Barr infections.

The clinical challenge is to differentiate the nonspecific symptoms of acute toxoplasmosis infection from the symptoms of pregnancy or common viral infections. An interesting study by the U.S. multicentered Toxoplasmosis Study Group (30) performed a detailed interview on 131 mothers of infants with proven congenital toxoplasmosis. Recognizing a serious recall bias, these women reported fever or night sweats (27%), flu-like illness or myalgia (26%), headache (11%), or any "infectious illness" (48%). Importantly, 52% reported no maternal illnesses. Similarly, 35% reported no cat or cat litter exposure and 50% reported no exposure to undercooked meat or poor meat preparation hygiene. In a combined fashion, only 48% had exposure to cat litter, undercooked meat, or toxoplasmosis-like illness during pregnancy. These findings suggest that more than 50% of patients may not be amenable to serologic screening based on risk factors or symptoms.

In immunocompromised patients (AIDS, cancer therapy, transplant patients), reactivation of tissue cysts from prior infection leads to local tissue destruction and, ultimately, systemic parasitemia. As the central nervous system is a common site for tissue cysts, the clinical manifestations include central nervous system abscesses, encephalitis, cognitive impairment, headache, and chorioretinitis. Toxoplasma encephalitis occurs in 30% to 40% of AIDS patients (31).

Most pregnant women are immunocompetent, and clinical expression of the infection ("flu" or lymphadenopathy) is mild and occurs in a minority (5–15%). Serologic evidence of maternal infection varies by maternal age and locale (15,32). The age-related incidence is 20% at less than 25 years, 23% at 26 to 35 years, and 35% at greater than 36 years old. Warm, moist climates have high seropositivity rates (40–60%) and cold, dry climates have much lower rates (10–20%). These observations support the theory that toxoplasmosis is related to the ubiquitous distribution of infectious oocysts and/or food contamination with tissue cysts.

Between 45% and 87% of women will be seronegative and at risk for primary infection during pregnancy. Between 0.5% and 2.3% of pregnant women will be described as being at high risk for fetal infection (probable maternal infection) as indicated by maternal seroconversion. Of these, 5% to 18% demonstrates fetal infection documented by neonatal signs or symptoms and/or positive neonatal *T. gondii*-specific IgM titers.

In a study by Zadik et al. (33), the rate of primary infection with toxoplasma was assessed by seroconversion. In that study, 1621 women had paired serum more than 500 days apart. Primary infection was determined by seroconversion alone. In 160 patients (9.9%), initial titers were positive. Only one seroconversion was detected in 2966 women years. The projected rate for primary infections was 0.23 (95% CI 0.0059–1.3) per 1000 pregnancies. This rate of maternal infection is much lower than predicted by combined serologic methods (i.e., high titer, rising titer, etc.). On the other hand, the neonatal infection rate may be higher as it is a primary infection and true infection is better defined.

While standard in vitro tests have shown little, if any, difference in humoral or cellular immunity between pregnant and nonpregnant women, later infection by certain organisms (i.e., varicella, human papilloma virus) may be reactivated during pregnancy. The combination of latent human immunodeficiency virus (or organ transplantation with immunosuppression), latent toxoplasmosis, and pregnancy often leads to maternal and fetal concerns of reactivation of the toxoplasmosis. In AIDS patients, reactivation usually occurs with CD₄ counts <100 cells/mm³. It appears that pregnant women have no greater risk than that defined by low CD₄ counts. Among 48 pregnant women receiving immunosuppressive therapy after organ transplantation, no cerebral toxoplasmosis was recorded. Among 105 HIV-positive women, only one case of cerebral toxoplasmosis occurred with a CD₄ count of 20 cells/mm² (30). Prophylactic treatment to prevent maternal reactivation and vertical transmission is not indicated for CD₄ counts >100 cells/mm³. At CD₄ counts under 100 cells/mm³, the risk is still small, but prophylaxis may be justified, although benefit is not proven. These observations raise a serious question of whether reactivation of latent toxoplasmosis actually occurs in immunocompetent pregnancies. Seroconversion, rather than high or rising titers, may be the major serologic marker for fetal infection.

Experimental infection of rhesus monkeys showed that transmission of *T. gondii* occurred in four of nine (44%) in second-trimester maternal infections and three of nine (33%) in the third trimester (34). Another four fetuses of mothers infected in the third trimester were probably infected, but the organism could not be isolated. The overall infection rate was 61%. Likewise, pregnant cats were orally inoculated with *T. gondii* (17). Among 8 animals euthanized at 10 or 31 days post-inoculation, 7 of 33 (21%) fetuses from all litters had *T. gondii* isolated. Eight additional pregnant cats were allowed to reach parturition and nurse their kittens. Of 40 kittens from all eight litters, 26 (65%) had *T. gondii* isolated from tissues; 25 of 26 kittens were severely ill by 24 days of life. It is apparent that in susceptible species (cats, rhesus monkeys, and man), the rate of intrauterine fetal infection is 40% to 70%.

Fetal infection is a combination of acute and persistent infection due to relative immune incompetence and reduced passive IgG transfer from the mother. Prior to 30 weeks of gestation, the fetal immune system is of little help; IgM, IgG, and cellular responses are limited and functionally immature (35). For example, in proven cases of in utero infection with toxoplasmosis in the first trimester, funicentesis at 20 to 24 weeks demonstrated four out of nine with toxoplasma-specific IgM (36). Placental transfer of maternal IgG is limited by gestational age and target antigen. Immunoglobulin G transport has been noted by 8 weeks, but remains less than 100mg/dL until 20 weeks. Subsequently, the fetal levels of maternal IgG rise until they are greater than maternal levels.

Acute fetal toxoplasmosis results from initial placental involvement and subsequent systemic fetal parasitemia and infection. The most consistent histologic placental finding is chronic inflammation in the decidua capsularis and focal reaction in the villi. Tissue cysts as well as tachyzoites may be seen. Systemic involvement results in splenomegaly, hepatomegaly, jaundice, anemia, thrombocytopenia, chorioretinitis, and encephalitis. Persistent infection due to limited immune response leads to extramedullary hematopoiesis in the liver and decreased plasma protein production. When coupled with cardiac involvement, nonimmune hydrops may result. Widespread tissue destruction manifests as clinically apparent growth restriction. The most characteristic damage in the central nervous system is extensive necrosis of brain parenchyma secondary to vasculitis; microcephaly is a common sequela. Periventricular and periaqueductal vasculitis is common in toxoplasmosis. Subsequent calcification of these areas is apparent on roentgenographic or ultrasonographic examinations. Obstruction of the aqueduct and/or meningeal involvement leads to hydrocephalus. Chorioretinitis may be present at birth or may develop in the first two decades after birth through recrudescence or persistence of the disease.

Table 2 describes the incidence of organ system involvement in 210 of congenitally infected neonates who were followed prospectively for 1 year (37). Twenty-one (10%) of the infants (including one death) had severe congenital toxoplasmosis

Table 2 Neonatal Toxoplasmosis (*n* = 210)

Prematurity (≤ 2500 g)	4%
Intrauterine growth restriction	6%
Jaundice	10%
Hepatosplenomegaly	4%
Thrombocytopenia	2%
Anemia	4%
Eosinophilia	2%
Microcephaly	5%
Hydrocephalus	4%
Hypotonia	6%
Seizures	4%
Psychomotor retardation	5%
Intracranial calcifications	11%
Abnormal cerebrospinal fluid	35%
Micro-ophthalmia	3%
Bilateral chorioretinitis	6%
Unilateral chorioretinitis	16%
Normal	55%

with central nervous system involvement. Seventy-one (34%) had a normal clinical exam except for peripheral retinal scarring or isolated asymptomatic intracranial calcifications. One hundred and sixteen (55%) were normal. Caution should be exercised when evaluating the incidence of injury. Most series are populations of referred neonates and represent a population with more clinically apparent diseases. Unless all pregnant women and neonates are screened and all infected neonates are systematically examined, the risk is lower than that published. In addition, women countries, which use universal screening to identify maternal seroconversion and use amniocentesis and PCR to identify fetal infection, are more likely to initiate antibiotic therapy after a significant percentage of women (about 40%) chose to abort (38). Antibiotic therapy may modify (lower) the incidence of severe disease at birth. In the latter study, 58 of 76 (77%) had asymptomatic infection after 84% received antibiotics prior to amniocentesis.

The timing of acute fetal toxoplasmosis greatly affects the sequelae (39) (Table 3). When it occurs early in gestation, especially prior to 13 weeks, the infection is more widespread and destructive. At 11 to 13 weeks, the fetal immune system begins to identify antigens as “self” or “non-self.” Toxoplasma antigens that are incorporated into fetal tissue may be misrecognized as “self” and harder to eliminate. In addition, the continuing immaturity of the fetal immune system and limited active transfer of toxoplasma-specific maternal IgG prior to 25 weeks poorly control the infection. Additionally, immune “protected” location, the central nervous system, and inner eye allow the organisms to avoid host responses.

Chronic Infection

Early reports of follow-up indicated that children with clinically apparent disease at birth had a poor prognosis: mental retardation, 93%; seizures, 81%; spasticity or palsies, 70%; impaired vision, 61%; hydrocephalus or microcephaly, 32%; deafness, 15%; and normal, 11% (40). Fortunately, many infants with congenital toxoplasmosis are completely normal at birth (40–55%). The prognosis in mildly affected or asymptomatic infection appears to be much better (Table 2).

A continued risk of damage is apparent in 20-year follow-up of congenitally infected children and in epidemiologic studies. Koppe et al. (41) followed 11 children for 20 years. One of five asymptomatic and treated infants and four of six (two with severe disabilities) symptomatic infants developed new chorioretinitis by 20 years. Wilson et al. (42) followed 23 children with subclinical infections at birth for 1.25 to 17.25 years. Of 23 children, 19 (83%) had one or more episodes of chorioretinitis, 11 (48%) had unilateral or bilateral

blindness, and 12 (53%) had a new diagnosis of central nervous system disorders. Sever et al. (32) performed a multivariate analysis of 22,845 patients in whom toxoplasmosis titers were correlated with poor outcomes during a standardized exam at 7 years of age. The results were controlled for race, maternal age, and socioeconomic index. Visual impairment, microcephaly, coordination problems, right and left identification, and soft neurologic signs correlated with toxoplasmosis titer. Bilateral deafness, extraocular movement, and IQ <70 correlated with the interaction variable, toxoplasmosis titer × maternal age.

A 20-year prospective study (1985–2005) of 676 pregnancies and 681 etuses gives more reassuring outcomes than prior data (43). Mothers who were IgG seronegative were followed with monthly serology. Antenatal therapy with spiramycin 9×10^6 SI units per day was initiated at recognition of maternal IgG seroconversion until an amniocentesis (4 weeks later) was performed to identify fetal infections by PCR. After definitive diagnosis of fetal infection, a regimen of sulfadoxine (1000mg/wk), pyrimethamine 950mg/week, and folinic acid 50mg/week was initiated until delivery. The same regimen was used in pediatric doses until 2 years of age. They reported that 17% (112 of 666) live borns had congenital toxoplasmosis after maternal seroconversion during pregnancy (monthly IgG serology). Of these, 74% were asymptomatic, 1.5% had severe manifestations at birth, and 26% were diagnosed with chorioretinitis; 6 of 28 infants with chorioretinitis had macular disease (unilateral). Two children had additional neurologic issues, seizures, and psychomotor delay. The partial improvement in outcomes from earlier data suggests a benefit to early recognition for fetal infection and fetal therapy.

Diagnosis

Behavioral Screening

Ideally, all women who are at risk for pregnancy or are trying to get pregnant need assessment and education concerning the risk of toxoplasmosis during pregnancy, that is, preconceptional counseling. Each woman should be asked about her ongoing exposures to potentially contaminated soil or water, cat exposures, kitchen and personal hygiene, and predilection to eating and undercooked meats or game. In high-risk women (any positive response), a preconceptional measurement of toxoplasma-specific IgG will identify potential risk of fetal infection during a subsequent pregnancy. If the toxoplasmosis-specific IgG is positive, then the risk of fetal toxoplasmosis is very small in an immunocompetent individual. If patient is seronegative, a program of primary prevention education is critical (Table 5). During pregnancy, monthly serology will be

Table 3 Time of Maternal Infection and the Frequency of Fetal Infection

	Time of maternal infection		
	First trimester <i>n</i> = 126	Second trimester <i>n</i> = 246	Third trimester <i>n</i> = 128
No infection	86%	71%	41%
Perinatal death	5%	2%	0%
Fetal infection	9%	27%	59%
Severe	6%	2%	0%
Mild	1%	5%	6%
Subclinical	2%	20%	53%

helpful in the early identification of fetal infection and initiation of antibiotics.

Serologic Screening

Maternal antibody response is normal to a toxoplasmosis infection; IgM appears first and rises sharply for 1 to 2 weeks and is sustained for 4 to 6 months (IgM-IFA) or 6 to 12 months (or years) when measured by more sensitive methods [double-sandwiched IgM enzyme-linked immunosorbent assay (IgM-ELISA)]. After the start of the increase in IgM, IgG rises slowly for 1 to 3 weeks (2–50 IU/mL, 1:10–1:200). Between 3 and 6 weeks, IgG antibodies rise sharply to >400 IU/mL or titers >1:1000. In 2% to 4%, the titers are >1:4000 [indirect hemagglutination test (IHA)] and persist at high levels for years. Again, IgG tests vary in their sensitivity.

The majority of infected pregnant women are asymptomatic, and a combination of testing for immunoglobulin G (IgG), M (IgM), and IgA antibodies is used to diagnose toxoplasmosis. These tests include the Sabin-Feldman dye test (dye test), complement fixation, IHA, indirect fluorescence antibody test (IFA), agglutination test, double-sandwiched IgM-ELISA, and the IgM immunosorbent agglutination assay (IgM-ISAGA).

Although the Sabin-Feldman (dye test) is the time-honored gold standard, its technical complexity (mouse inoculation and observation of a biologic response) limits application outside of research settings. In the IHA test, red blood cells tagged with toxoplasma antigen agglutinate when exposed to serum containing IgG and IgM antibodies to toxoplasma. This response occurs several months after an infection. As a result, as many as 50% of infants with fetal infection will have negative IHA in the first 6 months of life. Complement fixing antibodies appear later than dye test antibodies and, depending on the antigen employed, the results vary. The agglutination test uses parasites fixed in formalin and is very sensitive to IgM antibodies. Nonspecific agglutination may occur due to “naturally” occurring IgM (in mothers negative for toxoplasma-specific IgG and IgM antibodies). Unless the laboratory corrects for these antibodies, false positives can occur. The IFA test uses slide preparations of fixed toxoplasma that are washed with the patient’s serum at different dilutions and cross-reacted with fluorescein-tagged antiserum prepared against IgG (anti-IgG). Although the IFA test is equal to the dye test in specificity, patients with connective tissue disorders, that is, positive rheumatoid factor, may test false positive. Positive tests should be confirmed with a dye or IHA test.

The IgM titer is measured in three ways: IgM-indirect fluorescent antibody (IgM-IFA), IgM-ELISA, and IgM-ISAGA. IgM-IFA relies on antiserum specific to IgM. A titer >1:160 is diagnostic of an acute infection. If the antiserum cross-reacts with IgG, which is true of some testing kits, the results may be false positive. Additional problems include an inhibitory effect of high maternal IgG titers on fetal IgM titers and false positives created by autoimmune antibodies, that is, rheumatoid factor.

The conventional IgM-ELISA may also be false positive in patients with chronic infection or autoimmune disease. As a result, Naot et al. (44) developed a double-sandwiched IgM-ELISA. In a direct comparison with IgM-IFA in 55 serum samples from neonates with proven toxoplasmosis, the

double-sandwiched IgM-ELISA was more likely to be positive (81% vs. 25%) than was IgM-IFA.

The IgM-ISAGA combines the advantages of direct agglutination and double-sandwiched ELISA. The IgM-ISAGA does not use an enzyme conjugate and avoids cross-reactivity with rheumatic factor. It is more sensitive than the IgM-IFA or the IgM-ELISA and will be positive 1 to 2 weeks earlier than the latter tests.

Continual improvement in the specificity and sensitivity of toxoplasma-specific IgM testing has muted its usefulness. The more sensitive the test, the less likely it is to narrow the time of the maternal infection if preconceptual Toxoplasmosis IgG testing has not been performed. In the latter situation, the timing is critical. The earlier the infection, especially prior to 14 weeks, the less likely fetal infection has occurred, but it is more likely that severe disease will be manifest at birth. Diagnosis of fetal infection prior to 20 weeks allows the mother a more educated choice whether to carry or abort the pregnancy. In addition, earlier therapy may improve the efficacy of antibiotic therapy.

Commercial testing, the avenue for most clinicians in the United States, can create confusing and difficult decisions (45). The laboratory testing companies are most interested in producing a reliable result with the largest profit margin. Unless the laboratory pre-absorbs the naturally occurring anti-IgG IgM (rheumatoid factor), false positive, low levels of IgM are identified and reported. This occurs more often when the IgG is very high. Overreading the results may create enough concern by the mother to terminate her pregnancy when no fetal infection is present; one study suggests this occurs in 17.5% of women misinformed about the risk of infection (46). Retesting the same serum using different IgM methodologies and identifying other elevated immunoglobulins (IgA, IgE), an abnormal differential agglutination test, or low IgG avidity can identify true positives and reduce the risk of abortion to 0.4% (47). Most commercial laboratories do not save the serum and are reluctant or are inexperienced in the performance of confirmatory testing. The American College of Obstetricians and Gynecologists and the Centers for Disease Control and Prevention recommend contacting a reference laboratory prior to an intervention as a result of the primary serologic screening test. Other useful contact information includes reference laboratory for serology, isolation, and PCR assay (650-853-4828), Congenital Toxoplasmosis Study Group (U.S.), and Educational information on the Internet www.toxoplasmosis.org.

Seroconversion of IgG in a prior seronegative provides unequivocal evidence of infection occurring in the period of time between the two tests. However, most women become pregnant without knowledge of their antibody status and diagnosis must rely on a skilled and experienced interpretation of positive IgG serology, a positive IgM serology, rising antibody titers, or, occasionally, persistent, high titers. Unfortunately, the numerous tests used to measure antibody response have considerable inter- and intra-test variability.

Fetal Diagnosis

The advent of sophisticated ultrasound diagnosis and invasive fetal testing (funicentesis/cordocentesis) has heralded new options in the diagnosis and management of toxoplasmosis. Although serologic testing may identify 0.5% to 2.5% of

pregnant women at high risk of fetal toxoplasmosis, fetal infection is not an absolute diagnosis without measurement of fetal immunologic response or demonstration of the organism. By using advanced ultrasound diagnosis and invasive fetal testing, 5% to 20% of maternal infections in the first 20 weeks of pregnancy and 40% to 80% in the second 20 weeks of pregnancy result in fetal infection. The rapid identification of the fetal infections is the best management.

High-resolution obstetric ultrasound has a role in screening and diagnosis of fetal infection. The fetal findings include ventriculomegaly, microcephaly, intracranial calcifications, increased placental thickness, parenchymal liver calcifications, fetal hydrops, ascites, hyperechoic bowel, and fetal growth restriction. The presence of any one or a combination of these findings in the presence of positive serology has a sensitivity of 49%, specificity of 99%, positive predictive value of 98%, and a negative predictive value of 89% (48). The unanticipated identification of these findings should initiate toxoplasma-specific IgG and IgM serology testing. If positive serology is positive, an amniocentesis for AF-PCR testing is warranted.

Access to fetal tissues (amniotic fluid, amniocytes, chorionic villi, or fetal blood) allows unequivocal fetal diagnosis. In utero fetal infection may be diagnosed through demonstration of toxoplasma antigens (parasites or DNA), fetal immune response (IgM), or physical or laboratory evidence of fetal infection. Inoculation of mice or tissue cultures with fetal specimens is 50% to 70% sensitive in documenting fetal infection. Polymerase chain reaction identification of toxoplasma DNA significantly reduces the time and laboratory requirements for antigen detection. However, adequate laboratory support is essential, but currently there is limited access and availability.

The demonstration of a fetal IgM through cordocentesis is limited by gestational age. Prior to 24 weeks, the upper age limit for abortion in the United States, less than half of fetuses, will mount an IgM response. Abnormal laboratory findings on fetal blood include elevated white cell count, eosinophil count, monocytes, gamma-glutamyl transpeptidase, and lactic dehydrogenase activity (Table 4) (36,49).

Isolation of the parasite from the mother or infant provides unequivocal proof of infection. The parasite (bradyzoite or tachyzoite) can be isolated from blood, muscle, brain,

amniotic fluid, or placental tissue through inoculation of mice or tissue culture. The frequency of isolation from the placenta varies by the trimester in which toxoplasmosis was acquired and untreated: first trimester, 25%; second trimester, 54%; third trimester, 65%; and overall, 50% (50). However, the placenta may be negative in the presence of a congenitally infected fetus. Parasitemia in infected newborns varies by clinical stage: acute/generalized, 71%; neurologic or ocular, 17%; and subclinical, 52% (51). When the diagnosis is attempted by funicentesis in the second trimester, the fetal blood is positive in 70% of cases (52). Overall (term and preterm), the amniotic fluid sediment will contain toxoplasma in 60% of samples from fetuses with congenital infection. Although isolation of the organism is a powerful investigational tool, it requires time and specialized laboratories not readily available to the practicing physician.

Molecular genetics has provided a powerful new tool in antigen identification, the polymerase chain reaction (PCR) (52,53). In 43 cases, PCR was compared with mouse inoculation (tissue/amniotic fluid cultures) and IgM-ISAGA (IgM immunosorbent agglutination) on fetal blood. PCR correctly diagnosed toxoplasmosis as positive in 8 out of 10 samples with no false-positive diagnosis. More recently, Hohlfeld et al. (52) compared a competitive PCR test of amniotic fluid with conventional diagnostic methods (ultrasonography, fetal blood sampling, and serologic diagnosis) in 339 women who had acquired toxoplasmosis during pregnancy (combined serologic diagnosis). Conventional methods identified 34 of 37 (sensitivity 89.7%) neonates with serologically or pathologically confirmed toxoplasmosis at birth. The PCR test identified 36 of 37 infants (sensitivity 97.4%). In a more recent analysis, real-time PCR was 92% sensitive and had a 98% negative predictive value in a study 377 mothers with seroconversion during pregnancy (54). The PCR test on amniotic fluid is now the standard method for the diagnosis of fetal toxoplasmosis.

Universal Screening

The frequency of maternal (0.8%) and fetal (0.32%) infection, the frequency of long-term disability after fetal infection (50–90%), and the cost of caring for those disabilities (\$80,000–\$150,000 per case) describe the potential benefits of a universal screening program. This potential benefit compares favorably

Table 4 Antenatal Diagnosis of Fetal Toxoplasma

	Daffos et al. (36)	Foulon et al. (49)	Total
Number of high-risk mothers	746	50	796
Fetal infection	42	6	48 (6%)
Diagnosed in utero	39/42	5/6	44/48 (92%)
Positive specific IgM	9/42	1/3	10/45 (22%)
Elevated total IgM	22/37	—	59%
Elevated WBC	16/39	—	41%
Eosinophilia	8/33	2/3	10/36 (28%)
Elevated LDH	7/35	3/3	10/38 (26%)
Elevated GGT	24/34	3/3	27/36 (75%)
Abnormal ultrasound: ascites	2/42	0/3	2/45 (4%)
Ventricular dilation	17/42	1/3	18/45 (40%)
Intracranial calcification	—	1/3	33%

Abbreviations: LDH, lactic dehydrogenase; GGT, gamma-glutamyl transpeptidase.

with other universal screening programs: syphilis, gonorrhea, phenylketonuria, or maternal serum alpha-fetoprotein. Commercial laboratories would easily and happily accommodate the demand for serologic testing in a universal screening program. Finally, respected researchers endorse the concept of universal screening (55).

On the other hand, the cost, unreliability in testing, and the inadequacy and cost of resources to interpret, diagnose, and treat fetal infection are major obstacles to implementation. The immunofluorescent antibody test, which is used in 80% of commercial laboratories (56), costs \$80 to \$120. Each patient would require two to three tests: two tests to document seroconversion and three tests (in 40% of patients) to document a rising titer (paired samples or IgM). Universal serologic screening would cost an estimated \$320 to \$720 million.

A cost benefit analysis based on data from a Finnish prospective study (57) and on Finnish cost data was performed to compare the no-screening and screening alternative for primary toxoplasma infection during pregnancy (58). Given a 20.3% seropositivity and an incidence of fetal infection to be 2.4/1000 seronegative pregnancies, the total annual costs of congenital toxoplasmosis without screening were \$128 per pregnancy per year (U.S. dollars). With screening, the cost would be \$95. The authors concluded that universal screening, plus health education, is cost effective if the incidence of maternal primary infection exceeds 1.1/1000 pregnancies and the effectiveness of treatment is greater than 22%.

The diagnosis of fetal infection in high-risk mothers is necessary unless the practitioner and patient are willing to abort or treat 9 to 15 uninfected fetuses for each infected fetus. Amniocentesis and/or funicentesis would be needed in 296,000 (0.8% × 3.7 million) women per year, with each ultrasound-guided procedure costing a minimum of \$1500. The necessary expertise, laboratory support, and financial resources are not available for this demand.

In summary, while selected preconceptual screening for seronegativity and antenatal screening for seroconversion in behaviorally high-risk individuals may be warranted, first-trimester universal screening for toxoplasmosis is not warranted at this time in the United States. However, serologic screening should be considered when the patient has a "flu"-like syndrome, and/or has lymphadenopathy, or when the fetus, on ultrasonographic examination, has growth restriction, nonimmune hydrops, ascites, hydrocephalus, microcephaly, or intracranial calcification.

Antibiotic Therapy

Pyrimethamine, a substituted phenylpyrimidine antimalarial drug, cures toxoplasmosis in laboratory animals through folic acid antagonism. Pyrimethamine produces a reversible, dose-related bone marrow depression. Thrombocytopenia, with its associated bleeding sequelae, is the most common toxic affect, but anemia and leukopenia may occur as well. A semi-weekly complete blood cell and platelet count should be obtained while the patient is being treated.

Sulfadiazine (or sulfapyrazine, sulfamethazine, or sulfamerazine) acts synergistically with pyrimethamine with a combined activity against toxoplasmosis much greater than a merely additive affect. Like pyrimethamine, sulfa drugs disrupt

folic acid metabolism in bacterial species. Renal toxicity (crystalluria and hematuria), toxic dermal reaction (Stevens-Johnson syndrome), and blood dyscrasias are reported with sulfa drug therapies. However, these agents are well tolerated in most individuals. In the neonate, sulfa drugs displace bilirubin from albumin, and kernicterus may occur. The risk of neonatal kernicterus from maternal intake of sulfa drugs is quite small.

The evaluation of antibiotic efficacy depends on the time between the onset of infection and initiation of therapy. In human studies, the timing of fetal toxoplasmosis is very difficult to determine because the infection is usually asymptomatic. Experimental inoculation of infra-human primates, rhesus monkeys, and treatment with anti-toxoplasmosis antibiotics provides powerful insight into the pharmacokinetics of pregnancy and the efficacy of the antibiotics.

Schoondermark-Van de Ven et al. (59) established the dosage regimen for pyrimethamine and sulfadiazine in pregnant rhesus monkeys. The distributions of both drugs followed a one-compartment model. The maximum concentrations in serum were 88.7 µg/nL, 0.22 µg/nL for sulfadiazine and pyrimethamine, respectively. The serum elimination half-lives were much greater for pyrimethamine (44.4 hours) than sulfadiazine (5.2 hours).

Subsequent to the latter experiment, Back et al. used the dosage regimen to treat six rhesus monkeys that were infected with *T. gondii* at 90 days of gestation (second trimester) (60). Four similarly infected pregnant monkeys were used as controls. Infection was documented by isolation of *T. gondii* from amniotic fluid samples. The treated animals received pyrimethazine 1 mg/kg body weight and sulfadiazine 50 mg/kg/day for the remainder of the pregnancy. *T. gondii* was present at birth in three of four untreated neonates. In all animals treated with pyrimethazine and sulfadiazine, no parasite was identified in the amniotic fluid 10 to 13 days after initiation of therapy. No neonate demonstrated *T. gondii* at birth.

Spiramycin, a macrolide antibiotic, has an antibacterial spectrum similar to erythromycin and is active against toxoplasmosis in laboratory animals. With spiramycin 2g/day, the concentrations were maternal serum, 1.19 µg/nL; umbilical cord, 0.63 µg/nL; and placenta, 2.75 µg/nL. With spiramycin 3g/day, the concentrations were maternal serum, 1.69 µg/nL; umbilical cord serum, 0.78 µg/nL; and placenta, 6.2 µg/nL (59,60). Persistent, high tissue levels account for its greater activity against toxoplasmosis than erythromycin. During pregnancy, spiramycin is concentrated in placental tissue two to four times the serum levels, an important advantage, as placental infection is sentinel to fetal infection. Spiramycin seems to be well tolerated. When used as an antineoplastic agent in doses greater than 35 mg/kg, some patients experienced vertigo, nausea, vomiting, and anorexia. No impairment of the heart, blood, liver, or kidneys was noted (60).

Schoondermark-Van de Ven et al. (61) inoculated eight rhesus monkeys at 90 days of gestation (second trimester). The parasite was found in five of eight amniotic fluids at subsequent sampling. These monkeys with documented fetal infection were treated with intravenous spiramycin 20 mg/kg/day in two divided doses. At 14 days after initiation of spiramycin, *T. gondii* was still detectable by PCR analysis,

but not by mouse inoculation in four of five amniotic fluids. In four monkeys that had received spiramycin for 7 weeks, no *T. gondii* was detected by PCR or mouse inoculation in the placenta, amniotic fluid, or neonatal organs. One fetus that delivered prematurely after 2 weeks of spiramycin had *T. gondii* associated with its placenta based on PCR results alone. Spiramycin accumulated in extra-central nervous system tissues at concentrations 5 to 28 times umbilical cord concentrations; but no spiramycin was found in fetal/neonatal brains. These data suggest that in primates early treatment with spiramycin may eliminate fetal infection with moderate success, but if there is fetal central nervous system involvement, spiramycin is likely to be ineffective.

Clinicians have come to expect that antibiotics will effectively treat infection. Unfortunately, effective antibiotic treatment of fetal toxoplasmosis has not been realized. In the last 10 years, three separate meta-analyses have concluded little benefit from antibiotic therapy. No trials with randomized assignment of women with confirmed fetal toxoplasmosis have been performed; all are observational studies (62–64). The Systematic Review on Congenital Toxoplasmosis study group systematically reviewed 26 cohorts where spiramycin and/or pyrimethamine–sulfonamide were used to treat fetal toxoplasmosis (64). Overall, treatment did not change the frequency of any clinical manifestation: adjusted odds ratio = 1.11 ($p = 0.74$). In a sub-analysis, there was a small reduction in maternal to fetal transmission when spiramycin was initiated less than 3 weeks after maternal seroconversion: adjusted odds ratio (95th CI) = 0.48(0.28–0.80). Maternal to fetal transmission was strongly associated with gestational age at seroconversion. The odds of transmission increased by 12% per week of maternal gestation; the estimated rate of maternal to fetal transmission was 15% (95th CI 13–17%) at 13 weeks, 44% (40–47%) at 26 weeks, and 71% (66–76%) at 36 weeks.

The findings of early treatment after seroconversion and the results of the earlier quoted study of Berribi et al. (43), provide some guidance for therapy. In summary, a potential algorithm is preconceptional screening (or first prenatal visit) and monthly screening with *Toxoplasma* serology during pregnancy in seronegative women. If seroconversion occurs, then spiramycin initiated until an amniocentesis can be performed for diagnosis of fetal infection. If fetal infection is diagnosed, then treatment with pyrimethamine/sulfonamide and folic acid is initiated antenatally and neonatally.

Prevention

Primary prevention has the potential to greatly reduce the medical and economic costs of congenital toxoplasmosis. A combination of public education, that is, high school curriculum, preconceptional counseling, and early prenatal counseling, would be most effective in reducing congenital toxoplasmosis. In addition to material concerning the risks of toxoplasmosis, the role of cats and the general guidelines are listed in Table 5.

Foulon et al. (65) evaluated the reduction in the incidence of congenital toxoplasmosis using a primary prevention scheme (education) and a secondary prevention scheme (screening and treatment). Among the 11,286 consecutive pregnant women, primary prevention reduced the seroconversion rate by 63% ($p = 0.013$). Of 76 women determined to be at risk for

Table 5 Primary Prevention of Toxoplasmosis During Pregnancy

<i>Oocyst exposure</i>
Avoid the purchase of a new cat just prior to or during pregnancy
Avoid sick or feral cats
Use gloves for gardening
Have other family members clean the litter box
Clean the litter box daily
Sterilize the empty pan with boiling water for 20 minutes
Prevent flies and other vectors from contaminating food
Thoroughly wash fruits and vegetables
<i>Tissue cyst exposure</i>
Cook meat to 150°F (66°C)
Cleanse the preparation surface immediately after meat preparation
Wash hands immediately after meat preparation
Avoid contact with mucous membranes of the mouth and eyes while handling raw meat

delivering a child with congenital toxoplasmosis, 8 (11%) infected fetuses were detected by prenatal fetal diagnosis. Of these, secondary prevention (antibiotics) reduced the incidence of congenital toxoplasmosis by an additional 40%. Unfortunately, a recent meta-analysis of randomized trials showed poor design quality and no benefit in reducing the incidence congenital toxoplasmosis. Regardless, given the benefit of the Foulon et al. study and the low cost of behavioral interventions, the author recommends their continued use (66).

SUMMARY

The medical costs of maternal toxoplasmosis warrant the development of effective programs in primary prevention, diagnosis, and therapy. Maternal toxoplasmosis occurs in 0.5% to 1% of pregnancies, and 10% to 60% of their fetuses will be infected. While the majority (80–90%) of infected neonates will be asymptomatic at birth, a large proportion (20–90%) will develop one or more disabilities. These include hydrocephalus, microcephaly, chorioretinitis, mental retardation, and deafness.

Primary prevention through education and monitoring of food sources has an unfulfilled potential. The effectiveness of primary prevention is measured by changes in behavior and seroconversion rates. A universal screening program, especially preconceptional screening, will improve diagnosis and allow abortion as an option. However, the lack of standardized tests and poor correlation between maternal infection and fetal infection may result in many unnecessary abortions.

Fetal diagnosis allows more focused therapy. It will significantly reduce unnecessary abortion and antibiotic therapy. Unfortunately, fetal diagnosis requires sophisticated clinical skills, equipment, and laboratory support that are currently available only at major medical centers.

The inability to pinpoint the onset or severity of fetal toxoplasmosis limits the effectiveness of antibiotic regimens used to treat fetal toxoplasmosis. Despite therapy, 10% to 50% of fetuses infected in the first half of pregnancy will manifest injury. This failure rate may be related to an ineffective antibiotic regimen or inadvertently delayed treatment.

Comparative trials of antibiotics are critically important to the management of fetal toxoplasmosis in the future.

84 Human immunodeficiency virus (HIV)

Richard Basilan and William Salzer

EPIDEMIOLOGY

The number of people living with human immunodeficiency virus (HIV) worldwide reached an estimated 33.4 million in 2008, with 2.7 million new infections and 2 million acquired immune deficiency syndrome (AIDS)-related deaths that same year. The total number of people living with the virus in 2008 was more than 20% higher than the number in 2000, and the prevalence was roughly threefold higher than that in 1990 (1).

