CONE PENETRATION TESTING 2022

This volume contains the proceedings of the 5th International Symposium on Cone Penetration Testing (CPT'22), held in Bologna, Italy, 8-10 June 2022. More than 450 authors - academics, researchers, practitioners and manufacturers – contributed to the peer-reviewed papers included in this book, which includes three keynote lectures, four invited lectures and 170 technical papers. The contributions provide a full picture of the current knowledge and major trends in CPT research and development, with respect to innovations in instrumentation, latest advances in data interpretation, and emerging fields of CPT application.

The paper topics encompass three well-established topic categories typically addressed in CPT events:
- Equipment and Procedures
- Interpretation
- Applications.

Emphasis is placed on the use of statistical approaches and innovative numerical strategies for CPT data interpretation, liquefaction studies, application of CPT to offshore engineering, comparative studies between CPT and other in-situ tests. **Cone Penetration Testing 2022** contains a wealth of information that could be useful for researchers, practitioners and all those working in the broad and dynamic field of cone penetration testing.

Preface

This volume contains the contributions to the 5th International Symposium on Cone Penetration Testing, CPT'22, that took place in Bologna (Italy) from June 8th to 10th, 2022. The Symposium, built on the successful series of CPT events held in Delft (2018), Las Vegas (2014), Huntington Beach (2010) and Linköping (1995), was organized by the Italian Geotechnical Association (AGI) and the University of Bologna, under the auspices of the ISSMGE Technical Committee TC102.

Over the last decades, the use of the cone penetration testing for site investigation has steadily grown around the world, causing the CPT to be currently recognized as the major in situ testing technique in geotechnical engineering practice. Its widespread use has in turn stimulated the development of enhanced or new types of CPT equipment, aimed at both improving the accuracy of measurements and extending the field of application, along with the increasing demand for a sound understanding of penetration mechanisms and consistent interpretation methods, suitable for the characterization of a variety of soil deposits.

The CPT symposia have always provided a unique and fruitful forum for the exchange of new ideas and discussion on key issues within the largest gathering of world's experts, academics and non-academics, working in the broad and dynamic area of cone penetration testing. The objective of CPT'22 was therefore to foster a lively debate on current trends in cone penetration testing, among Researchers, Practitioners and Manufacturers, in a friendly and creative atmosphere for discussion and collaboration, as tradition of CPT events.

More than 450 Authors, coming from academic institutions, private companies and public bodies worldwide, contributed to the peer-reviewed papers included in this volume. The Symposium Organizing Committee was especially pleased with the unprecedented large number of contributions submitted, exceeding all expectations, and with the general high quality of the papers.

A total of 186 manuscripts were received and 170 of them were finally accepted for publication in the Symposium Proceedings. The papers were sorted into three well-established theme categories, according to the subject areas typically addressed in CPT events: Equipment and procedures, Interpretation, Applications. The volume also includes three outstanding keynote papers and four invited papers presented by renowned experts in specific thematic discussion sessions on selected key topics.

A significant effort was made to provide the Authors with a rigorous and fair review of the papers. The Editors are therefore very grateful to the almost one hundred Reviewers, for their generous and valuable work.

We gratefully acknowledge the support of the Italian Geotechnical Association, which organized the Symposium in cooperation with the University of Bologna. Special thanks are extended to the AGI Secretary, Mrs Susanna Antonielli, for her tireless work and patient assistance. We would also like to express our appreciation to all the Sponsors that helped us in making this conference a success.

Finally, many thanks to all Keynote Lecturers, Invited Speakers and Authors for their enthusiastic and proactive response to CPT'22, and for their contribution to this Proceedings volume.

We do hope you will find its content of valuable and long lasting use.

New CPT methods for evaluation of the axial capacity of driven piles

B.M. Lehane & E. Bittar
University of Western Australia, Australia

S. Lacasse, Z. Liu & F. Nadim
Norwegian Geotechnical Institute, Norway

ABSTRACT: High costs associated with offshore foundation installations have provided strong impetus to the offshore energy sector in the search for more reliable design methods. This paper provides a summary of an Industry sponsored project that led to the development of new CPT-based design methods for the evaluation of the axial capacity of driven piles. Particular attention was given to the need for the new methods to be applicable to large diameter offshore piles given that many existing methods are derived by calibration with capacities measured in static pile load tests on smaller diameter onshore piles. The basic mechanisms supporting the general format of the expressions proposed for shaft friction and end bearing in sands and clays are described. It is shown how the new expressions, which are calibrated against a database of the most reliable load tests reported in the literature, lead to better predictions of capacity compared to other methods and can also satisfactorily predict the capacity of piles driven into deposits comprising interbedded layers of sand, silt and clay. Recommendations for the prediction of pile displacements at working loads using CPT data are also presented.

1 INTRODUCTION

The popularity of the CPT and the similarity between the mode of penetration of a cone and a driven pile have provided strong motivation in the search for direct correlations between the CPT q_t value and axial pile capacity. The best known of initial correlations proposed for pile shaft and base resistance in a range of soil types were developed about 40 years ago and include methods recommended by de Beer (1972), Schmertmann (1978), de Ruiter & Beringen (1979), Zhou et al. (1982), Bustamante & Gianeselli (1982) and Van Impe (1986).

These and other methods have since been assessed using specific databases of static load tests by workers such as Briaud & Tucker (1988), Niazi & Mayne (2013), Eslami et al. (2014), Hu et al. (2012) and Amirmojahedi & Abu-Farsakh (2019). These studies show that there is no consensus of opinion regarding the relative reliability of the methods with some methods providing good predictions for a given database but poor predictions for other databases. This lack of consensus is partly due to significant inconsistencies between the respective databases which arise due to (i) different definitions of ultimate axial capacity, (ii) contradictory interpretations of load test data, (iii) uncertainty in CPT q_t values at test pile locations, (iv) inclusion or exclusion of layered/ mixed soil deposits and different pile types and (v) separate assumptions relating to the effects of time,

loading direction, re-testing and loading rate. In addition, the formulations of most methods do not explicitly incorporate many characteristics of driven pile behaviour that have been well proven in experimental research programmes (discussed below).

The Offshore Energy sector recognized the advantages of a CPT-based method for axial capacity assessment but also understood the need to quantify the reliability of such a method using a database that had the backing of much of the profession. A Joint Industry Project (JIP) was set up in 2014 to achieve this objective. The JIP was managed by the Norwegian Geotechnical Institute (NGI) with support from the University of Western Australia (UWA) and was sponsored by Equinor, Ørsted, Lundin, ONGC, Petrobras and DNV GL. A 'Team of Experts' worked over a period of 3 years with guidance from the JIP steering committee to assess the suitability of about 600 pile load tests for inclusion in the database. A good CPT coverage close to pile tests was required and only first-time load tests on driven piles that were statically loaded to a displacement of 10% of the pile diameter were included. The final tests selected make up, what is referred to as, the 'Unified database' and comprises 71 test piles in silica sand and 49 pile tests in clay. Full details of the 'Unified database' and the steps followed in its compilation are provided in Lehane et al. (2017).