Meanwhile, an estimated 1.1 million adults and adolescents were living with diagnosed or undiagnosed HIV in the United States at the end of 2006, according to Centers for Disease Control and Prevention (CDC) estimates (2). During the same year, an estimated 54,230 new infections occurred in the United States (3). Although women make up only 25% of the HIV-infected population in the United States, certain subgroups, particularly African-Americans and Latinas, are disproportionately affected. African-American women, for example, have a prevalence rate nearly 18 times that of the rate of white women (2). In 2005, HIV disease was the third leading cause of death for African-American women aged 25 to 44 years and the fourth leading cause of death for African-American women aged 45 to 54 years (4).

Differences in the rates of HIV maternal to child transmission (MTCT) serve to highlight the disparities between resource-rich and resource-limited areas. While there were 390,000 children newly infected with HIV in sub-Saharan Africa in 2008, there were less than 500 new cases in North America, Western Europe, and central Europe combined (1). Analysis of national surveillance data shows that the number of pediatric AIDS cases that were reported to the CDC decreased from 858 in 1992 to only 41 in 2004, a decrease of about 95% (5). There has also been a marked decline in perinatal HIV transmission from an estimated 1650 in 1991 to between 144 and 236 in 2006 (6). The reduction in perinatal HIV transmission, now estimated to be less than 2% in the United States (7), is the result of a combination of universal maternal prenatal HIV counseling and testing, antiretroviral (ARV) prophylaxis, scheduled cesarean delivery when appropriate, and avoidance of breast-feeding. By contrast, perinatal transmission rates in resource-poor areas can be as high as 25% to 30% in the absence of any intervention (8).

ETIOLOGY

AIDS was first recognized in June 1981 when five previously healthy men who have sex with men (MSM) presented with *Pneumocystis carinii* pneumonia in Los Angeles (9). This was followed by a report of 26 MSM with Kaposi's sarcoma, with or without *P. carinii* pneumonia in New York and Los Angeles (10). The discovery of the HIV, initially named human T cell leukemia virus III, followed in 1983, and its causal relationship to AIDS was firmly established by the

following year (11,12). A reliable screening test (HIV ELISA) was developed in 1985, and since that time our understanding of HIV and its pathogenesis continues to increase and has led to successful treatment regimens not just for HIV but for other viral illnesses as well.

HIV belongs to the family of human retroviruses (Retroviridae) and the subfamily of lentiviruses. HIV-1 is the predominant cause of HIV disease in the world. HIV-2, which can also cause AIDS, is closely related to simian immunodeficiency virus and is largely confined to West Africa, although occasional cases occur worldwide. The HIV virion is an icosahedral structure containing numerous external spikes formed by the two major envelope proteins, the external gp120, and the transmembrane gp41. The virion attaches via gp120 to cells expressing the CD4 molecule, which acts as the cell receptor for the virus. The CD4 molecule is expressed mainly in a subset of T lymphocytes responsible for helper function in the immune system, but can also be found on the surface of monocytes/macrophages and dendritic/Langerhans cells (13). A conformational change then occurs in the gp120 molecule, allowing it to bind to one of two cellular coreceptors (CCR5 or CXCR4). Binding is followed by insertion of viral gp41 into the CD4 cell, resulting in membrane fusion followed by release of the viral core into the cell cytoplasm.

HIV, like other retroviruses, is an RNA virus. The virus transcribes its RNA using RNA-dependent DNA polymerase (*reverse transcriptase*) into DNA, which is then incorporated into the host DNA by a viral integrase. Following transcription, HIV mRNA is translated into proteins that are processed further by viral proteases, allowing for assembly of new virions that are then released to infect other cells. These steps in the viral replication cycle have been the target of highly active ARV therapy, which has revolutionized the management of HIV infection.

PATHOPHYSIOLOGY

The most common mode of HIV infection is sexual transmission through the genital mucosa (14), with initial infection of a small number of T lymphocytes, macrophages, and dendritic cells located in the lamina propria. Initial replication occurs in the regional lymph nodes, followed by migration of infected T lymphocytes or virions into the bloodstream, where secondary amplification in the gastrointestinal tract, spleen, and bone marrow results in massive infection of susceptible cells (15). The period of peak viremia, which occurs in the first 6 weeks, results in a symptomatic illness in 40% to 90% of patients, termed *acute HIV infection*. The most common symptoms include fever, fatigue, pharyngitis, lymphadenopathy, and myalgias. A maculopapular rash involving the trunk also occurs in 40% to 80% of patients (16). Oral or genital ulcers can also occur. Given the

nonspecific mononucleosis like symptoms of acute HIV infection, the diagnosis is often missed. A high index of suspicion is required to make the diagnosis, because commonly used screening tests for HIV antibody are negative for the first 4 weeks following infection. Detection of the p24 antigen or HIV RNA by PCR in the absence of HIV antibodies would confirm the diagnosis. This has important public health implications as the patient is unaware of being infected with HIV and yet is highly infectious because of the very high viral load.

Despite the initial immune response during primary HIV infection, the virus continues to replicate at a high rate in untreated patients, with production of 10^{10} virions daily. Viral replication is error prone, producing multiple quasi-species. This helps the virus evade the immune system and facilitates development of resistance to ARV agents. The virus subsequently establishes a reservoir in resting memory CD4+ cells, as well as in immune-sequestered sites such as the central nervous system (CNS). The patient remains asymptomatic during this chronic phase, which on average lasts about 10 years. During this time, there is persistent viral replication and immune activation resulting in a gradual decrease in the number of circulating CD4+ cells. As the CD4+ count falls, patients become more susceptible to opportunistic infections, the hallmark of AIDS.

Transmission of HIV from mother to child can occur in utero, perinatally, or postpartum through breast-feeding (6). Multiple factors have been associated with an increased risk of MTCT, but the greatest risk is with higher maternal plasma HIV RNA levels. Although the risk of MTCT decreases with lower maternal plasma HIV RNA levels (8), particularly when it is <1000 copies/mL, it should be emphasized that MTCT can occur even at low or undetectable HIV RNA levels (17). Other factors that have been found to increase MTCT rates include vaginal delivery with plasma HIV RNA levels >1000 copies/mL, delivery at earlier gestation, prolonged interval between membrane rupture and delivery, chorioamnionitis, coinfection with other sexually transmitted diseases (STDs), illicit drug use, and cigarette smoking.

DIAGNOSIS AND MANAGEMENT

A critical component of caring for HIV-infected patients is knowledge of evidence-based treatment guidelines. Guidelines for management of HIV infection in pregnancy are published by the Department of Health and Human Services (DHHS) in the United States, the European AIDS Clinical Society (EACS) and the World Health Organization (WHO). Differences in CD4-based criteria for initiation of ARV therapy, preferred agents and regimens, and management of infant prophylaxis exist between these guidelines. The practitioner caring for HIV-infected patients should be familiar with the recommendations for their region of the world, as well as the availability of local resources, such as laboratory testing, ARV agents, prevalence of HIV drug resistance and coexisting infections (i. e., TB, malaria, Hepatitis B), demographic and sociocultural issues, and organizational support for the patients.

LABORATORY TESTING

Laboratory testing for HIV infection involves screening with a highly sensitive test, usually an enzyme-linked immunosorbent assay (ELISA), also known as enzyme immunoassay, for

HIV antibodies. The high sensitivity of the test makes it an effective screening tool, but requires a highly specific assay for confirmatory testing, such as western blot for antibodies to specific viral proteins. Virologic assays (PCR for HIV RNA) can be used for confirmatory testing when the western blot is indeterminate. Testing for HIV RNA by PCR is also used in neonates or when acute HIV infection is suspected. In recent years, multiple rapid tests using blood or saliva have been introduced for point-of-care testing, but it should be noted that all rapid tests require further confirmatory testing because of their high false-positive rate.

After a diagnosis of HIV infection is confirmed, further testing includes obtaining the patient's HIV RNA viral level (or viral load), CD4 count, as well as baseline complete blood count (CBC), comprehensive metabolic panel, and for African-Americans, urinalysis. Screening for coinfection with other STDs (gonorrhea, chlamydia, syphilis, hepatitis B and C), tuberculosis, and toxoplasma should also be performed.

The CDC recommends HIV screening for all patients aged 13 to 64 in health-care settings (18). Repeat HIV testing should be offered at least annually to women who use injection drugs, have had an STD in the past year, have had more than one sexual partner since their most recent HIV test, engage in sexual intercourse in exchange for drugs or money, or are partners of injection drug users or HIV-infected persons. Opt-out screening, in which the patient is notified that HIV testing be performed as a routine part of gynecologic and obstetric care unless she declines, should be performed (19). HIV-uninfected women with a known HIV (+) partner should be counseled regarding the risk for acquiring the infection and should have a second HIV test during the third trimester, before 36 weeks if possible. If such a patient presents in labor without a second HIV test, a rapid test should be done. Suspicion for acute seroconversion should prompt both rapid HIV testing and checking for plasma HIV RNA levels (20).

Laboratory testing for neonates must take into account that maternal antibodies cross the placenta and persist in the child's circulation, making tests for HIV antibodies unreliable. Exclusion of HIV infection therefore relies on virologic tests (i.e., p24 antigen testing or plasma HIV RNA levels) done on two separate samples drawn after 1 month of age, with at least one sample being drawn after 4 months of age. HIV antibody tests can be utilized after 6 months of age, but also require verification by repeat testing using a second, separately drawn sample. In addition to negative laboratory test, the child should also have no current or previous AIDS-defining condition before being declared as HIV uninfected (21).

Testing for ARV drug resistance should be done prior to starting ARV therapy (whether for therapy or prophylaxis), as well as when considering modification of a patient's drug regimen. Assays for HIV drug resistance require that the patient has a detectable viral load, which is usually the case in untreated individuals and patients failing therapy.

ARV THERAPY

The use of highly active ARV therapy has revolutionized the management of HIV infection, leading to better quality of life, decreased morbidity, prolonged survival, and decreased transmission, including MTCT. There are now five different

classes of ARV drugs, with 24 individual ARV agents and 6 additional combination pills available for managing HIV infection in the United States. HIV therapy requires the use of drug combinations to decrease the development of drug resistance and requires a minimum of two, and ideally three, fully active agents at a time. As with most chronic infections requiring multidrug therapy, addition of a single agent to a failing regimen should be avoided as this fosters the development of resistance to the added agent.

Nucleoside reverse transcriptase inhibitors (NRTIs) were the first drugs active against HIV to be developed with the introduction of zidovudine or azidothymidine in 1987. The NRTIs are nucleoside analogs and require intracellular phosphorylation in order to become active. They are incorporated into the DNA chain and terminate DNA chain elongation by acting as nonactive substrates for the viral reverse transcriptase. Nonnucleoside reverse transcriptase inhibitors (NNRTIs), on the other hand, bind to the reverse transcriptase enzyme and induce conformational changes at the active site, thereby rendering the enzyme nonfunctional. Protease inhibitors (PIs) target the viral protease, an enzyme required for cleavage of precursor proteins (gag and gag-pol), thereby preventing the final assembly of the inner core of viral particles (22). Entry inhibitors block the penetration of HIV virions into their target cells by either preventing fusion (enfuvirtide) or by blocking the CCR5 coreceptor required for entry (Maraviroc). A newer class of ARVs act by inhibiting the enzyme required for integration of the transcribed viral genome into the host DNA (integrase), aptly named integrase inhibitors. Available ARV agents are summarized in Table 1.

The decision to initiate ARV therapy in adults is based on multiple factors, including the presence or absence of AIDS-related conditions, other comorbidities (such as hepatitis B coinfection or HIV-associated nephropathy), CD4 count, as well as the patient's readiness to start lifelong therapy. There is a general consensus that ARV therapy should be started on all patients with symptomatic HIV infection as well as asymptomatic patients with a CD4 count less than 500 cells/ μ L. Timing of initiation of ARV therapy in asymptomatic patients with CD4 counts >500 cells/ μ L is a subject of continuing debate and is not recommended by the WHO or EACS in asymptomatic patients without significant coinfection or comorbidities (23,24). However, in recent years, data on benefits of earlier initiation of ARV therapy have led to recommendations in the United States to start ARV therapy for all patients with CD4 counts <500 cells/ μ L and to consider starting ARV therapy at CD4 counts >500 cells/ μ L (25). These newer recommendations are based on observational cohort studies showing a potential decrease in mortality as well as in the incidence of such conditions as HIV-associated nephropathy, liver disease progression from hepatitis B or hepatitis C, cardiovascular disease, malignancies (both AIDS defining and non-AIDS defining), neurocognitive decline, and blunted immunologic response in patients started on highly active ARV treatment therapy at CD4 counts >500 (20).

It is recommended that all HIV-infected pregnant women receive ARV therapy regardless of CD4 or viral load. Use of ARV agents in pregnant women should consider two separate, but related issues: treatment of maternal HIV infection and prevention of MTCT. As in all HIV-infected patients,

evaluation of the patient's HIV viral load and CD4 count should be done, as well as initial testing for drug resistance if this has not been done previously. Patients with a CD4 count less than 200 cells/ μ L should be started on prophylaxis for *Pneumocystis jiroveci* (previously named *Pneumocystis carinii*) using trimethoprim sulfamethoxazole at a dose of 80mg/400mg daily. Alternatives include dapsone, atovaquone, or aerosolized pentamidine. A patient with CD4 count less than 50 cells/ μ L is at high risk for other opportunistic infections, including *Mycobacterium avium* complex, and prophylaxis using azithromycin 1200mg weekly is recommended. Like any medication taken during pregnancy, the potential benefits of therapy should be weighed against potential risk to both the mother and the fetus.

For ARV-naïve, nonpregnant patients who meet criteria for initiation of ARV therapy, present guidelines recommend the use of an NNRTI-based, a PI-based, or an integrase inhibitor-based regimen. All regimens would also include two NRTIs. Purely NRTI-based regimens, such as Trizivir (a combination of zidovudine, lamivudine, and abacavir), are no longer recommended as they have been found to have higher rates of virologic failure. For an NNRTI-based regimen, the preferred agents include efavirenz with emtricitabine and tenofovir (available as combination pill Atripla™). Use of efavirenz should be avoided during the first trimester of pregnancy, as well as in women who are of reproductive age and are not taking sufficient steps to avoid pregnancy, given its known teratogenicity in animal and human studies. An alternative NNRTI-based regimen would include nevirapine with zidovudine and lamivudine (Combivir™). It should be noted that nevirapine should be avoided in patients with moderate-to-severe hepatic impairment (Child Pugh B or C), as well as females with a CD4 count >250 cells/ μ L as both groups have an increased risk for potentially fatal hepatitis.

Protease-based regimens may also include emtricitabine and tenofovir, combined with either atazanavir or darunavir boosted with ritonavir. In the pregnant patient, lopinavir boosted with ritonavir (lopinavir/r or Kaletra™) is the preferred PI. The addition of ritonavir at a low dose (boosting) inhibits CYP450 3A4 resulting in an increase in the serum levels of most PIs. An integrase inhibitor-based regimen would use raltegravir in addition to two NRTIs.

A list of preferred initial ARV regimens is presented in Table 2.

The following management strategies have been adapted mainly from present DHHS guidelines (20) unless otherwise stated. Updated versions are available online at www.aidsinfo.nih.org.

ANTEPARTUM CARE

In reproductive age, nonpregnant HIV-infected women, preconception counseling should be done to minimize the risk of unintended pregnancies. ARV agents with known teratogenic potential, such as efavirenz, should be avoided if there is insufficient effort to avoid conception. Ideally, two methods of contraception should be used in such circumstances, noting that certain ARV agents decrease the efficacy of oral contraceptive pills.

If the patient desires to conceive, the risks of MTCT should be discussed with the patient. In couples with discordant HIV

Table 1 Antiretroviral Agents and Common Adverse Effects

Drug	FDA pregnancy category	Common side effects	Notes
NRTIs			
Abacavir (ABC)	C	Lactic acidosis, hepatic steatosis, lipodystrophy Hypersensitivity reaction (can be fatal), rash, possible risk of MI	Test for <i>HLA-B*5701</i> . Do not use if patient is <i>HLA-B*5701</i> positive (high risk for hypersensitivity reaction)
Didanosine (ddI)	B	GI intolerance, peripheral neuropathy, pancreatitis, lactic acidosis, noncirrhotic portal hypertension	Do not use with stavudine (additive toxicities such as lactic acidosis)
Emtricitabine (FTC)	B		Preferred component of therapy during pregnancy
Lamivudine (3TC)	C		
Stavudine (d4T)	C	Highest incidence of lactic acidosis, hepatic steatosis, and lipodystrophy Peripheral neuropathy, Pancreatitis	Do not use with didanosine or zidovudine
Tenofovir (TDF)	B	Renal impairment, decreased bone mineral density, headache, GI intolerance	
Zidovudine (AZT, ZDV)	C	Headache, lactic acidosis, GI intolerance, bone marrow suppression	Preferred component of therapy during pregnancy. Do not use with stavudine (antagonistic effects on HIV activity)
NNRTIs			
Efavirenz (EFV)	D	Rash, including Stevens–Johnson syndrome, Drug–drug interactions Neuropsychiatric, <i>teratogenic</i> in nonhuman primates with reports of <i>neural tube defects</i> in human infants following first-trimester exposure	A component of Atripla, a combination pill used commonly given preferred status. Should be used in pregnancy only if other agents not tolerated and benefits outweigh risk
Etravirine (ETR)	B		Do not use with unboosted PIs, or ritonavir-boosted atazanavir, fosamprenavir, or tipranavir
Nevirapine (NVP)	B	Higher rate of rash, hepatotoxicity (may be severe and life threatening, especially in women w/CD4 count >250)	Risk of hepatotoxicity higher in first 18 months of therapy, hepatitis B or C coinfection, women w/CD4 count >250, men w/CD4 count >400 cells/ μ L
Protease inhibitors			
Atazanavir (ATV)	B	Hyperlipidemia, insulin resistance and diabetes, lipodystrophy, increased LFTs, drug interactions, osteonecrosis Hyperbilirubinemia, PR prolongation, nephrolithiasis	Do not use with indinavir (additive hyperbilirubinemia)
Darunavir (DRV)	C	Rash, liver toxicity	
Fosamprenavir (f-APV)	C	GI intolerance, rash, possible increased risk of MI	
Indinavir (IDV)	C	Nephrolithiasis, GI intolerance	Do not use with atazanavir
Lopinavir + ritonavir (LPV/r)	C	Possible increased risk of MI, PR, and QT prolongation, GI intolerance	Preferred component of therapy during pregnancy
Nelfinavir (NFV)	B	Diarrhea	
Ritonavir (RTV)	B	GI intolerance, hepatitis	
Saquinavir (SQV)	B	GI intolerance	
Tipranavir (TPV)	C	GI intolerance, rash, hyperlipidemia, liver toxicity, cases of intracranial hemorrhage	
Entry inhibitors			
Enfuvirtide (T-20)	B	Infection site reactions, hypersensitivity reactions, increased risk of bacterial pneumonia	
Maraviroc (MVC)	B	Drug interactions, abdominal pain, hepatotoxicity, rash, URIs	
Integrase inhibitors			
Raltegravir (RAL)	C	Nausea, headache, diarrhea, CPK elevation	

Abbreviations: LFTs, liver function tests; GI, gastrointestinal; MI, myocardial infarction; URIs, upper respiratory infections; CPK, creatine phosphokinase; PIs, protease inhibitors. Source: From Ref. 20.

Table 2 Preferred Initial Antiretroviral Regimen

NNRTI based	Tenofovir/emtricitabine/efavirenz daily
PI based	Atazanavir boosted with ritonavir + tenofovir/emtricitabine daily
	Or Darunavir boosted with ritonavir + tenofovir/emtricitabine
Integrase inhibitor based	Raltegravir + tenofovir/emtricitabine
Pregnancy	Lopinavir boosted with ritonavir + zidovudine/lamivudine
<i>Source:</i> From Ref. 20.	

status, alternative methods for conception, such as in vitro fertilization, should be explored to decrease the risk to the HIV-uninfected partner. Ideally, the patient's HIV viral load should be suppressed to undetectable levels prior to conception. Modifiable factors that decrease MTCT, including avoiding alcohol and illicit drug use, smoking cessation, and STD prevention, should be addressed.

The present consensus for the management of HIV infection in pregnancy is that of recommending ARV therapy or prophylaxis to all pregnant HIV-infected women, regardless of plasma HIV RNA levels. The benefits and risks of therapy should be individualized and discussed with the patient, with particular emphasis on the importance of adherence to drug therapy. Every attempt should be made to coordinate comprehensive services for such patients before, during, and after delivery.

In pregnant HIV patients who have indications for initiation of ARV therapy, the goals of ARV therapy include control of HIV viremia to undetectable levels, immune reconstitution to avoid opportunistic infections, and decreased MTCT. As with other HIV patients, multiple factors should be considered when designing a drug regimen, including comorbidities, patient adherence potential, convenience, potential adverse effects, drug interactions, and results of genotypic resistance testing. In addition, pharmacokinetic (PK) changes in pregnancy (particularly with PIs) and potential teratogenic effects on the fetus and other adverse effects on the fetus or newborn would also need to be considered. ARV agents with teratogenic potential, such as efavirenz, should be avoided particularly during the first trimester unless the risk is outweighed by the anticipated benefits.

Patients who are already on effective therapy (i.e., with undetectable HIV viral load) for their HIV infection should continue the same regimen, with the exception of efavirenz in the first trimester. Patients with detectable viral load should have genotype testing for drug resistance in an effort to design an optimized drug regimen. Patients may require modifications of their ARV regimen, with particular attention to the factors previously noted. For patients who meet criteria for initiation of ARV therapy, the preferred initial regimen consists of zidovudine and lamivudine (available as a combination pill Combivir) and lopinavir boosted with ritonavir (available as a combination pill Kaletra) taken twice a day. All regimens should include zidovudine if possible, as this drug has the best evidence-based data to support efficacy in reducing MTCT and also has good safety data for use during pregnancy (8). Alternative regimens include zidovudine/

lamivudine with either (i) another PI, such as atazanavir/ritonavir, indinavir/ritonavir, nelfinavir, or saquinavir/ritonavir or (ii) an NNRTI such as nevirapine. Efavirenz use after the first trimester can be considered if other alternatives are not tolerated. Nevirapine should not be started in pregnant women with CD4 counts >250 cells/ μ L unless the anticipated benefits outweigh the potential risk of severe, sometime fatal hepatotoxicity. ARV therapy can be started during the first trimester if indicated for maternal health.

Patients who do not meet criteria for initiating ARV therapy (asymptomatic, CD4 counts \gg 500 cells/ μ L, low-level viremia) should still be advised to take ARV therapy to decrease maternal viremia and provide prophylaxis for the fetus in an attempt to decrease MTCT. As most drug teratogenic effects occur early in the first trimester while majority (but not all) of maternal-to-child infections occur during late pregnancy and delivery, it would be worthwhile to wait until 10 to 12 weeks of gestation before starting antiviral therapy. However, this approach leaves the fetus exposed to persistent viremia for several weeks, and the risks and benefits of starting ARV therapy early versus waiting until the second trimester should be discussed with the patient.

Combination three-drug therapy with zidovudine/lamivudine and lopinavir/ritonavir would still be recommended in the United States as this regimen appears to be safe and effective in decreasing MTCT. Alternative regimens (first-line regimens per WHO guidelines) include either zidovudine/lamivudine or tenofovir/lamivudine plus either nevirapine or efavirenz, noting that efavirenz should be avoided during the first trimester of pregnancy). Concerns over fetal exposure to multiple drugs during pregnancy may prompt the use of monotherapy with zidovudine as an alternative if the patient's viral load is less than 1000 copies/mL. This approach, derived from the original Pediatric AIDS Clinical Trial Group (PACTG) study to reduce MTCT published in 1994, has been a mainstay in the WHO guidelines particularly because of its availability in resource-limited areas. In the United States, the use of zidovudine monotherapy as maternal prophylaxis for reduction of MTCT is now controversial and is generally not recommended particularly for patients with higher HIV viral RNA levels. ARV therapy given only to decrease MTCT can be discontinued following delivery if there is no indication for therapy for the mother and/or if there are no plans for breastfeeding.

There are conflicting data as to whether ARV drugs are associated with adverse outcomes such as preterm delivery, with some studies showing up to a twofold increase in risk while others fail to demonstrate any increased risk for preterm delivery. Patients on PIs were found in a recent meta-analysis to be at slightly higher risk for premature delivery (odds ratio 1.35) compared with those on regimens without a PI (26). There is also concern regarding mitochondrial dysfunction in neonates exposed to NRTIs, but this occurs rarely. These risks should be discussed with the patient, but are generally thought to be outweighed by the significant benefit of improved maternal health and decreased MTCT of HIV infection. Pregnant patients on ARV therapy should be enrolled in the ARV pregnancy registry available online at www.APREgistry.com.

As there remain limited data on the effects of ARV therapy on the fetus, a second ultrasound during the second trimester

is generally recommended to assess fetal anatomy in addition to the staging ultrasound done in the first trimester. Although no perinatal transmission of HIV infection has been documented following amniocentesis in patients taking ARV therapy, a small risk of MTCT cannot be ruled out. Therefore, amniocentesis should be performed only after initiation of ARV therapy or prophylaxis and ideally with undetectable HIV viral RNA levels. Plasma RNA levels should be rechecked at 34 to 36 weeks to guide the decision regarding the preferred mode of delivery.

INTRAPARTUM MANAGEMENT

Patients already on ARV therapy should be continued on their regimen, with the oral route being preferred whenever possible. Intravenous zidovudine is recommended for all HIV-positive women during labor, even if drug resistance to this drug has been documented. If the patient was taking zidovudine as part of a combination regimen, the other components of her ARV therapy should also be continued. Zidovudine should be given at a dose of 2mg/kg IV over 1 hour, followed by an infusion of 1mg/kg/hour until the time of delivery, and should ideally be started 3 hours prior to surgery in the event of planned caesarian section. This dose is based on the original protocol used in the PACTG 076 (8) published in 1994, which demonstrated a marked reduction in MTCT from 25.5% in the placebo group to 8.3% infants in the zidovudine group. Stavudine (d4T) should be discontinued when administering zidovudine because of antagonism between these two drugs.

Patients presenting in labor with unknown HIV status should have a rapid antibody test performed. A positive result should prompt administration of intravenous zidovudine to the mother and the infant, with continuation of infant prophylaxis for 6 weeks. Please see Table 3 for specific dosing. A confirmatory maternal HIV test should be done postpartum, with discontinuation of infant prophylaxis if the test is negative.

Patients should be counseled regarding risks and benefits of caesarian versus vaginal delivery. In general, HIV-infected

patients undergoing caesarian delivery are at higher risk for surgical complications compared with HIV-infected women undergoing vaginal delivery, as well as compared with HIV-uninfected women undergoing caesarian delivery. However, these risks do not outweigh the benefit of decreased transmission to those at high risk. Therefore, women whose HIV RNA levels are unknown or >1000 copies/mL near the time of delivery should be scheduled for elective caesarian delivery around 38 weeks of gestation regardless of whether or not they are on ARV therapy. The benefits of caesarian delivery after rupture of membranes remain unclear, and the decision as to mode of delivery in such cases should be made after considering other clinical factors. Likewise, caesarian delivery for patients with HIV RNA levels <1000 copies/mL may not decrease the rate of perinatal transmission any further.

Procedures that risk fetal exposure to maternal blood have been suggested to increase MTCT by some authors. Older data have suggested up to a twofold increase in MTCT in these situations, but more recent observation studies have shown much less risk, particularly with the use of ARV therapy. Although limited data exist, invasive fetal monitoring (e.g., fetal scalp electrodes) should be avoided unless obstetrically indicated and the duration is expected to be short. Operative vaginal delivery using forceps or vacuum extractor as well as episiotomy would theoretically have an increased risk of transmission but should not be delayed if clear obstetric indications exist (27,28).

The use of methergine, a drug metabolized through the hepatic CYP3A4 pathway, for postpartum hemorrhage should be avoided in women receiving PIs (potent CYP3A4 enzyme inhibitors) because of the risk of exaggerated vasoconstrictive response. If other alternatives (oxytocin, misoprostol, PGF2 alpha) are not available, a lower dose should be used and the duration of use should be minimized. Conversely, if methergine must be used in a patient taking a potent CYP3A4 inducer (such as efavirenz), additional uterotonic agents may be needed given the possibility of lower methergine levels.

Table 3 Intrapartum Maternal and Neonatal Zidovudine (ZDV) Dosing for Prevention of Mother-to-Child Transmission of HIV

	Dosing	Duration
Maternal intrapartum	2mg/kg IV over 1 hour, followed by continuous infusion of 1 mg/kg/hr	Onset of labor until delivery of infant
Neonatal		
>35 weeks of gestation	2mg/kg/dose oral Or 1.5mg/kg/dose IV started within 6–12 hours of delivery, then every 6 hours	Birth to 6 weeks
<35 to >30 weeks of gestation	2mg/kg/dose oral Or 1.5mg/kg/dose IV started within 6–12 hours of delivery, then every 12 hours, advanced to every 8 hours at 2 weeks of age	
<30 weeks of gestation	2mg/kg/dose oral Or 1.5mg/kg/dose IV started within 6–12 hours of delivery, then every 12 hours, advanced to every 8 hours at 4 weeks of age

POSTPARTUM MANAGEMENT

HIV-infected patients are commonly faced with multiple medical and social challenges, making the coordination of maternal postpartum follow-up between obstetric, pediatric, and HIV specialists even more important. The need for continued counseling and comprehensive medical care cannot be overemphasized in this period. Supportive services should ideally be assured prior to discharge, including obstetric/gynecologic, pediatric, HIV specialty care and mental health services, substance abuse counseling, family planning services, and social work/case worker services.

The decision regarding continuation of maternal ARV therapy during this period would depend on the CD4 count nadir (lowest documented level), clinical symptoms, disease stage, presence of other indications for ARV therapy (e.g., chronic hepatitis B infection), and patient and provider preference. Patients who have had symptomatic HIV infection or are known to have had a CD4 count below the established criteria for starting treatment for asymptomatic patients should be encouraged to continue their ARV regimen. They should also be advised regarding potential challenges with regard to compliance in light of the physiologic and lifestyle changes associated with the postpartum period.

If the only indication for initiation of ARV therapy was to reduce MTCT, then consideration can be given to stopping ARV therapy after delivery. Because NNRTIs have much longer half-lives than drugs from other classes, patients on NNRTIs should be advised to take their NRTIs for at least 7 to 30 days after stopping their NNRTI (NRTI tail) to avoid development of NNRTI resistance. An alternative approach is to substitute a PI for the NNRTI, continuing the regimen for 7 to 30 days, and then stopping all ARV drugs at the same time. This becomes important when the patient presents with a need for ARV therapy, whether for maternal indications or for prophylaxis during subsequent pregnancies. Even single-dose nevirapine, if given without an NRTI tail within the prior 12 months, would necessitate the empiric use of a non-NNRTI-based regimen (i.e., protease- or integrase-based regimen) (24).

Women with positive rapid HIV test result in labor should have their confirmatory tests done prior to discharge, as this would have important implications on infant prophylaxis and breast-feeding options. Further management of newly confirmed HIV infection at this stage would be similar to that of any other newly diagnosed HIV patient.

Ideally, the risk of HIV transmission through breast-feeding would have been discussed with the patient prior to delivery and would be reiterated at this phase. In resource-rich areas where safe alternatives are available and culturally acceptable, such as *in the United States, breast-feeding is not recommended*. MTCT through breast-feeding is a well-documented phenomenon even in patients on ARV therapy, and for patients on ARV therapy, limited data on pharmacokinetics of ARV drugs in breast milk can pose issues related to drug toxicity or drug resistance if drug levels in breast milk are too high or too low. It should be noted that in resource-limited areas where there is limited access to nutritional alternatives or clean water, the benefits of breast-feeding outweigh the risk of MTCT and should be encouraged. Withholding breast-feeding in such scenarios results in increased mortality not only from diarrheal

illnesses, but also from other locally prevalent infectious diseases such as tuberculosis and malaria, as poor nutritional status increases susceptibility to these diseases.

Contraceptive counseling is critical to prevention of MTCT. Condom use is important for prevention of HIV and STD transmission, although the unintended pregnancy rate is high with condom use alone. It should be noted that drug interactions between oral contraceptives and many PIs and NNRTIs could potentially decrease the efficacy of oral contraceptive pills, so more than one method of contraception should be in place at any given time. For women who are certain they do not wish future childbearing, thorough counseling and discussion about permanent contraceptive methods should be done (20).

NEONATAL POSTNATAL CARE

Infants born to mothers with unknown HIV infection status should have rapid HIV antibody testing of the mother or infant performed. If the rapid test is found to be positive, ARV prophylaxis should be started immediately while waiting for the confirmatory tests. If the confirmatory test is negative, then ARV prophylaxis should be discontinued. A positive confirmatory test for HIV antibodies should be followed by a virologic test (HIV RNA by PCR) done on the neonate. A positive virologic test on the neonate should prompt immediate referral to a pediatric HIV specialist for confirmation and initiation of combination ARV *therapy* as well as pneumocystis pneumonia (PCP) prophylaxis.

All newborns with known ARV exposure in utero should have a CBC with differential performed as a baseline before starting zidovudine, with follow-up depending on the results as well as other clinical factors (gestational age, medications, maternal antepartum therapy, etc.). Liver function tests should also be checked in infants exposed to ARV therapy in utero. If the infant develops severe clinical symptoms of unknown etiology, particularly of the CNS, serum lactate levels should be checked, and ARV prophylaxis discontinued if levels are found to be elevated. Consultation with a pediatric HIV specialist is recommended if significant abnormalities are found with the above tests.

Diagnosis of HIV infection in infants <18 months of age involves the use of virologic tests (HIV RNA levels), which should be done at age 14 to 21 days, 1 to 2 months, and 4 to 6 months. Some experts would also test at birth. Oral PCP prophylaxis using trimethoprim sulfamethoxazole should be initiated at 4 to 6 weeks unless HIV infection has been ruled out. PCP prophylaxis is indicated in HIV-infected infants regardless of CD4 count and should be continued until they are 1 year of age. At 1 year of age, PCP prophylaxis should be continued if the child's CD4 count is <500 cells/ μ L or <15% (29). Physical examination of the newborn, as well as maternal risk factors and laboratory studies, should guide specific testing for coinfection with other agents (cytomegalovirus, herpes simplex virus, hepatitis B and C, syphilis, toxoplasmosis, or tuberculosis) as appropriate.

A 6-week course of zidovudine chemoprophylaxis is recommended for all HIV-exposed neonates in the United States, ideally initiated within 6 to 12 hours of delivery. It may be appropriate to shorten the course to 4 weeks in situations where concerns exist regarding adherence or toxicity, as the

optimal duration for neonatal chemoprophylaxis is not known. In other countries, such as the United Kingdom and Ireland, a 4-week course is the recommended regimen, while WHO guidelines indicate a 4- to 6-week course of zidovudine to be appropriate. Please see Table 3 for specific dosing for zidovudine.

Consultation with a pediatric HIV specialist should be done when dealing with premature babies or when use of additional ARV agents is being considered because of increased transmission risk, such as those with higher maternal HIV RNA levels near delivery or had vaginal delivery.

Children with significant organ system abnormalities of unknown etiology (particularly of the CNS or heart) should be evaluated for mitochondrial dysfunction. As other possible early and late effects of in utero ARV drug exposure are not fully known, follow-up should include a yearly physical examination into adulthood, particularly given the theoretical risk of carcinogenicity of nucleoside analogs.

HIV MANAGEMENT IN RESOURCE-LIMITED SETTINGS

HIV management in resource-limited settings, where the vast majority of perinatal transmission occurs, presents multiple challenges during all stages of pregnancy, and significant differences exist between U.S. (DHHS and UNAIDS) and WHO guidelines. These differences result from limited availability of maternal prenatal HIV testing and limited access to ARV drug therapy. The benefits of earlier initiation of ARV therapy in asymptomatic patients in much of the world is thwarted by limited availability and access to ARV drugs, systems for delivering medical care, monitoring therapy, management of drug toxicity, and assessing drug resistance and having alternative drug regimens for patients with known or suspected drug resistance.

An NNRTI-based regimen (nevirapine or efavirenz with either lamivudine/zidovudine or tenofovir/emtricitabine) is recommended in the WHO guidelines as first-line therapy for maternal prophylaxis to prevent MTCT (as opposed to the United States, where this regimen is considered as an alternative to a lopinavir/ritonavir-based regimen). In addition, monotherapy with zidovudine starting at 14 weeks remains an option, followed by single-dose intrapartum nevirapine and a 1-week NRTI tail consisting of lamivudine and zidovudine.

Despite the well-documented risk of MTCT of HIV infection through breast-feeding, the much greater risk of mortality from malnutrition and infections makes breast-feeding necessary in many areas. Multiple options have been studied in such a scenario where breast-feeding is deemed necessary. Breast-feeding mothers on triple ARV agents for their own health are advised to continue doing so, while the infant should continue to receive the standard twice-daily zidovudine for 4 to 6 weeks. Breast-feeding mothers who are on triple ARV agents for *prophylaxis* should continue doing so until 1 week after cessation of breast-feeding, while the infant continues 4 to 6 weeks of zidovudine. Breast-feeding mothers who were only on zidovudine for *prophylaxis* should receive a single dose of nevirapine at the start of labor, as well as lamivudine and zidovudine at the start of labor up to a week following delivery. In such cases, the infant should receive nevirapine from birth up 4 to 6 weeks, or up to a week after

stopping breast-feeding, if cessation of breast-feeding is done earlier.

These recommendations were based on recent trials, including one done in Malawi comparing maternal with child HIV transmission during a 4-week breast-feeding period. This study showed a higher risk of transmission in the placebo group receiving only single-dose nevirapine and 7 days of zidovudine/lamivudine (5.7%) compared with infants who received nevirapine for 28 days (1.7%, $p < 0.001$) and breast-feeding mothers on ARV therapy for 28 days (2.9%, $p = 0.009$) (30). It has also been shown that three-drug maternal ARV therapy, whether NRTI, NNRTI, or PI based, showed similar rates of virologic suppression and decreased MTCT to 1.1% (31).

A simplified dosing regimen has been developed for use in resource-limited settings for infant prophylaxis. This regimen includes the use of zidovudine 10mg twice a day for infants weighing less than 2.5kg at birth, and 15mg twice a day for infants weighing more than 2.5kg at birth. Another alternative approach has been to give a daily dose of nevirapine for 4 to 6 weeks. Use of combination therapy has been used, but has not been proven to be additional benefit.

The field of HIV management continues to change rapidly. Updated guidelines are available online at www.aidsinfo.nih.gov as well as at the American College of Obstetricians and Gynecologists and WHO Web sites. In the United States, the National Perinatal HIV hotline (1-888-448-8765) also provides free clinical consultation on all aspects of perinatal HIV care.

HUMAN PAPILLOMA VIRUS

Human papillomavirus (HPV) is an icosahedral, non-enveloped, double-stranded deoxyribonucleic acid (DNA) virus of approximately 55nm in diameter (1). The genome of HPVs consists of approximately 8 kilobase paired molecules of circular, double-stranded DNA. All the proteins are encoded on one of the two DNA strands. All papilloma viruses share a similar genomic organization consisting of an early (E) gene region, a late (L) gene region, and a regulatory region. The five “early” proteins (E1, E2, E5, E6, E7) are required for viral replications and/or cellular transformation. Transformation of the “late” structural L1 and L2 transcripts and of the E1 to E4 spliced transcript is restricted to differentiating epithelium where viral assembly occurs (2,3). The L1 protein comprises the majority of the virus shell. The L1 gene is the most highly conserved gene among individual types. The L2 protein of 77 kDa is known as the minor capsid protein because it contributes a smaller percentage of the capsid mass than does the L1 protein.

More than 100 different types of HPV have been identified and fully sequenced and at least an additional 50 to 100 putative types have been partially characterized (4). HPV types are assigned numbers/designations when the DNA sequence has been established and a comparison with previously known types has found less than 90% sequence identity in the L1, E6, and E7 genes of the virus (5). An isolate with more than 90% homology to a known HPV type is classified as a subtype.

All HPV types are epitheliotropic and fully differentiated squamous epithelium is required for completion of the HPV life cycle. HPV infects keratinocytes, the predominate cells of epithelial surfaces. It is believed that only basal or undifferentiated keratinocytes are infected. The viral replication cycle is complicated as the keratinocytes undergoes the process of differentiation. Virus is assembled in the nuclei of most differentiated keratinocytes and can be detected in these cells as desquamation occurs from the epithelium (6).

HPV is transmitted by close contact with desquamated keratinocytes from an infected individual. The desquamated keratinocytes contain viral particles that are thought to infect a new host through microabrasions in the epithelial surface (7).

Approximately 40 HPV types infect the genital tract. HPV infection of the human genitalia causes a range of clinical states including asymptomatic infections, genital warts, abnormal pap smears, preinvasive and invasive cervix, and vaginal and vulval cancers (8). The different HPV types can be subdivided into two categories: “high risk” and “low risk” based on whether the HPV could be found in cancer specimens. The “low-risk” types such as HPV-6 and HPV-11 are associated with benign hyper-proliferative lesions commonly referred to as genital warts or condyloma acuminata and cause abnormal pap smears and low-grade dysplastic lesions (9). “High-risk” HPV

types such as HPV-16 and HPV-18 cause low- and high-grade dysplastic lesions of the cervix and invasive cervical cancer. Other HPV-related genital malignancies include vulval cancer (10), vaginal cancer, and anal cancer (11). Approximately 45% of penile cancer is associated with HPV (12). HPV-16 causes more than 50% of the non-cervical genital tract cancers. The HPV types most commonly associated with anogenital lesions are HPV-6, -11, -16, -18, -31, -33, -35, -45, -52, and -58 (13).

Epidemiology

Genital HPV infection is primarily transmitted through sexual intercourse. In, virtually, all studies of HPV prevalence and incidence, the constant predictors of infection have been measures of sexual activity, most importantly the number of sex partners (lifetime and recent) (14,15). Transmission of HPV through other types of genital contact in the absence of penetrative intercourse (i.e., oral genital, manual genital, genital–genital contact) has been described but is less common than that through sexual intercourse. Genital HPV transmission by nonsexual routes is uncommon. Nonsexual routes include transmission from a mother to a newborn baby (16).

The 2002 National Survey of Family Growth indicated that 24% of females in the United States were sexually active by age 15 years (17) increasing to 40% by age 16 years and 60% by age 18 years.

Natural History of HPV Infection

The majority of HPV infections are transient and asymptomatic and cause no clinical problems. The majority (70%) of new HPV infections clear within 1 year and approximately 90% clear within 2 years (15,18). The median duration of new infections is 8 months. Persistent infection with the same high-risk oncogenic HPV is a prerequisite for cervical cancer precursors and invasive cervical cancer (19).

HPV Prevalence and Incidence in the United States

It is estimated that 6.2 million new HPV infections occur every year among persons aged 14 to 44 years (20, 21).

This is an underestimate as HPV infections occur in persons younger than age 14 and over 44 years (22, 23). Modeling estimates suggest that >80% of sexually active women will have acquired genital HPV by age 50 (24).

HPV infections are not reportable diseases. The HPV disease spectrum includes abnormal cytology, genital warts, low-grade squamous intraepithelial lesion (LGSIL), -high-grade squamous intraepithelial lesion (HGSIL), carcinoma in situ, adenocarcinoma, and invasive squamous cell carcinoma (Table 1). Evaluations from gynecologic exams from a variety of offices and clinics have documented the prevalence of HPV DNA ranging from 14% to 90% (25). Prevalence was the highest among sexually active females aged <25 years and

Table 1 Incidence of Human Papillomavirus Spectrum Diseases Annually in the United States

Cervical cancer (21)	11,000
HGSIL (22)	330,000
LGSIL (22)	1,400,000
Genital warts (23)	1,000,000
Abnormal cytology	1.5–2.0 million

Abbreviations: HGSIL, high-grade squamous intraepithelial lesion; LGSIL, low-grade squamous intraepithelial lesion.

decreasing with age (26). In a study of sexually active women aged 18 to 25 years, the prevalence of any HPV was 26.9%. Prevalence of types 6 or 11 was 2.2% and prevalence of types 16 or 18 was 7.8% (27). Prevalence was the highest among women aged 20 to 24 years (44.8%).

Studies of incident HPV infections that have evaluated HPV DNA detection over time demonstrate that acquisition occurs soon after sexual debut. In a prospective study of college women in the United States, the cumulative probability of incident infection was 38.9% by 24 months after first sexual intercourse. HPV-6 acquisition was highest (10.4%); 5.6% had acquired HPV-18 (14).

Clinical Sequelae of HPV Infection

In the United States, approximately 50 million women undergo annual pap cytologic testing; approximately 3.5 to 5.0 million of these tests will require follow-up including 2.0 to 3.0 million with atypical squamous cells of undetermined significance (ASC-US), 1.25 million LGSIL, 300,000 HGSIL, and 1.0 million with genital warts (28).

All anogenital warts (condylomata) are caused by HPV and approximately 90% are associated with HPV types 6 and 11. The average time for the development of new anogenital warts after infection with HPV types 6 and 11 is 2 to 3 months. Not all persons who acquire HPV types 6 and 11 develop warts. Approximately 30% of warts regress spontaneously except during pregnancy or in states of immunosuppression when the rate of regression is much lower.

Reoccurrence of anogenital warts tends to be more common following periods of immunosuppression, either exogenous or endogenous. Infection with HPV resulting in clinical genital warts will lead to activation of cell-mediated immunity, which will prevent infections with the same HPV type. However, since many HPV infections are not cleared but become latent, immunosuppression will be followed by either active genital warts or abnormal cytology. In a majority of women who develop genital warts during pregnancy, by 6 weeks postpartum, the genital warts are totally resolved or dramatically decreased in size.

Infection in the tracheobronchial tree with HPV types 6 and 11 may result in recurrent respiratory papillomatosis (RRP), a disease characterized by recurrent warts or papillomas in the upper respiratory tract, particularly the larynx. RRP is divided into juvenile onset (JORRP) and adult onset based on diagnosis before or after 18. JORRP is believed to result from vertical transmission of HPV from mother to infant during delivery, although the median age of diagnosis is 4 years. A multicenter registry of JORRP during 1999 to 2003 demonstrated that although the clinical course of JORRP was variable, it is associated with extensive morbidity, requiring a median of

13 lifetime surgeries to remove warts and maintain an open airway. Estimates of the incidence of JORRP range from 0.12 to 2.1 cases per 100,000 children aged <18 years in two cities (29,30).

Prevention of HPV Infection

Condom use may reduce the risk for HPV and HPV spectrum diseases (e.g., genital warts and cervical cancer). Pap testing can detect precancerous changes in the cervix by evaluation of cytology, and HPV vaccines can prevent HPV diseases due to HPV types in the HPV vaccines.

At the current time, two HPV vaccines are licensed by FDA. The vaccine licensed in June 2006 was the quadrivalent HPV vaccine (HPV types 6, 11, 16, 18) Gardasil® manufactured by Merck & Co. The second HPV vaccine, a bivalent vaccine (HPV types 16,18) Cervarix® licensed by the FDA in October 2009, was manufactured by GlaxoSmith Kline. The quadrivalent vaccine is licensed for women for the prevention of HPV types 6, 11, 16, 18 related cervical, vaginal, and vulval cancer precursor and dysplastic lesions and genital warts. In October 2009, the quadrivalent vaccine was licensed by the FDA for the prevention of genital warts on males of age 9 to 26 years. The bivalent vaccine, Cervarix, has been licensed for the prevention of cervical cancer precursors and cervical cancer due to HPV types 16 and 18 (Table 2).

Recommendations for Vaccine Use

Advisory committee on immunization practices (ACIP) recommends routine vaccination of males and females aged 11 to 12 years with three doses of quadrivalent HPV vaccine. The vaccine series can start as early as age 9 years. Vaccinations are also recommended for males and females aged 13 to 26 who have not previously been vaccinated or who have not completed the full series. The recommendation for the bivalent vaccine is similar but does not have the male indication.

At this time, neither HPV vaccines are recommended for use in pregnancy. However, pregnancy testing is not needed before vaccination. Any exposure to the vaccine during pregnancy should be reported to the appropriate vaccine registry:

- 1-800-986-8999 (Merck + Co) for quadrivalent vaccine
- 1-888-452-9622 (GlaxoSmith Kline) for bivalent vaccine

MOLLUSCUM CONTAGIOSUM

Molluscum Contagiosum is a human disease with a worldwide distribution and is found in persons of all age and caused by members of the Poxvirus group (31). The disease is spread by sexual intercourse or fomites.

The disease is characterized by a long incubation period from 2 weeks to 2 months. The disease presents by the appearance of firm, shiny, flesh-colored lesions that become pearly white and umbilicated and discharge a caseous material. The lesions are characterized by proliferation, hyperplasia, thickening, and degeneration of the epidermis. The infected cells become enlarged and develop large intracytoplasmic eosinophilic hyaline inclusion bodies. The lesions are not pruritic and they measure 1 to 5 mm in diameter but may form larger clusters. The lesions typical of molluscum contagiosum

Table 2 Differences in Human Papillomavirus Vaccines Currently Licensed by FDA

	Quadrivalent, Gardasil® ^a	Bivalent, Cervarix® ^a
Licensed by FDA for women	June 2006	October 2009
Licensed by FDA for males	October 2009	None
HPV types in vaccine	6, 11, 16, 18	16, 18
Licensed to prevent	Genital warts, precursor lesions, and cancer of cervix, vagina, and vulva	Precursor lesions and cancer of cervix
Age of vaccine recipients	9–26 years	9–26 years
Recommended by ACIP—women	June 2006	October 2009
Recommended by ACIP—males	October 2009	None
Vaccine administrators' schedule	0, 2, 6 months	0, 1, 6 months
Vaccine Information statement (VIS), CDC. ^a March/30/2010. <i>Abbreviations:</i> HPV, human papillomavirus; ACIP, advisory committee on immunization practices.		

are characterized by complete lack of immunocompetent cells in the epithelial component of the lesions (32).

The principal sites of involvement include the eyelids, face, trunk, and anogenital areas. Molluscum lesions evolve over 1 to 2 months and are frequently traumatized resulting in autoinoculation. Secondary bacterial infections may occur. The lesions may persist for as long as 1 year but have persisted longer. Spontaneous regression without scarring usually occurs and recurrences are rare. Patients who are immunosuppressed may develop extensive involvement (33).

The diagnosis of molluscum contagiosum is usually made by inspection of the characteristic umbilicated white papule. The differential diagnosis includes lichen planus, verrucous papules, basal cell epithelioma, and pyogenic granuloma. If the diagnosis is in doubt, the caseous material should be examined for intracytoplasmic eosinophilic inclusions. Treatment by sharp curettage or expression of porous material will facilitate healing without scarring.

INFLUENZA

See chapter on Maternal Immunization (Chapter 71).

PARVOVIRUS

Epidemiology

The human parvovirus B19 is a member of the DNA virus family Parvoviridae (34). This virus is one of the smallest known DNA viruses approximately 18 to 25 nm in size, about 5.5 kb in length, and with single-stranded DNA (34). The virus lacks an envelope, but does code for at least two major structural or capsid proteins and at least one nonstructural protein.

The human parvovirus B19 was first discovered by British investigators in 1975 while screening blood specimens for hepatitis B antigen. Subsequently, B19 was found to be associated with aplastic anemia crisis and erythema infectiosum or "fifth disease" (34,35). This virus has also been associated with chronic bone marrow suppression, arthritis or arthropathy, fetal hydrops, and purpura.

Infection with parvovirus B19 is worldwide and is commonly seen in children aged 5 to 14 years. Outbreaks are most common in winter and spring, but there is a year-to-year variation in incidence. Estimates of positive seroprevalence rates in adults range from 28% to 72% (34,36).

Parvovirus is mildly contagious with an infection rate of 30% following primary exposure. The highest rates of secondary infection are seen in household exposure where the infection rate is as high as 50% (37).

Transmission of the virus is by respiratory droplets, and the incubation period is 4 to 14 days. Viremia develops 7 to 8 days after initial infection, lasting approximately 4 days (34). The rash associated with B19 appears following the viremic phase. The primary host is no longer infectious once the rash appears. Initial infection and seroconversion provide the host with lifelong immunity and reinfection is rare.

Pathophysiology

Parvovirus B19 viral replication and encapsulation take place in the host cells' nucleus. Host cell enzymes are used in viral replication. Rapidly dividing cells are preferentially infected, perhaps a product of S phase of cell replication, a requirement for viral growth. Parvovirus B19 is particularly trophic and cytotoxic for erythroid progenitor cells (34,35).

Following initial incubation and viremia, there is a transient inhibition of erythropoiesis, and reticulocytopenia occurs in the infected host. Similar changes are seen in other blood cell lines to a lesser degree. The bone marrow depression is first seen approximately 7 days after the initial infection and lasts for approximately 7 days. In the host with normal red cell survival or in a non-immunosuppressed state, this bone marrow depression is usually asymptomatic and self-limited. Aplastic crisis is seen particularly in patients with abnormally shortened red blood cell survival, in conditions such as sickle cell anemia, heredity spherocytosis, pyruvate kinase deficiency, thalassemia, and autoimmune hemolytic anemia. The immunocompromised host may develop bone marrow suppression of all cell lines secondary to an inability to clear the virus.

Transplacental fetal infection and subsequent fetal anemia may result in fetal hydrops and demise. The fetus is an ideal host for human parvovirus B19 because of an immature immune system and accelerated erythropoiesis with markedly shortened red cell life span (34,35). It has also been proposed that the marked fetal anemia observed may lead to tissue anoxic and subsequent high output or hypoxic cardiac failure (37). While transplacental infection may lead to fetal anemia and hydrops, parvovirus B19 is not a common cause of congenital anomalies or neonatal disease. The period of peak fetal morbidity following maternal infection is approximately 4 to 6 weeks after maternal symptoms (37). The fetal loss rate following maternal infection has been estimated to be as low as 2.5% (38).

The rash associated with human parvovirus B19 infection occurs 17 to 21 days after infection and is probably secondary to antigen-antibody reaction (35). Arthritis or arthropathy, a

probable postinfection phenomenon, may manifest with a purpuric rash—like illness, often associated with other signs of vasculitis. This rash may begin as a vesiculopapular eruption and is often distributed in the buttocks and lower extremities.

Diagnosis and Management

As with many viral infections, infection with human parvovirus B19 may be asymptomatic or carry symptoms of only a mild flu-like illness. The rash is more common in children than in adults but adults are more likely to develop arthritic complaints. The rash is characterized as a lacy rash especially on the face providing the “slapped cheek” appearance. A variable rash on the extremities may follow with a morbilliform, confluent, circinate, or annular appearance. This usually does not involve the trunk, palms, or soles and may be pruritic. The rash usually disappears within 1 to 2 weeks but may recur especially with stress, exercise, sunlight, or bathing (34,35).

Cultured human parvovirus B19 requires bone marrow cells and therefore clinically difficult. Enzyme-linked immunoassay for B19 antigen and antibodies are available to aid in diagnosis. Diagnosis can be made through DNA hybridization techniques including DNA amplification via the polymerase chain reaction (37). Maternal IgM antibodies can be detected in 3 to 4 days after onset of clinical illness, whereas IgG antibodies are seen within 7 days. IgM antibodies persist for 3 to 4 months and IgG antibodies persist for years (36). Patients who demonstrate positive IgG with a negative IgM are considered immune and carry little risk from exposure to parvovirus B19. Those patients who have had an acute infection will have a positive IgM and are at significant risk for an adverse fetal outcome.

Fetal infection can be monitored by ultrasound for evidence of fetal hydrops, and percutaneous umbilical blood sampling can be used to diagnose fetal anemia. Demonstration of parvovirus B19 antigens or parvovirus-specific IgM antibody DNA will confirm the diagnosis.

Serial middle cerebral artery (MCA) blood flow analysis can detect early signs of fetal heart failure.

Infection is strongly suggested if eosinophilic inclusion and margined chromatin are seen in infected fetal erythroid precursors (36).

If the initial ultrasound examination of the fetus is normal, including MCA measurements, the fetus should be followed with serial ultrasound examinations up to 12 weeks after maternal symptoms. Ultrasound-documented fetal hydrops resolves spontaneously in some cases of infection. While transplacental infection and hydrops fetalis have been successfully treated with percutaneous exchange transfusion, it has been observed that spontaneous resolution is frequent. Another observation that fetuses older than 20 weeks seem to have more spontaneous resolution may occur because of a more developed immune system (38).

Maternal serum alpha fetoprotein levels are elevated in association with intrauterine infection prior to the development of fetal hydrops as detected by ultrasound. The value of the test is limited by its nonspecific nature. Also the value of intravenous gammaglobulin for postexposure prevention of infection has not been fully evaluated. Vaccines or antiviral therapies specific for parvovirus B19 have not been developed.

ENTEROVIRUSES

Etiology

Human enteroviruses are members of the family of RNA Picornaviridae and are some of the most common human viruses (3). There are at least 72 serotypes of enteroviruses. The four recognized classes of enterovirus are poliovirus, coxsackie A virus, coxsackie B virus, and echovirus. To date, there are three polio subtypes, 23 coxsackie A serotypes, 6 coxsackie B serotypes, and more than 30 echovirus serotypes (39–41). Echovirus serotype 72 has been identified as hepatitis A virus. This chapter will focus on non-polio enteroviruses. Hepatitis A virus will be discussed in another chapter.

Viruses of the genus enterovirus are small (27 nm), single-stranded RNA with approximately 7500 bases. These viruses are icosahedral and lack an envelope. Enteroviruses have a nucleocapsid that is composed of 60 structural subunits (39,40).

Epidemiology

The true incidences of disease due to enteroviruses are not known and those infections are not reportable. It is thought that between 50% and 80% of infections are asymptomatic. Infections occur throughout the year and are most prevalent from June to October in temperate climates (39,40). Serotypes vary by region or year. The usual route of transmission is by either respiratory droplets or the gastrointestinal route.

Of all the infections, 80% to 90% are in children and adolescents 16 years old or younger (40). Adults account for approximately 8% of the non-polio enteroviral infections. Neonatal infections within the first month of life are common. In one study, 12.8% of newborns acquired enteroviral infection within 1 month of life and all infants recovered without difficulty (39). Women contracting enteroviral infection in late pregnancy are usually asymptomatic while those displaying symptoms are mild and nonspecific.

Pathophysiology

Diseases attributed to enteroviruses include aseptic meningitis, encephalitis, myocarditis, hepatitis, pneumonia, pleurodynia, and orchitis. Though often asymptomatic, infection may manifest with rashes, pharyngitis and conjunctivitis, parotitis, pericarditis, and pancreatitis. Rarely, the infection may be fulminant and fatal.

Following initial infection, viral replication occurs in the submucosal lymphoid tissue and within 1 to 3 days can be identified in regional lymph nodes (39) with subsequent viremia. The virus can be found in distant lymphoreticular tissue, that is, liver, spleen, and bone marrow (39). After replication in the lymphoreticular tissue, a more generalized infection with inflammation occurs, affecting multiple organs or tissues such as the central nervous system (CNS), striated muscle, and the heart. Animal studies have demonstrated a shorter incubation period and higher virus titers in pregnancy. Susceptibility to infection appears to increase with gestational age, but reverts rapidly to that of the nonpregnant state following delivery (39). Sites of primary infection in the gastrointestinal tract do not show evidence of this destructive process; therefore, diarrhea will not ensue in most patients.

The host immune response to enteroviral infection includes the production of both humoral and mucosal antibodies as well as a cytotoxic T-lymphocyte cellular response (39).

Most perinatal infections occur secondary to transmission of the virus to the neonate during parturition or in the immediate postnatal period (41). Vertical transmission of enteroviruses is rare but has been documented (39,41). As for infection of children and adults, the severity of disease in the neonate may range from mild to fatal, causing diseases of the CNS, liver, or heart (41). The neonate who has acquired an enteroviral infection by vertical transmission in the immediate peripartum period is thought to be at greater risk of serious disease when compared with the infant who has become infected following postnatal transmission. This serious infection is thought to result from a lack of maternal antibodies to the enteroviral infection.

Less is known about neonatal infection with coxsackie A virus. There are case reports of in utero fetal death with disseminated coxsackie A virus. It is rare for coxsackie A virus to be passed to the fetus (42). There appears to be no association between echovirus or coxsackie B virus infection and an increased spontaneous abortion rate. Stillbirth in late pregnancy increases with both maternal echovirus and coxsackie B viral infection. The association between maternal coxsackie B virus infection and a slightly greater risk of fetal urogenital defects and congenital heart defects is tenuous (39,41). Coxsackie B virus, particularly serotypes B3 and B4, has been implicated in neonatal myocarditis (43).

Diagnosis and Management

The typical presenting symptoms of maternal enteroviral infection are those of an upper respiratory tract infection such as fever of a few days of duration with or without rash. The patient may have abdominal pain of such intensity that it may be mistaken for abruptio placentae or chorioamnionitis in the pregnant patient. Rarely, the patient presents with aseptic meningitis or myopericarditis. A presumptive diagnosis can be made by demonstrating virus-specific IgM antibodies or by documenting rising IgG titers in maternal serum. Definitive diagnosis requires culturing of the virus from either respiratory secretions or stool.

If maternal infection is established more than 5 to 7 days prior to delivery, the maternal immune response provides IgG antibody that crosses the placenta and protects the neonate against serious illness. Multiple studies have indicated that when the neonate has severe echovirus, or coxsackie B virus infection, approximately 60% of the pregnant patients will have been symptomatic during the perinatal period, usually within 1 week of delivery.

There is no specific treatment, effective vaccine or reliable immune globulin or specific vaccine for enteroviral infection. Vertical transmission at birth causes the most neonatal harm. Owing to the absence of passive immunization via maternal antibodies, it is suggested that delivery should be delayed for over 1 week after the onset of disease.

MUMPS

Etiology

The mumps virus is an RNA virus in the paramyxovirus family. The virus has a lipid membrane envelope with both the neuraminidase and the hemagglutinin. The envelope carries

“S” antigen; however, the antigen does not cross-react with other paramyxoviruses. The core antigen “v” is more specific to the mump virus (44).

Epidemiology

Mumps is found worldwide and the virus is spread by respiratory droplets or fomites (44). Epidemics may occur especially in urban settings or where susceptible individuals are in close quarters. The infected person is contagious from 6 days prior to and up to 9 days after the onset of disease (45). The virus may be isolated from the throat, saliva, and urine during the first 3 days of illness and may be found in the urine up to 2 weeks after it has disappeared from other sites. The virus may also be isolated from blood, breast milk, and the testis.

As in the pre-vaccine era, mumps is predominantly a disease of school age children of ages 5 to 14 years. A live virus vaccine was introduced in 1967 but uptake of the vaccine was scant until 1977 when less than 50% of children had been immunized (46). The incidence of mumps in pregnancy is estimated to be between 0.8 and 10 cases per 10,000 pregnancies.

Pathophysiology

Mumps is usually a benign and self-limited disease. Following infection and incubation, viremia occurs. The disease is asymptomatic in 30% to 60% of patients. Most symptomatic patients experience moderate debilitation (46). Typical symptoms include fever, malaise, and swelling of one or both parotid glands. If the parotid glands are swollen, other salivary glands may also be involved. Viral replication occurs in multiple organs as the virus is disseminated. Pancreatitis, arthritis, and myocarditis are rare complications (45). Approximately 20% of postpubertal males will develop orchitis. Infection of the thyroid and breast may occur in the postpubertal females.

The virus may be cultured from cerebrospinal fluid in the asymptomatic patient and meningeal signs can be seen in 5% to 25% of infections (46). The incidence of mumps encephalitis may be as high as 5 per 1000 reported cases. The cranial nerves may be involved and the most common residual CNS symptom is deafness.

Symptomatic reinfection has been known to occur (45). Although mumps infection may be fatal, the mortality rate is extremely low. Fatal cases of mumps are more common in adults with approximately one-half of mumps-associated deaths in patients 20 years.

The mumps virus can infect the placenta and infection can cause transplacental infection. One study reported a 27% spontaneous abortion rate when mumps occurred in the first trimester (46). Mumps have not been associated with prematurity.

Diagnosis and Management

The diagnosis of mumps may be made on clinical symptoms if present. The diagnosis can be confirmed by serologic studies demonstrating virus-specific IgM or using titer of virus-specific IgG. The virus can be easily cultured in African green monkey kidney cells, embryonated hen's eggs, and human cells (47).

In contrast to other viral infections such as influenza or varicella zoster, mumps does not demonstrate increased

virulence or severity in the pregnant patient (44). Treatment is supportive.

Special precautions with delivery in isolation if possible has been suggested when the obstetric patient has overt mumps or if the patient has had proven or suspected onset of mumps within the 10 days preceding delivery (45). The same recommendations are suggested for the nonimmune patient exposed in the 3 weeks prior to labor. Postpartum care should be provided in isolation, though there is no need to separate the patient and her infant, and breast-feeding should be permitted. It is estimated that approximately one-half of newborns delivered to patients with overt mumps will acquire asymptomatic disease and be contagious up to 4 weeks of age. Nonimmune hospital personnel should not care for patients with mumps pointing out the need for all hospital personnel to be current with their measles–mumps–rubella vaccination.

The measles–mumps–rubella (MMR) vaccine is an effective live-attenuated viral vaccine that is part of the childhood vaccination schedule when the first dose of MMR is recommended at 12 to 15 months of age and a second dose at 4 to 6 years. Two doses of MMR vaccine are recommended for students attending colleges and one dose for health-care workers (47). In response to the resurgence of measles in 1989, this recommendation also had the effect of decreasing outbreak of mumps in high schools and college students. A study from the United Kingdom using MMR vaccine indicated vaccine effectiveness of 64% after one dose and 88% after two doses (48).

During the first 6 months of 2006, the United States reported a mumps outbreak of 2597 cases in 11 states (49). The outbreak highlighted the limitation of the 1998 recommendations and ACIP issued new recommendations (Table 3). The MMR vaccine is not indicated for use during pregnancy. Women should avoid pregnancy for 1 month following vaccination. Inadvertent immunization during pregnancy is not an indication for termination of pregnancy. Immune globulin has not been shown to be effective in the prevention of mumps and is not recommended (45,46).

MEASLES

Etiology

Measles is an exanthematous disease caused by a member of the paramyxovirus family. This virus differs from other

members of this family in that it does not demonstrate a neuraminidase.

Prior to the introduction of measles vaccination in 1963, epidemics of measles were seen every 2 to 3 years with 500,000 cases reported annually and approximately 400 to 500 deaths attributed to the complications of measles. In the 1980s, the reported incidence of measles fell to 1500 to 3000 cases per year (44). Measles is primarily a disease of children between ages 2 and 6 years. The incidence of measles in pregnancy is rare with estimates ranging from 6 to 40 cases per 100,000 pregnancies (51). Congenital measles are rare.

Prior to vaccination, measles were very contagious with an attack rate of approximately 90% in the nonimmune patient. Transmission is by respiratory droplets with the mucosa of the nose, oropharynx, or conjunctivas as the portal of entry. The usual incubation period is 10 to 14 days but may be as short as 7 days. The patient is infectious for 2 to 3 days prior to symptoms and 3 to 4 days after the appearance of the rash.

Pathophysiology

After the initial infection and incubation, viremia occurs and the patient demonstrates an influenza-like illness. There is usually a 3-day prodromal period with fever, inflammation of the mucosal membranes, cough, and coryza. Examination of the pharyngeal mucous membranes may reveal pathognomonic Koplik's spots. Subsequently, the patient develops a generalized maculopapular exanthema and malaise (52).

Complications of measles can be very serious. The most common complication is otitis media. Secondary bacterial pneumonia may follow measles viremia and is the most lethal complication. Encephalitis may be seen at any age and occurs in 1 per 1000 cases. If encephalitis complicates measles, it usually appears within 3 to 7 days after the appearance of the rash and carries a mortality of approximately 10%. The overall mortality rate of measles is estimated at less than 0.1% but is higher in children <1 year of age (53).

Diagnosis and Management

In an epidemic, the clinical signs and symptoms may allow a clinician to make a diagnosis. The differential diagnosis of measles includes a number of viral exanthematous diseases. The case definition includes fever (>101°F) rash for more than 3 days and cough, coryza, or conjunctivitis. Hemagglutination inhibition (HI) serologic tests are the most widely used for diagnosis. A fourfold rise between acute serum (within 3 days of the rash) and convalescent serum up to 20 days later is diagnostic. The HI antibody persists for years and is useful to determine immune status. The presence of IgM HI-specific antibody will also diagnose a new case of measles. The IgM antibody will usually disappear 2 to 5 days after the appearance of the rash.

There is a higher complication and mortality rate in pregnant women. Pneumonia has been noted to be the most frequent fatal complication (44).

The virus infrequently crosses the placenta. Gestational measles has been linked to a higher incidence of premature labor. Maternal measles may lead to premature labor and delivery and therefore increase neonatal mortality. Pregnancies complicated by measles have not been firmly associated with congenital malformations or a higher rate of malformations (51).

Table 3 The 2006 Advisory Committee on Immunization Practices Recommendations on Mumps

Acceptable presumptive evidence of immunity
Documentation of adequate vaccination with two doses of live MMR vaccine for
Adults including health-care workers
Students at post-high school institution
Routine vaccination for health-care workers
Persons born after 1957: two doses of MMR vaccine
Persons born before 1957: one dose of MMR vaccine
For outbreak settings
Children aged 1–4 years and adults: consider a second dose of MMR vaccine
Health-care workers born before 1957: strongly consider two doses of MMR vaccine (50)

Abbreviation: MMR, measles–mumps–rubella.

Newborns receive passive immunity from maternally derived IgG measles-specific antibody secondary to either maternal infection or immunization.

Nonimmune patients can be protected against measles following exposure if they are provided with passively acquired immunoglobulin within 3 days of exposure. The recommended dose of IgG is 0.2 ml/kg body weight intramuscularly (51,52).

Measles can be prevented with administration of MMR-attenuated live virus vaccine prior to pregnancy. In 1985, Gazala et al. reported the outcome of five pregnancies at 28 to 34 weeks of gestation complicated by a measles epidemic in Israel from December 1981 to May 1982. All five pregnancies were complicated by premature delivery with a mean duration between onset of illness and delivery of 3.5 days. The infants demonstrated low birth weight, and three of four live births had severe respiratory distress. The fifth infant was stillborn. Each live-born infant received IgG intramuscularly at a dose of 0.2 ml/kg on day 1 of life. None of the infants demonstrated any clinical signs or symptoms of measles.

RUBELLA

Etiology

The rubella virus is a member of the togavirus group and is a spherical, enveloped RNA virus, 50 to 100 nm in diameter (54).

Epidemiology

Rubella has worldwide distribution and prior to vaccine availability, pandemics occurred approximately every 20 years, with epidemics in 6- to 9-year cycles (54,55). Rubella is endemic throughout the year but in temperate climates demonstrates a peak incidence from March to May. Prior to rubella vaccination, the primary disease occurred in children aged 5 to 9 years where as in the postvaccination era there is a major shift to persons older than age 15 (55).