A subsequent phase of the JIP began in 2017 (sponsored by Equinor, Lundin Norway, Ørsted, ONGC, BP, Total, ExxonMobil, EnBW, EDF,

Aramco, SSER and HDEC) with the aim of developing new 'Unified' methods for the prediction of the axial capacity of driven piles in sand and clay. This initiative was motivated by the desire of Industry to replace the 4 CPT-based methods for driven piles in sand included in the API (2011) recommendations with a single method. The term 'unified' is employed as the method was developed with input from the proponents of the 4 most current CPT-based sand methods used offshore. Although no CPT method for driven piles in clay and silt are currently provided in API/ISO documentation, the inclusion of such a method was seen to be an important step forward to reduce dependence on laboratory measurements of undrained strength required by the existing 'alpha' method.

The JIP was concluded successfully in 2021 and the methods developed will be incorporated in the next versions of the ISO-19901-4 and API recommendations.

This paper provides an overview of the new CPT methods with a focus on justification of the basis of the formulations employed. A full description of the methods is provided in Lehane et al. (2020, 2022) and in Nadim et al. (2021). The 'sand' and 'clay' formulations were calibrated using the Unified database and their application to interbedded deposits comprising sand, silt and clay layers is examined in this paper. Recommendations are also provided to assist prediction of the displacement of driven piles at working loads using CPT data.

2 CPT METHODS FOR CAPACITY OF DRIVEN PILES IN SAND

2.1 *Approaches for evaluation of shaft friction*

Traditional CPT methods relate the local ultimate friction (τ_f) directly to the cone resistance (q_t) via a single factor, β:

$$\tau_f = q_t / \beta \qquad (1)$$

Bustamante & Gianeselli (1982), for example, recommend β values for driven steel tubular piles of 120 and 200 in loose and dense sands respectively and propose limiting τ_f values in each of these deposits to respective maximum values of 35 kPa and 120 kPa. These and other similar recommendations reported in the literature ignore the following well-known characteristics of driven piles in sand observed from instrumented pile tests (Lehane et al. 2020):

i. Ultimate shaft friction (τ_f) varies is direct proportional to the tangent of the interface friction angle between the sand and pile shaft (tan δ) i.e. shaft friction is governed by Coulomb's law.

ii. τ_f developed in any soil horizon reduces with the distance of that soil horizon from the pile tip (h); this arises largely due to the progressive cycling of sand at any particular level as installation progresses.

iii. Smaller diameter piles generate larger frictions due to constrained dilation under shear at the interface.

iv. Open-ended pipe piles generate lower shaft frictions than closed-ended piles due to lower levels of displacement imparted to the sand mass.

v. Ageing effects lead to increases in shaft friction with time after pile installation.

These characteristics are not incorporated in Eqn. 1 and prompted the development of a new generation of CPT methods included in API (2011), namely those referred to as Fugro-05 (Kolk et al. 2005), ICP-05 (Jardine et al. 2005), NGI-05 (Clausen et al. 2005) and UWA-05 (Lehane et al. 2005). While all of these newer methods do not include all of the characteristics listed above, each incorporates a direct proportional relationship between τ_f and q_c and a reduction of τ_f with distance from the pile tip (h). These dependencies were first clearly revealed in experiments conducted in 1989 with the Imperial College instrumented pile in medium dense sand at Labenne, France (Lehane 1992). Figure 1 plots bounds to a large number of equalised radial stress measurements (σ'_{rc}) obtained in these experiments and displays an obvious trend for the σ'_{rc}/q_c ratio to be constant in a given soil horizon and to reduce with increasing distance of that horizon above the pile tip (noting that there is a direct relationship between τ_f and σ'_{rc} via Coulomb's law).
Figure 1. Dependence of equalised radial effective stress on q_c and normalised distance from the pile tip (h/R) at Labenne, France (Lehane 1992) [R=D/2 and τ_f varies directly with σ'_{rc}].

The trend shown on Figure 1, which has since been confirmed by Chow (1997) and others, is the key element of the shaft friction formulations of the

4

UWA-05, NGI-05, ICP-05 and Fugro-05 methods. These shaft frictions correspond to frictions that can be developed in the 2 to 4 week period following driving as the methods' calibrations employed static load test data recorded in the same period.

2.2 *Approaches for evaluation of base resistance*

Given the comparable modes of penetration, all historical CPT methods for closed-ended driven piles in sand relate the ultimate end bearing directly to the q_c value in the vicinity of the pile tip. However, the ultimate end bearing stress, defined at a displacement of 0.1D ($q_{b0.1}$), is typically only about 50% of q_c for a closed-ended piles driven in homogeneous sand deposits because a displacement of the pile tip of order of 1D is required to reach steady state penetration conditions (as exist during cone penetration). In addition to partial mobilisation at a displacement of 0.1D, Van Mierlo & Koppejan (1952) recognised the importance of the scale difference between a pile and a penetrometer. Recognition of this effect subsequently led to a variety of proposals for q_c averaging techniques, the most popular of which relates $q_{b0.1}$ to a simple average value of q_c values in a zone extending 1.5D above and 1.5D below a pile tip.

Compared with closed-ended piles, pipe piles induce lower levels of displacement (or disturbance) to the sand near their bases during installation. The degree of partial plugging (and hence disturbance) reduces as the pile diameter increases. Consequently, as shown by Gavin & Lehane (2003), the end bearing of large diameter piles under static loading (when the plug remains stationary) reduces to that of a bored pile for which $q_{b0.1}$ is typically about 15% of the q_c value (Lehane & Randolph 2002). This diameter dependence is incorporated in a number of different ways in the Fugro-05, ICP-05, NGI-05 and UWA-05 correlations for $q_{b0.1}$. No set-up of end bearing resistance has been observed for driven piles in sand.

2.3 *Performance of CPT methods in API (2011)*

The Fugro-05, ICP-05, NGI-05 and UWA-05 CPT methods included in API (2011) were calibrated using databases compiled specifically for the development of these methods. It is therefore of interest to examine their performance against the 'Unified database', which is fully supported by all researchers involved in the four methods. The findings from this exercise are summarised in Table 1, which presents statistics for ratios of measured to calculated capacities (Q_m/Q_c) for the four methods as well as for the earth pressure theory method in API RP2A (2011) and the new 'Unified method' (discussed below).

The results in Table 1 show that, while the earth pressure approach in API over-predicts pile capacities by an average of 66%, the mean Q_m/Q_c ratio of measured to calculated capacity for the four API

CPT methods is close to unity. The spread in predictions for the earth pressure approach, as measured by the CoV for Q_m/Q_c, is also higher than for the CPT methods and is indicative of a significantly lower level of reliability. The UWA-05 and ICP-05 methods are the best performing methods with the lowest CoVs.

Table 1. Mean (μ) and coefficient of variation (CoV) of Q_m/Q_c for the Unified database of driven piles in silica sand.