Transmission of rubella is by aerosolized respiratory droplets. The usual incubation period is 16 to 18 days with a range of 14 to 21 days (54,55). The infected individuals may shed virus for 1 week prior to and for approximately 1 week after the appearance of the typical rash. The virus may be isolated from respiratory secretions during this time, but the virus may be present in the urine and blood prior to the rash (55). A mild prodrome of malaise, low-grade fever, headache, and conjunctivitis may precede the rash by 1 to 5 days.

Pathophysiology

The initial infection occurs on the respiratory mucosa where the primary viral replication occurs (54). During incubation, for approximately 1 week prior to the onset of the rash, the virus can be isolated from leukocytes, conjunctiva, urine, and stool. The immune response of the host is both humoral and cell mediated. Viral-specific antibodies may be detected within 24 to 48 hours of the onset of the rash.

Infection with rubella is usually self-limited and mild. Postauricular, suboccipital, and posterior cervical lymphadenopathy are distinguishing features of the disease. The adenopathy will often herald the onset of the typical rash.

The most significant complication occurs secondary to transplacental transmission of the virus to the fetus during maternal viremia. In utero, infection may occur at any gestational

age (31). The virus may infect the placenta and result in granulomatous changes and necrosis of chorionic villi. Fetal rubella infection may cause spontaneous abortion or stillbirth. Once established, fetal infection is chronic and persists well beyond birth (55). The rubella virus may be persistent in the most severely affected infants for up to 1 year. The exact pathologic mechanism of fetal infection and subsequent tissue damage is not well understood. Rubella is not cytolytic like measles and inflammation is not a prominent feature of infected cells. Infected cells do show reduced mitotic activity and there is a reduction in this total number of body cells.

The rate of congenital infection and the effect of transplacental infection appear to vary with gestational age at the time of infection. In a large prospective study of 1016 women with confirmed rubella infection, the rate of congenital infection was 81% in the first 12 weeks, 54% at 13 to 16 weeks, 36% at 17 to 22 weeks, 30% at 23 to 30 weeks, 60% at 31 to 36 weeks, and 100% from 37 weeks to delivery (55). No congenital anomalies were seen if infection occurred after 16 weeks. Another prospective study found no congenital anomalies if maternal infection occurred after 17 weeks of gestation (56,57).

The congenital rubella syndrome (CRS) symptoms in decreasing frequency are hearing loss, mental retardation, cardiac malformations, and ocular defects (56,57). The greatest risk to the fetus is when maternal infection occurs in the first trimester. Congenital anomalies of the heart, eye, and CNS have been seen only if maternal infection occurred between 3 and 12 weeks. Deafness is the most common anomaly occurring in 58% of affected offspring and in 40% as a single defect (56). Patent ductus arteriosus was the most common cardiac defect and accounted for 79% of the cardiac anomalies seen (56,57).

Diagnosis and Management

The symptomatic patient may experience a syndrome of malaise, low-grade fever, and tender and swollen lymphadenopathy of the suboccipital, postauricular, and posterior cervical lymph nodes prior to the onset of a rash. The rash of rubella initially appears over the face and posterior to the ears as a small, faint pink circular macular rash that eventually spreads to the neck, trunk, and extremities. The rash may also appear as a general blush in the face and may be described as petechial or purpuric. The rash generally disappears in 3 days.

Clinical history and examination are not reliable for making a diagnosis. Culture is slow and expensive and not recommended. The diagnosis of rubella is confirmed by serology. Rubella-specific IgM and IgG may be detected by a variety of techniques including HI, ELISA, complement fixation, and radioimmunoassay. As with other diseases, the presence of IgM indicates acute illness as does a fourfold rise with IgG. IgM will disappear after 4 to 6 weeks.

All obstetric patients should be screened for rubella community on their first physician visit. If a patient suspects possible exposure and her immunity has not been established, serology should be obtained immediately and retested in 3 weeks.

The patient who shows a fourfold rise in titer of IgG antibody has a confirmed infection. If this occurs in the first 20 weeks of

pregnancy, the patient should be counseled regarding implications for the fetus and should consider termination of pregnancy.

Vaccines for rubella were licensed in 1969 and are available with measles and mumps as MMR vaccine. ACIP recommends vaccination of all infants between 12 and 15 months and an additional dose for adolescents. All patients who are non-immune on obstetric screening should receive MMR immediately postpartum. There is no risk to the postpartum patient or to the breast-feeding infant. Contraindication to MMR vaccine includes pregnancy, febrile illness, immunodeficient states, or receipt of immune serum globulin within preceding 3 months.

The risk to the fetus of inadvertent administration of MMR in pregnancy is not known. In a review, there were no defects compatible with CRS in 552 infants born to 635 women who received vaccine during pregnancy; women who receive MMR should not get pregnant within 1 month of vaccine administration.

86 Chlamydial infection

Joyce A. Ibana and Danny J. Schust

Chlamydia trachomatis is an obligate intracellular pathogen, which is now recognized as the most prevalent sexually transmitted bacteria in the world (1). In 1999, the World Health Organization (WHO) estimated that of the 340 million cases of sexually transmitted infections, 92 million were due to *C. trachomatis* infection. This high prevalence rate makes it an important public health concern. In women, *C. trachomatis* infection has detrimental effects on reproductive health and carries considerable health-care costs. Genital infection in women is primarily localized to the endocervix, causing a clinical syndrome of mucopurulent cervicitis. The majority (70–90%) of women infected with *C. trachomatis* are asymptomatic (2). In untreated women, this infection can ascend into the endometrium and fallopian tubes to establish a chronic infection that can result in pelvic inflammatory disease (PID) and salpingitis. Of women with a single episode of PID, 9% develop ectopic pregnancy and 11% develop tubal factor infertility (3). In pregnant women, *C. trachomatis* infection is associated with premature rupture of membranes and an increased risk of preterm delivery (4). This infection can also be vertically transmitted, causing pneumonia and conjunctivitis in newborns.

In addition to its role in genital diseases, *C. trachomatis* infection of the eye (trachoma) is one of the world's leading causes of preventable blindness. In 2002, the WHO reported that this infection accounts for about 3.6% (1.3 million) of total blindness worldwide. This disease is endemic in 56 countries including many in Africa, the Middle East and some parts of Asia, Latin America, and the Western Pacific. Trachoma is transmitted through contact with eye droplets from contaminated hands, clothing, and eye-seeking flies. The most affected populations are those living in poverty where resources are limited, hygiene is poor, and conditions permit facile transmission of the infection (5).

C. trachomatis can also cause a systemic sexually transmitted disease, Lymphogranuloma venereum (LGV), which is characterized by genital ulceration and inguinal lymphadenopathy (buboes). This disease can progress and result in hemorrhagic proctocolitis, rectogenital scarring, and lymphedema. LGV is endemic in some areas of Africa, Asia, South America, and the Caribbean but is uncommon in industrialized countries (6).

TAXONOMY

C. trachomatis is a member of the family chlamydiaceae. Three species under this family are commonly associated with human diseases: *C. trachomatis*, *C. pneumoniae*, and *C. psittaci*. Under a classification revised in 1999, chlamydiaceae is divided into two genera, chlamydia and Chlamydophila. *C. trachomatis* is under the genus chlamydia, while *C. pneumoniae* and *C. psittaci* are classified under the genus Chlamydophila (7). Some of the

properties that differentiate the three chlamydiaceae species that represent important human pathogens are summarized in Table 1.

The two *C. trachomatis* biovars (trachoma and LGV) are further differentiated into 19 serovars based on antigenic differences in the major outer membrane proteins (MOMPs). The trachoma biovar includes serovars A, B, Ba, and C, which primarily infect the conjunctiva, and serovars D, Da, E, F, G, Ga, H, I, Ia, J, and K, which primarily infect the urogenital tract. The LGV biovar consists of serovars L1, L2a, L2b, and L3 and primarily infects the inguinal lymph nodes.

In addition to these serovars, several other variants have been previously identified (8,9). One new variant of *C. trachomatis* (nvCT) was discovered in Sweden in 2006 (10). It carries a deletion in the target sequences used for standard nucleic acid amplification-based diagnostic methods and escaped detection until recently. In 2007, nvCT spread throughout Sweden, accounting for 20% to 65% of chlamydia cases in that country (11). The majority of those cases that were detected in other countries had epidemiologic links to Swedish contacts (12).

MICROBIOLOGY AND PATHOGENESIS

The major disease symptoms associated with *C. trachomatis* infection are caused not by direct pathogen activity, but rather by the host immune response to infection. The conventional view holds that manifestations of chlamydial diseases result from classical delayed-type hypersensitivity (DTH) reactions. Clinical and animal studies suggest that DTH is stimulated by chlamydial heat shock protein 60 (13–16). However, other studies also suggest that the inflammatory response that is elicited by the infected host cells themselves is sufficient to cause chronic inflammation, tissue remodeling, and subsequent scarring. Following in vitro infection with *C. trachomatis*, genital epithelial cells produce and secrete large quantities of pro-inflammatory chemokines, including IL-8, GRO α , granulocyte–macrophage colony-stimulating factor (GM-CSF), IL-1 α , IL-11, and IL-6 (17,18). IL-1 has been shown to initiate human fallopian tubal damage during *C. trachomatis* infection in an ex vivo model (19). Overall, the increase in epithelial secretion of pro-inflammatory chemokines results in the recruitment of immune cells to the site of infection. Persistence of the inflammatory response within the genital tract results in tissue scarring (20).

C. trachomatis infection can also directly destroy infected genital epithelial cells during replication. *C. trachomatis* is an obligate intracellular bacterium that has a unique developmental life cycle. It enters target host cells as a small (300–400nm) elementary body (EB), metabolically inactive but infectious. Chlamydial organisms never contact the host cell cytoplasm. Rather, the entry of chlamydial EB induces the formation of a

Table 1 Human Pathogenic Chlamydiaceae

Property	<i>Chlamydia trachomatis</i>	<i>Chlamydia pneumoniae</i>	<i>Chlamydia psittaci</i>

Biovars	Trachoma and LGV	TWAR	Many
Diseases	Ocular trachoma, oculogenital diseases, infant pneumonia and lymphogranuloma venereum	Upper and lower respiratory tract infection	Psittacosis
Inclusions stain with iodine	Yes	No	No
Susceptibility to sulfonamides	Yes	No	No

Abbreviations: LGV, lymphogranuloma venereum; TWAR, Taiwan acute respiratory agent.

new intracellular compartment partially derived from the host cell's Golgi apparatus. This compartment, called an inclusion body, inhibits phagolysosomal fusion. Chlamydial EBs within the inclusion body utilize host adenosine triphosphate for energy. Within 6 to 8 hours after entry, chlamydial EBs undergo primary differentiation and transform into larger (800–1000 nm) actively dividing reticulate bodies (RBs). RBs are metabolically active and noninfectious. RBs continuously divide over the next 18 hours by binary fission to produce 300 to 500 progeny. At 48 to 72 hours after infection, *C. trachomatis* RBs transform back into EBs through secondary differentiation. Upon completion of their developmental cycle within the host cell, EBs exit the epithelial cell to infect neighboring uninfected cells.

An alternate growth mode of chlamydia, commonly referred to as persistent growth, has also been observed in vitro. Persistent growth is induced by factors such as amino acid deprivation (21), penicillin treatment (22), and exposure to suboptimal levels of interferon gamma (23). This growth mode is characterized by enlarged and pleomorphic RBs that do not undergo binary fission and differentiation into EB. During persistent growth in the host cell, chlamydial organisms are viable but not cultivable. This condition, however, can be reversed upon removal of the persistence-inducing factor (24). Although direct evidence of persistent growth in vivo has not been clearly established, this phenomenon may explain chronic infection resulting from reactivation of these alternate persistent forms. Cycles of dormancy and reactivation may contribute to the pathologic changes observed in chronic disease (Fig. 1).

EPIDEMIOLOGY

In the United States, 1,108,374 chlamydial infections were reported to the Centers for Disease Control and Prevention (CDC) in 2007, corresponding to a rate of 370.2 cases per 100,000 people. This rate translates to a more than fourfold increase from 1988 when 87.1 cases were reported per 100,000 people (25). Independent studies in different cities in the United States and in different countries around the globe, however, have demonstrated variation in prevalence rates depending on several factors, including high-risk sexual behavior and age (26,27). A comparative study conducted in the Philippines between high-risk female sex workers attending a social hygiene clinic and low-risk women attending an

obstetrics and gynecology clinic showed that high-risk women have a fivefold higher chlamydial prevalence rate compared with low-risk women (28). In addition, multiple studies have shown that young age is the factor most closely associated with *C. trachomatis* infection (29,30). Infection rates in sexually active adolescents are consistently at least two- to threefold higher than that in adult women (31).

In the same 2007 CDC report, the overall rate of chlamydial infection in women in the United States was 543.6 cases per 100,000. The rate of chlamydial infection in men is lower than that in women with 190.0 reported cases per 100,000 people. This lower rate in men may reflect the higher number of women screened for *C. trachomatis* and may also indicate that sex partners of infected women may not be diagnosed or reported. This is a major deterrent to efforts at controlling the rate of infection in women because men provide a continuous, untreated reservoir for transmission of new and recurrent infections.

Approximately 5% to 15% of pregnant women in the United States are infected with *C. trachomatis* (32). Independent studies in other countries show that prevalence rates in pregnant women are widely divergent (Table 2). Assessment of *C. trachomatis* infection prevalence rates, however, is complicated by the use of several different diagnostic methods among different studies. These methods may vary markedly in their sensitivities (see section on Diagnosis and Screening) and specificities. Comparison among studies is also compounded by biases in the selection process and heterogeneity in inclusion criteria among investigations. An evaluation limited to those persons seeking medical care in clinics may not be representative of the entire population. Thus, there exist significant limitations in generalizations made based on these studies.

Risk Factors of Chlamydia Infection in Pregnancy

The risk factors for chlamydial infection in pregnant women were summarized in a review article by Tiller et al. and include young age (<20 years of age), coinfection with other sexually transmitted diseases, abacteriuric pyuria, unprotected sex within the past 3 months, a partner with nongonococcal urethritis, and more than one sexual partner in the last 3 months (41). Like studies in nonpregnant women, young age is consistently associated with chlamydial infection among pregnant women.

Figure 1 Chlamydial growth cycle. Chlamydia travels between susceptible cells as small, metabolically inert forms, called the elementary bodies (EBs). EBs attach to cells and enter into a phagosomal compartment partially derived from the host cell Golgi apparatus. Within the phagosomal compartment, now called an inclusion, EBs transform into larger, metabolically active forms called reticulate bodies (RBs). RBs reproduce by binary fission, filling the enlarging inclusion. Late in the chlamydial life cycle (36–48 hours), RBs reorganize into EBs and EBs are released into the extracellular space to infect surrounding susceptible cells. Under certain in vitro conditions, chlamydial RBs undergo differentiation into large atypical forms that may persist within the infected cell for prolonged periods of time. Clinical and epidemiologic characteristics of chlamydial infections also support persistence. C. trachomatis infection in pregnant women increases the risk of pre-term delivery, premature rupture of membranes, and perinatal mortality. Thus, prenatal screening of high-risk pregnant women and treatment of newly diagnosed infections can help to prevent adverse pregnancy outcomes and transmission to neonates. The CDC recommends screening at the onset of prenatal care, then again in the third trimester.

Perinatal Risks of chlamydial Infection

Based on a recent study of vertical transmission of *C. trachomatis* in China, the transmission rate of *C. trachomatis* from infected mother to infants born through vaginal passage is approximately 66.7%. In comparison, the risk to those born by cesarean section is 8.3% (42)

Transmission of *C. trachomatis* infection from mother to infant may also occur via exposure to intrauterine infection during late pregnancy (43). Intrauterine infection may be responsible for chorioamnionitis, a frequent cause for prematurity and respiratory insufficiency at risk neonates (44). chlamydial infection may also result in neonatal conjunctivitis and in infant pneumonia that may progress to obstructive lung disease.

Early spontaneous pregnancy loss has been attributed to *C. trachomatis* infection-based seroepidemiologic evidence and on the detection of chlamydial antigens, in endometrial curettage samples (45,46). This correlation, however, is not without controversy (47). An association between *C. trachomatis* infection and premature rupture of the membranes has also been suggested and intrauterine lung infection by

C. trachomatis has been demonstrated has been demonstrated in premature infants (48).

DIAGNOSIS AND SCREENING

Traditional diagnostic testing for chlamydial infection involves cell culture techniques using urethral-, cervical-, or conjunctival-derived patient specimens. Specimens are inoculated on cycloheximide-treated McCoy cells, a susceptible tissue culture cell line, and examined after 24 and 72 hours of incubation. Chlamydia inclusions are then stained using immunofluorescent chlamydia-specific antibodies and examination of chlamydial growth is performed using standard microscopy. In competent hands, this method can have a specificity as high as 100%; therefore, culture-based detection of chlamydial infections has long been used as a reference standard for assessing the validity of new diagnostic tests and is the method of choice for medicolegal purposes. The cell culture method, however, is technically difficult, time consuming, and expensive. Furthermore, its sensitivity has been estimated to be only 60% to 85% (49,50). The performance of these techniques can vary between handlers and even within a laboratory. Thus, although some laboratories have maintained culture techniques for their high specificity, most others now use nonculture-based alternatives. These simpler techniques are more practical for routine work and offer higher sensitivity. They include detection of chlamydial antigens using directly labeled fluorescent antibodies (DFAs) and enzyme immunoassays (EIAs) and detection of chlamydial genetic material (RNA/DNA) using nucleic acid amplification tests (NAATs).

DFA involves the use of fluorescein-conjugated antibodies to directly detect chlamydial EBs within patient specimens. This test is rapid and its sensitivities and specificities range from 70% to 100% and 87% to 99%, respectively, for men and 68% to 100% and 82% to 100%, respectively, for women (51,52). The use of this technique is much faster than cell culture techniques but also requires highly skilled personnel. The EIA assay, on the other hand, does not require highly skilled personnel and has sensitivities and specificities that range from 62% to 97% and 92% to 100% for men and 64% to 100% and 89% to 100% for women (53). The sensitivity of the EIA method, however, has recently been questioned (54,55).

Because chlamydial genetic material can be shed into the urine, NAAT can be performed on specimens collected noninvasively. The major target sequence used in nucleic acid amplification techniques for the diagnosis of chlamydial infection is the *omp1* gene, which codes for the MOMP present in all three human pathogenic chlamydial species (56). Because this method includes an amplification step that improves sensitivity, NAAT has a better sensitivity than EIA for detecting chlamydia in urine specimens. NAAT is now also considered an effective method for detecting asymptomatic chlamydial infections. Currently, there are several NAAT platforms available for chlamydial diagnostic and screening purposes. A recent evaluation using first void urine specimens and three automated NAAT systems [ProbeTec ET reagents on Viper platform (BD Diagnostics), Aptima Combo 2 reagents on Tigris platform (Gen-Probe) and Abbott RealTime CT/NG reagents on an m200 platform (Abbott Molecular Diagnostics)] revealed that these approaches are all suitable for

C. trachomatis detection and each offers high sensitivity and specificity (57).

The use of urine specimens for NAAT testing is also the method of choice for screening men for chlamydial infections. It is noninvasive and differences in sensitivity and specificity between urethral swabs and urine samples are not significant. Screening targeted to men is beneficial from a public health perspective, as men provide a reservoir for continuous transmission to women. The rates of *C. trachomatis* infection in men vary from 4% to 6% of which approximately 90% are asymptomatic (58–60). The availability of an effective noninvasive method for screening men may provide more widespread detection of asymptomatic *C. trachomatis*-infected individuals in the community. Furthermore, this methodology can be readily used in school-based health centers in high-prevalence communities. Such noninvasive diagnostics could greatly increase the identification of infected individuals for treatment and help to prevent the spread of infection.

The use of vaginal swabs for NAAT testing offers an effective alternative for screening women for chlamydial infection. An evaluation of the use of vaginal swab specimens in the Aptima NAAT system revealed that NAAT provides excellent sensitivity and specificity. Using NAAT for detecting chlamydia on patient-collected vaginal swabs gives a sensitivity and specificity of 98.3% and 96.5% respectively, and for clinician-collected swabs, 97.2% and 95.2% respectively (61). Thus, the use of vaginal swab specimens for NAAT provides an excellent alternative to pelvic examination and endocervical specimen collection. To prevent the adverse effects of chlamydial infection on pregnancy outcomes, the screening of all pregnant women is recommended by the CDC. For these purposes, the noninvasive NAAT is the method of choice. In short, widespread, noninvasive screening for chlamydial infection in men and women should lead to early detection and treatment, thereby reducing reproductive tract morbidities and preventing vertical and horizontal transmission.

TREATMENT AND MANAGEMENT

Treatment of *C. trachomatis*-infected patients is essential not only for clearing infection and eliminating symptoms, but also for the prevention of transmission to sex partners. In pregnant women, treatment is also given to prevent vertical transmission to infants. Based on the latest CDC guidelines (62), the recommended first-line treatment for *C. trachomatis* is either a single 1-g oral dose of azithromycin or a twice daily, 100-mg oral dose of doxycycline for 7 total days. In populations in which adherence to the 7-day doxycycline regimen is typical, azithromycin and doxycycline are equally efficacious, with microbial cure rates of 97% and 98% respectively. However, in populations with poor compliance or unpredictable follow-up, cure rates for the azithromycin regimen exceeded those using doxycycline. Since the majority of gonococci in the United States are susceptible to azithromycin and doxycycline, either of these treatment regimens may also provide coverage for chlamydia patients coinfecting with *Neisseria gonorrhoeae*. Recommended alternative regimens for *C. trachomatis* treatment include erythromycin, ofloxacin, and levofloxacin. Ofloxacin and levofloxacin, however, offer no dosage advantages and are more expensive than erythromycin-based treatments.

For pregnant women, doxycycline, ofloxacin, and levofloxacin are contraindicated. Thus, the recommended first-line treatment for a chlamydia-infected pregnant woman is the single 1-g oral dose of azithromycin or a 500-mg oral dose of amoxicillin, three times a day for 7 days. Alternative regimens include erythromycin base or erythromycin ethylsuccinate. Frequent occurrence of gastrointestinal side effects with use of erythromycins discourages compliance and consequently reduces treatment efficacy. Lower erythromycin doses for longer duration are alternative regimens that may improve gastrointestinal tolerance. Notably, erythromycin estolate is contraindicated during pregnancy because of drug-related hepatotoxicity. To ensure therapeutic cure, testing for chlamydial infection must be repeated 3 weeks after the completion of therapy in pregnant subjects. This reduces the risk of maternal and neonatal sequelae with persistent disease. It is also recommended that sexual partners of pregnant women be tested and treated if they have sexual contact within 60 days after treatment. If either partner is positive for chlamydial infection, he/she should be instructed to avoid sexual contact until both have been cured and are without symptoms.

For infants with ophthalmia neonatorum or pneumonia due to chlamydial infection, the recommended regimen is erythromycin base or erythromycin ethylsuccinate. Efficacy using

erythromycin treatment is only 80%, so follow-up testing on infants is recommended. If infection was not cleared, a second course of similar therapy is recommended (Table 3).

PREVENTION AND FUTURE RESEARCH

Implementation of a comprehensive *C. trachomatis* screening program can lead to a 60% reduction in the incidence of PID (63). With the availability of noninvasive, highly specific, and sensitive methods for the detection of *C. trachomatis* infection, opportunistic chlamydia screening has great potential for controlling the spread of infection through early detection and early treatment. Importantly, this includes the detection and treatment of subjects with asymptomatic infection. Combined, these screening efforts should help to prevent the development of adverse sequelae and further transmission of the infection.

Despite the efficacy of antibiotics in treating *C. trachomatis* infection, treatment is primarily given to those with symptomatic infections. Continued transmission by untreated individuals with asymptomatic infection hampers control efforts difficult. To achieve more effective control measures, the development of a safe and efficacious human vaccine is necessary, but has eluded researchers to date. Ongoing animal studies, however, do have promise. Novel antigens that induce protective immunity in *C. trachomatis* mouse models have been identified (64,65) and provide vaccine candidates that may be suitable for human study. Also in murine models, the intranasal administration of a secreted chlamydial protein was found to enhance resolution of infection and provide protection against oviduct pathology (66). These advances in chlamydia vaccine development should ultimately lead to better chlamydial control measures and a reduction in the global prevalence rate of *C. trachomatis* infection.

Table 3 Treatment Recommendations for Chlamydial Infections

Recommended regimens

- Azithromycin 1g orally, single dose, or
- Doxycycline 100mg orally twice a day for 7 days

Alternative regimens

- Erythromycin base 500mg orally four times a day for 7 days, or
- Erythromycin ethylsuccinate 800mg orally four times a day for 7 days, or
- Ofloxacin 300mg orally twice a day for 7 days, or
- Levofloxacin 500mg orally once daily for 7 days

For pregnant women

Recommended regimens

- Azithromycin 1g orally, single dose, or
- Amoxicillin 500mg orally three times a day for 7 days

Alternative regimens

- Erythromycin base 500mg orally four times a day for 7 days, or
- Erythromycin base 250mg orally four times a day for 14 days, or
- Erythromycin ethylsuccinate 800mg orally four times a day for 7 days, or
- Erythromycin ethylsuccinate 400mg orally four times a day for 14 days

For newborns

- Erythromycin base or ethylsuccinate 50mg/kg/day orally divided into four doses daily for 14 days

For children who weigh <45kg

- Erythromycin base or ethylsuccinate 50mg/kg/day orally divided into four doses daily for 14 days

For children who weigh >45kg but who are aged <8 years

- Azithromycin 1g orally, single dose

For children aged >8 years

- Azithromycin 1g orally, single dose, or
- Doxycycline 100mg orally twice a day for 7 days

87 *Candida* and parasitic infection: Helminths, trichomoniasis, lice, scabies, and malaria

Jeanna M. Piper

CANDIDIASIS IN PREGNANCY

Yeast infection is an important issue in women's health, even though systemic fungal infection is exceedingly rare in women of childbearing age. The presence of *Candida* organisms is almost universal. Three-fourths of all women have symptomatic *Candida* vulvovaginitis during their lifetime and almost half of those with an initial attack have additional episodes (1). *Candida* organisms are also isolated by culture in 8% of asymptomatic females (2). The dysuria, itching, and inflammation that accompany symptomatic infections may be severe enough to interrupt daily activities and prompt the patient to seek medical attention or use of over-the-counter products to relieve symptoms.

More than 100 species of *Candida* have been identified, with many further classified to the strain level (3). Only seven species of *Candida* are identified frequently in human clinical cultures. *Candida albicans* and *C. tropicalis* form 80% of all clinical isolates (4,5). *C. glabrata* and *C. parapsilosis* comprise an additional 10% to 15%, leaving 5% to 10% distributed among other species (5,6).

The species breakdown in vulvovaginal specimens differs in that *C. albicans* is identified in 80% to 85% of all positive vaginal cultures, *C. glabrata* in 10% to 15%, and *C. tropicalis* in 5%, with minimum identification of other species (7).

Pathophysiology of *Candida* Infection

Candida are dimorphic organisms with blastospore and mycelial forms. The blastospore form (budding yeast) is associated with transmission and colonization, and is the form found in the bloodstream in systemic infection. Germinated yeast with mycelia and pseudohyphae is the tissue-invasive form that causes symptomatic disease. The *Candida* life cycle is one of rapid budding, maturation, and degeneration. Budding occurs as a new cell outgrowth from the mother blastospore. Following mitosis, a septum partitions the two cells and budding resumes in each cell. Mycelium formation begins as a cylindrical outgrowth from the cell wall. Septa are laid down behind the apical tip as the hyphae shoot lengthens. Blastospores are then produced just behind the newly created septa. Pseudohyphae are a morphologic derivative between budding and hyphal growth that is found in all *Candida* species (8).

The attachment of *Candida* to vaginal cells has been reported to be mediated by mannose-containing receptors on the surface of the mucosal epithelial cells (3). The effect of estrogen in increasing vaginal epithelial avidity for candidal adherence may involve these surface receptors (1). Intracellular receptors for estradiol and corticosteroids have been identified in *C. albicans* and *C. glabrata* (9,10). Although the

mechanisms of action of these receptors have not yet been elucidated, high levels of estrogens and corticosteroids are associated with increased candidal virulence and tissue invasion.

The human host defense mechanism against candidal vaginitis is primarily based on the natural bacterial flora of the vagina, particularly lactobacilli. Lactobacillus is thought to decrease fungal growth via competition for nutrients, mechanical interference with candidal mucosal adherence, and chemical inhibition by lactobacillus secretions (1). Cell-mediated immunity also plays a role in preventing infection. Monocytes and leukocytes prevent deep tissue invasion and systemic infection. IgG and IgM are elicited systemically and IgA is secreted in cervical mucus in response to acute candidal infection, but infection rates are not increased in patients with isolated immunoglobulin deficiencies (1).

Factors that predispose a patient to *Candida* vulvovaginitis can be categorized as systemic, localized, or exogenous. Systemic conditions associated with genital candidiasis include diabetes, nondiabetic glycosuria, endocrinopathies, debilitating disease, older age, and pregnancy. Local conditions that alter the barrier function of the perineal epithelium allow higher infection rates including tissue maceration (from moisture accumulation, urinary leakage, or abrasion from tight-fitting clothing) and thinning of the skin (from menopause or topical steroid use). Exogenous factors include commonly prescribed medications such as antibiotics (particularly tetracycline, ampicillin, and oral cephalosporins), immunosuppressive agents, and systemic steroids. Oral contraceptives were previously thought to increase infection rates, but recent studies with the low-dose combination pills have shown no effect (1).

Diagnosis of Candidiasis

Although the diagnosis of *Candida* infection is generally suspected on the basis of physical findings, confirmation should be obtained. The use of saline or potassium hydroxide (KOH) wet mounts of the vaginal secretions is the most rapid and least expensive confirmatory test. If a saline preparation is used, dark-field or phase-contrast microscopy may aid in visualization of the fungal elements. Potassium hydroxide (10–20% solution) lyses the epithelial cells, allowing the *Candida* to be seen more easily. Wet-mount analysis is highly specific, but sensitivity is poor (as low as 20%) (11). Other microscopic methods of *Candida* detection include Gram stain of smears or touch preps and Papanicolaou smears. If microscopic analysis is negative despite persistent symptoms following therapy, culture should be performed prior to further treatment. Infected secretions are inoculated into tubes

of candida culture media [Sabouraud's dextrose slants or Nickerson's medium have the highest sensitivity (90%) and specificity (70%) for *Candida* strains] (12) and incubated at 25°C to 37°C (3). *Candida* grows quickly, often within 24 hours. Isolates from sterile sources should be subcultured and identified to the species level, but vaginal specimens need only categorization to either albicans or non-albicans. Species differentiation is based on subculture characteristics. *C. albicans* exhibits both germ tube and chlamydospore growth (3). *C. parapsilosis*, *tropicalis*, and *glabrata* produce neither.

Culture of yeast from blood or tissue specimens is more challenging. Automated systems such as the Bactec radiometric system (Johnston Laboratories, Towson, MD) can detect *Candida* in 2 to 4 days. Use of biphasic media further improves sensitivity, but requires 5 to 9 days for adequate growth (3). Tissue biopsy may inadvertently reveal candidal infection (when performed for other indications, not recommended if candida suspected) with partial or total destruction of the surface epithelium and filaments of fungus extending into the underlying tissues, covered by a thick film composed of inflammatory cells, necrotic debris, yeast cells, and pseudohyphae (13).

Clinical Presentations of Candidal Infections

Vulvovaginal itching and burning are the most common symptoms of *Candida* vulvovaginitis (reported by 60% of women with positive yeast cultures) (11) along with external dysuria and a white, curdled vaginal discharge. One-third of females with positive vaginal *Candida* cultures are asymptomatic, while one-fourth of women with negative cultures have symptoms (11). The symptom spectrum of vulvovaginal candidiasis goes from acute/exudative (sudden onset, heavy discharge loaded with yeast) to progressive/inflammatory (minimal discharge, few organisms, severe itching). The pruritus may be a hypersensitivity reaction and may worsen with occlusive clothing and in the premenstrual phase of the cycle (14).

Classic physical findings for *Candida* vulvovaginitis are bright erythema and skin erosions with satellite pustules. The pustules are non-follicular and are scattered around the eroded areas. The erosions are superficial with a narrow white border of scale. In advanced cases, the entire perineum may appear

scalded and oozing, with excoriations and fissures. Edema may be a finding in both early and advanced disease. Inguinal lymphadenopathy may accompany perineal involvement. Speculum examination reveals inflamed, erythematous, edematous mucosa with white thrush patches and pooling of the thick, white, curd-like discharge in the posterior fornix. The cervix may become red, inflamed, and quite friable.

Males with *Candida* balanitis (inflammation of the glans penis) have swelling, itching, and burning of the glans and shaft of the penis. Symptoms are more common in uncircumcised males (75%); circumcised men with positive yeast cultures are usually asymptomatic (90%) (2). Physical findings in the male with *Candida* balanitis include edema, erythema, and peeling of the glans penis and scrotum. Transient nonprogressive penile inflammation following intercourse may be due to a hypersensitivity reaction to *Candida* in the female partner's genital tract (2).

Therapy of Vulvovaginal Candidiasis

Current recommended therapy for vulvovaginal candidiasis is use of a topical imidazole. Imidazoles inhibit fungal cell wall synthesis and are absorbed in small amounts through mucous membranes (15). There are five topical azoles for the treatment of vulvovaginal candidiasis currently available in the United States (butoconazole, clotrimazole, miconazole, terconazole, and tioconazole) (16) many of which have multiple dosing forms as well as multiple brand names associated. Dosing information for current intravaginal azole treatments are listed in Table 1. There are no significant differences in efficacy or safety between the currently available topically applied azole products, with the caveat that longer duration of therapy typically results in slightly higher cure rates, so choice of product can be based on cost and convenience of dosing regimen.

Oral treatment of vulvovaginal candidiasis has become quite common with the approval of single dose, oral fluconazole 150mg (Diflucan®). Fluconazole has been shown to be as effective as intravaginal clotrimazole (200mg/day for 3 days) (17), intravaginal miconazole (1200mg single dose) (18), and oral ketoconazole (400mg/day for 5 days) (19). Short-term response rates of 94% (symptomatic) and 85% (mycologic) have been reported (20). The older oral medication used for

Table 1 Topical Azoles for Treatment of *Candida* Vulvovaginitis

Generic name	Formulation	Daily dose	Duration of dosing
Butoconazole	2% cream	5g	3 days
Butoconazole ^a	2% cream	5g	1 day
Clotrimazole	1% cream	5g	7–14 days
Clotrimazole	2% cream	5g	3 days
Miconazole	2% cream	5g	7 days
Miconazole	4% cream	5g	3 days
Miconazole	Suppository	100mg	7 days
Miconazole	Suppository	200mg	3 days
Miconazole	Suppository	1200mg	1 day
Terconazole ^a	0.4% cream	5g	7 days
Terconazole ^a	0.8% cream	5g	3 days
Terconazole ^a	Suppository	80mg	3 days
Tioconazole	6.5% ointment	5g	1 day

^aAvailable only by prescription in the United States.

vulvovaginal candidiasis, ketoconazole (Nizoral®), may still be considered for use in recurrent or resistant cases, but its use is limited by gastrointestinal side effects and ability to cause idiosyncratic hepatitis. When taken daily (400 mg for 14 days, then 100 mg for 6 months), ketoconazole has been shown to reduce recurrence rates in complex cases (21).

Currently recommended alternative treatments for use in resistant cases or women with azole allergies include nystatin, boric acid, and gentian violet. Nystatin (Mycostatin®) is a polyene antifungal, which binds to sterols in the fungal membrane, causing membrane incompetence and allowing intracellular components to leak out (15). Polyenes are not well absorbed orally or via mucous membranes. Boric acid powder is placed in capsules, with a 30-day cure rate of 72% when given as 600 mg daily for 14 days (22). Boric acid therapy can provide a very low-cost alternative for therapy of yeast vaginitis for resource-limited settings. Gentian violet (1% solution painted onto the affected areas two or three times a week) can provide rapid symptomatic relief, but is quite inconvenient due to permanent staining of skin and clothing. Gentian violet is fungicidal via interference with fungal enzymes (15).

Vulvovaginal Candidiasis in Pregnancy

Vaginal colonization with yeast occurs in 30% to 40% of all pregnancies (23). The attack rate is higher in the third trimester and symptomatic recurrence is more common than that in nonpregnant patients. The cause of increased prevalence in pregnancy is not known, but theories include fungal growth promotion via estrogen receptors on the vaginal mucosa and within the yeast cells, as well as improved fuel for growth due to higher mucosal glycogen content (23). Intra-amniotic infection with yeast is exceedingly rare with intact membranes, but can be seen in the presence of a foreign body, such as a cerclage or an intrauterine device, and may cause preterm labor or spontaneous abortion by invading the umbilical cord and major fetal organs (15). Up to 80% of infants that pass through an infected birth canal at delivery are colonized with yeast typically resulting in oral colonization (thrush) or diaper dermatitis, both easily treated with local therapy (24). Congenital cutaneous candidiasis is a disseminated papulovesicular to pustular dermatitis involving mainly the head, neck, palms, and soles, which resolves rapidly with topical antifungal therapy and carries little risk of progression to systemic infection in normal neonates (24).

Treatment of *Candida* vulvovaginitis in pregnancy is typically limited to topical azoles and nystatin (16,25). For many years, nystatin was the primary drug used for *Candida* vulvovaginitis in pregnancy because its extremely poor absorption was felt to improve its safety (pregnancy category B) (25). As studies have proven, the increased efficacy of the azole antifungal agents, miconazole, clotrimazole, butoconazole, and terconazole, has become the mainstays of therapy in pregnancy. They have been used extensively in human pregnancy with no adverse effects or increase in congenital malformations noted, but most remain pregnancy category C due to the absence of adequate controlled human studies. There is no clear leader from this group in terms of efficacy and patient satisfaction, so selection may be based on availability and cost. Seven-day treatment is usually needed in pregnancy due to the higher rates of treatment failure and

recurrence. Cure rates are typically 5% to 10% lower than those in nonpregnant women for the same dosing regimen.

None of the alternative agents are recommended for use in pregnancy. Fluconazole is associated with fetal loss in animal studies with several small human studies that have shown no safety concerns, but are not adequate to recommend use in pregnancy (pregnancy category C) (25). Ketoconazole given orally has been shown to increase abortion and fetal loss in mice and rats, with no adequate human studies to document its effect on human pregnancy; therefore, its use for vaginitis in pregnancy is not recommended (pregnancy category C) (25). Boric acid is not recommended in pregnancy due to limited absorption of borate through the mucous membranes (less than 1 mg/mL serum levels). Gentian violet is not recommended for use in pregnancy because no adequate studies have been performed to judge its safety (pregnancy category C).

Recurrent Vulvovaginal Candidiasis

Almost one-half of women with an initial infection will have additional episodes. The subsequent attacks may be newly acquired cases or persistent infection due to incomplete eradication. Studies of culture-proven vaginal candidiasis with appropriate antifungal therapy show persistence of the same *Candida* strain in 20% to 25% of patients at 4- to 6-week follow-up (1). Recurrent candidal vaginitis may be due to chronic recolonization of the vagina from the intestine. Studies have shown a high strain correlation between the vagina and the intestine in those with intestinal colonization (1), but several studies of intestinal treatment with nystatin and ketoconazole have shown reduction or complete eradication of intestinal yeast with no impact on vaginal recurrence rates (21,26).

The role of male-partner penile colonization in promoting recurrent vaginitis is unresolved. Evidence in favor of a role for this includes a fourfold higher rate of asymptomatic penile colonization and the presence of *Candida* in the ejaculate of partners of women with recurrent vaginitis (1). Evidence against this includes the lack of documentation of sexual transmission previously outlined and the lack of improved recurrence rates following treatment of the male partner. Attention to hygiene should be recommended in all cases of *Candida* vaginitis. A trial of therapy in the male partner may be attempted if other therapy is unsuccessful in resolving recurrent infections.

All patients with recurrent episodes of vulvovaginal candidiasis without an obvious precipitating factor should be evaluated for underlying systemic disease (diabetes, HIV, or other debilitating disease) and use of over-the-counter or "home" remedies for the perineal and vaginal areas. Patients with continued pruritus without evidence of organisms may be experiencing an allergic reaction, not only to the *Candida*, but also to the antifungal medications in which case the inflammation should improve following cessation of therapy. Refractory vaginitis is a multifocal problem with no single solution. Inadequate therapy, resistant organisms, intestinal colonization, male-partner colonization, vaginal flora abnormalities, immunodeficiency, hypersensitivity reaction, and hampered barrier function may all be involved to a differing extent in individual patients with recurrent candidal

infections. Adequate evaluation, with therapy aimed at individual components, is the best approach.

Systemic Candidiasis

Systemic candidiasis typically occurs in debilitated patients with diabetes, acquired immunodeficiency syndrome, intravenous drug use, malignancies, chemotherapy, prolonged antibiotic or steroid therapy, and intravenous hyperalimentation (27). Systemic infection can be subdivided into disseminated infection, fungemia, and single-organ infection (meningitis, endocarditis, pneumonia, arthritis, peritonitis, laryngitis, endophthalmitis, and urinary tract infections). Systemic candidal infection is usually associated with an indwelling foreign body (intravenous catheter, Foley catheter, endotracheal tube, etc.). Symptoms are variable; however, persistent fever, in spite of broad-spectrum antibiotic coverage, is the most frequent clue, but may be masked in patients on high-dose steroids. Hypotension and mental status changes (confusion to obtundation) are also common signs. The diagnosis of disseminated candidiasis may be difficult. Blood cultures may be negative in 40% to 60% of cases proven by autopsy. Tissue biopsy, culture of fluids from sterile spaces, and urine cultures may be used to enhance detection in those at risk.

Treatment of systemic candidiasis has been changed significantly with the recent approval of new medications including additional second-generation triazoles (voriconazole and posaconazole) and a novel class of antifungals, the echinocandins (caspofungin, micafungin, and anidulafungin) (28,29). These new products have replaced amphotericin B and 5-fluocytosine for the treatment of candidemia with the echinocandins currently recommended as the drugs of choice due to higher efficacy and voriconazole/posaconazole as second-line treatment due to similar efficacy to amphotericin with a much improved side effect profile (28). Choice of echinocandins is usually based on local availability and cost. Unfortunately, survival rates for systemic candidiasis remain quite low despite improved therapy due to delays in diagnosis (resulting in delayed treatment) and the severity of underlying disease, particularly immunocompromise and diminished renal function (27). Since the new triazoles and echinocandins are quite expensive, amphotericin B and 5-fluocytosine continue to be commonly used in low-resource settings.

Systemic Candidiasis in Pregnancy

Systemic candidiasis in women of childbearing age is quite rare, but occasionally seen in cases with significant underlying disease (25). There are no adequate controlled studies during pregnancy for any of the medications used for systemic candidiasis; however, the life-threatening nature of this infection clearly outweighs any concerns over impact of the medications on pregnancy. Animal data available for both caspofungin and micafungin showed fetal loss and other issues (impairment of ossification for caspofungin and visceral abnormalities for micafungin) in both rats and rabbits with inadequate human data, resulting in both being labeled as pregnancy category C (25). The most experience exists for amphotericin B (pregnancy category B) (25), but the increased efficacy of the echinocandins should still be considered in the selection of treatment. Consultation with infectious disease

specialists and hospital infection control officers is recommended for these unusual life-threatening infections in pregnancy.

HELMINTHIC INFECTION IN PREGNANCY

Introduction

Helminths are parasitic worms that spend at least a portion of their life cycle in an animal or human host. Helminths include cestodes (tapeworms), trematodes (flukes), and nematodes (roundworms). Helminthic infection has a worldwide distribution, but is more prevalent in underdeveloped countries. Although the prevalence rates have fallen in the developed world, helminthic infection has by no means disappeared. Life-threatening parasitic infection in pregnancy is uncommon in industrial nations of the world, but may be seen in individuals who have recently immigrated from less developed areas.

The effects of helminthic infection on pregnancy, although generally benign, should be recognized and treated. Anemia is a common feature of intestinal parasitic infection (owing to intestinal blood loss) and may compound anemia of pregnancy. Malnutrition may occur as a result of competition for nutrients. Chronic helminthic infection may lead to a debilitated state, with the possibility of superimposed bacterial infection. Since most helminthic infections in pregnancy are only mildly symptomatic, previously most were treated symptomatically until the postpartum period when definitive treatment was given. More recently, there have been increasing recommendations not to delay treatment, particularly in cases impacted by anemia. Each organism, however, has to be considered individually for therapeutic recommendations.

The diagnosis of helminthic infection must be individualized, but may be suspected on the basis of gastrointestinal symptoms (nausea, vomiting, and diarrhea) and a history compatible with exposure. With notable exceptions, helminthic infection is diagnosed by demonstration of eggs or larvae in feces. In heavy infection, eggs and larvae may be seen directly in saline wet mounts. To evaluate lighter infections, concentration must be performed via zinc sulfate flotation or formalin–ether sedimentation prior to saline wet-mount examination. Traditionally, examination of stool specimens from 3 consecutive days has been recommended to increase sensitivity in detection of ova and parasites in lightly infected cases. In moderately to heavily infected cases, a single-specimen evaluation should be as effective as multiple testing (30).

A description of the classification system for helminths is followed by review of the more commonly identified helminths. The chapter is completed by a description of the commonly used anthelmintic agents and their status for use in pregnancy and lactation. Treatment recommendations for all of the helminths detailed in this chapter are based on (i) the current treatment guidelines in the CDC parasites A to Z Web site (www.cdc.gov/parasites/az/index.html) section for each organism (obtained by selecting the organism from the index and then selecting “Resources for Health Care Professions”) or (ii) The Medical Letter article entitled “Drugs for Parasitic Infections” available at The Medical Letter Web site (www.medicalletter.org). Additional information regarding laboratory diagnosis of helminthic infections can be obtained

at the DPDx Web site (www.dpd.cdc.gov/dpdx/HTML/DiagnosticProcedures.htm), which is a service of the CDC Division of Parasitic Diseases and Malaria. Links to the applicable sections of the Medical Letter “Drugs for Parasitic Infections” may also be accessed via the treatment tab for each organism on the DPDx Web site.

Classification and Description of Common Helminthic Infections

All helminths are classified as Platyhelminthes (flatworms) or Nematoda (roundworms). Flatworms are further divided into cestodes and trematodes (Table 2). Cestodes, or tapeworms, have segmented bodies consisting of proglottids attached via the neck zone to a head or scolex. The scolex provides attachment and locomotion via grooves, suckers, and hooks extending from its surface (Fig. 1). Tapeworms are hermaphroditic, with both male and female reproductive organs contained in each segment. There is no organized digestive tract; nutrients are absorbed via the integument. Excretory and nervous systems are present, but only in primitive form (31).

Trematodes, or flukes, have a flattened, leaf-like body with one or more ventral muscular suckers to provide attachment. Flukes are monoecious (hermaphroditic), with separate male and female reproductive organs that connect at the common genital atrium. Trematodes have a more advanced alimentary canal, nervous system, and excretory system (Fig. 2). All trematodes require a period of external development in a snail host (31). Nematodes are unsegmented worms with an external cuticle, developed internal organ structures,

and somatic musculature (Fig. 3). Most nematodes are dioecious (heterosexual), with male and female sexual differentiation, and mating required for reproduction. The alimentary, excretory, and nervous systems of nematodes are more differentiated than those of other helminths. Most nematodes undergo four molts, with shedding or resorption of the old external cuticle, and formation of a new cuticle (31).

Cestodes

Taenia saginata and Taenia solium

Taenia saginata and *T. solium* have a worldwide distribution and cause taeniasis or tapeworm infection. Adult taenias are 3 to 8 m in length and comprise a small scolex (1–2 mm) and multiple proglottids, each about 0.5 cm × 1–2 mm in size (32). *Taenia* eggs are yellow to brown and spherical, with thick shells (Fig. 4). The life cycle of the taenias involves a definitive host (humans) and an intermediate host (*T. saginata*, cattle; *T. solium*, pigs). Eggs are passed in feces and reach pastures where they are ingested by the intermediate host. The larvae hatch and migrate to the muscle tissue, where they remain until the raw beef or pork is ingested by the definitive host. The infective form (cysticerci) requires 3 to 5 months to mature to adulthood. *Taenia* adult worms may live in the human small intestine for 25 years. The diagnosis of taenia infection is based on identification of eggs or proglottid segments in the patient’s stool specimen (32).

T. solium eggs can be directly infective if ingested by humans, causing cysticercosis. Extreme care must be taken in

		<i>Dirofilaria</i>

Figure 1 *Taenia saginata* adult scolex, showing suckers. Source: From Ref. 32.

handling all specimens with taenia eggs, as *T. solium* are not easily distinguished from *T. saginata* (32). Cysticercosis is the disease caused by larval migration throughout the body. Cysticercosis may be severe, even fatal, due to inflammation of vital organs, particularly cardiac muscle (33).

The clinical effects of taeniasis are usually minimal, but a minority of cases report abdominal discomfort, vomiting, and diarrhea (31). Rare cases of appendicitis and intestinal obstruction do occur. The treatment of choice is praziquantel (single 5–10 mg/kg oral dose), regardless of pregnancy status; niclosamide (single 2-g oral dose) is an alternative. Taenia infection generally has minimal effects on pregnancy and can typically be left untreated until the postpartum period, unless a symptomatic infection with *T. solium* is diagnosed (owing to the risk of cysticercosis).

Diphyllobothrium latum

Diphyllobothrium latum, or fish tapeworm, is found in northern Europe, North America, and Japan, specifically in temperate areas with cold, clear lakes. *D. latum* adult worms are 4 to 10 m long, with a small scolex (3 × 1 mm) and wide, short proglottids (32). The eggs are yellow to brown and ovoid, with an operculum (a lid-like structure). The life cycle begins as eggs that are passed in feces into water, where they hatch 2 weeks later, with coracidium released. The coracidium are ingested by copepods, where they develop to the procercoid

Figure 2 *Clonorchis sinensis* adult fluke (carmine stain). Source: From Ref. 32.

stage. Following ingestion of the copepod host by fish, the infective form (plerocercoid or sparganum) matures to await ingestion of raw fish by humans or other carnivores. *D. latum* migrates to the small intestine, where it attaches and matures to an adult. The adult worm may survive for up to 25 years, releasing its eggs in the feces (32). Diagnosis is based on finding eggs in feces (34).

Fish tapeworm infection may be asymptomatic or may have mild-to-severe gastrointestinal symptoms. Praziquantel (single 5–10 mg/kg oral dose) and niclosamide (single 2-g oral dose) are the most commonly used therapies. Unless infection is severe, anthelmintic therapy is typically delayed until the postpartum period. Diphyllbothriasis may cause vitamin B₁₂ deficiency in pregnancy, owing to malabsorption; therefore, vitamin B₁₂ supplementation is recommended.

Figure 3 *Enterobius vermicularis* adult female. Source: From Ref. 32.

Hymenolepis nana

Hymenolepiasis or dwarf tapeworm infection is cosmopolitan in distribution. *Hymenolepis nana* adult worms are small tapeworms measuring 2 × 4 cm, with short wide proglottids (32). The eggs are spherical with a thin hyaline shell (Fig. 5). The definitive hosts of *H. nana* are mice and humans; beetles are intermediate hosts. The life cycle involves passage of eggs in feces with subsequent ingestion by beetles. The beetles are eaten by mice in the natural life cycle. Humans can be infected directly, by ingestion of the eggs. In humans, the eggs hatch, cysticercoids develop in the wall of the small intestine, and tapeworms emerge into the lumen of the intestine to mature to adulthood. Eggs are then passed in feces to restart the cycle. Hymenolepiasis is diagnosed by the finding of characteristic eggs in feces (32).

The clinical effect of dwarf tapeworm infection in humans is variable. There may be no symptoms or gastrointestinal complaints (diarrhea, nausea, anorexia, or vomiting) (31). The course is generally not severe. Praziquantel (single 25 mg/kg oral dose) is the drug of choice. Pregnancy is not threatened by hymenolepiasis, and treatment is typically deferred to the postpartum period.

Figure 4 *Taenia* egg (*T. solium* and *T. saginata* eggs are indistinguishable). Source: From Ref. 32.

Figure 5 *Hymenolepis nana* egg. Source: From Ref. 32.

Echinococcus granulosus, *Echinococcus multilocularis*, and *Multiceps multiceps*

The definitive hosts of echinococcus and multiceps species are dogs and wild carnivores. On occasion, humans are an incidental host, infected by the ingestion of infective eggs. The embryos hatch in the intestine and migrate through the body to various organs, where cysts develop. Clinical diagnosis is

based on biopsy of the cyst/granuloma area or on immunologic testing.

Symptoms occur as the cysts enlarge and create a space-occupying lesion (31). *Multiceps multiceps* cysts are commonly located in the subarachnoid space and may cause meningitis (31). Pregnancy can be threatened if the echinococcal cysts are located in the uterine muscle. Intrauterine growth retardation and even impairment of labor may result from uterine cysts. Migration and encystment in vital organs can be life-threatening. Treatment is immediate, regardless of pregnancy status. Surgery to resect the cyst is the best therapy. Albendazole (440 mg orally BID \times 1–6 months) can be used to reduce cyst size prior to surgery and may resolve smaller cysts without surgery. If surgery is not feasible and antepartum therapy is needed, praziquantel [100 mg/kg orally (divided into three doses) \times 1 day, followed by 50 mg/kg/day orally (divided into three doses per day) \times 28 days] is an alternative therapy that may be preferred for use in pregnancy (35), but it is not as effective in reducing cyst size.

Trematodes

Schistosoma mansoni, *Schistosoma japonicum*, and *Schistosoma haematobium*

Schistosomiasis or bilharziasis is mainly seen in the Middle East, Africa, and South America, but can be found in immigrant populations worldwide. Adult flukes are 0.5 to 2 cm in length, with females longer than males. Male flukes are wider with a posterior fold, the gynecophoric canal, in which the female rests. All schistosoma eggs are non-operculate with a transparent shell and either a lateral spine (*S. mansoni*) or terminal spine (*S. japonicum*) (32). Schistosoma adult worms live in the small blood vessels of the pelvic venous plexi. The female lies within the canal of the male for copulation and oviposition. The eggs migrate through the vessel wall and intervening tissues to reach the bladder or bowel, from which the eggs are excreted. If passed into water, the eggs hatch into a miracidial form that can penetrate and infect snails, the intermediate host. While in the snail, the miracidia mature to cercariae. The cercariae burst out of the snail host into water, where they directly infect humans through skin penetration. The schistosomule is transported via the venous system, through the heart and pulmonary vessels, to be propelled into the arterial system by the left ventricle. The schistosomules mature in the large vessels prior to migration to the terminal vascular beds, where the life cycle is completed (36). All therapies destroy only the flukes and have no effect on the migrating eggs (36). Diagnosis of schistosomal infection is based on the finding of eggs in urine, feces, or vaginal secretions, or the identification of adult worms or eggs in biopsy of the granulomas.

Initial infection (schistosome penetration) results in itching and papular rash. The migration of immature flukes causes fever, cough, allergic symptoms, and gastrointestinal complaints 2 to 4 weeks after initial exposure. Chronic schistosomiasis may cause anemia, cirrhosis, and urogenital disease. In females, this may include obstructive uropathy, abdominal pain, menorrhagia, salpingitis, oophoritis, sterility, and ectopic pregnancy (36). Praziquantel (20 mg/kg orally BID \times 1 day for *S. mansoni*, *S. haematobium* or *S. intercalatum*, or 20 mg/kg

orally TID \times 1 day for *S. japonicum* or *S. mekongi*) is the treatment of choice for schistosomiasis.

Schistosome infiltration of the placenta has been reported, but is quite rare (36). Infection of a fetus with schistosomiasis was last reported in 1920 (36). Schistosomiasis has been associated with a number of adverse pregnancy outcomes including spontaneous abortion, preterm labor, low birth weight, and maternal morbidity/mortality, but additional prospective data are needed to quantify the impact (37). Heavy maternal schistosomal infection has been associated with decreased hemoglobin levels and increased prevalence of anemia in pregnant women, additive upon the typical anemia of pregnancy. Maternal anemia is strongly associated with low birth weight and maternal mortality (particularly in cases with antepartum or postpartum hemorrhage). Chronic schistosomiasis has also been associated with increased release of pro-inflammatory cytokines, which have been implicated in both the decreased appetite seen with schistosomiasis (which may contribute to low birth weight through maternal malnutrition) and with inflammation of the placenta (which may cause abortion and preterm labor) (37).

In the past, treatment of schistosomiasis in pregnant women was typically postponed until after delivery, but with more information associating maternal infection with adverse pregnancy outcomes, World Health Organization (WHO) recommended in 2002 that pregnant women with schistosomiasis be treated with praziquantel (dose same as listed above for nonpregnant adults) upon diagnosis and that pregnant women not be excluded from mass drug administration (MDA) programs aimed at the elimination of schistosomiasis (38,39). The “informal” WHO recommendation remains controversial since praziquantel is not specifically licensed for use in pregnancy, but efforts are underway to obtain the prospective human safety data needed to convince resistant in-country authorities to implement this recommendation (37).

Nematodes

Enterobius vermicularis

Enterobiasis or pinworm infection is universally distributed and is mainly seen in children. Adult male worms are small (2–3 mm) and females are larger (8–13 mm), both with long, pointed tails (40). Pinworm eggs are elongated with one flat side and have thick, colorless shells (Fig. 6). The definitive hosts for *Enterobius vermicularis* are humans. The female pinworms exit the rectum to lay eggs on the perianal skin overnight. The eggs embryonate in 4 to 6 hours to become infective. Eggs that are ingested hatch and develop in the lower intestinal tract (the cecum, appendix, and colon). Ingestion is facilitated by hand-to-mouth transmission or fomites. The adult worms may live for several months in the colon and rectum (32). Diagnosis is based on clinical suspicion and cellulose tape prep from perianal skin. Eggs are not found in feces. Cellulose tape prep is performed by taking clear cellulose tape, touching it to the perianal skin, and then adhering it to a microscope slide for examination (32). The tape prep is most accurate if done immediately upon arising, prior to bathing. The symptoms of pinworm infection are all related to the perianal egg deposition. Insomnia, restlessness, perianal itching/inflammation, and perianal bacterial infection

Figure 6 *Enterobius vermicularis* eggs. Source: From Ref. 32.

(secondary to excoriation) are the common clinical effects (31). Albendazole (single 400-mg oral dose followed by a second dose 14 days later), mebendazole (single 100-mg oral dose, followed by a second dose 14 days later), and pyrantel pamoate [single 11-mg base/kg (maximum 1-g base) oral dose, followed by a second dose 14 days later] are the drugs most commonly used for treatment. The entire family should be treated simultaneously, and clothing and bedding should be washed with hot water or chlorine bleach.

Pinworms can migrate through the vagina, uterus, and fallopian tubes, but no detrimental effect on the fetus or the pregnancy has been reported (41). Therapy is typically delayed until after delivery, unless the infection is potentially compromising the pregnancy. Pyrantel pamoate can be used after the first trimester (41).

Trichuris trichiura

Trichuriasis, or whipworm infection, is cosmopolitan in warm, moist areas. Adult whipworms are 3 to 5 mm long, with a slender, whip-like anterior end used to thread its way into the colonic mucosa (32). Whipworm eggs are barrel shaped, with a thick shell and plugs at each end (Fig. 7). Humans are the definitive host for *Trichuris trichiura*. Whipworm eggs pass in feces into the soil for further development. Infective eggs are ingested and hatched. The larvae migrate to the large intestine, where they mature to adulthood. The adult worms may remain in the colon for more than 10 years. Whipworm infection is diagnosed by finding eggs in feces (32).

Symptoms vary from none, in light infection, to colitis with bloody, mucous diarrhea in heavier infestation (31). Chronic infection can result in rectal prolapse, due to inflammation. Whipworm may be treated with albendazole (400 mg orally \times 3 days), mebendazole (100 mg orally BID \times 3 days), or

Figure 7 *Trichuris trichiura* egg. Source: From Ref. 32.

ivermectin (200 μ g/kg/day orally \times 3 days). The impact of whipworm infection on pregnancy is mainly anemia due to increased gastrointestinal blood loss. Fetal infection has not been reported. Therapy for pregnant women is typically deferred until after delivery.

Trichinella spiralis

Trichinosis has a worldwide distribution, but is most prevalent in Europe and North America. The adult *Trichinella spiralis* are 1 to 4 mm in length (32). The female is viviparous, delivering larvae; thus, there is no external egg stage. All carnivorous species, including humans, are the definitive hosts. Most human infections result from ingestion of inadequately cooked meat. Bear, wild pig, boar, horse, and dog meat are the usual sources, but pork is the most common cause in the United States (42). Adult worms, living in the small intestine, release larvae into the mucosal epithelium. The larvae enter the bloodstream and migrate to muscle tissue, where they embed and mature to the infective stage. A cyst envelops the larva, and it remains infective until the cyst calcifies, killing the larva. When meat containing encysted larvae is ingested, the cysts are dissolved by gastric secretions, and the infective larvae are released. Within 36 hours, maturation occurs, and within a week larvae are produced, to become encysted in this new host. Diagnosis of trichinosis is based on the history of ingestion of undercooked meat and a compatible clinical picture (32). Definitive diagnosis requires either laboratory detection of specific antibodies or muscle biopsy finding encysted larvae (31).

The clinical effects of trichinosis in humans range from no symptoms to fatality. The initial ingestion of infected meat may cause diarrhea and gastroenteritis. The majority of symptomatology results from the larval migration and the resultant inflammatory response. Fever, edema, dyspnea, urticaria, weakness, and myositis are common manifestations (31). The ocular muscles are generally the most severely affected, but myocardial involvement is the most common cause of death (42). Therapy is a combination of anthelmintic agents, corticosteroids, anti-inflammatory agents, and supportive care (40). Mebendazole (200–400 mg orally TID \times 3 days followed by 400–500 mg

orally TID \times 10 days) and albendazole (400 mg orally BID \times 8–14 days) are the recommended drugs. Anthelmintic destroy adult worms, not the larvae; however, once larval production ceases the disease is self-limited; symptoms resolve as soon as all larvae are encysted.

Trichinosis in pregnancy typically follows a moderate course, but may result in abortion, preterm labor, or intrauterine fetal death (42). Intrauterine infection has been reported twice, resulting in fetal/neonatal death (42). Trichinosis in pregnancy should be treated with mebendazole or albendazole as above when the maternal condition is such that the benefit to the mother outweighs the potential risk to the fetus.

Ascaris lumbricoides

Ascariasis or roundworm infection is most prevalent in warm, moist climates, but can be seen anywhere. Adult worms are quite large (15–30 cm long), with males longer and thinner than females (32). Ascaris eggs have thick, bile-stained shells (Fig. 8). Humans are the definitive host. The life cycle begins as eggs are passed in feces into soil or water. The infective eggs are then ingested, with larvae released in the small intestine. The larvae migrate through the venous system to the lungs, where they cross into alveoli and climb the bronchial tree. The larvae are then swallowed, and return to the small intestine, to mature into adults (32). The life span of adult ascaris is less than 1 year (41). Ascariasis is diagnosed by finding eggs in feces or on barium enema, when elongated filling defects occur (31).

There are two types of clinical disease related to ascariasis. Loeffler's syndrome is heralded by inflammation and pulmonary symptoms due to the migration of the larvae. Migration of the adult worms may cause obstruction of the bile duct or the appendix (41). Migration of adult females into the hepatic duct allows eggs to be released into the liver,

Figure 8 *Ascaris lumbricoides* egg. Source: From Ref. 32.

resulting in multifocal abscess formation (31.) Most patients, however, have minimal or no symptoms. Albendazole (single 400-mg oral dose), mebendazole (100 mg orally BID \times 3 days or single 500-mg oral dose), and ivermectin (single 150–200 μ g/kg oral dose) are recommended for treatment.

Ascariasis in pregnancy is generally asymptomatic. Transplacental infection has been reported, but is quite rare (41). Pregnant women should, however, be treated prior to labor or cesarean section, because of the risk of adult worm migration, stimulated by the stress of labor or general anesthetics.

Capillaria hepatica and *Capillaria philippinensis*

Hepatic capillariasis has a worldwide distribution, whereas intestinal capillariasis is seen mainly in the Philippines and Thailand. The adult worms are 2 to 4 mm long (32). *Capillaria hepatica* adults live in the liver parenchyma, whereas *C. philippinensis* adults remain in the small intestine. *Capillaria* eggs have striated shells and are unembryonated. Humans are incidental hosts; birds and rodents are the definitive hosts. The *C. hepatica* life cycle involves passage of eggs into feces, which then embryonate and are ingested by rodents (or humans). The larvae hatch and migrate to the liver to mature. The adult worms deposit eggs in the liver, where they remain until the rodent is consumed by a carnivore. In digestion, the eggs are released from the liver and pass in the carnivore's feces to restart the cycle (32). *C. philippinensis* eggs pass into water, where they are ingested by fish, and develop to the infective stage. Birds (or humans) are infected by eating raw fish. The adult worms live in the birds' (or human's) intestine and pass eggs in its feces (32).

Hepatic capillariasis is quite uncommon in humans and requires liver biopsy for diagnosis. Intestinal capillariasis is more common and can be diagnosed by finding eggs in feces (32). The clinical course resembles sprue, with diarrhea and severe gastrointestinal symptoms (31). Human autoinfection can occur, worsening the prognosis significantly.

Capillariasis in pregnancy may be left untreated until postpartum if symptoms are mild. Severe cases must be treated antepartum. Mebendazole (100 mg twice a day for 3 days) is the drug of choice, regardless of pregnancy status (40).

Strongyloides stercoralis

Strongyloidiasis has a worldwide distribution, but is most common in warm climates with a high water table. Adult worms are all females. They measure 2 to 3 mm in length and live in the small intestine. *Strongyloides* eggs are thin shelled (32). Female worms deposit eggs in the intestinal mucosa, where they hatch, releasing larvae. The larvae migrate into the lumen and pass in the feces into soil. Following maturation in the soil, infective larvae infect humans through direct skin penetration. The larvae then migrate, via the venous system and lungs, to the intestine, where they mature to adulthood and lay eggs. The entire life cycle may occur outside the body (in soil) or inside the body (internal autoinfection) (32). Strongyloidiasis is difficult to diagnose. Fecal concentration techniques are required to find larvae in feces, owing to the low number present.

The clinical effects of *Strongyloides stercoralis* infection include rash or pruritus (penetration phase); pneumonitis and cough (migration phase); and abdominal pain, diarrhea,

nausea, and vomiting (intestinal phase) (31). Immunosuppressed patients are at high risk from fulminant autoinfection. The drug of choice for treatment is ivermectin (200 µg/kg/day orally × 2 days) with albendazole (400 mg orally BID × 7 days) listed as an alternative. Strongyloidiasis in pregnancy may be left untreated until postpartum if symptoms are mild. Severe cases should be treated antepartum.

Necator americanus and *Ancylostoma duodenale*

Hookworm infection is common throughout Africa, Asia, and the South Pacific. Adult worms are small (7–11 mm in length), with females being larger than males. Hookworm eggs are thin shelled and colorless (32). Adult hookworms may live in the human intestine for 5 to 15 years, with the eggs being passed in feces. The eggs enter soil, hatch, and mature to third-stage (infective) larvae (Fig. 9). Infective larvae directly penetrate human skin and migrate, via the lungs, to the small intestine, where they mature to adulthood (41). Hookworm infection is diagnosed by finding eggs in feces (32).

Light hookworm infection is asymptomatic. Heavy infection produces hypochromic macrocytic anemia, due to intestinal blood loss (31). Treatment is albendazole (single 400-mg oral dose), mebendazole (100 mg orally BID × 3 days or single 500-mg oral dose), or pyrantel pamoate [11 mg base/kg/day (maximum 1-g base) orally × 3 days].

Prior to modern therapy, severe hookworm infection in pregnancy was associated with significant maternal (27%)

Figure 9 *Necator/Ancylostoma* (hookworm) infective third-stage larva. Source: From Ref. 32.

and perinatal (23%) mortality (41). Maternal anemia, if untreated, may result in debilitation and heart failure (43). This maternal morbidity may cause fetal loss through abortion, preterm delivery, or stillbirth. Congenital infection has been reported (41). In 2002, WHO published a new guidance document recommending immediate treatment of hookworm infections in pregnant women beyond the first trimester, based in part on 20 years of experience using mebendazole in antenatal clinics in Sri Lanka without excess adverse events (38,39). Clinical trials of anthelmintic treatment for hookworm in pregnancy suggest that treatment is safe and may reduce maternal anemia, low birth weight, and infant mortality (44). Addition of iron therapy to anthelmintic treatment may further improve maternal anemia (44).

Toxocara canis

Toxocara canis (visceral larva migrans) is cosmopolitan, with dogs as the definitive host. The adult worms are 4 to 10 cm long and inhabit dog intestines. *Toxocara* eggs are thick shelled and spherical. Humans are incidental hosts (32). *Toxocara* eggs pass into soil, mature, and are ingested by rodents. Upon ingestion, the larvae are released and migrate throughout the body. Dogs ingest infected meat, with release of larvae in the stomach and maturation in the intestine. Human infection, called visceral larva migrans, occurs via ingestion of infective eggs with subsequent larval release and migration (32). Clinical diagnosis is based on history of contact with a pet and clinical examination. Laboratory diagnosis can be made by serologic testing for larval antigens, but there is some cross-reactivity with *Ascaris lumbricoides*. Clinical diagnosis is considered sufficient for treatment.

Human infection generally occurs in children who have contact with outdoor pets. The clinical syndrome varies based on the number of migrating larvae and the degree of inflammation and immune response to those larvae. It may include fever, cough, wheezing, abdominal pain, and hepatomegaly. Eosinophilia is usually present. Treatment with steroids and anti-inflammatory medications is indicated to reduce the inflammation associated with migration of the larvae. Albendazole (400 mg orally BID × 5 days) and mebendazole (100–200 mg orally BID × 5 days) are the recommended anthelmintic treatments. Infections during pregnancy may be left untreated until postpartum if symptoms are mild. Severe cases must be treated antepartum.

Anthelmintic Agents and Their Status for Use in Pregnancy

Anthelmintic agents are quite effective, with cure rates of 70% to 100% following a single course of therapy (34). Niclosamide, praziquantel, and pyrantel pamoate are the anthelmintic agents commonly used in pregnancy (Table 3). Mebendazole and albendazole are avoided, if possible, owing to the teratogenicity in rat and rabbit models but have quite a bit of reassuring human data despite the absence of large randomized trials to prove safety. Ivermectin is also avoided if possible due to teratogenicity in animals with very limited human experience thus far. Table 4 summarizes the classification of anthelmintic agents for use in pregnancy or lactation.

Pyrantel pamoate, a pyrimidine derivative, acts by paralyzing nematodes, allowing them to be expelled. Its action is similar to depolarizing neuromuscular blocking agents (41).