Method	All open & closed-ended piles (total capacity) 71 Piles		
	μ		CoV
API (2011), K tan δ (β) approach	1.66		0.56
Fugro-05	0.99		0.40
ICP-05	1.04		0.27
NGI-05	0.99		0.34
UWA-05	1.06		0.26
Unified Method	1.05		0.24

3 UNIFIED CPT METHOD FOR DRIVEN PILES IN SAND

While the UWA-05 and ICP-05 methods performed relatively well against the 'Unified database', a primary aim of the JIP was to develop a unified and un-affiliated method that had the support of those involved in the derivation of the API β method and the four API CPT methods. The first point of agreement was that, in line with the findings of Lehane et al. (1993), and others, the following expression should form the basis of the correlation for peak shaft (τ_f):

$$\tau_f = (\sigma'_{rc} + \Delta\sigma'_{rd})\tan \delta_f \qquad (2)$$

where σ'_{rc} is the stationary (equalised) radial effective stress, $\Delta\sigma'_{rd}$ is the increase in radial effective stress during pile loading (attributed to dilation) and δ_f is the constant volume sand-pile interface friction angle. On review of the state-of-the-art, it was agreed that the Unified method should incorporate considerations described in the following.

3.1 *Interface friction angle (δ_f)*

In the absence of site-specific tests to measure ultimate interface friction angles (δ_f), the ICP-05 and UWA-05 methods propose the variation with the mean effective particle size (d_{50}) indicated by the curve shown in Figure 2. This variation was deduced from direct shear box tests on steel interfaces with a roughness typical of industrial piles but that did not include pre-shearing to large relative displacements. Yang et al.

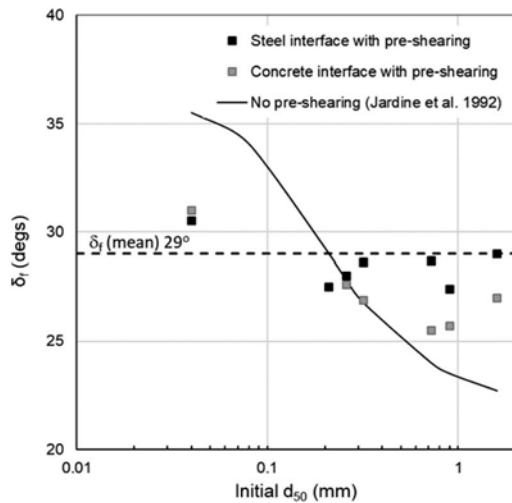
(2010), and others, have since shown that crushing of sand at the pile tip and subsequent shearing during installation reduces the grading to that of a fine sand. Interface shear angles measured in the Bishop ring shear apparatus in tests that induced a large level of pre-shearing are plotted on Figure 2 confirmed the relatively low sensitivity of δ_f to the initial d_{50} value. Similar tests reported by Liu et al. (2019) also show that δ_f has virtually no dependence on the (non-plastic) fines content of typical siliceous sands and on the normal stress level. It was therefore concluded that, in the absence of site specific ring shear interface tests, adoption of a constant δ_f value of 29° is a reasonable assumption for all piles in the load test database.


Figure 2. Interface friction angle and d_{50} for roughness typical of industrial piles (centreline average roughness of 5 to 20μm) (Barmpopoulos & Ho, 2009); Ho et al., 2011).

3.2 Increase in radial stress ($\Delta\sigma'_{rd}$) during pile loading

The restraint to dilation at the pile shaft during pile loading provided by the surrounding sand leads to an increase in radial stress on the pile shaft ($\Delta\sigma'_{rd}$) and hence to the peak shaft friction. This increase can be assessed from cavity expansion (CE) theory, where G is the operational shear modulus of the sand mass, y is the dilation of the sand at the shaft interface and $y/2D$ is the cavity strain:

$$\Delta\sigma'_{rd} = 4Gy/D \qquad (3)$$

The UWA-05 and ICP-05 methods assume that the cavity strain is small enough for conditions to be fully elastic and hence the methods equate G with the small-strain elastic value (G_0). However, data from constant normal stiffness direct shear interface

tests and tests on centrifuge piles with a range of diameters presented in Lehane et al. (2005) show that the cavity strains can be relatively large and that the operational G value is less than G_0 for typical pile diameters in the 'Unified database'. The following revised approximate expression was deduced using $\Delta\sigma'_{rd}$ measurements on jacked piles and parallel numerical analyses (Lehane et al. 2020):

$$\Delta\sigma'_{rd} = \left(\frac{q_c}{10}\right)\left(\frac{q_c}{\sigma'_v}\right)^{-0.33}\left(\frac{d_{CPT}}{D}\right) \qquad (4)$$

with d_{CPT} =35.7mm, which is the usual CPT diameter.

Most piles in the Unified database have a diameter (D) between 350mm and 800mm. Equation (4) predicts that the increase in peak friction due to dilation (=$\Delta\sigma'_{rd}$ tanδ_f) for a 20m long pile in medium dense sand is about 35% for D=350mm but only 10% for D=800mm. The relative influence of dilation is clearly an important consideration when extrapolating from the smaller diameter piles in the database to larger diameter offshore piles. The relative influence of dilation is also greatest in looser sands and for longer piles.

3.3 Allowance for partial plugging

Many of the pipe piles in the Unified database (with D= 550 ± 250mm) experienced partial plugging during pile driving. The additional shaft and base capacity that such plugging induces (e.g. see Gavin & Lehane 2003) needs to be accounted for correctly in the database analysis to ensure safe extrapolation to the capacity of full scale offshore piles.

White et al. (2005) used a cavity expansion analogy to deduce that the equalised lateral effective stress acting on the pile shaft (σ'_{rc}) varies with the effective area ratio (A_{re}) raised to a power of between about 0.3 and 0.45 while Xu et al. (2008) present experimental data showing how $q_{b0.1}$ varies in proportion to A_{re}.

A_{re} provides a measure of the level of soil displacement in any given soil horizon, and is defined as:

$$A_{re} = 1 - IFR(D_i/D)^2 \qquad (5)$$

where IFR is ratio of the change in plug length to change in pile embedment and D_i is the internal pile diameter. A_{re} varies from unity for a closed-ended or fully plugged pile to a value of 4t/D for a large diameter coring pile (where t is the pile wall thickness). As the IFR is not measured routinely, the analysis of the unified database substituted the plug length ratio (PLR) for IFR, noting that the PLR is the average IFR during pile driving and equal to the ratio of the final plug length to the embedded pile length.

The PLR is primarily a function of the internal pile diameter (D_i) (e.g. see Gudavalli et al. 2013) and the following approximate expression was derived based on available records (d_{CPT} =35.7mm):

$$PLR \approx IFR = \tanh\left[0.3\left(\frac{D_i}{d_{CPT}}\right)^{0.5}\right] \qquad (6)$$

The database analysis examined the influence of various exponents of A_{re} in the search for a best-fit expression for τ_f.