Table 3 Summary of anthelmintic Therapy and Recommendations for Treatment in Pregnancy

	First choice	Alternative
Cestodes		
Taenia ^c	Praziquantel	Niclosamide
Diphyllobothrium ^c	Praziquantel + vitamin B ₁₂	Niclosamide+ vitamin B ₁₂
Hymenolepis ^c	Praziquantel	
Echinococcus ^a	Surgery	Albendazole/praziquantel
Trematodes		
Schistosoma ^b	Praziquantel	
Nematodes		
Enterobius (pinworm) ^c	Pyrantel pamoate	Albendazole/mebendazole
Trichuris (whipworm) ^c	Mebendazole/albendazole	Ivermectin
Trichinella ^b	Steroids + mebendazole/albendazole	
Ascaris ^d	Albendazole/mebendazole	Ivermectin
Capillaria ^c	Mebendazole	
Strongyloides ^c	Ivermectin	Albendazole
Ancylostoma/necator (hookworm) ^c	Pyrantel pamoate + iron	Albendazole/mebendazole
Toxocara (visceral larva migrans) ^c	Steroids + albendazole/mebendazole	

^aTreat immediately. ^bTreat in second or third trimester. ^cTreat postpartum unless severe. ^dTreat prior to delivery.

Table 4 Summary of Pregnancy/Lactation Recommendations

Anthelmintic agent	Pregnancy use category	Recommendations for breastfeeding women
Albendazole	C	NR (no data)
Mebendazole	C	Compatible
Ivermectin	C	NR (no data)
Pyrantel pamoate	B ^a	Compatible
Niclosamide	B	NR (no data)
Praziquantel	B	Compatible

^aBased on available data, but never assigned by the FDA. Abbreviation: NR, Not recommended.

Pyrantel pamoate is very poorly absorbed, with half remaining in the intestinal tract unabsorbed. This poor absorption is the basis for its recommendation as first-line therapy in pregnancy. Blood levels of pyrantel pamoate are quite low, but it is not known whether it crosses the placenta. Animal teratology studies were negative, and no human malformations have been reported (compatible with pregnancy category B, but never labeled by the FDA). Pyrantel pamoate is considered safe for use while breastfeeding, due to its low absorption. Side effects (gastrointestinal complaints) are generally minimal and are not increased in pregnancy. Pyrantel doses can be calculated from the pamoate form or the free base (1 mg base = 2.9 mg pamoate form). Anthelmintic doses are 5 to 10 mg/kg pyrantel base or 15 to 30 mg/kg pyrantel pamoate (maximum daily dose, 1-g pyrantel base) (41).

Niclosamide, a salicylanilide, inhibits oxidative phosphorylation in the cestode mitochondria, killing the worm on contact. Niclosamide has been shown to have no teratogenic effect in rat and rabbit studies (45). No human malformations have been reported (pregnancy category B). The drug is poorly absorbed, but no information is available on niclosamide levels in breastmilk or on its ability to cross the placenta. There are inadequate data to assure the safety of uninterrupted breastfeeding following niclosamide therapy. Since single-dose therapy is used, temporary interruption (24 hours) of breastfeeding with disposal of milk can accommodate this therapy.

Praziquantel (an isoquinolone) is the drug of choice for most trematode infections in pregnancy (43). It is well tolerated with minimal side effects (36). Studies of teratogenicity have been negative in mice, rats, and rabbits (46,47). There are no reports of human malformations (pregnancy category B). Praziquantel is secreted in breastmilk at 29% of the maternal serum level (34). Praziquantel use is considered compatible with breastfeeding. In order to reduce potential infant exposure with single-dose maternal therapy, the mother can pump and discard the milk for 1 to 2 days to allow clearance of the drug.

Ivermectin is an anthelmintic macrocyclic lactone similar to macrolide antibiotics but with no antibiotic activity. Its activity against helminths comes from affecting ion channels in the cell membrane to increase permeability causing cell death. Ivermectin is a pregnancy category C drug, due to animal data suggesting teratogenicity, without controlled data in humans. There are only a few case reports of ivermectin use in pregnancy thus far, but there were no issues noted in those cases. Use of ivermectin in pregnancy is thus recommended only when the benefit to the mother outweighs any potential risk to the fetus. Ivermectin is excreted into breastmilk at low levels so its use during breastfeeding is likewise recommended only if the benefit to the mother outweighs any risk to the infant.

Albendazole and mebendazole (benzimidazole derivatives) are the drugs of choice for treatment for most nematode infections. Both are pregnancy category C based on animal data suggesting teratogenicity without controlled data in

humans. Mebendazole has been used extensively in the second and third trimesters in Sri Lanka, Nepal, and Madagascar, where it is routinely used for deworming in antenatal clinics without evidence of increased adverse outcomes (48). Both albendazole and mebendazole have been used in a number of second- and third-trimester clinical trials to study the benefit of deworming in pregnancy with more than 400 women having been exposed with no increase in adverse events reported (44). There was a case series from Sri Lanka reporting increased congenital anomalies with first-trimester mebendazole use so that is not recommended unless the maternal condition is severe enough to require immediate treatment without regard for fetal risks (49). Mebendazole has very limited excretion in breastmilk so is compatible with breastfeeding. There are inadequate data on albendazole to recommend use during breastfeeding.

PROTOZOAN INFECTIONS IN PREGNANCY

Trichomoniasis

Trichomonas vaginalis is an extracellular flagellated single-cell protozoon that colonizes the female lower urogenital tract and male urethra. Humans are the only host for *T. vaginalis* and the organisms cannot survive outside their human hosts for very long. *T. vaginalis* replicates by binary fusion of the trophozoite form. Trichomoniasis is transmitted from person to person, typically via genital contact at the time of sexual intercourse. Although transmission via fomites, such as towels or clothing, has been theorized, non-venereal transmission has not yet been documented.

Diagnosis of trichomoniasis has classically been performed by wet-mount microscopy, which is highly specific, but not very sensitive missing up to 40% of infections. There are two FDA-cleared rapid tests for detection of trichomoniasis in vaginal secretions, OSOM Trichomonas Rapid Test (Genzyme Diagnostics, Cambridge, Massachusetts), and the Affirm VIP III (Becton Dickinson, San Jose, California). Both were developed as point-of-care tests with results in 10 and 45 minutes respectively. Both have improved sensitivity over wet mount (>83%), but even though the specificity is quite high (>97%), false-positive test results can be a problem in low-prevalence settings (50). Trichomonas culture is also sensitive and highly specific. Several nucleic acid detection techniques are available for diagnosis of trichomoniasis and are particularly useful for diagnosis in men due to higher sensitivity than the previously used culture techniques.

Colonization with *T. vaginalis* is asymptomatic in most males and initially in many females, but it is estimated that 50% to 90% of women with vaginal colonization will ultimately become symptomatic if left untreated (23). Symptoms in women include a profuse, malodorous, frothy, yellow-green vaginal discharge and vulval itching or burning. Males have symptoms consistent with non-gonococcal urethritis, including urethral discharge, local itching/burning, and pain with urination. Treatment of trichomoniasis is typically limited to drugs from the nitroimidazole family—metronidazole (single 2-g oral dose or 500mg orally BID \times 7 days) and tinidazole (single 2-g oral dose) (50). Simultaneous treatment of all sexual partners prior to next sexual contact is recommended to prevent immediate recolonization. There has been some controversy over the

legal status of providing trichomoniasis treatment to the patient to deliver to his/her partners in the absence of direct contact between the partners and the health-care system, but many U.S. states have now enacted legal protection for partner-delivered therapy for sexually transmitted diseases. Assessment of local standard of care and legal requirements is recommended prior to initiating a practice of partner-delivered therapy.

Trichomoniasis in pregnancy has been associated with adverse pregnancy outcomes including premature rupture of membranes and preterm delivery. A large multicenter trial was conducted to see whether treatment of asymptomatic trichomoniasis at the end of the second trimester could reduce the rate of preterm birth (51). Unfortunately, this study reported a somewhat increased rate of preterm delivery in the treated women as compared with the placebo group. This increase has not been confirmed in other studies and there has been much discussion of potential limitations of this trial (including the timing and dosage of the treatment), but to date there has been no benefit identified for treatment of asymptomatic pregnant women (52). By contrast, treatment of symptomatic pregnant women with metronidazole (single 2-g oral dose) is recommended upon diagnosis (50). Metronidazole has no evidence of teratogenicity in animal studies and extensive use during human pregnancy (pregnancy category B). Some women may prefer to await completion of the first trimester prior to treatment to avoid exposure during organogenesis. Tinidazole has evidence of increased fetal mortality in animal studies with no controlled human studies (pregnancy category C). Since tinidazole has no advantage over metronidazole with potential for increased risks, tinidazole is not recommended for use during pregnancy. Metronidazole is excreted into breastmilk at levels similar to those found in maternal plasma after oral dosing, thus the American Academy of Pediatrics recommends that women pump and discard breastmilk for 12 to 24 hours following maternal single-dose oral metronidazole therapy to reduce infant exposure (50). It should be noted that the levels seen in the infant after maternal therapy during breastfeeding are lower than levels achieved in infants directly treated with metronidazole. Tinidazole is also excreted into breastmilk at levels similar to maternal plasma following oral dosing. Since tinidazole is still detectable in breastmilk up to 72 hours after the last dose, pumping and discarding milk for 3 days are recommended to reduce infant exposure.

Lice

Head Lice

Pediculosis capitis is caused by *Pediculus humanus capitis*, an ectoparasite that infests the human head. Humans are the only hosts. Adult lice require human blood to survive and die within 1 to 2 days if unable to feed. Adult lice live for about 30 days attached to the proximal hair shafts to provide close proximity to the scalp for feeding. Adult females may lay up to eight eggs (nits) per day adjacent to the scalp to allow the warmth from the head to incubate them. The nits are small (<1 mm) white-yellow oval eggs that hatch to form nymphs within a week, leaving the empty shell attached to the hair shaft. The nymphs are initially tiny, but grow rapidly to

become adults in about 7 days when the lifecycle begins again. The diagnosis is based on seeing either adult lice or nits in the hair.

Pediculosis capitis is quite common with the estimated 6- to 12-million infestations per year in the United States alone, mostly in school-aged children. Head lice are usually transmitted via head to head contact with an infected individual, but may be transmitted via fomites such as hats, towels, combs, or bed linens recently used by an infected person. The high prevalence among school children is thought to be due to frequent contact through sports or play as well as the sharing of combs and hair brushes. Infestation with head lice is not related to the level of hygiene. Clinical manifestations of infection are typically itching of the scalp due to hypersensitivity to the louse bites. Itching may not occur until 4 to 6 weeks after the first infection due to the time required to develop an allergic reaction. Although adult lice move from person to person, head lice are not known to transmit other diseases (53).

The diagnosis of pediculosis is often made by the infected person or a family member seeing the adult lice or nits in the hair or on a comb or brush. A number of further diagnostic techniques have been employed including visual inspection (with or without magnification), use of combing (either dry with a special fine-toothed comb or wet following washing and application of a conditioner), shampooing with use of a strainer to collect the rinse water, and collection of hair clipping from hairdressers (54). In comparison, self-diagnosis is almost as sensitive (80%) as wet or dry combing, with visual inspection being by far the least sensitive technique, even with magnification. Since dry combing requires less equipment (only need the fine-toothed comb; no need to wash and condition the hair as required for wet combing) and can thus be performed in any setting, it is typically the diagnostic test of choice, particularly in school-based screening.

Treatment of head lice is recommended for all infected persons. It is important to assess household members of an infected individual for active infection (as described above) in order to treat all infected household members at the same time. Prophylactic treatment of anyone who shares the same bed with an infected person has been recommended, but mass treatment of the entire household is not. Treatment of head lice is performed using a pediculicide applied to the hair and scalp then washed off. Since the medications typically kill only adult and nymph lice (not the nits), retreatment is usually required in 7 to 9 days to kill any recently hatched lice. Commonly used products available over-the-counter in the United States are pyrethrins combined with piperonyl butoxide (Pronto®, RID®) and the synthetic pyrethrin, permethrin 1% lotion (Nix®). Pyrethrins are neurologic toxins to insects by alterations of the sodium channels resulting in neurologic paralysis and death to exposed insects. Worldwide resistance to pyrethrins appears to be increasing, so repeating treatment beyond a third dose is not recommended (55). Alternative products used primarily for resistant cases that do not respond to treatment with a pyrethrin include Malathion 0.5% lotion, benzyl alcohol 5% lotion, and lindane 1% shampoo (all available only by prescription) (56). Supplemental measures, such as thorough combing to remove nits, washing of bed linens, bombs, and brushes in hot water, and

sealing unwashable items in sealed plastic bags for 2 weeks, may assist in eradication of infection, but are not essential. Since the adult lice and nits die rapidly when removed from the human host, extensive household cleaning is not typically required. There is no role for household fumigation or other use of insecticides in the management of pediculosis.

Pediculosis capitis during pregnancy follows a similar course to nonpregnant adults so treatment prior to delivery is not required, but there is typically a desire to treat due to the itching and psychologic distress of carrying a parasite in a visible location. Permethrin is the drug of choice for treatment in pregnancy and breastfeeding due to the low systemic absorption (<2% of the applied dose) and rapid clearance (53). There was no teratogenicity noted in animal studies of permethrin and there are no controlled human trials so it is a pregnancy category B drug. Observational reviews of use in humans have not identified any increased risk of adverse pregnancy outcomes (53). Permethrin use is considered to be compatible with use during breastfeeding due to the very low levels found in breastmilk. Malathion is also a pregnancy category B drug, but is typically not used in pregnancy or breastfeeding. Lindane and benzyl alcohol have been associated with abnormal neurodevelopment in animal teratogenicity studies (pregnancy category C) so should not be used in pregnancy unless absolutely necessary.

Body Lice

Pediculosis humanus corporis is caused by the ectoparasite *Pediculus humanus humanus*. Similarly to head lice, humans are the only host for body lice. The life cycle is quite similar to head lice, with the entire lifecycle occurring on hair shafts in close proximity to the skin. Body lice infestations typically occur in conditions of poor hygiene and overcrowding, such as those seen among homeless individual or in refugee camps. The primary clinical manifestation is itching, with the potential for skin thickening in chronically infected areas.

A major difference between head lice and body lice is the ability of body lice to transmit other diseases. Typhus, trench fever, and endemic relapsing fever have all been transmitted by body lice (57). *Pediculus humanus humanus* has recently been shown to be capable of transmitting *Yersinia pestis* as well and may have contributed to the transmission of the Black Plague (58). Body lice are diagnosed by visualization on clothing or skin, which may require magnification. Body lice can typically be resolved by improved hygiene, including use of a clean change of clothing at least weekly with laundering of clothing and towels in hot water (59). Treatment with a pediculicide is not typically required, but if needed the same medications used for head lice are used for body lice. There are no specific issues related to pregnancy.

Pubic Lice

Pediculosis pubis is caused by the ectoparasite, *Phthirus pubis*. As was true for head and body lice, humans are the only host for pubic lice and the life cycle is quite similar. Similar to head lice, pubic lice have not been reported to transmit other diseases. A common lay term for pubic lice is “crabs” due to the more rounded crab-like appearance of pubic lice compared with the more elongated head and body lice. Pubic lice are found on the coarse body hair located in the pubic

region, but may also be seen on other coarse body hairs including beards, mustaches, eyelashes, eyebrows, and axillary hair. Transmission of pubic lice is generally via body contact during sexual intercourse, thus pubic lice are most commonly found in adults. Finding of pubic lice on the eyelashes or head of a child raises the question of potential sexual abuse; however, fomites such as towels, clothing, and bed linens may be involved in transmission so sexual contact is not always involved.

Treatment of pubic lice is usually performed with permethrin 1% lotion or pyrethrin with piperonyl butoxide applied to the affected area and washed off 10 minutes later (60). Alternative therapies include Malathion 0.5% lotion and ivermectin. Unlike head lice, a second treatment is required only after 9 to 10 days if live lice are noted at that time. A notable exception to the use of these medications is infection of eyebrows or eyelashes that are most commonly treated by physical removal of lice and nits, with application of ophthalmic-grade petrolatum ointment two to four times per day for 10 days. Supplemental measures including physical removal of nits, laundering of clothing and bed linens in hot water, and placement of unwashable items in sealed plastic bags for 2 weeks are more strongly recommended than that was the case for head lice. Also all sexual partners for the past month should be informed of their risk for infection and treated prior to resuming sexual contact. Since pubic lice is a sexually transmitted disease, it is prudent to evaluate for the presence of other sexually transmitted diseases (60). Pregnant women should be treated with the primary therapies of permethrin or pyrethrin; use of Malathion and ivermectin in pregnancy should be avoided if possible.

Scabies

Scabies is an ectoparasitic infestation caused by the human itch mite, *Sarcoptes scabiei var hominis*, for which humans are the only host in which replication can occur. Animal mites can infest human skin temporarily, but cannot replicate in humans and thus their infestation is self-limited. Adult female mites make characteristic serpentine burrows into the skin, usually between fingers and around the wrist in humans, where they lay 2 to 3 eggs per day as the burrow lengthens (61). Eggs hatch in 3 to 4 days to form larvae, which exit the serpentine burrow to dig a shallow molting pouch. Larvae develop into nymphs and then adults within 10 to 14 days inside the molting pouch. Adult male mites leave their molting pouch to burrow into the molting pouch of an adult female mite in order to fertilize the female who then continues to be fertile the remaining month of her life. Once impregnated, the adult female mite leaves the molting pouch to find a site to begin her own serpentine burrow and egg deposition, thus restarting the life cycle.

The diagnosis of scabies can be made clinically based on the presence of characteristic burrows or visible mites. Skin scraping can be performed to look for mite or eggs, but treatment should be provided for suspected cases without confirmation of the presence of mites since a typical infection may involve only 10 to 15 female mites (61). In addition to microscopic examination of skin scrapings with oil, skin scrapings can also be submitted for PCR to detect *S. scabiei* DNA. When using PCR to verify resolution of infection, it is important to wait at least 28 days after the last treatment to

allow time for skin to shed with new epithelium developed, since the DNA from dead organisms will persist in the skin until it has been shed (62). Scabies is transmitted by close interpersonal contact, particularly in crowded living conditions. Outbreaks have been identified in nursing homes, hospitals, orphanages, and refugee camps (63). Transmission may occur with sharing of a bed and often occurs among adults via sexual contact. Children may be infected via sharing of beds or direct contact during play. Scabies is not considered to be an indication of potential sexual abuse due to its frequency in non-abused children. Fomites, such as clothing, towels, and sheets, may be involved with spread in some cases, but are not thought to be a major contributor.

The primary clinical manifestation of scabies is itching due to a hypersensitivity reaction to the organism, which may take several weeks to develop following first exposure, but may develop rapidly with subsequent exposures. A classic rash occurs with visible burrows on the hands, wrists, and ankles. Papules may occur in those locations as well as on the forearms, axilla, breasts, and penis. The visible burrows and papules are the sites from which mites could possibly be obtained via skin scraping. The treatment of choice for uncomplicated scabies is permethrin 5% cream (Elimite®) applied to the entire body below the neck with specific attention to folds and creases including those between the fingers and toes as well as beneath the nails, which is washed off after 8 to 14 hours (64,65). A second application a week later may be required to eliminate all mites. Note that this is a higher dose of permethrin than that used for lice and this product is not available over-the-counter in the United States. Alternative treatments include ivermectin (200 µg/kg/day in 2 doses 14 days apart), crotamiton 10% lotion or cream, and lindane 1% lotion but all have a lower efficacy than topical permethrin for uncomplicated scabies (64,65). Supplemental measures such as washing of clothes, bed linens, and towels in hot water may be helpful, but are not essential for uncomplicated scabies as there are few organisms involved.

Treatment of scabies in pregnancy is typically performed with permethrin (64) (pregnancy category B) for which there is no evidence of teratogenicity in animals and there are no controlled studies in humans. There is a retrospective study of women who received either permethrin 4% lotion ($n = 196$) or benzyl benzoate 25% lotion ($n = 444$) for treatment of scabies during pregnancy (primarily second and third trimesters, but 10% first trimester as well) (66). They found no difference in pregnancy outcomes between treated women and their matched controls. They did note a higher need for retreatment with benzyl benzoate lotion than with permethrin (16.4% vs. 9.7%), compatible with the higher efficacy for permethrin seen in nonpregnant adults.

In debilitated or immunocompromised individuals, an aggressive form of scabies called crusted or Norwegian scabies may develop. Crusted scabies is highly infectious with potentially more than a million organisms infecting a single individual. The crusting patches and gray flaky plaques may be difficult to distinguish from psoriasis or eczema and may be localized, extensively covering the hands, feet, trunk, face, and scalp. Optimal treatment for crusted scabies is not yet known, but current recommendations are combined treatment with a topical scabicide (daily dose as described above) and oral

ivermectin (200 µg/kg/day) on days 1, 2, 8, 9, and 15 with additional treatments on days 22 and 29 if needed (64). Supplemental measures including washing of all bed linens, clothing towels, and other items of direct contact are essential to eliminate the infestation due to the high volume of organisms and the propensity for the flaky plaques to fall of bearing high numbers of mites. Close cropping of nails may also be of benefit. Increased rates of crusted scabies have not been described during pregnancy in the absence of underlying debilitation. Treatment of crusted scabies in pregnant women should be individualized with the use of ivermectin if clinically indicated for the health of the mother.

Malaria

Malaria is typically caused by infection with one of four protozoa, *Plasmodium falciparum*, *Plasmodium vivax*, *Plasmodium ovale*, or *Plasmodium malariae*. Humans are infected with malaria when bitten by an *Anopheles* mosquito carrying the organism. Plasmodium sporozoites are transferred from the mosquito to the human bloodstream, where they travel to the liver and infect liver cells. Inside the liver cells, the sporozoite matures to a schizont, which then ruptures releasing merozoites that invade erythrocytes and either multiple asexually to develop a ring stage schizont (which will again rupture releasing merozoites) or develop into a gametocyte. The gametocytes can then be taken up by the *Anopheles* mosquito to begin the mosquito portion of their life cycle, which includes fertilization of the female gametocyte in the mosquito stomach, maturation in the mosquito midgut wall, and migration of the mature sporozoites to the mosquito salivary gland for injection during the next mosquito blood meal to begin the human portion of the life cycle.

Clinical symptoms of malaria are similar to those of a flu-like illness, with fever, chills, headache, myalgia, malaise, arthralgia, weakness, nausea, vomiting, and diarrhea (67). The degree of symptoms and speed of disease progression varies depending on the infecting organism (*P. falciparum* is typically most severe), the level of parasitemia, and the immune status of the individual. Symptoms can develop as quickly as 7 days or as long as 2 months following exposure. Severe infections with *P. falciparum* can progress rapidly to acute renal failure, central nervous system involvement, severe anemia, respiratory distress syndrome, and death. Malaria is estimated to cause about 1 million deaths per year, mostly due to *P. falciparum* infections in children in Africa, but there are deaths each year among developed world travelers who visit the developing world, particularly the African region. Physical findings associated with malaria include hepatomegaly, splenomegaly, fever, increased respiratory rate, weakness, and mild jaundice.

In the developed world, suspicion of malaria based on identification of potential exposure is the first key to diagnosis. Diagnosis is based on either identification of parasites in blood by microscopy or detection of malaria antigens or enzymes in blood. On microscopic examination of blood smears, the gametocyte form is typically the easiest to identify as other forms (such as ring-stage schizont) may be quite difficult to distinguish. More recently, a variety of rapid diagnostic tests (RDTs) have been developed to detect either antibodies or enzymes produced by the *Plasmodium* organisms, allowing expanded diagnosis in resource-poor settings (67). Assistance

with diagnosis and treatment in the United States can be obtained from the U.S. Centers for Disease Control and Prevention (CDC, www.CDC.GOV), who maintain a malaria control hotline for emergency assistance. Outside the United States, The WHO (www.who.org) maintains guidelines for diagnosis and treatment of malaria and assists with drug procurement in the developing world.

Treatment for malaria is based on the infecting organism and the likelihood of resistance based on the location in which the infection was acquired. The WHO updated their malaria treatment guidelines (67) in 2010 to stress the need for diagnosis prior to treatment and to promote a move toward use of artemisinin-based combination therapy (ACT) as opposed to monotherapy to reduce the spread of artemisinin resistance already widely seen in Southeast Asia. In the United States, chloroquine-sensitive malaria is usually treated with chloroquine as the first-line therapy. Atovaquone–proguanil (Malarone®), artemether–lumefantrine (Coartem®), or quinine plus doxycycline or tetracycline are currently the first-line regimens for *P. falciparum* infections likely to be chloroquine resistant. Since treatment guidelines have recently been undergoing frequent modification to keep up with changing patterns of resistance, it would be advised to check the WHO or CDC Web site or other frequently updated resources for current recommendations prior to initiating treatment.

The best treatment for malaria, however, is prevention. There are a number of recommended prophylactic regimens for travel into malaria-endemic areas. Atovaquone–proguanil (Malarone) and doxycycline can be used in all areas, with chloroquine and mefloquine (Lariam®) limited to areas with no evidence of resistance and primaquine limited to areas with only *P. vivax* infections. Supplemental measures are also quite important to avoid contact with the *Anopheles* mosquito including using insecticide-treated bed nets, limiting exposed skin by wearing long pants and sleeves, using insecticide spray or lotion on exposed skin, and staying in a mosquito-resistant building in the evening when mosquitoes are most likely to bite.

Malaria in pregnancy is associated with high risk of maternal and perinatal morbidity and mortality, presumably due to impaired immune response to the infection. Increased adverse outcomes include spontaneous abortion, fetal death, preterm birth, low–birth weight infants, and maternal death (68). The increase in maternal mortality may be directly related to severe malarial infection or may be due to the impact of severe anemia-causing congestive heart failure or death due to postpartum hemorrhage. Malaria organisms can be sequestered in the placenta, where they may be resistant to treatment and may also increase fetal pathology.

Treatment of malaria in pregnancy is also impacted by type of organism and likelihood of chloroquine resistance. For chloroquine-sensitive malaria, chloroquine is the drug of choice, as it is for nonpregnant adults. For chloroquine-resistant malaria, quinine plus clindamycin is currently the first-line therapy for the first trimester due to lack of experience with either of the other first-line combinations (atovaquone–proguanil or artemether–lumefantrine, both pregnancy category C) (67,68), with the caveat that one of those regimens should be used if quinine/clindamycin is either unavailable or is not tolerated. The 2010 WHO guidelines recommend use of ACT known to be effective in the local area

after the first trimester due to the enhanced efficacy (67), whereas the CDC recommendations are to continue the use of quinine plus clindamycin throughout pregnancy unless intolerance or treatment failure is seen. Quinine is pregnancy category C and is known to cross the placenta, but extensive experience has revealed no increase in adverse pregnancy outcomes with its use. Clindamycin is pregnancy category B with no teratogenicity seen in animal studies and extensive human experience with no increase in adverse outcomes seen.

Prophylaxis for pregnant travelers is very complicated since both primaquine and doxycycline are contraindicated during pregnancy and atovaquone-proguanil is also not recommended for pregnancy use. Chloroquine is considered safe, but has little benefit in areas with extensive resistance. Mefloquine is pregnancy category C and should not be used in pregnancy unless prophylaxis for travel to an area with chloroquine resistance is absolutely needed and only after the first trimester due to animal data showing embryotoxicity (69). Supplemental measures (as discussed above) are even more important for pregnant women due to the limitations of other prevention and treatment options.

Elimination of malaria will clearly require more than treatment of symptomatic individuals and prophylaxis for travelers. Two techniques recommended by WHO are mass screening and treating of asymptomatic individuals who are infected and MDA. Mass screening and treatment requires much higher levels of resources than MDA so it is the technique most commonly employed. To date, MDA campaigns have not been able to achieve complete eradication with the exception of one closed island community with limited contact with the outside world where *P. falciparum* was eradicated rapidly (5 weeks), but it took 5 years to eradicate *P. vivax* (67). Inclusion or exclusion of pregnant women from MDA has been quite controversial due to the frequent use of drugs not commonly used in pregnancy being contrasted with the severe consequences of malarial infection during pregnancy. Reviews of data to date indicate no increase in adverse pregnancy outcome with inclusion in MDA or the more specific use of intermittent preventive therapy (IPT) targeting pregnant women [usually performed as one dose at quickening (18–20 weeks) with a second dose a month or more later (68,70)]. One key issue raised has been the importance of using highly effective drugs if MDA or IPT are to be used in pregnancy as opposed to using older, less effective, or completely ineffective drugs simply because there is more experience with them in pregnancy. Exposure to an ineffective drug in pregnancy is all risk with no benefit.

88 Routine maternal immunizations for all pregnant women

Stanley A. Gall

The concept of adult immunization in general and maternal immunization specifically has been receiving an increased attention from clinicians and medical writers as new vaccines have come into the market. However, the general population's knowledge of the need for vaccination and which vaccines to obtain is very limited. Unfortunately, physicians who provide care to adults are also hampered by an incomplete knowledge of adult vaccines. The general public has an overall awareness of the significant reduction that has occurred in the incidence of measles, mumps, rubella, polio, diphtheria, and tetanus. However, the general public does not understand that failure to maintain immune status to diseases such as tetanus, diphtheria, hepatitis A, hepatitis B, herpes zoster, varicella influenza, pneumococcal disease, and human papillomavirus can result in serious diseases. Each of these diseases has an effective vaccine and need to be seriously considered for adult immunization.

The benefit of vaccination in pregnancy is to protect (i) the mother from disease and (ii) the neonate from disease with passive maternal antibodies. This is the best two for one deal in nature.

Active immunization is the administration of an antigen, which may be a live attenuated organism, inactivated viruses, recombinant viral particles, purified proteins, bacterial capsular polysaccharides, or exotoxin derivatives (toxoids) with the projected effect of preventing, abbreviating, or ameliorating natural infection.

Passive immunization is the transfer of performed antibodies from immune individuals by potential administration of pooled human or equine serum or by placental transfer of immunoglobulin G (IgG) from mother to fetus.

Current adult vaccines and their use in pregnancy are seen in Tables 1 and 2. Immunoglobulin G and antitoxins that are available in the United States are listed in Table 3.

Table 1 lists the vaccines that should be routine for every pregnancy. This assumes that there are universal recommendations for each of these vaccines. Table 2 lists other licensed vaccines that may be considered to be used during pregnancy in special circumstances.

VACCINATION IN PREGNANCY

It is seen from Tables 1 and 2 that a total of 6 vaccines should be used during each pregnancy and 12 vaccines that are licensed may be used if indicated. However, the vaccines that should be routinely administered to all pregnant women who have not been immunized previously are influenza, hepatitis A and hepatitis B, tetanus, diphtheria, acellular pertussis (Tdap), and pneumococcal and meningococcal vaccines. It is tragic for any pregnant women to develop an infectious disease that is vaccine preventable. This universal approach is a change in practice from ignoring the pregnant woman and assuming she

is protected to a policy of active inquiry as to her vaccine status and a program of active immunization. The result is protection of the pregnant women from disease and protection of the neonate for a variable length of time from passive maternal antibodies. The inactive vaccines and toxoids are safe to administer during pregnancy, and practicing obstetricians should adopt this positive management advance (2).

An immunization history should be obtained at the first prenatal visit. In an ideal world, the patient should be immune to measles, mumps, rubella, tetanus, diphtheria, pertussis, poliomyelitis, varicella, and hepatitis A and B. However, in the real world, adults generally are not aware of their needs for vaccination and the release of new vaccines, and many physicians are not aware of vaccine requirements. As a result of this vast lack of knowledge and information, the majority of patients are either no longer protected from disease or they have never received the appropriate vaccines.

The Advisory Committee for Immunization Practices (ACIP) at the Centers for Disease Control and Prevention (CDC) is a 15-member committee, which advises the CDC with recommendations for vaccine use. While the vaccine recommendations for pediatric vaccines are based on an age-related schedule, the adult recommendations are risk based. The risk-based strategy causes confusion for the practitioner since as many as 26 risks are identified for hepatitis B and numerous risks for other vaccines. Few physicians will remember the many risks as indications for vaccine administration. A simplified approach is to select the six important vaccines to be routinely administered during pregnancy and routinely administer these vaccines to all pregnant women as universal vaccines. A simple vaccine questionnaire is seen in Table 4. This questionnaire assumes that the six vaccines listed should be administered to all patients who have not been previously immunized, asks about allergies to vaccines, and lists whether the vaccine information statement (VIS) has been given to the patient and whether the patient has been immunized or refused immunization on the visit day. The form then becomes a record of vaccine refusal (potential medical-legal benefit), VIS given (federal requirement), and vaccine administered.

INFLUENZA EPIDEMIOLOGY

Influenza is an acute febrile illness associated with headaches, migraines, upper airway respiratory complaints, and gastrointestinal symptoms. Primary influenza pneumonia, which is frequently fatal, may occur in patients who have not been vaccinated and/or have underlying cardiopulmonary disease. Most fatalities associated with influenza are due to secondary bacterial pneumonia, usually *Streptococcus pneumoniae* (3,4). Influenza is caused by one of two viral isotypes: influenza A or influenza B. Influenza A and B are the two types that cause

epidemic human disease. Influenza A is the most common and the most virulent strain. Influenza A viruses are further characterized into subtypes based on two surface antigens, hemagglutinin (H) and neuraminidase (N). Influenza B viruses are separated into two distinct genetic lineages (Yamagata and Victoria) but cannot categorize into subtypes.

Table 1 Licensed Vaccine Recommended to All Pregnant Women

Vaccine	Type	Route	Use in pregnancy
Hepatitis B	Recombinant viral particle	IM	Yes
Hepatitis A	Killed virus	IM	Yes
Tdap	Toxoids, inactivated acellular pertussis antigens	IM	Yes
Pneumococcal	Bacterial polysaccharide	IM or SC	Yes
Influenza	Trivalent inactivated viral	IM	Yes
Meningococcal	Protein conjugate	IM	Yes

Source: From Ref. 1. Abbreviation: IM, intramuscular.

The hemagglutinin (H) antigen on the influenza A viral surface enables entry of the viral genome into the host cell. The neuraminidase (N) antigens lead to cell lysis after replication of the viral genome in a host cell. These viral antigens are critical components in the mechanisms by which influenza A viruses infect host cells and cause disease. However, the H and N antigens stimulate an immune response, acting as target antigens in developing prophylactic vaccines (5).

Influenza viruses are RNA viruses and undergo periodic genetic mutation. This alters the genetic composition of the virus allowing it to evade the natural host immunity acquired from previous exposure to vaccines or infection. The changes in the viral genome are usually minor and described as “antigenic drift.” This minor change does not result in reclassification of the viral subtype. Antigenic drift results in a novel strain that can cause disease in a naive population despite previous exposure to a genetic variant outbreak. The continual process of antigenic drift necessitates the development of new influenza A vaccines on an annual basis. Influenza B viruses are more stable and undergo antigenic drift less frequently than influenza A viruses (6).

While antigenic drift describes minor genetic changes in the viral genome, “antigenic shift” refers to major genetic alteration. The major pandemic strain in 1917 to 1918 was caused by an H1N1 subtype influenza A virus and this

Table 2 Licensed Vaccines May Be Used During Pregnancy in Special Circumstances

Vaccine	Type	Route	Circumstances for use in pregnancy
Anthrax	Inactivated bacteria	SC	For use in epidemics
BCG	Live bacteria	ID	None
Japanese encephalitis	Inactive virus	SC	Yes, if traveling to endemic area
Measles	Attenuated live virus	SC	No
Measles, mumps, rubella	Attenuated live virus	SC	No
Herpes zoster	Attenuated live virus	SC	No
Polio, inactive	Inactivated live virus (three types)	IM	Yes, if traveling to endemic area
Rabies	Inactivated virus	IM	Yes, use when indicated
Typhoid (parenteral)	Inactivated bacteria	SC	Yes, if epidemic
Typhoid (oral)	Live bacteria	Oral	No
Varicella	Attenuated live virus	SC	No, give postpartum if indicated
Yellow fever	Attenuated live virus	SC	No, use when indicated

Abbreviations: BCG, Bacillus Calmette–Guerin; ID, intradermal; IM, intramuscular; SC, subcutaneous. Source: From Ref. 1.