3.4 Time effects

The shaft capacity of driven piles in silica sand increases with time over a period of least one year (e.g. Chow et al. 1998, Jardine et al. 2006, Karlsrud et al. 2014, Gavin et al. 2015). Such increases are not exhibited by bored piles and may be viewed as a recovery process following the 'trauma' of driven pile installation (Lim and Lehane 2014, Anusic et al. 2019). The new CPT method is calibrated using the Unified database comprising static load tests with a median equalisation period (or set-up time) of about two weeks. It is therefore likely to underestimate long term capacities and over-estimate short term capacities (including driving resistance).

3.5 Formulation for σ'_{rc}

The observed reduction in the equalised radial effective stress (σ'_{rc}) with the distance from the pile tip (h) or normalised distance from the pile tip (h/D) can be described as a power law relationship (as in the ICP-05 and UWA-05 methods) or as an exponential relationship (proposed by Randolph et al. 1994 and Salgado et al. 2011). Lehane et al. (2020) show that the bias in the database, with respect to diameter, of the ratio of measured to calculated capacities (Q_m/Q_c) can be removed when a h/D term is used instead of 'h' (as proposed by Alm & Hamre 2001). Lehane et al. (2020) also show that while the power law and exponential variations with h/D lead to very similar statistics for the Q_m/Q_c ratios, the exponential relationship tended to predict marginally larger capacities for piles with L/D<20 compared with the power law form. The power law form was retained as many piles used in the offshore wind Industry have lower L/D values.

3.6 Tension compression ratio

The database piles clearly showed that shaft friction measured in tension are, on average, about 75% of the shaft friction of compression piles. Limited data exist in relation to differences in the distribution of τ_f along test piles and, in the absence of other information, the global (best-fit) tension to compression ratio (f_L) of 0.75 was employed in the new method.

3.7 Formulation for end bearing

The Unified method relates the ultimate end bearing ($q_{b0.1}$) with the effective area ratio (A_{re}) for pipe piles in line with observations of Gavin & Lehane (2003) and as adopted in the UWA-05 method. The end bearing formulation of ICP-05 incorporates this dependency indirectly by allowing $q_{b0.1}$ for pipe piles to reduce with pile diameter.

The Unified method relates $q_{b0.1}$ with q_p, where q_p is the end bearing resistance expected for an 'imaginary cone' that has the same diameter as the pile being considered (or equivalent diameter for a pipe pile= $(A_{re}/\pi)^{0.5}$). The value of q_p is determined using a component of a 'thin-layer' procedure described by Boulanger and DeJong (2018) and its application in piling calculations is explained by Bittar et al. (2020). Although q_p is a rational and objective way of obtaining an averaged cone resistance near a pile base of given diameter, its determination requires use of software (freely downloadable from *https://faculty.engineering.ucdavis.edu/boulanger/research-interests/*) which is not appealing to many practitioners. The new ISO-19901-4 recommendations therefore suggest taking q_p as the average q_c value in the zone extending 1.5D above and below the pile tip, unless conditions at the pile tip are highly variable. Separate studies show that q_p for the Unified database piles is, on average, 20% higher than q_{Dutch}, where q_{Dutch} is the CPT resistance determined using the 'Dutch' averaging technique (Van Mierlo & Koppejan 1952)

3.8 Formulation of Unified CPT method in sand and predictive performance

The final formulations decided upon for the Unified CPT method for piles in sand (Zone 6 of the soil behaviour type chart) are provided in Table 2. When these are applied to the Unified database, the average ratio of measured to calculated capacities (Q_m/Q_c) is 1.05 while the CoV for Q_m/Q_c is 0.24. These statistics are a marginal improvement on those for the UWA-05 and ICP-05 methods (see Table 1). The method is, however, considered to be a significant step forward as it replaces the four API CPT methods with full support of the authors for these methods and it incorporates state-of-the-art understanding of the mechanisms controlling the axial capacity of driven piles in sand. It should be noted that the method potentially under-estimates axial capacity in gravelly sands (Zone 7 of the SBT chart), where the presence of gravels leads to higher average q_c values. The method is only applicable to piles driven in a conventional manner and should not be used for jacked piles or piles installed by vibration.

Table 2. General formulations for Unified method in sands, silts and clays *(see https://pile-capacity-uwa.com/).*

$Q_{shaft} = \pi D \int_0^L \tau_f \, dz$
$Q_{base} = q_{b0.1} \, (\pi D^2/4)$

Capacity estimate for piles for flexible piles in strain-softening clays requires load-transfer analysis using load transfer curves given in API (2011)

Sands: Zone 6 of SBT chart (I_c< 2.1)

$\tau_f = f_L \, (\sigma'_{rc} + \Delta\sigma'_{rd}) \tan 29°$
$q_{b0.1} = [0.12 + 0.38 A_{re}]q_p$; for plugged base (expected when L/D>5)
$q_{b0.1} = A_{re} \, q_p$; for unplugged base
$\sigma'_{rc} = (q_c/44) \, A_{re}^{0.3} \, [Max[1, h/D]]^{-0.4}$
$\Delta\sigma'_{rd} = (q_c/10) \, (q_c/\sigma'_v)^{-0.33} \, (d_{CPT}/D)$
$A_{re} = 1 - PLR \, (D_i/D)^2$
$PLR \approx \tanh [0.3 \, (D_i/d_{CPT})^{0.5}]$
$f_L = 0.75$ in tension, 1.0 in compression
q_p can be taken as the average q_c within a zone 1.5D above and below the pile tip or determined using the procedure described Boulanger & De Jong (12018) and Bittar et al. (2020)

Clays: Zones 1,2,3 & 4 of SBT chart

$\tau_f = 0.07 \, F_{st} \, q_t \, [Max[1, h/D^*]]^{-0.25}$
$q_{b0.1} = [0.2 + 0.6 A_{re}]q_p$

$F_{st} =1$ for clays with I_{z1}>0, in Zones 2, 3 and 4 on the SBT Chart ($I_c \geq 2.6$)
$F_{st} =0.5\pm0.2$ clays with I_{z1}<0, in Zone 1 on the SBT Chart
$D^* = (D^2-D_i^2)^{0.5}$ for an open-ended pile and D^*=D for a closed-ended pile
$I_{z1} = Q_{tn} - 12exp^{(-1.4F_r)}$
q_p =average q_t value in zone between the pile tip and 1D below the pile tip (closed-ended/ plugged pile) or average q_t to a depth of $20t$ below the pile tip (large diameter, unplugged pile)

Silts: Zone 5 of the SBT chart (2.1< I_c <2.6)

Apply equations as for Zone 6 using corrected q_c value determined as:
$q_c = [3.93 \, I_c^2 -14.78 \, I_c +14.78] \, q_t$

Notation

h	$L - z$, where L is pile embedment length and z is the depth)
D	Pile outer diameter
D_i	Internal diameter of a pipe pile
f_s	Cone sleeve friction
F_r	Friction ratio (expressed as a percentage)=$f_s/(q_t$-$\sigma_{v0})$
q_t	Total (corrected) CPT end resistance (=q_c in sands)
Q_{tn}	Normalised cone resistance $[(q_t$-$\sigma_{v0})/p_a]/(p_a/\sigma'_{vo})^n$; p_a=ref. stress=100 kPa
I_c	Consistency index, function of Q_{tn} and F_r; see Robertson (2009)
n	Stress exponent for Q_{tn}, function of I_c and σ'_{v0}; see Robertson (2009)
t	Pile wall thickness
SBT	Soil Behaviour type; see Robertson (2009)
σ_{v0}	Total vertical stress
σ'_{v0}	Effective vertical stress
Figure 3. Mean recorded variations of normalised radial total stresses (S_i) with h/D measured during installation of closed-ended instrumented piles.