Table 3 Immunoglobulins and Antitoxins Available in the United States

Immunobiologic	Type	Indication
Botulinum antitoxin	Specific equine antibodies	Treatment of botulism
Cytomegalovirus Immunoglobulin (IG) intravenous	Specific human antibodies	Prophylactic for bone marrow and kidney transplants
Diphtheria antitoxin	Specific equine antibodies	Treatment of respiratory diphtheria
IG intravenous	Pooled human antibodies	A
Hepatitis B, IG	Specific human antibodies	B
Hepatitis A, IG	Specific human antibodies	C
Human rabies IG	Specific human antibodies	Suspected rabies attack
Tetanus IG	Specific human antibodies	Tetanus exposure
Varicella zoster IG	Specific human antibodies	D

All preparations are given IM except when noted (A) Replacement therapy for antibody deficit, ITP, hypogammaglobulinemia CLL. (B) Hepatitis B postexposure to infant of HBsAg-positive mother at birth. (C) Postexposure prophylaxis or pre-exposure prophylaxis. (D) Postexposure prophylaxis of susceptible persons and certain susceptible pregnant women and their exposed newborns. Abbreviations: CLL, Chronic lymphocytic leukemia; ITP, idiopathic thrombocytopenia purpura. Source: From Ref. 1.

presented until 1957 when the H2N2 subtype appeared. The H2N2 subtype underwent a major antigen shift in 1968 resulting in the H3N2, which has been circulating until the present time. An H1N1 subtype emerged in 1977 and has been co-circulating with the H3N2 subtype. Current influenza vaccine contains one H3N2 strain, one H1N1 strain, and one influenza B strain. In March 2009, a novel H1N1 subtype emerged in Mexico and is the result of influenza A strains from pigs, birds, and humans. Recombinant analysis showed triple-reassessment swine H1N1 influenza virus coming from classic swine, North American lineage; avian, North American lineage; human (seasonal) H3N2 and human seasonal (H1N1) strain initiated a worldwide pandemic (7).

1958 caused by an H2N2 subtype (10). Recently, it has been reported an increased risk for serious illness and hospitalization in pregnant women suffering from the respiratory complications of influenza during non-pandemic influenza seasons (11). The risk ratio for hospitalization was 5.1 among women without comorbidities and 7.9 among women with comorbidities. The relative risk for pregnant women without comorbidities rose from 1.7 in the first trimester to 5.1 in the third trimester for women with comorbidities. The relative risk for hospitalization for an influenza infection rose from 2.9 in the first trimester to 7.9 in the third trimester. ACIP and the American College of Obstetrics and Gynecologists (ACOG) have recommended that all pregnant women receive influenza vaccine during their pregnancy (4).

INFLUENZA AND PREGNANCY

Influenza increases the risk for morbidity and mortality in all pregnant women. While increased risk of influenza-associated morbidity and mortality is present throughout pregnancy, it increases dramatically in the third trimester (3,8). Excess maternal deaths were reported during the influenza pandemic of 1917 to 1919 caused by an H1N1 subtype (9) and in 1957 to

This pandemic H1N1 2009 influenza has shown an increased likelihood of adverse outcomes in pregnant women and has shown an increased risk of maternal mortality (3). A number of reasons for the increased morbidity and mortality of influenza A in pregnancy have been proposed. They include i) an increasing relative immunosuppression to viral antigens as the pregnancy progresses, ii) physiologic changes in pregnancy

with a 20% to 100% expansion of circulating blood volume having to traverse the lungs giving them a heavy quality, and iii) induction of a “cytokine storm” in patients without circulating influenza antibodies to the infectious strain (12).

It is important to remember that influenza vaccines are not teratogenic, and no convincing evidence has been published regarding fetal adverse outcomes (2). Some authors include “theoretic concerns” of fetal effects in their writing but when questioned about the theoretical risk, they are unable to locate supporting data.

ACIP and ACOG advise that all pregnant women receive trivalent inactivated influenza vaccine (TIV) at any time during the pregnancy. It is advisable to receive TIV earlier in the pregnancy so adequate time is available for the mother to develop an immune response and transfer passive antibodies to the fetus thereby protecting the fetus for the influenza season (13).

TETANUS, DIPHTHERIA, PERTUSSIS

In the minds of many people, tetanus, diphtheria, and pertussis have been thought of as being eliminated or controlled. By the 1970s, widespread implementation of tetanus diphtheria (Td) vaccine targeting pregnant women resulted in an almost universal disappearance of tetanus and diphtheria in the mother and the disappearance of neonatal tetanus when Td was used prior to or during pregnancy. Whole-cell pertussis vaccine was developed and brought into clinical practice in the late 1930s and 1940s, which led to a dramatic decrease in the incidence of pertussis. However, the number of cases of pertussis began to rise in the late 1970s primarily in adolescents and young adults. This was thought to be due to waning immunity to pertussis antigens. The vaccine available at that time was DPT and was indicated for persons up to 5 years of age. In 1992, a new formulation of DPT was developed with the introduction of “T” (full strength), “d” (reduced strength), and acellular pertussis (Tdap) for children up to 5 years of age. The acellular pertussis vaccine was significantly less reactogenic. In 2005, the Tdap vaccine was licensed for adults up to age 65 years.

Pertussis is an acute respiratory infection caused by *Bordetella pertussis*. The organism produces multiple toxins that damage the respiratory epithelium and can have symptomatic effects including lymphocytosis. *B. pertussis* infection in adolescents and adults covers a spectrum of severity from asymptomatic to a mild cough illness to classic pertussis (14).

The incubation period for pertussis is 7 to 10 days (range 5–21 days). Classic pertussis is characterized by three phases: Catarrhal, paroxysmal, and convalescent. The catarrhal phase lasts 1 to 2 weeks and consists of injection of the conjunctiva, frequent sneezing, a watery nasal discharge, and frequent cough. The cough suggests that tracheal irritation is short, hacking, isolated, and present equally day or night. Fever is uncommon during any phase.

The paroxysmal phase lasts 4 to 6 weeks. During this phase, the patient has intermittent periods of intense coughing (paroxysmal). The paroxysms are characterized by severe spasms of coughing, choking, post-tussive and inspiratory whoop. Adults and adolescents with pertussis make repeated visits for medical care and miss work and school (15,16).

Table 5 Hospitalization and Complications Among 16,431 Infants Aged <12 Months with Pertussis (2000–2005)

Complication	Number (% of total)
Hospitalization	8067 (61.7)
Apnea	7377 (56.3)
Pneumonia	1419 (12.8)
Seizures	169 (1.3)
Deaths	130 (0.8)

Source: From Ref. 17.

Unknown	353	57
Mother	84	14
Father	39	6
Grandparent	22	4
Sibling	52	8
Other	67	11
Total	616	100

Source: From Ref. 18.

Pertussis is transmitted from person to person via large respiratory droplets generated by coughing or sneezing. Persons with pertussis are highly infectious especially during the catarrhal and early paroxysmal phases. Patients can remain infected for up to 6 weeks or more.

Case reports suggest that morbidity from pertussis is not increased among pregnant women as compared with non-pregnant women. Reports of fetal morbidity among pregnant women with pertussis are rare and no causal relationship with abnormal fetal development, fetal morbidity, or adverse outcome of pregnancy has been confirmed.

Unfortunately, the brunt of burden of disease occurs in the infants less than 1 year of age (Table 5). It is to be noted that apnea is a prominent finding in children admitted to the hospital. Infant deaths are characterized by an increased rate of primary and secondary pneumonia and coinfection with bacterial or viral pathogens.

The source of pertussis for the neonatal patient is largely unknown (Table 6). Although the mother is the source in 14%, the father in 6%, and grandparents and sibling in an additional 12%, immunization programs targeting mothers postpartum and their support groups are likely to be unsuccessful. The neonatal patient receives active pertussis vaccine at 2, 4, and 6 months of life and is not protected from disease until 6 months of life.

Therefore, immunization during pregnancy will protect the mother against pertussis disease and the passive antibodies that cross to the fetus will protect the neonate against disease. The newer recommendations for routine Tdap vaccinations are listed in Table 7. Tdap is recommended during the second and third trimesters and will likely need to be repeated in 10 years.

HEPATITIS B

Acute hepatitis B virus infection during pregnancy can result in severe disease for the mother and chronic infection in the

Table 7 Recommendations for Routine Tdap Vaccination

Adolescents and adults should receive a single dose of tetanus, reduced diphtheria, and acellular pertussis (Tdap) to replace a single dose of Td for active booster vaccination if they have received their last dose of Td greater than 2 years ago. Although previous recommendations have indicated 10-year intervals for Td, the interval between Td and Tdap of 2 years is now recommended for a single dose of Tdap. The American College of Obstetricians and Gynecologists recommend that Tdap may be administered during pregnancy. For those women who do not receive Tdap during pregnancy, they should be given Tdap in the postpartum period. Lactating women may receive Tdap. Health-care workers who have direct patient contact should receive a single dose of Tdap.

Table 8 Risk Groups for Preexposure Prophylaxis for Hepatitis B

All persons age 0 to 19 years
 All newborns
 All heterosexual persons who are not in a long-term mutually monogamous relationship
 Men who have sex with men (MSM)
 Injecting drug users (IDU)
 All persons screened for a sexually transmitted disease
 All persons tested for a sexually transmitted disease
 All persons receiving hemodialysis
 All persons with end-stage renal disease not on dialysis
 Persons with chronic liver disease of any type
 HIV-infected persons
 All health-care workers
 All public safety workers at risk for blood exposure or containing bodily fluids
 Staff of correctional facilities
 Inmates in federal, state prisons, jails, or juvenile correctional facilities
 Residents of institutions for developmentally disabled
 Sexual and household contacts of HBsAg-positive persons
 Family members of HBsAg-positive immigrants and international adoptees
 International travelers to moderate or high endemic areas
 Victims of sexual assault
 Persons who are not previously vaccinated or immune to HB virus infectious
 Persons who desire to become vaccinated
 The ACIP has published recommendation for use of Hepatitis A virus based on risk (Table 10)

Source: From Ref. 20. Abbreviation: ACIP, Advisory Committee for Immunization Practices.

Table 9 Risk Groups for Past Exposure Prophylaxis for Hepatitis B

Occupational exposure to blood or bodily fluids that contain blood
 Sexual and household contacts of persons with acute hepatitis B infection
 Sexual and household contacts of persons with chronic hepatitis B infection
 Victims of sexual assault
 Newborn infants whose mothers are HBsAg positive
 Perinatal HB virus exposure

Source: From Ref. 20.

Table 10 Current Risk-Based Recommendations for Hepatitis A Vaccinations

International travelers
 Men who have sex with men (MSM)
 Household and sexual contacts of persons infected with HAV
 Laboratory workers who handle live HAV
 Laboratory workers who work with nonhuman primates
 Illicit drug users (injecting and non-injecting)
 Carriers of chronic hepatitis B
 Persons with chronic liver diseases
 Persons with clotting-factor disorders
 All persons who desire protection from HAV
 All public food handlers

Source: From Ref. 22.

Pregnancy should be considered an indication for the initiation of the hepatitis B vaccine series. The ACIP has recommended hepatitis B vaccine for any person, pregnant or not, who fall into any of the 22 risk groups or 6 postexposure risk groups (Tables 8 and 9).

The ACIP recommendations are complex and almost impossible to remember all the risk groups (Table 10). It is important to remember that all pregnant women are screened for six sexually transmitted diseases and all pregnant women qualify for HBV vaccine. The American Academy of Pediatrics has stated that no adverse effect to the developing fetus has been observed when pregnant women are immunized. Because severe hepatitis B virus infection can cause chronic infection in the mother and the infant, all pregnant women should be considered candidates for the HBV vaccine series if they have not been previously immunized.

Ingardi and colleagues analyzed serum antihepatitis B levels in 37 maternal serum–umbilical cord pairs following maternal vaccination (21). At the time of delivery, 18 of 37 (49%) had appropriate HBsAb levels of 10 MIU/mL or greater. The ratio of cord blood titer to maternal titer of HBsAb increased with the ratios for first, second, and third doses of vaccine were 0.55, 0.67, and 0.72 respectively. When maternal HBsAb levels exceeded 35 MIU/mL, all cord blood titers were in the seroprotective range.

HEPATITIS A VACCINE

Hepatitis A virus is transmitted through the fecal–oral route, spreading primarily through close personal contact. The acute disease is characterized by nausea, malaise, abdominal pain, and jaundice. HA virus infection does not cause chronic

neonate if a live birth occurs. Pregnancy in a woman with chronic acute hepatitis B virus infection can result in vertical transmission to the fetus and chronic infection in the neonate if no postexposure therapy occurs. The acute infection is characterized by a prolonged viremic phase that persists weeks to months. Chronic hepatitis B infections occur in 1% to 5% of adult patients with acute hepatitis B infection. Maternal infection with HBsAg positive and HBeAg positive carries a fetal transmission rate of 90%, with 50% of the neonates developing chronic hepatitis (19).

Table 11 Acute and Chronic Disease Burden Estimates for Viral Hepatitis in the United States

	Hepatitis A virus (HAV)	Hepatitis B virus (HBV)	Hepatitis C virus (HCV)
Total infection	32,000	46,000	19,000
Vaccine preventable	Yes	Yes	No
Chronic infections	NA	1 million/ 1.25 mil	3.2 million
Chronic liver deaths	NA	5000	8000–10,000

Source: From Ref. 24.

infection and vertical transmission has not been described. During the period 1987 to 1997, an average of 28,000 cases of hepatitis A occurred annually in the United States. After induction of hepatitis A vaccine in 1995, a significant reduction in the annual number of cases reported has occurred.

The general public perceives HAV infection as either nonserious or very mild. One has to be reminded of a large outbreak of HAV infection in fast-food restaurant in Western Pennsylvania in 2004.

More than 600 persons became ill, with 194 admissions and four deaths. The source of HAV was not the employees but imported green onions that was used to make salsa (23,24). This emphasized the vulnerability of the population to contaminated food and that universal protection is indicated. This is further indicated by the large burden of acute and chronic disease for viral hepatitis in the United States (Table 11) or that behavioral risk factors are not always predictable, thereby leaving individuals at risk until the time they come to medical attention. Importantly, the current recommendation have resulted in rates of HBV infection that are actually increasing among men aged >20 years and among women >40 years (25). Additionally, risk-based approaches have been abandoned for all pediatric vaccines and most of the adult vaccines. Unfortunately, the universal recommendations that pertain to infants, children, and adolescents have not yet been equally applied to adults (26).

Table 11 presents acute and chronic disease burdens estimated for viral hepatitis in the United States. The disease burden is great and the clinical presentation is similar for all the types of hepatitis. An active program of hepatitis A and B vaccination can be important in reducing the number of persons infected.

Problems are present with the current ACIP recommendations regarding hepatitis A and hepatitis B vaccinations. The major deficit in the current recommendations is that they are risk based and therefore likely to miss many persons at risk who would receive vaccination if the recommendation were universal. In addition, the risk categories are tedious and the majority of practitioners are unaware of multitude of risk categories. The ACIP recommendations ignore the prevailing epidemiology of these diseases. For example, <50% of patients with HAV and HBV infections do not have an identifiable risk factor for infection, specifically, whether and when an individual becomes at risk, particularly, through a lifestyle change.

Table 12 Current Advisory Committee for Immunization Practices Recommendations for Pneumococcal (PS-23) Vaccine

persons aged 65 or more
persons with surgical or functional splenectomy
person with cardiac disease
persons with pulmonary disease
persons with asthma
persons who are smokers
persons with diabetes mellitus
persons with thyroid disease
persons with renal disease

PNEUMOCOCCAL VACCINE

Streptococcus pneumoniae infection is a significant health problem in the United States (27). It is estimated that 3000 cases of meningitis, 500,000 cases of pneumonia, and 7 million cases of otitis media are due to the pneumococcus. This translates into 175,000 hospitalizations and an adult fatality rate of 40,000 persons per year. With aging populations, an increasing antibiotic resistance to *S. pneumoniae*, and more adults immunosuppressed, the annual number of fatalities will rise.

Pneumococcal pneumonia is the most serious clinical presentation of pneumococcal disease among adults. The incubation period is 1 to 3 days. Symptoms include an abrupt onset of fever and chills with other symptoms such as pleuritic chest pain, cough, productive of purulent, rusty sputum, dyspnea, tachypnea, hypoxia, tachycardia, malaise, and weakness.

Pneumococci account for up to 36% of adult community-acquired pneumonia and 50% of hospital-acquired pneumonia. Pneumonia is a common bacterial complication of influenza and measles. The case fatality rate is 5% to 7% and may be higher in elderly patients.

The ACIP recommendations for administration are largely risk based and therefore miss many persons (Table 12).

It is noted that there are 18 risk indications for the use of pneumococcal vaccine. The issue of risk-based recommendations is raised again as in hepatitis A and hepatitis B vaccine recommendations. The risk indication listed in Table 12 also applies to pregnant women. The VIS for pneumococcal vaccine states that there is no evidence that pneumococcal vaccine is harmful to either a pregnant women or to her fetus and women with the indications that put them at risk for pneumococcal disease should receive pneumococcal vaccine prior to pregnancy or during pregnancy (28).

MENINGOCOCCAL VACCINE

Neisseria meningitidis is the second most common cause of meningitis in the United States. Large epidemics are often the

Table 13 Immunization During Pregnancy (Active Immunization)

Vaccine	Risk from disease to pregnant women	Risk from disease to fetus or neonate	Type of immunizing agent	Risk of immunization to fetus	Indication for maternal immunization	Dose schedule	Comments
Influenza	Increase in morbidity and mortality especially during epidemic with new antigenic strain	Anatomical fetal damage, 50% mortality in neonatal disease	Trivalent inactivated vaccine (TIV)	None. Fetus receives passive antibodies from mother	All women pregnant during influenza season, any trimester	One dose annually	Passive antibodies to fetus protects from influenza
Hepatitis B	Possibly increased disease in third trimester	Increase rate, spontaneous abortion, and preterm labor. Neonatal hepatitis. High risk of chronic carrier state	Recombinant vaccine	None	All women should receive vaccine	Three dose series 0,1, 6–12 months	Birth dose strongly advised. Also HBIG for infants born of HBsAg-positive mothers
Hepatitis A	Severe morbidity, low morbidity	Increase in spontaneous abortion	Killed viral vaccine	None	All women should receive this vaccine	Two doses 0, 6–12 months	Combination HAV and HBV vaccine available
Tetanus diphtheria acellular pertussis (TdaP)	Severe morbidity tetanus morbidity 30% diphtheria mortality 10% pertussis mild morbidity	Most mortality in infants <6 months hospitalization 70% Apnea 60%	Tetanus = toxoid Diphtheria = toxoid Pertussis – 3–5 antigens	None	All pregnant women who received last Td >2 years ago	Booster single IM injection Primary 3 doses 0, 1, 6–12 months	Fetus protected with passive antibodies; immigrants usually not immunized
Pneumococcal	Severe morbidity and mortality. Increased risk of pulmonary complications	Determined by mothers' morbidity, vaccine reduces otitis media in neonate	Polyvalent polysaccharide vaccine	None	All pregnant women in 2–3 trimesters	1 dose SC or IM, repeat in 6 years for medical high risk	Reduction in otitis media first 4 months of life
Meningococcal vaccine	Severe morbidity and mortality	Determined by mothers' morbidity	Protein conjugate vaccine	None	Adolescent women International travel	One dose IM	

Abbreviations: HBIG, Hepatitis B immune globulin.

Table 14 Immunoglobulin Use in Pregnancy

Immunobiologic agents	Risk form disease in pregnant women	Risk of disease to fetus or neonate	Type of immunization agent	Risk of agent to fetus	Indication during pregnancy	Dose schedule	Comments
Measles	Significant morbidity	Increase in spontaneous abortion, may cause malformation	Standard immune globulin	None	Postexposure prophylaxis	0.25 mg/kg one dose of IG up to 15 mL	Must be given within 6 days of exposure
Hepatitis B	Increase severity in third trimester	Increase in spontaneous abortion, preterm delivery. Neonatal hepatitis, high chronic carrier rate	Hepatitis B immune globulin	None	Postexposure prophylaxis	0.06 mL/kg IM	HBV vaccine is given with HBIG if mother is HBsAg positive
Rabies	Nearly 100% fatal not altered by pregnancy	Determined by maternal disease	Rabies IG	None	Postexposure prophylaxis	20 IU/Kg ½ dose in wound ½ dose in Deltoid	Use with rabies viral vaccine
Varicella	Increase in morbidity and mortality	Congenital varicella 1–2% first trimester	Varicella immune globulin	None	Postexposure prophylaxis for mother exposure	One dose IM 125 u/10 kg Max: 625 U	Dose within 96 hours of exposure. Neonatal if mother developed varicella within 4 days before delivery or 2 days after delivery
Hepatitis A	Severe morbidity Low mortality	Increase in spontaneous abortion	Standard IG	None	Postexposure prophylaxis	One dose 0.02 mg/kg IM	Give hepatitis A vaccine with immune globulin
Rh Immunoglobulin	Death to fetus None	Rh isoimmunization with possible hydrops and deaths	Rh immune globulin	None	Rh-negative mother	One dose IM 300 mg	Administrate 28–30 weeks

Abbreviations: HBIG, Hepatitis B immune globulin.

result of infection with *N. Meningitidis* serotype A and C. A protein conjugate meningococcal vaccine (MCV4) providing protection against serotypes A, C, Y and W-135 is now available (29).

Approximately 2500 persons get meningococcal disease each year in the United States with fatality rate of 10% to 15% with another 1% to 19% losing arms or legs, becoming deaf, become mentally retarded, or suffer seizures or strokes.

MCV4 vaccine is recommended for the following persons:

- Adolescents aged 11 through 18 years
- College freshmen living in dormitories
- U.S. military recruits
- Anyone traveling to a part of the world where meningococcal disease is common
- Persons who have had a surgical splenectomy or have a functional splenectomy
- Persons with a terminal compliment disorder
- Persons exposed to meningitis during an outbreak

Meningitis vaccine should be administered to adolescent pregnant women. The major vaccines that should be administered to *all* pregnant not previously immunized are summarized on Table 13. The summary of immunoglobulin that can be used in pregnancy is seen on Table 14. This chapter strongly advocates for maternal immunization as a routine to protect the mother from disease and to protect the infant with passive maternal antibodies. The shortcomings and inadequacy of the CDC's recommendations on hepatitis A and B vaccines and pneumococcal as well as Tdap are emphasized. The goal should be to prevent all vaccine preventable diseases in the mother and thereby prevent the disease in the infant by timely maternal vaccinations.

89 Neonatal diseases I

John Pardalos

APNEA OF PREMATURITY

Apnea of prematurity is a condition frequently seen in preterm infants. It is defined as a cessation in breathing for more than 20 seconds, or less than 20 seconds if it is associated with bradycardia and/or cyanosis (1). The incidence of this disorder increases with decreasing gestational age, but luckily most infants outgrow this disorder by the time they reach 35 to 36 weeks postconceptional age. Over the last 20 years, the prevalence of this disorder has increased as smaller, more preterm infants are now surviving. With advances in ventilator management and surfactant therapy, many preterm infants are currently being extubated within days of admission to the neonatal intensive care unit. The goal is to keep them off the ventilators to prevent potential trauma to the developing lungs. As a result, neonatologists are faced with a dilemma about when is the frequency of apnea high enough to require reintubation.

For decades, neonatologists have been looking for ways to treat these infants without resorting to mechanical ventilation. Many times these infants are placed on some type of positive pressure device post-extubation to help the infants maintain adequate respiratory dynamics while using minimal pressures to achieve this. Some of the various devices used to accomplish this include nasal prong continuous positive airway pressure [CPAP (NCPAP)], nasal prong CPAP with a rate (known as NIPPV), SiPAP, and high-flow nasal cannula. These devices provide positive pressure to the infant's airway that helps stent the airways open, allowing for easier flow of air into and out of the lungs, which helps prevent obstructive apnea. NIPPV generates increased pharyngeal pressure intermittently based on the peak inspiratory pressure and rate that may activate the dilator muscles of the pharynx and stimulates respiratory drives to abort the apnea spell (2). In studies comparing NIPPV with NCPAP, it was noted that those infants treated with NIPPV had a greater reduction in the number of apneic spells compared with those treated with NCPAP (2–5).

Since the 1970s, methylxanthines have been used to treat apnea of prematurity. Over the years, various methylxanthines have been used including theophylline, aminophylline, and caffeine. Currently, caffeine is most commonly used due to a wide therapeutic window with fewer risks of side effects. We do not have to draw levels with caffeine compared with theophylline and aminophylline. The mechanism of action of methylxanthines is unknown, but they have been shown to decrease apneic events, increase minute volumes, improve respiratory system compliance, reduce diaphragmatic fatigue, and act as a diuretic (6,12,14). In fact those infants treated with caffeine required mechanical ventilation, noninvasive ventilation, and/or supplemental oxygen therapy for 1 week less on average compared with those infants treated with placebo. Those infants treated with

caffeine, however, did show slower weight gain compared with the placebo group at least initially (7,13,14).

Another concern with methylxanthines was that they may interfere with the neurodevelopmental outcome of infants. In animal models, adenosine was noted to protect the brain from energy failure or cell death during hypoxia and ischemia and methylxanthines inhibit adenosine receptors (8). The Caffeine for Apnea of Prematurity (CAP) trial was conducted to see what short- and long-term risks and benefits caffeine provided infants. The trial found that caffeine reduced the incidence of bronchopulmonary dysplasia and decreased the need for supplemental oxygen therapy and assisted ventilation of any type. The CAP trial followed these patients to 2 years of life and found that caffeine also improved the neurodevelopmental outcome at 18 to 21 months of age. Caffeine was noted to decrease the incidence of cerebral palsy and cognitive delay but no change in death, severe hearing loss, or bilateral blindness was found (6,8,12,13). The study did find that those infants who were started on caffeine while they were still on some type of respiratory support had the greatest improvement in their neurodevelopmental outcomes (6).

Other medications used to attempt to treat apnea of prematurity include carnitine and doxapram. Carnitine deficiency can be a cause of apnea in infants and adults but no trial has shown that supplementation with carnitine made a difference in the frequency of apnea (9,10). Doxapram is another respiratory stimulant that has been used to treat apnea of prematurity. Doxapram must be administered intravenously, however, and potentially has the following side effects: seizures, liver dysfunction, and gastrointestinal irritation, which has limited its use. In a recent Cochrane review that compared the use of doxapram versus methylxanthine in the treatment of apnea found no difference between the two medications (11).

LATE PRETERM NEWBORNS

Infants born at 34 0/7 weeks to 36 6/7 weeks of gestation were called near-term until 2005 when the National Institute of Child Health and Human Development of the National Institutes of Health held a workshop entitled "Optimizing Care and Outcome of the Near-Term Pregnancy and the Near-Term Newborn Infant." At this workshop, a decision was made to call these infants late preterm infants to signify that even though these infants many times were of the physical size of term infants, physiologically and metabolically they were immature (15,16). When compared with term infants, late preterm infants are more likely to have respiratory distress, temperature instability, hypoglycemia, hyperbilirubinemia, apnea, sepsis, and feeding problems. They were also noted to have higher mortality and rehospitalization rates during the newborn period (15–20). Therefore, it is important that late

preterm infants not be treated like healthy term infants but monitored closely to make sure that if they develop any morbidities noted above, they are treated promptly.

Between 1990 and 2005, the overall preterm birth rate increased by 20% from 10.6% in 1990 to 12.7% in 2005. During this same time period, the late preterm infant birth rate increased by 25% from 7.3% in 1990 to 9.1% in 2005. In 2005, 71% of all preterm births (<37 0/7 weeks of gestation) occurred in the late preterm gestation (34 0/7 to 36 6/7 weeks) group (21). Three factors that may have contributed to this increase in the overall preterm birth rate as well as the late preterm birth rate include increased percentage of women waiting until later in life to have children, increased use of assisted reproductive technology to have children, and increased rates of multiple births (twins, triplets, etc.). These three factors are interrelated, and it is difficult to ascertain the effect on the preterm birth rate by any one factor. Studies have shown that preterm delivery frequency is higher in women less than 16 years old and in those over 35 years old by 2% to 4% compared with the rate seen in women 21 to 24 years old. In addition, studies have shown that using assisted reproductive technology to become pregnant increases the risk of multiple births, which are more likely to deliver prematurely but this increased risk of preterm birth is also seen with singleton births conceived using assisted reproductive technology (22).

As stated previously, late preterm infants have a higher mortality rate compared with term infants (16,17,21–25). From 1995 to 2002, the overall infant mortality rate (0–364 days) for late preterm infants decreased from 9.5 per 1000 to 7.9 per 1000 and for term infants it decreased from 3.0 per 1000 to 2.4 per 1000. Congenital malformations accounted for 42% of the deaths in the late preterm infants and 31% in the term infants (23). In a study conducted by Young et al., all infants born in Utah between 1999 and 2004 with a gestation age of 34 to 42 weeks were evaluated to see whether they died prior to their first birthday. They also found that the most common reason for the death of infants during their first year of life was due to birth defects. In addition, they determined the early neonatal (1–7 days), neonatal (1–28 days), and infant (1–365 days) mortality rates by gestational age excluding infants with birth defects. In all three categories, they found that the 34-week-gestational-age infants had the highest mortality rate while the 39- to 41-week-gestational-age infants had the lowest rates. For example, infants without birth defects had an early neonatal mortality rate of 1.27 per 1000 at 34 weeks of gestation, 1.06 per 1000 at 35 weeks of gestation, 0.66 per 1000 at 36 weeks of gestation but a rate of 0.08 per 1000 at 40 weeks of gestation. This gave a risk ratio of 3.25, 3.21, and 2.69 at 34, 35, and 36 weeks of gestation respectively when compared with 40 weeks of gestation. Infants in this study had a neonatal mortality rate of 1.90 per 1000 at 34 weeks of gestation, 1.41 per 1000 at 35 weeks of gestation, 0.99 per 1000 at 36 weeks of gestation, but a rate of 0.22 per 1000 at 40 weeks of gestation. This gave a risk ratio of 3.24, 3.20, and 2.68 at 34, 35, and 36 weeks of gestation respectively when compared with 40 weeks of gestation. These infants had an infant mortality rate of 3.79 per 1000 at 34 weeks of gestation, 3.16 per 1000 at 35 weeks of gestation, 2.55 per 1000 at 36 weeks of gestation, but a rate of 0.80 per 1000 at 40 weeks of gestation. This gave a risk ratio of 4.62, 3.91, and 3.14 at 34,

35, and 36 weeks of gestation respectively when compared with 40 weeks of gestation (24). When birth weight was taken into account, the neonatal and infant mortality rates again decreased with increasing gestational age from 34 to 41 weeks of gestation. Those infants who were small for gestational age (SGA) at any gestational age had the highest mortality rate. Late preterm infants who were SGA were 44 times more likely to die during the first 28 days of life and 21 times more likely to die during the first year of life compared with term appropriate-for-gestational-age (AGA) infants. When infants with congenital anomalies were excluded, late preterm infants who were SGA continued to have a higher risk of dying compared with term AGA infants during both the neonatal and infant periods (25).

When late preterm infants are born, there are a variety of potential complications that they are at a higher risk of developing compared with their term counterparts for which they need to be monitored closely. In a study by Wang et al. in 2004, they looked at infants born between October 1997 and October 2000 at Massachusetts General Hospital and randomly selected 90 late preterm infants (35 0/7 to 36 6/7 weeks of gestational age) and 95 term infants (37 to 40 weeks of gestational age) who met the inclusion criteria. They found that the late preterm infants were more likely to have temperature instability (10% vs. 0%; OR: infinite), hypoglycemia (15.6% vs. 5.3%; OR: 3.30; 95% CI: 1.1–12.2), require intravenous infusion (26.7% vs. 5.3%; OR: 6.48; 95% CI: 2.27–22.91), respiratory distress (28.9% vs. 4.2%; OR: 9.14; 95% CI: 2.9–37.8), and were clinically jaundiced (54.4% vs. 37.9%; OR 1.95; 95% CI: 1.04–3.67) compared with the term infants. The late preterm infants were also more likely to require a sepsis evaluation compared with the term infants (36.7% vs. 12.6%; OR: 3.97; 95% CI: 1.82–9.21). Even though more of the late preterm infants ended up receiving a full 7-day course of antibiotics, it was not statistically significant (20). Because of these morbidities, late preterm infants are more likely to have prolonged hospitalizations (required hospitalization after their mother was discharged). In a study by Pulver et al., they found that 75% of 34-week-gestational-age infants, 50% of 35-week-gestational age, and 25% of 36-week-gestational-age infants had a prolonged hospitalization. The average length of stay for these infants was 12.6, 6.1, and 3.8 days for 34-, 35-, and 36-week-gestational-age infants respectively (18).

In a study by Shapiro-Mendoza et al., they looked for risk factors that increased the morbidity rate in singleton late preterm infants who were considered healthy at birth. These infants were considered healthy if they were discharged before a fourth-night hospital stay, weighed at least 2000 g at birth, and did not have any significant health problems or procedures. They found that having an Asian/Pacific Islander mother, being firstborn, being breastfed at discharge, having a mother with complications at labor and delivery, and having a public payer source at the time of delivery all increased the risk of a neonatal morbidity. They also found that these healthy late preterm infants had a 4.8% risk of being readmitted to the hospital and 1.3% had an observation stay within 28 days of life. They found that those infants who were breastfed were more likely to require readmission to the hospital or have an observation stay due to inadequate weight gain, jaundice, or

feeding problems (19). Therefore, it is important to make sure that healthy late preterm infants are truly feeding well prior to discharge from the hospital and have close follow-up after discharge to prevent the need for readmission to the hospital.

At 34 weeks of gestation, the brain weighs about 65% that of a term infant's brain and very few sulci and gyri are present, so studies have been conducted to look at the long-term neurologic outcome of late preterm infants. These studies have found that late preterm infants have worse neurologic outcomes compared with term infants. For example, in a study by Woythaler et al., they looked at 6300 term and 1200 late preterm infants at 24 months of age. They looked at the mental developmental index (MDI) and psychomotor developmental index (PDI) on the Bayley Scales of Infant Development Short Form—Research Edition. These indices have a mean score of 100 with a standard deviation of 15, so a score less than 70 indicates significant delay and a score of 70 to 84 indicates mild delay. In this study, they found that the late preterm infants had a mean score of 85 and the term infants had a mean score of 89 on the MDI while on the PDI, the mean scores were 88 and 92 for the late preterm and term infants respectively. About 21.2% of the late preterm infants and 16.4% of the term infants had a score <70 on the MDI while 6.1% of the late preterm infants and 6.5% of the term infants had a score <70 on the PDI. When they controlled for gestational age, plurality, maternal race, education, marital status, depression, prenatal care, primary language, infant gender, poverty level, delivery type, fetal growth, and any breastmilk feedings, the adjusted odds (95% CI) of a late preterm infant having more severe mental developmental delay (MDI score <70) was 1.51 (95% CI: 1.26–1.82) and milder mental developmental delay (MDI score 70–84) was 1.43 (95% CI: 1.22–1.67) compared with a term infant. In addition, the adjusted odds ratio that a late preterm infant having more severe psychomotor developmental delay (PDI score <70) was 1.56 (95% CI: 1.29–1.88) and milder psychomotor developmental delay (PDI score 70–84) was 1.58 (95% CI: 1.37–1.83) compared with a term infant (26). In another study by Morse et al., they looked at healthy late preterm infants (spent <72 hours in the hospital at birth) to see whether they were ready for kindergarten. They looked at 7152 healthy late preterm infants and 152,661 term infants and found that the late preterm infants had a 36% higher risk of developmental delay or disability, a 19% higher risk of suspension in kindergarten, and a 10% to 13% higher risk of having disability in pre-kindergarten, requiring exceptional student education or requiring retention in kindergarten (27). These studies show that even though these late preterm infants appear healthy at birth, they should be monitored closely and placed in early educational interventions if they start to show delays to help improve their outcomes.