4 CPT METHODS FOR CAPACITY OF DRIVEN PILES IN CLAY

4.1 *Shaft friction*

Relationships between shaft friction and the measured and corrected cone resistances (q_c and q_t) for driven piles in clay have been proposed for many years e.g. Bustamante & Gianeselli (1982), Almeida et al. (1996), Lehane et al. (2000, 2013), Eslami & Fellenius (1997) and Niazi & Mayne (2016). The newly proposed Unified CPT method for clays builds on these methods but is based primarily on observations made in high quality instrumented pile experiments conducted by a number of institutions, most notably at the Norwegian Geotechnical Institute and Imperial College London.

The basis of the correlation between shaft friction and the (corrected) CPT end resistance (q_t) for the new Unified method is the observation that, in any particular clay, the radial total stress developed during installation (σ_{ri}) on the shaft of a closed-ended displacement pile varies directly with q_t and reduces with the normalised distance from the pile tip (h/D). Examples of observed trends are shown on Figure 3, which plots the mean measured variation of the normalised radial total stress in six different clays against h/D, where the normalised radial total stress (S_i) is defined as follows and u_0 is the hydrostatic or ambient pore pressure:

$$S_i = (\sigma_{ri} - u_0)/q_t \qquad (7)$$

The mean trend lines indicated on Figure 3 have a typical standard deviation of 25% and are evidently dependent on the clay type. Following installation,

instrumentation on driven piles shows that radial total stresses fall as excess pore pressure dissipate while radial effective stresses (σ'_r) increase. σ'_r reaches a fully equalised value (σ'_{rc}) after equalisation of radial total stresses and full pore pressure dissipation. When a pile is loaded to failure after equalisation, radial effective stresses reduce attaining a value of σ'_{rf} at peak local shear stress (τ_f).

These stages in the life of a driven pile are incorporated in the following expression for τ_f, which is based on Coulomb's friction law:

$$\tau_f = \sigma'_{rf}\tan\delta = q_t S_i (S_c/S_i) \ f_l \tan\delta_f \qquad (8a)$$

where

$$S_c = (\sigma_{rc} - u_0)/q_t = \sigma'_{rc}/q_t \qquad (8b)$$

$$f_l = \sigma'_{rf}/\sigma'_{rc} \qquad (8c)$$

Equation (8) illustrates that the relationship between τ_f and q_t depends on the degree of relaxation of radial total stresses during equalisation (expressed by S_c/S_i), the relative change in σ'_r during load testing (f_l) and the interface friction angle between the pile and clay (δ_f). Numerical simulations such as those of Whittle & Baligh (1988), as well as experiments, indicate that S_c/S_i ratios are lower in sensitive and low OCR clays where installation causes a significant degree of remoulding and reduction in effective stress. The S_c/S_i values measured experimentally range from 0.15 in (highly sensitive) Lierstranda clay to 1.0 in the heavily overconsolidated London clay. Measured values of f_l are in the range of 0.8 to 1.0 in all clays but average at about 0.6 in Lierstranda clay. The operational coefficient of friction (tan δ_f) is strongly affected by the clay mineralogy, amongst other factors, and for the six clays considered in Figure 3 varies by more than a factor of 2 (from a tan δ_f value of 0.23 in London Clay to 0.55 in Bothkennar clay).

The compounding effects of differences in respective clays of the S_c/S_i, f_l and tan δ_f values as well as the S_i relationship with h/D (shown on Figure 3) reveal a complex relationship between τ_f and q_t. Nevertheless, when ratios of τ_f/q_t with h/D measured in instrumented pile tests are plotted, as shown in Figure 4a, it is evident that a number of compensatory factors lead to a relatively consistent relationship between τ_f/q_t and h/D in all of clays apart from Lierstranda, where the product of S_c/S_i and f_l is, on average, about four times less than the other clays. Best-fit mean trend lines for the instrumented data included in Figure 4a are presented on Figure 4b and, as shown later, are consistent with best-fit expressions for the capacities of the piles in the Unified database.

4.2 End bearing

The contribution of end bearing to the capacity of driven piles in clay is relatively small and therefore
Figure 4. (a) Average measured variations of τ_f/q_t with h/D (showing envelope for all clays except Lierstranda clay), (b) best-fit mean trend lines.

has not been the subject of extensive research. The assumption of a simple direct relationship between $q_{b0.1}$ and the average q_t value near the pile tip is considered adequate for practical purposes. On the basis of a review of existing correlations, Lehane et al. (2022a) propose the following relationships for typical onshore driven piles (D <0.75m)

$$q_{b0.1} = 0.8 q_t \,(\text{closed–ended pile}) \qquad (9a)$$

$$q_{b0.1} = 0.4 q_t \,(\text{open–ended pile}) \qquad (9b)$$

5 UNIFIED CPT METHOD DRIVEN PILES IN CLAY

The development of the new Unified CPT method for clays recognised the compensatory effects of factors evident on Figure 5a but investigated potential systematic dependence on (i) clay plasticity index, (ii) soil behaviour type (SBT), (iii) CPT sleeve friction (f_s) and

(iv) vertical effective stress level (σ'_v). The calibration of the method with the Unified database also included consideration of the aspects detailed below.

5.1 Dependence of τ_f on loading direction

Compression and tension tests on piles with identical configurations in seven different clays in the Unified database indicate that, in general, there is not a clear dependence of ultimate shaft friction on the load direction. A load direction factor (f_L) of unity was found to provide a best fit to the full Unified database.

5.2 Friction on open-ended piles

Instrumented pile test data reported by Doherty & Gavin (2011) show that lower levels of soil displacement during installation of open-ended piles lead to lower installation radial total stresses (σ_{ri}) and lower ultimate shaft frictions after equalisation. There is, however, a considerable shortage of such data in different clays and, in the absence of such data, the regression analyses conducted for the Unified method assumed the following potential dependencies (where Equation 10a is comparable to the Unified CPT sand method and Equation 10b is a similar format to the ICP-05 method for sands):

$$\tau_f = f(A_{re}, h/D) \tag{10a}$$

$$\tau_f = f(h/D*); D* = \left(D^2 - D_i^2\right)^{0.5} \tag{10b}$$

Lehane et al. (2017) show that Equations 5 & 6, which were derived from data for piles in sand, may also be used to approximate A_{re} values for pipe piles in clays.

5.3 Progressive failure

A number of piles in the clay database exhibit post-peak softening of shaft shear stress. The calibration of the Unified method assumed that peak shear stresses corresponded to the measured peak axial capacity or, if such a peak was not observed, to the axial resistance at a displacement of 0.1D. This approach is considered reasonable for the majority of the database (which comprised relatively rigid piles) but is moderately conservative for a few very long piles in clays where strain softening can be significant.

5.4 Silt layers

Occasional silt layers with a soil behaviour type (SBT) index, I_c, in the range 2.05 to 2.6 occur within the clay strata of the database. For these deposits, the calibration process employed the Unified sand method adopting the equivalent clean sand q_t value ($q_{t,sand}$) for the silt. This was derived using the following relationship which is equivalent to the proposal of Robertson & Wride (1998) but adapted to a simplified format and modified to give a correction factor of unity at $I_c = 2.05$:

$$q_{t,sand} = q_c = \left[3.93 I_c^2 - 14.78 I_c + 14.78\right] q_t \text{ for } 2.05 < I_c < 2.6 \tag{11}$$

5.5 End bearing of large diameter pipe piles

Eqn. 9 was employed in the calibration of the relatively small diameter piles in the Unified database. For large diameter offshore piles, the following expression is considered more appropriate; this was based on findings of Doherty and Gavin (2011) from measurements of twin-walled instrumented piles during installation.

$$q_{b0.1} = [0.2 + 0.6 A_{re}] \, q_t \tag{12}$$

where q_t is the average corrected cone resistance value in the zone extending from the pile tip to a depth of $20t$ below the pile tip (t = pile wall thickness)

5.6 Formulation of Unified CPT method in clay and predictive performance

The formulations for the Unified clay method are provided in Table 2. These were established following various optimisation analyses which revealed that, as inferred from instrumentation pile test data, τ_f is primarily correlated to the CPT q_t value and the normalised distance from the pile tip (h/D*). The analyses also showed that the shaft friction generated in high sensitivity clays (within Zone 1 of the SBT chart) is typically 50% of the shaft friction in other clays (although there is significant variability). The formulations developed are remarkably similar to those deduced independently from instrumented pile test data (compare formulae in Figure 5 with those in Table 2). Surprisingly, the fit to the capacities of the database piles was not improved by consideration of additional factors such as cone sleeve friction, plasticity index and overconsolidation ratio (inferred by examination of a q_{net}/σ'_{v0} term).

The predictive performance for the Unified clay database of the new clay method was compared by Lehane et al. (2022a) with a number of other current methods. This comparison is summarised in Table 3, which also lists the main input parameters in the τ_f correlation for each method (noting that differences in the end bearing formulations had little impact on calculated capacities). Evidently the CoV of Q_m/Q_c for the new method is a good improvement on existing methods and is significantly lower than the corresponding CoV for the existing '$\alpha - s_u$' method recommended by API/ISO. It should be noted, however, that part of the reason for the substantial reduction in the CoV with respect to other methods arises due to application of a separate equation for Zone 1 (sensitive) clays.

Table 3. Comparison of predictive performance for driven piles in clay of the Unified method with other methods (in terms of mean and CoV of measured to calculated capacity ratios).

Method	Parameters controlling τ_f	Mean Q_m/Q_c	CoV for Q_m/Q_c
API (2011)	s_u & s_u/σ'_v	1.05	0.43
Fugro-96 (Kolk & van der Velde 1996)	s_u, h/D & s_u/σ'_v	1.04	0.35
ICP-05 (Jardine et al. 2005)	OCR, σ'_v, h/D*, δ & S_t	1.12	0.55
NGI-05 (Karlsrud et al. 2005)	s_u, s_u/σ'_v, I_p & σ'_v	1.1	0.36
UWA-13 (Lehane et al. 2013)	q_t & h/D*	1.12	0.33
Fugro-10 (Van Dijk & Kolk 2010)	q_{net}, h & q_{net}/σ'_v	0.98	0.37
Unified method (Lehane et al. 2022a)	q_t, h/D* & S_t	0.99	0.23

The Unified method in clay is calibrated on a relatively small number of pile tests (49) and, as may be inferred from the instrumented pile test data, its relatively good predictive performance arises partly because of compensating factors. For example, interface friction angles (δ) for clays in the Unified database range from 12° to 30°, implying a range in capacities of about 2.5 if τ_f varied only with tan δ. However, encouragingly, Lehane et al. (2022a) examined the performance of the new method against a different 'Test database' comprising 24 pile tests in clay and found a mean Q_m/Q_c ratio of 1.09 (i.e. a 9% over-prediction, on average) and a CoV for Q_m/Q_c of 0.22; this CoV is a substantial improvement on the CoV of 0.43 determined for the API $\alpha - s_u$ method (Table 3).

6 APPLICATION TO LAYERED DEPOSITS

The Unified CPT methods for sand and clay were calibrated against test data for piles that were driven into predominately sand or clay deposits. However, many deposits encountered in practice contain sand, silt and clay layers and it is therefore important to assess the reliability of the methods at such sites. Bittar et al. (2022) conducted such a study involving 23 load tests on piles driven into mixed stratigraphies. Ten of these load tests were on piles with diameters between 0.9m and 2m in diameter which is considerably larger than the mean D value of about 0.4m for the piles in the Unified database. An average of 55% of the layers in these case histories were coarse grained and two cases involved sensitive zone 1 soils.

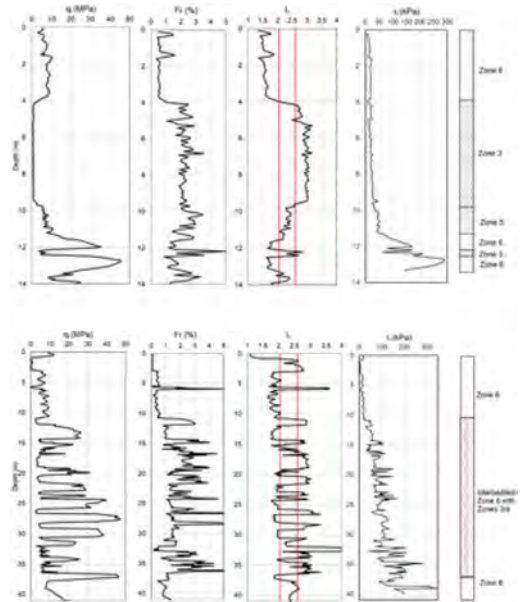
Sample predictions for two driven steel pipe pile case histories examined are presented in Figure 6a for a tension test in Oakland California on a 13.3m long, 610mm pile and in Figure 6b for a compression test in Minnevika, Norway on a 40m long, 405mm diameter pile. As seen with reference to the plotted I_c profiles in these figures, a 5.5m thick layer of Zone 3 clay is present along the central portion of the pile shaft whereas the stratigraphy at Minnevika comprises alternating 1.5m to 2m thick layers of sand and clay. The calculated τ_f distributions were determined in a simple spreadsheet using the I_c dependent expressions, as summarized in Table 2; calculations can also be performed using UWA freeware at *https://pile-capacity-uwa.com/*. These τ_f distributions lead to ratios of measured to calculated capacities (Q_m/Q_c) of 1.15 at Oakland and 1.16 at Minnevika (ignoring potential strain softening).