As you can see, late preterm infants should not be treated like term infants. They have a higher risk of developing neonatal morbidities, require rehospitalization, and have poor neurologic outcomes. These infants need to be monitored closely throughout their childhood, and if they start to develop any issues, they need to be treated quickly to allow them to have the best possible outcome.

THERAPEUTIC HYPOTHERMIA

Hypoxic-ischemic encephalopathy (HIE) occurs in infants when cerebral perfusion is impaired resulting in hypoxic injury to the brain. It occurs in 3 to 5 per 1000 live births with moderate or severe HIE occurring in 0.5 to 1 per 1000 live births (28,29). HIE accounts for 23% of the 4 million neonatal deaths globally each year (28,30).

Studies have shown that neuronal death following a hypoxic-ischemic injury occurs in two phases. Initially, the lack of oxygen causes primary energy failure that results in neuronal death via necrosis or apoptosis. Necrosis is characterized by swelling of the plasma membrane until the cell eventually ruptures releasing intracellular toxins while apoptosis is a slower form of neuronal death due to a less severe or prolonged hypoxic event often described as cell suicide. Once reperfusion of the brain occurs, the energy levels in the neurons “normalize.” This period is characterized by normal blood pressure and intracellular pH, transient improvement in cellular edema, and an absence of seizures. Then a second energy failure occurs during which delayed neuronal death occurs. This is caused by hyperemia, cytotoxic edema, mitochondrial failure, accumulation of excitotoxins, apoptosis, nitric oxide synthesis, free radical damage, and cytotoxic actions of activated microglia. It is this secondary energy failure that leads to the highest proportion of neuronal death and leads to encephalopathy and seizures. Therefore, the time between the primary and secondary energy failures provide a window of opportunity to provide some intervention that may prevent the more devastating secondary event from occurring (28,31).

Scientists have been looking for interventions that could be initiated during this therapeutic window to try to improve the outcome of infants who suffer from HIE, but to date, nothing has shown promise except for hypothermia. Hypothermia has been shown to modify cells programmed for apoptosis leading to their survival. It may also protect neurons by reducing their metabolic rate, attenuating the release of excitatory amino acids (glutamate and dopamine), ameliorating the ischemia-impaired uptake of glutamate and decreasing the production of toxic nitric oxide and free radicals (28,29). Studies in animal models have shown that a 2°C to 3°C drop in the temperature of the brain after a hypoxic-ischemic event decreased energy expenditure, improved subsequent performance testing, and/or decreased histologic neuronal loss (29). Other studies found that the earlier the hypothermia was initiated, the better the outcome. This neuroprotective effect of hypothermia was seen up to 6 hours post insult. Still other studies found that moderate hypothermia of the brain in the 32°C to 34°C range that was continued for 24 to 72 hours again had the best outcomes in animal models. Temperatures lower than this range revealed an increase in potential systemic adverse effects such as mortality, hypoglycemia, decreased cardiac contractility and cardiac output, sinus bradycardia, hypotension, ventilation–perfusion mismatch, increased blood viscosity, coagulopathy, acid/base imbalance, electrolyte imbalance, and increased risk of infections (31).

Currently there are two ways to provide hypothermia to neonates, selective brain cooling or total body cooling. Recently there were four large multicenter randomized control trials that were conducted to evaluate the effect of

hypothermia in neonates with moderate or severe HIE using one of these two methods of hypothermia. The CoolCap trial included 234 infants who were ≥ 36 weeks of gestational age with moderate to severe HIE and abnormal amplitude-integrated electroencephalography (aEEG). These infants were randomized to either receive selective head cooling for 72 hours with a goal rectal temperature of 34°C to 35°C or standard care. Therapy with hypothermia was to be initiated within 6 hours of birth. The inclusion criteria were an Apgar score of ≤ 5 at 10 minutes after birth, continued need for resuscitation including endotracheal or mask ventilation at 10 minutes after birth, or severe acidosis defined as a $\text{pH} < 7.00$ or a base deficit of ≥ 16 mmol/L on either a cord gas or an arterial or venous sample drawn within 60 minutes of birth. Eligible infants were then assessed for clinical evidence of moderate or severe HIE using the Sarnat criteria (lethargy, stupor, or coma with one or more of the following symptoms: hypotonia, abnormal reflexes (including oculomotor or pupillary), an absent or weak suck, or clinical evidence of seizures. Next an aEEG was used to determine whether the infant had a moderate or severely abnormal aEEG tracing for 20 minutes prior to initiation of hypothermia. Those infants who were randomized to hypothermia were kept cool for 72 hours and then gradually rewarmed by no more than $0.5^{\circ}\text{C}/\text{hr}$ until the infant's temperature was normal (36.5 – 37.5°C). They ended up with 116 infants who were treated with hypothermia and 118 who received standard therapy. These infants were followed for 18 months and they found no difference in the primary outcomes of death or severe disability, but when they looked at the subset of infants with moderately abnormal aEEG, those who were cooled had an improved outcome ($n = 172$, odds ratio 0.42; 95% CI 0.22–0.80; $p = 0.009$) (32).

The NICHD Neonatal Research trial included 208 infants who were ≥ 36 weeks of gestational age with moderate-to-severe HIE. These infants were randomized to either receive whole-body cooling for 72 hours with a goal esophageal temperature of 33.5°C or standard care. Therapy with hypothermia was to be initiated within 6 hours of birth. The inclusion criteria were infants with severe acidosis defined as a $\text{pH} < 7.00$ or a base deficit of ≥ 16 mmol/L on either a cord gas or any blood sample drawn within 60 minutes of birth or those infants with a pH of 7.01 to 7.15, a base deficit of 10 to 15.9 mmol/L, or no blood gas available with additional criteria of an acute perinatal event (e.g., late or variable decelerations, cord prolapse, cord rupture, uterine rupture, maternal trauma, hemorrhage, or cardiorespiratory arrest), and either an Apgar score of ≤ 5 at 10 minutes after birth, or continued need for resuscitation including endotracheal or mask ventilation at 10 minutes after birth. Eligible infants were then assessed for clinical evidence of moderate or severe HIE or seizures. HIE was defined as having one or more signs in at least three of the following six categories: level of consciousness, spontaneous activity, posture, tone, primitive reflexes (suck or Moro), and autonomic nervous system (pupils, heart rate, or respirations). Those neonates that were randomized to hypothermia were kept cool for 72 hours and then gradually rewarmed by no more than $0.5^{\circ}\text{C}/\text{hr}$ until the infant's temperature was normal (36.5 – 37.0°C). They ended up with 102 infants who were treated with hypothermia and 106 who received standard therapy. These infants were followed for 18 to 22 months and

they found death or moderate/severe disability occurred in 44% of the hypothermia group and 62% of the control group (risk ratio 0.72; 95% CI 0.54–0.95; $p = 0.01$). Death occurred in 24% of the hypothermia group and 37% of the control group and cerebral palsy occurred in 19% of the hypothermia group and 30% of the control group (33).

The TOBY trial included 325 infants who were ≥ 36 weeks of gestational age with moderate to severe HIE. These infants were randomized to either receive whole-body cooling for 72 hours with a goal rectal temperature of 33.5°C or standard care. Therapy with hypothermia was to be initiated within 6 hours of birth. The inclusion criteria were infants with severe acidosis defined as a $\text{pH} < 7.00$ or a base deficit of ≥ 16 mmol/L on either a cord gas or any blood sample drawn within 60 minutes of birth or an Apgar score of ≤ 5 at 10 minutes after birth or continued need for resuscitation including endotracheal or mask ventilation at 10 minutes after birth. Eligible infants were then assessed for clinical evidence of moderate or severe HIE (indicated by lethargy, stupor, or coma) and either hypotonia, abnormal reflexes (including oculomotor or pupillary), an absent or weak suck, or clinical seizures. Finally, they had to have an abnormal aEEG pattern on a 30-minute tracing. Those infants who were randomized to hypothermia were kept cool for 72 hours and then gradually rewarmed by no more than $0.5^{\circ}\text{C}/\text{hr}$ until the infant's temperature was normal (37.0°C). They ended up with 163 infants who were treated with hypothermia and 162 who received standard therapy. These infants were followed for 18 months and they found death or moderate/severe disability occurred in 45% of the hypothermia group and 53% of the control group (risk ratio 0.86; 95% CI 0.68–1.07; $p = 0.17$). Survival without neurologic abnormalities was improved in the hypothermia group (risk ratio 1.57; 95% CI 1.16–2.12; $p = 0.003$). In addition, cerebral palsy was decreased in the hypothermia group (risk ratio 0.67; 95% CI 0.47–0.96; $p = 0.03$) and improved outcomes were noted on the MDI and the PDI of the Bayley Scales of Infant Development II ($p = 0.03$ for each) (34).

As you can see, when you look at these three randomized control trials, hypothermia appears to decrease the mortality rate or major disability at 18 months of age especially in those infants with only moderate HIE (28). This was confirmed in the neo.nEURO.network trial, which included 111 infants who were ≥ 36 weeks of gestational age with moderate to severe HIE. These infants were randomized to either receive whole-body cooling for 72 hours with a goal rectal temperature of 33.5°C or standard care. Therapy with hypothermia was to be initiated within 6 hours of birth. The inclusion criteria were infants with at least one of the following criteria: severe acidosis defined as a $\text{pH} < 7.00$ or a base deficit of ≥ 16 mmol/L on either a cord gas or arterial blood gas drawn within 60 minutes of birth, or an Apgar score of less than 5 at 10 minutes after birth, or continued need for resuscitation including endotracheal or mask ventilation at 10 minutes after birth. Eligible infants were then assessed for clinical evidence of moderate or severe HIE (indicated by lethargy, stupor, or coma) and at least one of the following criteria: hypotonia, abnormal reflexes (including oculomotor or pupillary), an absent or weak suck, or clinical seizures. Finally, they had to have an abnormal standard EEG or aEEG pattern on a

30-minute tracing. Those infants who were randomized to hypothermia were kept cool for 72 hours and then gradually rewarmed by no more than 0.5°C/hr until the infant's temperature was normal (37.0°C). They ended up with 53 infants who were treated with hypothermia and 58 who received standard therapy. Both groups were treated with either morphine or fentanyl to reduce the discomfort due to the HIE or the hypothermia. These infants were followed for 18 to 21 months, and they found death or severe disability occurred in 51% of the hypothermia group and 83% of the control group (odds ratio 0.21: 95% CI 0.09–0.54: $p = 0.001$). This was even true in the severe HIE group (odds ratio 0.17: 95% CI 0.05–0.57: $p = 0.005$) (35). As you can see from these studies, hypothermia appears to help improve the outcomes of infants with HIE more so with those who are moderately affected, but hypothermia is not a cure-all and more studies combining hypothermia with other neuroprotective interventions need to be conducted.

RESPIRATORY PROBLEMS IN TERM INFANTS

Unlike the typical respiratory problems of prematurely delivered newborns that result from inadequate surfactant production, the mechanisms of respiratory problems in term infants (≥ 37 weeks of gestation) are associated with inadequate pulmonary perfusion (e.g., persistent pulmonary hypertension of the newborn) as well as surfactant deficiency due to both inadequate production (e.g., in the late preterm infant) and inactivation [e.g., meconium aspiration syndrome (MAS), congenital pneumonia]. Finally, both spontaneous airleaks and congenital abnormalities of airway, pulmonary parenchyma, or pulmonary vascular development (e.g., congenital diaphragmatic hernia, alveolar-capillary dysplasia) present as respiratory distress in the term newborn. Although term infants are less likely to suffer from respiratory problems than preterm infants, their risk for respiratory distress has been estimated at 0.6% in one large prospective study (1) and their risk for severe respiratory distress that requires mechanical ventilation at $\sim 0.2\%$ (2).

MAS

Although most infants delivered after exposure to meconium-stained amniotic fluid will exhibit no symptoms, a subgroup may develop severe respiratory failure. Understanding the pathophysiology of this subgroup has been enhanced by understanding fetal lung physiology. Net fluid flow in the fetal lung results from an egress of fluid from pulmonary epithelial cells into future airspaces and airways. The flow of fetal lung fluid across the glottis into the amniotic cavity keeps contaminants in the amniotic fluid (e.g., meconium, squamous cells, and blood) downstream from pulmonary epithelial cells in utero. Aspiration of these agents may occur if the fetus is "gasping," a fetal behavior associated with severe hypoxia or ischemia. Exposure of the pulmonary epithelium to meconium leads to evidence of significant injury with elaboration of cytokines associated with inflammation, altered surfactant metabolism, and histologic evidence of airspace overdistention. These pathophysiologic mechanisms help explain the ventilatory problems associated with MAS and increased risk of airleaks (3). The associated hypoxia and acidosis, particularly if preceded by prolonged intrauterine distress with increase in the thickness of the muscularis layer in the smaller pulmonary branch vessels (4), contribute to failure to achieve normal pulmonary vasorelaxation and to worsening hypoxia and hypercarbia in a cyclic fashion. Thus, both severe pulmonary parenchymal injury and pulmonary hypertension contribute to the presentation and must be treated.

MAS occurs in 0.6% to 0.7% of all newborn infants with any respiratory symptoms and in 0.04% of newborn infants who

require mechanical ventilation (2,5,6). Although risk for other common respiratory problems [e.g., transient tachypnea of the newborn (TTN) or respiratory distress syndrome (RDS)] decreases with advancing gestational age, risk for MAS increases with advancing gestational age. Approximately one-third of symptomatic infants will require mechanical ventilation, and despite surfactant replacement and availability of high-frequency oscillatory ventilation (HFOV) and nitric oxide (NO) treatment, mortality is reported in 2.5% of infants who require ventilatory support (down from 12% before widespread adoption of HFOV and NO).

Over the last decade, approaches to intrapartum and immediate postpartum prevention of MAS have moved away from attempts to evacuate the upper airway of meconium by obstetricians at delivery of the head and by pediatricians after the delivery is complete. These interventions were found to be helpful in small historical control studies in the 1970s. However, larger randomized controlled trials reported in the 1990s failed to demonstrate any improvement in outcomes and raised concerns about associated iatrogenic injury to the upper airway in some infants. The official 2005 recommendation of the American Heart Association and the American Academy of Pediatrics makes clear that in the setting of infants born with thick meconium staining, the priority is to reserve intubation only for the infants who are most depressed at birth and not routinely to aspirate the mouth and nose (7). Similarly, although initial randomized studies of amnioinfusions for meconium-stained amniotic fluid found a beneficial effect on neonatal respiratory outcomes without increased maternal morbidity, a large multicenter randomized study (8) reported no routine benefit from amnioinfusion. The American College of Obstetrics and Gynecology revised its practice guideline to indicate that although amnioinfusion remains an appropriate intervention for treatment of fetal distress (with or without meconium-stained amniotic fluid) evaluated by heart rate monitoring, it is not effective for reduction of risk of MAS (9,10).

TTN

First described by Mary Ellen Avery in 1966 (11), this self-limited (hours to a few days) condition is characterized by presentation within the first few hours of life with tachypnea, a radiographic picture of increased perihilar pulmonary vascular markings, fluid in the pulmonary lobar fissure, and increased lung volumes. Both the severity and duration of symptoms vary but are generally less intense than those seen in respiratory disorders like MAS or congenital pneumonia. As noted earlier, net fetal lung liquid production leads to egress of fluid into the amniotic cavity. Just prior to birth, this

chloride-rich fluid production by the lung epithelium switches to fluid resorption driven by amiloride-sensitive sodium channels. The reversal of chloride and water transport leads to a decrease in total lung water before delivery. This process is dependent on long-term, developmentally regulated changes in the expression of sodium channels and their adrenoceptor sensitivity, more acute changes in ambient catecholamine levels associated with labor and delivery, and transition to the relatively oxygen-rich postnatal environment (12). Failure of this process of adaptation to the extrauterine environment in the absence of infection, surfactant deficiency or inactivation, or relevant birth defects is believed to cause the symptom complex known as TTN.

In keeping with this proposed mechanism, the risk factors associated with higher risk of TTN are those that interfere with normal adaptation from placenta-dependent gas exchange in utero to lung-dependent gas exchange in the extrauterine environment. Shorter gestation may lead to lower levels of expression of critical components of the sodium channel assembly, its catecholamine regulators, and surfactant (the risk of developing TTN increases with decreasing gestational age). Additionally, absent or shortened labor (e.g., in the settings of elective cesarean section without labor or of rapid second phase of labor) provides less time for alveolar fluid resorption and is associated with the development of TTN. Finally, disease risk may be increased by genetic factors, for example, polymorphisms in β adrenoceptor gene (13). Recent studies have reinforced the association of TTN with both earlier gestational age and cesarean delivery mode (14–16).

RESPIRATORY DISTRESS IN PRETERM INFANTS

Despite advances in the care of infants born prematurely, prematurity (delivery at <37 weeks of gestation) remains one of the leading causes of neonatal death (17). The incidence of RDS, a major complication of prematurity, is directly related to lower gestational age at birth. The incidence of RDS in infants born at 25 weeks of gestation approaches 100%. At 27 weeks of gestation, the incidence decreases to approximately 85%, at 30 weeks of gestation to 55%, at 32 weeks of gestation to 30%, and by 35 weeks of gestation to 10% (18). In addition to prematurity, other factors that predispose to RDS include male gender, European ancestry, maternal diabetes, perinatal hypoxemia, hypothermia, multifetal pregnancy, and cesarean delivery (19). An increase in the rate of preterm deliveries over the last several years, attributable primarily to infants delivered between 34 and 37 weeks of gestation (late preterm infants) (See section below entitled “Late Preterm Neonates.”), has contributed significantly to the burden of newborn respiratory distress (20).

In 1959, Mary Ellen Avery and Jere Mead described the relationship between preterm birth, lung surface tension, and RDS (21). Since that time, understanding the biology of pulmonary surfactant and its role in preterm respiratory distress has been one of the triumphs of newborn medicine. This understanding has led to the use of exogenous surfactant replacement as a primary treatment for preterm RDS. Available surfactant preparations include bovine- or porcine-derived products and synthetic surfactant preparations that are administered to preterm infants via endotracheal tube. Multiple studies have demonstrated the efficacy of exogenous

surfactant in reducing newborn mortality and airleaks, especially when given as multiple doses early after birth in a prophylactic, as opposed to rescue, manner (22,23). Although a consistent reduction in the development of chronic lung disease (bronchopulmonary dysplasia) in preterm infants treated with surfactant has not been demonstrated, there is evidence that the severity of chronic lung disease has decreased in the era of surfactant therapy (24). Combined management strategies, for example, surfactant treatment and early extubation to continuous positive airway pressure (CPAP), show promise in decreasing not only the severity but the incidence of chronic lung disease in preterm infants with RDS as well (25,26).

In the late 1960s, Graham Liggins made the seminal observation that lambs exposed in utero to corticosteroids and delivered prematurely had less respiratory distress, more mature appearing lungs, and decreased mortality (27). By 1972, the first human trial demonstrating the efficacy of antenatal corticosteroids in reducing RDS in preterm human infants had been completed (28). Since the 1970s, multiple clinical trials have demonstrated the effectiveness of antenatal glucocorticoid treatment of women in preterm labor in reducing the incidence and severity of RDS (29). Although significant concern has been raised regarding the association of postnatal steroid treatment of preterm infants with poorer neurodevelopmental outcomes, there has been no consistent evidence that administration of antenatal corticosteroids results in neurodevelopmental delay (30,31).

The identification of genetic mutations that result in lethal respiratory failure in newborn infants has led to the discovery of genetic polymorphisms associated with an increased risk of respiratory distress in the premature newborn (32). Polymorphisms associated with an increased risk of RDS in preterm infants have been identified in the surfactant protein-A, surfactant protein-B, surfactant protein-C, and the ATP-binding cassette transporter A3 (ABCA3) genes (33–35). Additionally, polymorphisms associated with preterm RDS have also been identified in genes not directly related to surfactant synthesis and secretion including mannose-binding lectin, interleukin-10, and the G protein-coupled receptor for asthma susceptibility (36–38). Elucidating the interactions between and among genetic variants, environment, and developmental factors may lead to novel management strategies in preterm infants with RDS.

LATE PRETERM NEONATES

Terminology and Epidemiology

An expert panel convened by the National Institute of Child Health and Human Development in July, 2005, recommended that infants born between 34 0/7 weeks (day 239) and 36 6/7 weeks (day 259) of gestation be referred to as late preterm (39,40). Late preterm infants account for 360,000 of more than 4 million births in the United States (40). Davidoff and Dias et al. found that two-thirds of the last decade’s increase in the rate of all preterm births was associated with an increase in the rate of late preterm births. Also noteworthy was that 74.1% of all singleton preterm births in 2002 occurred at 34, 35, and 36 weeks of gestation (41). Late preterm births also accounted for 61% of preterm multiple births (41). Since late preterm infants constitute such a large proportion of preterm infants,

Table 1 Neonatal Infections by Timing of Onset

Onset	Transmission	Risk Factors	Predominant Organisms
Early Birth to 2–7 days	Vertical	Maternal colonization/infection Prolonged premature rupture Prematurity	Group B <i>Streptococcus</i> <i>Escherichia coli</i>
Late >2–7 days to 1 month	Horizontal Vertical less common	Invasive hardware/procedures (vascular catheters, endotracheal tubes, surgery) Environmental contact Prematurity	Coagulase-negative staphylococci <i>Staphylococcus aureus</i> <i>Escherichia coli</i> <i>Pseudomonas species</i> <i>Candida</i>

even a modest increase in their birth rate can have a significant impact on infant outcomes and health-care costs. Maternal and fetal indications commonly associated with late preterm delivery include pre-eclampsia, multiple gestation, and abnormal presentations (42). A portion of late preterm delivery may be preventable, especially those births that result from “maternal preference” (43,44).

Morbidity

Although historically called “near term,” multiple morbidities associated with delivery between 34 and 37 weeks of gestation including respiratory distress, temperature instability, hypoglycemia, hyperbilirubinemia, apnea, seizures, and feeding problems, as well as higher rates of rehospitalization suggest that infants at these gestational ages are not prepared for successful fetal–neonatal transition (39,45). For example, temperature instability, hypoglycemia, and jaundice were observed more frequently in late preterm infants (10%, 15.6%, and 54.5%, respectively) than term babies (0%, 5.3%, and 37.9%, respectively) (45). Similarly, poor feeding was observed more frequently in late preterm than term infants (77.8% vs. 45.3%). Apnea and bradycardia are seen in late preterm infants (45) with prevalence rates as high as 10% (46). Late preterm infants are more likely to be evaluated with a complete blood count and blood culture and treated with antibiotics for 48 hours or 7 days compared with term babies (45) due to the difficulty of excluding sepsis as an underlying cause for multiple transitional symptoms including respiratory distress, hypothermia, and poor feeding. Delay in discharge among late preterm infants is more common as a result of these problems, with poor feeding as the most common reason for the delay (45). Respiratory complications are also prevalent among late preterm infants. The most common respiratory diagnoses among late preterm infants who require assisted ventilation include RDS, MAS, and pneumonia/sepsis (20). When compared with infants born at 37 to 42 weeks of gestation, the frequency of RDS is greater in late preterm infants (62% vs. 43%), while the frequency of MAS is less (1.3% vs. 9.7%) (20). Earlier studies also demonstrate increased need for mechanical ventilation as gestational age decreases among late preterm infants (1). Need for extracorporeal membrane oxygenator (ECMO) therapy for respiratory failure among late preterm infants has also been increasing (47). Among 15,590 infants in the Extracorporeal Life Support Organization National Registry treated with ECMO between 1989 and 2006, 2258 (14.5%) were late preterm infants (47).

Death is more common in late preterm infants than term infants: risk of early neonatal death (birth to 28 days of age) is

5.2-fold greater, late neonatal death (28 days to 1 year of life) is 2.9-fold greater, and total infant mortality (all deaths from birth to 1 year of age) is 2.5-fold greater (39,48). Risk for increased morbidity also persists as evidenced by increased emergency department visits and rehospitalizations (49–51). Studies by Kinney et al. suggest that although the brain is more mature in late preterm than very preterm infants, it is still immature and can be disrupted or damaged by late preterm delivery (52). Substantial brain growth occurs between 34 and 41 weeks of gestation in utero: brain size increases by 33% in the final 6 to 8 weeks of gestation accompanied by a fivefold increase in brain volume. Late preterm infants can also develop periventricular leukomalacia, a white matter injury marker for subsequent cerebral palsy. The exact prevalence of brain pathology is unknown as systematic brain imaging is not currently recommended at this gestational age (52). Longer term follow-up studies suggest that late preterm infants are at increased risk for lower reading and math scores from kindergarten through elementary school and for participation in special educational programs (53).

Conclusion

Late preterm infants are at significantly greater risk for short-term and long-term morbidity and mortality than was previously recognized.

NEONATAL BACTERIAL SEPSIS

Despite improvements in perinatal and newborn care, sepsis continues to be a leading cause of neonatal mortality, ranked sixth among causes of neonatal deaths in the United States (54). Neonatal sepsis refers to systemic infections that occur in infants <1 month of age. While infection with bacterial, viral, or fungal organisms may present identically in the newborn infant, this section will focus on bacterial infections. Among developed countries, the reported incidence of systemic bacterial infection ranges from 1 to 8 per 1000 live births (55,56), with increasing incidence as birth weight decreases (55,57). Neonatal sepsis is typically classified by timing of onset: early-onset sepsis (EOS) occurs from birth to a week of life, and late-onset sepsis (LOS) after the first week through the first month. The two categories differ not only by age of onset, but also by mode of transmission, risk factors, and causative organism (Table 1). For EOS, despite recent advances in preventing perinatal transmission with selective intrapartum chemoprophylaxis (see Chapter 74), group B *Streptococcus* (GBS) continues to be the most common causative organism. As the incidence of GBS has decreased,

the contribution from *Escherichia coli*, particularly among the very low–birth weight population (VLBW, <1500 g), has increased. These two organisms account for 60% to 70% of all EOS (55,58,59). Other less common pathogens include *Enterococcus* species, *Streptococcus viridans*, *Staphylococcus aureus*, a variety of gram-negative bacilli, and *Listeria monocytogenes*. For EOS in VLBW infants, the profile of organisms has recently changed. Gram-negative organisms are now the predominant causative organisms with ampicillin-resistant *E. coli* accounting for approximately 40% of cases (60,61). Gram-positive organisms including GBS and coagulase-negative staphylococcus (CONS), account for another 45% of EOS cases among VLBW infants.

In LOS, gram-positive organisms predominate in all weight and gestational-age categories. For infants discharged from the hospital, the incidence of LOS caused by GBS has remained unchanged despite the use of intrapartum prophylaxis (62). In addition, LOS also occurs commonly in infants who require prolonged hospitalization in the neonatal intensive care unit (NICU). Gram-positive bacteria are the primary causative organisms with CONS accounting for approximately 40% of cases (55,60). Other organisms include *S. aureus* with increasing frequency of methicillin resistance (MRSA), *E. coli*, and other gram negatives.

The clinical presentation of sepsis in the newborn is distinct from older children and adults. Signs and symptoms may often be subtle, nonspecific, and similar to a variety of neonatal illnesses. Common manifestations include temperature instability, tachypnea, lethargy, apnea, poor feeding, and abdominal distention (63,64). Temperature instability is more commonly manifested as hypothermia, although temperatures above 37.8°C can be significant in a newborn infant when not associated with iatrogenic causes. The overlap of symptoms with respiratory, gastrointestinal, central nervous system, and metabolic disorders means that septicemia should be part of the differential diagnosis for infants with any of these findings.

The definitive diagnosis of sepsis is made by isolation of microorganisms from blood. Diagnosis by blood culture, however, is limited by test sensitivity, blood volume drawn, and can be contaminated by skin flora that may also be pathogenic in this population (65,66). As a result, diagnosis and treatment are often based on a combination of clinical symptomatology and other diagnostic markers. Evaluating the white blood cell count and peripheral differential is an important first step in assessment but has variable sensitivity and poor specificity (67). Additional hematologic parameters include the absolute neutrophil count and ratio of immature to total cells within the neutrophil series (I:T ratio) (67). Evaluation of biochemical markers associated with the host inflammatory response, such as C-reactive protein (CRP) (67,68), may also be used. CRP requires 8 to 10 hours for synthesis making it much more sensitive in the later phase of infection. Serial CRPs (two levels obtained 24 hours apart, 8–48 hours after presentation) have a reported sensitivity of 80% to 90% and negative predictive value of 99% (69). The low sensitivity of CRP early in sepsis progression makes withholding initiation of antibiotics based on a low, early CRP value inadvisable, but serial CRPs may be useful in determining the duration of antibiotic course.

Approximately one-fourth to one-third of infants with sepsis also has meningitis (70). Among symptomatic infants,

consideration of performance of lumbar puncture for examination and culture of cerebrospinal fluid is important as meningitis (pleocytosis, increased protein, hypoglycorrachia, and positive culture) will determine duration and type of antibiotic treatment. Because viral and bacterial infections may present similarly, testing for viruses, particularly herpes simplex virus, in blood and spinal fluid should also be considered (see Chapter 74). Beyond the first few days of life, evaluation and culture of urine by catheterization or suprapubic bladder aspiration are also indicated to identify potential urinary tract foci of infection. Additional testing should be based on clinical findings and may include radiologic evaluation of the chest and abdomen.

Rapidity of progression of sepsis in the newborn infant requires prompt initiation of antibiotics once cultures have been obtained. The choice of empiric antibiotic therapy should be based on the timing and setting of infection (EOS vs. LOS, community vs. NICU) as well as the profile of microorganisms and their susceptibility patterns among specific populations. For EOS, a combination of ampicillin and gentamicin is frequently used. If meningitis is suspected, consideration should be given to addition of cefotaxime for its improved cerebrospinal fluid penetration. For LOS, therapy should be tailored to the individual patient, her/his risk factors, and past microbial flora. The frequencies of CONS, MRSA, and gram-negative organisms have resulted in the common use of vancomycin and an aminoglycoside. A worsening clinical course should result in consideration of broadening of coverage to include *Pseudomonas* species, drug-resistant gram negatives, and common fungi (e.g., *Candida*). Isolated bacteremia without meningitis or other focus is treated with 7 to 10 days of antibiotics. Treatment is otherwise largely supportive, with close monitoring and intervention for respiratory failure, hypotension, and central nervous system disturbances. Given the compromised immune response of the newborn infant, several immunologic therapies have also been investigated (71–73) of which only intravenous immune globulin has demonstrated a statistically significant reduction in mortality in cases of subsequently proven infection (71).

NEWBORN SCREENING FOR METABOLIC DISORDERS

Newborn screening for metabolic disorders is the most widely performed genetic testing in the United States. Nearly all of the more than 4 million infants born each year undergo newborn metabolic screening. The specific battery of screening tests is determined by individual state statute. As of 2005, the number of different screening tests performed varied from 4 to 46 among the states (74). Funding for the screening programs and follow-up services also varies from state to state. Ninety percent of the state screening programs have a fee paid by the family or third party payer, 61% receive funds from the Maternal and Child Health Services Title V block grant, 33% rely on at least partial funding from state general revenues, and 24% receive direct Medicaid reimbursement (75). In addition to the screening programs in the United States, most developed and many developing countries have newborn screening programs (76–79).

Newborn metabolic screening was introduced in the 1960s with the development by Robert Guthrie of a bacterial assay for phenylalanine used for the diagnosis of phenylketonuria.

Table 2 ACMG Recommendations for Newborn Screening

Core panel	Secondary targets
<i>Organic acid metabolic defects</i>	
Isovaleric acidemia	Methylmalonic acidemia (Cbl C,D)
Glutaric acidemia type I	Malonic acidemia
3-Hydroxy-3-methylglutaric aciduria	Isobutyryl-CoA dehydrogenase deficiency
Multiple carboxylase deficiency	2-Methylbutyryl-CoA dehydrogenase deficiency
Methylmalonic acidemia (mutase)	2-Methyl-3-hydroxybutyric aciduria
3-Methylcrotonyl-CoA-carboxylase deficiency	3-Methylglutaconic aciduria
Methylmalonic acidemia (Cbl A, B)	
Propionic acidemia	
β -Ketothiolase deficiency	
<i>Fatty acid oxidation disorders</i>	
Medium-chain acyl-CoA dehydrogenase deficiency	Short-chain acyl-CoA dehydrogenase deficiency
Very long-chain acyl-CoA dehydrogenase deficiency	Glutaric acidemia type II
Long chain L-3-hydroxyacyl-CoA dehydrogenase deficiency	Medium/short-chain L-3-hydroxyacyl-CoA dehydrogenase deficiency
Trifunctional protein deficiency	Medium-chain ketoacyl-CoA thiolase deficiency
Carnitine uptake deficiency	Carnitine palmitoyltransferase II deficiency
	Carnitine/acylcarnitine translocase deficiency
	Carnitine palmitoyltransferase I deficiency
	Dienoyl-CoA reductase deficiency
<i>Amino acid metabolism disorders</i>	
Phenylketonuria	Benign hyperphenylalaninemia
Maple syrup disease	Tyrosinemia type II
Homocystinuria	Biopterin cofactor metabolism defects
Citrullinemia	Argininemia
Argininosuccinic acidemia	Tyrosinemia type III
Tyrosinemia type I	Biopterin cofactor regeneration defects
	Hypermethioninemia
	Citrullinemia type II
<i>Hemoglobinopathies</i>	
Sickle cell anemia (Hb SS)	Variant hemoglobinopathies
Hemoglobin S/ β -thalassemia	
Hemoglobin S/C disease	
<i>Other</i>	
Congenital hypothyroidism	Galactokinase deficiency
Biotinidase deficiency	Galactose epimerase deficiency
Congenital adrenal hyperplasia (21-hydroxylase deficiency)	
Classic galactosemia	
Hearing loss	
Cystic fibrosis	

Guthrie's other major contribution to newborn screening was a method for using a dried infant blood spot on filter paper (the eponymous "Guthrie card") that allows for easy collection and processing of a large number of samples (80). As additional assays were developed that could be performed on blood spots, the scope of newborn metabolic screening was expanded. Criteria for inclusion of a test in the screening panel include benefit of early detection due to availability of an effective treatment, availability of a test with appropriate sensitivity and specificity, and opportunity for early detection of a potentially treatable condition during the neonatal period when it might otherwise not be clinically apparent (81). Screening programs should also provide mechanisms for appropriate confirmatory testing as well as referral for counseling and management.

With the recent development of tandem mass spectroscopic (MS/MS) methods to detect metabolites on Guthrie cards, there has been a major expansion in the metabolic diseases for which screening is now available. In 2005, the American College of Medical Genetics recommended that all states begin

screening for 29 core conditions plus an additional 25 conditions (secondary targets) that can be detected by the screening methods but may not have an effective therapy or their natural history may not be well understood (82). Table 2 lists the recommended screening tests. This list includes some assays that utilize methods other than MS/MS. Although this recommendation has been controversial, it has been endorsed by the American Academy of Pediatrics (81,83,84). The American College of Obstetrics and Gynecology has also issued a supportive opinion (85). This building consensus has resulted in an increase in the number of tests included on the screening panels in most states (74). In the future, as DNA microarray technology advances and becomes less costly, newborn metabolic screening may also incorporate this technology (86).