Figure 5. Stratigraphy and predicted τ_f distribution for (a) tension test on 610-mm diameter, 13.3m long pipe pile in Oakland and (b) compression tests on 405-mm diameter, 40m long pipe pile at Minneveka.

Bittar et al. (2022) show that the mean and coefficient of variation of the Q_m/Q_c values for the 23 load test database were 1.02 and 0.17 respectively i.e. the spread in predictions is less than that of the Unified databases for sand and clay sites. It can therefore be concluded that the Unified methods can be applied with the same level of confidence to layered stratigraphies as to 'single soil type' deposits. However well instrumented test piles that accurately measure the distribution of shaft friction in layered stratigraphies are needed for verification of the method. There is also a great shortage of skin friction data for

piles installed in in Zone 5 (silt) of the SBT chart. Such data would help to resolve the discontinuity in the expressions for τ_f at the boundary between Zone 4 and 5 (at I_c=2.6), where τ_f calculated using the clay expression is typically double that calculated using the clean sand correction approach for silt.

7 LOAD DISPLACEMENT RESPONSE USING THE UNIFIED CPT METHOD

The load-displacement response of piles is normally predicted in a load transfer analysis where the shear stress-displacement (τ-w) springs (also called t-z springs) at various levels along the pile shaft are scaled in proportion to the ultimate shaft friction (τ_f) and the base spring (q_b-w_b) is scaled with the ultimate end bearing ($q_{b0.1}$). The application of the new Unified CPT method to this approach is examined in the following.

7.1 *Piles in sand*

Lehane et al. (2020b) examined the accuracy of pile displacement predictions for driven piles in the Unified sand pile database sand using the τ-w and q_b – w_b load transfer relationships recommended in API (2011). These relationships are provided in tabular form in API (2011) but may be expressed as follows, where w_f is the displacement to peak shear stress (τ_f) and is assigned a mean value of 0.01D in API (2011):

$$\frac{\tau}{\tau_f} = 2\,\frac{w}{w_f}\left[1 - \frac{w}{2w_f}\right] \qquad (13)$$

$$\frac{w_b}{D} = 0.01\left[\frac{q_b/q_{b0.1}}{1 - 0.9\,(q_b/q_{b0.1})}\right] \qquad (14)$$

Although Equation (14) is not a perfect match to the API tabulated values when $q_b/q_{b0.1}$>0.5, this is not a concern as settlement predictions are required for the serviceability limit state when applied loads are rarely greater than 70% of the pile capacity.

API (2011) recommends adoption of a mean w_f/D value of 0.01. However the analyses showed that use of a constant value did not capture the tendency for softer pile responses in tension compared with compression and for stiffer responses in denser sands and longer piles. On examination of the trends shown by the piles in the Unified database, Lehane et al. (2020b) proposed the following expression for w_f/D:

$$\frac{w_f}{D} = \frac{q_c^{0.5}\sigma_v'^{\,0.25}}{Ap_a^{0.75}} \qquad (15)$$
Figure 6. Comparison of measured pile load-displacement response with the calculated response using the Unified method with (i) w_f/D given by Equation 15 and (ii) w_f/D=0.01. The symbols CEC and OET denote closed ended piles tested in compression and open-ended piles tested in tension respectively.

12

where the constant *A* is 1250 in compression and 625 in tension.

Comparisons of measured and calculated load-displacement responses are plotted for typical cases from the Unified database on Figure 7, where calculations were performed using Equations 13 and 14 combined with the Unified method to determine τ_f and $q_{b0.1}$. Figure 7 presents calculated responses for a constant w_f/D value of 0.01 and for w_f/D values at various levels along the pile shaft determined using Equation 15. The improved fit obtained using Equation 15 for tension piles and for longer piles is evident on Figure 7. Lehane et al. (2020b) show that the error in calculated displacements at 50% of the ultimate capacity is typically about 0.002D and is less than 0.005D. Equation 15 will be included in the next version of the API/ISO recommendations.

7.2 *Piles in clay*

Lehane & Bittar (2022) repeated the exercise described above for the Unified database of piles in clay, for which API (2011) recommends the same format of load transfer curves apart from the allowance for post-peak softening to a shear stress of (0.8 ±0.1) τ_f at a displacement of 0.02D. It was found that a combination of the Unified CPT method in clay (Table 2) with these load transfer curves provides good predictions of the displacements of both the tension and compression piles in the database. The standard deviation of the difference between measured and calculated displacements was 0.002D.

8 CONCLUSIONS

There are clear advantages to CPT-based design approaches for the assessment of the axial capacity of driven piles. The CPT-based methods have the full support of the geotechnical community as they remove subjectivity associated with parameter assessment, provide essentially continuous profiles of soil behaviour and allow direct rapid and automated calculation of capacity at any CPT location.

There has been a concerted effort over the past decade to first quantify and then increase the reliability of design methods for piles. This was made possible by the thorough, detailed and careful compilation of a database of static pile load tests (the Unified database) that had the support of the proponents of recent existing CPT methods and the support of a large and active group of energy companies from around the world.

The creation of the Unified database highlighted the level of uncertainty associated with design methods in common use and prompted the development of the new non-affiliated 'Unified CPT method' described in this paper. The new method captures key characteristics of driven piles, as observed in high quality instrumented pile test programmes completed over the past 30 years. The method is shown to have higher reliability than existing approaches.

As for most empirical methods, further developments and improvements are still to come. Such improvements include the need to better quantify the effects of time in various soil types and how the resistance to pile driving as well as the long term capacity can be assessed with more confidence. More static load tests on large diameter instrumented piles are clearly required while greater understanding of factors controlling the influence of the installation mode and friction in silt is needed.

It is hoped that the 'Unified database' can be expanded on an ongoing basis with each additional pile test included satisfying the strict selection criteria applied in the database development to date.

Material Point Method simulations of cone penetration and CPT interpretation

R. Salgado

V. Bisht
Itasca Consulting Group, Minneapolis, USA

M. Prezzi
Purdue University, West Lafayette, USA

ABSTRACT: It is now possible to realistically simulate cone penetration in either sand or clay using the Material Point Method (MPM). To do that, the following requirements must be met: (1) a realistic constitutive model must be used; (2) stress integration of the constitutive model must be accurate; (3) the explicit scheme for the solution of the governing equation must be accurate, robust and efficient; and (4) shear strain localization must be correctly captured. The paper provides an overview of how to correctly perform such simulations and then discusses the implications for the future of CPT interpretation of the availability of accurate, reliable cone penetration simulation methods.

1 INTRODUCTION

1.1 *The cone penetration test*

One of the attractions of the cone penetration test ("CPT") as originally conceived is its simplicity. A penetrometer with a simple, axisymmetric shape is pushed into the ground, and the resistance to penetration at its tip is measured. Given the simplicity of the test, one would expect that a theoretical basis for its interpretation would have been in place for some time. Unfortunately, what is simple in concept is not necessarily so once implemented (Salgado 2012). The complexity appears when we try to develop methods of analysis for realistic interpretation of CPT results. For example, when we attempt to estimate fundamental state variables or direct functions of state variables – such as relative density ("DR") for sand or undrained shear strength ("su") for clay – we find out that there have not been rigorous theories to guide us.

The two main sources of difficulties in cone penetration simulation are: (1) the modeling of the soil response itself and (2) the method of solving the global equation of motion. To address (1), researchers have developed constitutive models that are now accurate and reliable, at least in the absence of cycling. To address (2), researchers have explored a variety of approaches, which are detailed next.

1.2 *Methods of cone penetration simulation*

To remedy the gap in the theoretical basis for CPT interpretation, efforts started early. Initial attempts relied on modeling the soil as a rigid-plastic material with either a Tresca or Mohr-Coulomb yield surface and applying the notion of a limiting equilibrium to an axially loaded penetrometer and a surrounding soil mass. The Durgunoglu & Mitchell (1976a) model was the most successful of these early models, but fell short when people tried to use it. A major shortcoming of the model was its reliance on perfect plasticity and an interpretation based on estimating the friction angle of the soil. As discussed elsewhere (e.g., Salgado 2012), the mobilized friction angle varies across the soil domain in any boundary-value problem involving real soil, so any method based on such an over-simplification of soil response is fatally flawed.

The next main thrust in developing a framework for CPT simulations was cavity expansion theory (e.g., Salgado et al. 1997; Salgado and Prezzi 2007; Salgado and Randolph 2001). Cavity expansion theory was an approximation to the problem based on the requirement that the cone must expand a cylindrical cavity in the soil in order to advance. With the exception of Salgado and Randolph (2001), these efforts concentrated on the use of simple elastoplastic soil models with Tresca or Mohr-Coulomb yield criteria, although with some modifications attemping to capture the effects of soil nonlinearities. It produced useful relationships

(e.g., Salgado and Prezzi 2007) that can be used in CPT interpretation, but it could not truly simulate a process that is much more involved than a simple cavity expansion process.

The strain path method (Teh and Houlsby 2009) was proposed for analysis of cone penetration in clay, and it was a reasonable approximation to the penetration process, but its impact was again limited by a simple elasto-plastic model with a Tresca yield criterion.

Early application of the Finite Element Method ("FEM") also met with difficulties. In geomechanics applications, FEM has traditionally followed a Lagrangian approach. This means that the nodes of a mesh are tracked throughout the analysis, and it is through node displacements that solutions are obtained. Deformation follows from relative node displacements, and stress follows from deformation. After considerable deformation has occurred, mesh elements may be so distorted that accurate solutions are no longer possible. In fact, a solution may not even be possible, with the analysis crashing instead.

The Arbitrary Lagrangian-Eulerian ("ALE") FEM approach (Belytschko and Kennedy 1978) and the material point method ("MPM") (Schreyer et al. 1994) were proposed to avoid this limitation. In ALE FEM, mesh distortion is limited by remeshing or node repositioning after some threshold level of deformation has happened. When nodes are repositioned or a new mesh formed, we need to map the state varia-bles from quadrature points on the old mesh to quadrature points on the new mesh. The remapping can lead to stress states that lie outside the yield surface for plasticity models with single yield surface or outside the bounding surface for bounding surface mod-els. Remapping can be challenging with bounding surface models or complex models with several variables to map. In contrast to ALE FEM, MPM does not require remapping of variables because the state variables are carried by the same material points throughout the computations. The material point method is discussed next.

2 THE MATERIAL POINT METHOD

2.1 *Fundamentals of the method*

The material point method can be best understood as a variant of the finite element method in which Gauss points are replaced by so called material points. A material point ("MP") may be a point (as in classical MPM), but it may also be a small area (for two-dimensional analysis) or small volume (for three-dimensional analysis). In contrast with Gauss points, material points may move within and even across elements. This key difference between FEM and MPM has a number of computational consequences.

The most important and most useful implication of the use of material points instead of Gauss points as used in ALE FEM is that the approach is a pure Lagrangian approach, with material point displacements being the basis for the solution. Whereas grid nodes do move during a computation step, they can be repositioned to their original locations before the next computation time step. It may also be advatageous to consider parts of the grid to either translate in some direction or to compress one-dimensionally. This means that, whether the grid remains static, moves in some direction or is unidirectionally compressed in MPM, it does not get distorted as in FEM, escaping therefore the difficulties created by mesh distortion.

The second most important implication of the use of material points instead of Gauss points in an analysis is that the absolute rigor of FEM with respect to integration of the constitutive model is, to some extent, lost. This happens mainly because Gauss integration is no longer possible. This is not fatal, but a number of remedial measures must be taken to limit any error from this partial loss of rigor.

The next sub-section reviews the MPM formulation used for the analyses whose results are presented in this paper and the key steps in an MPM computation time step.

2.2 *The MPM formulation*

The MPM formulation used in the simulations discussed later is based on the uniform generalized interpolation material point method ("uGIMP" or, in this paper, also "GIMP") variant of MPM discussed in detail by Bisht and Salgado (2018), Bisht et al. (2021b) and Salgado and Bisht (2021).

Figure 1 shows how space and matter can be discretized for a cone penetration problem. Space can be discretized in the form of a computational grid, and the soil and cone can be discretized using material points. The grid can be a rectangular grid with elements sufficiently small around the cone penetrometer. Material point discretization is achieved derivatively: the initial number of material points per element is fixed across the grid (e.g., four material points per element), and finer discretization is therefore achieved where the grid is itself made finer.

How fine the grid must be depends on whether shear strain localization is expected. The smallest element size in any zone in which shear bands are expected to form should have a width equal to the width of the shear band. We discuss this in greater detail later.

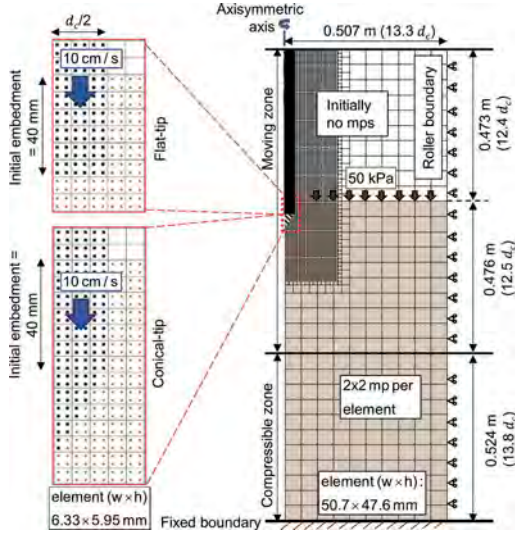
There are two other aspects of discretization that should be briefly discussed. First, the grid can be set up so that part of it moves with the cone penetrometer during penetration and another part, at the bottom of the grid, compresses vertically. Second, when material points flow into a grid element for which they are too large, they are split in a way that conserves energy, momentum and mass. What these two measures accomplish is that, when the cone moves down, together with the fine grid around it, material points located in the coarser grid elements below it will subdivide as they enter the fine grid around the cone, maintaining the required level of material discretization and a sufficient number of material points per element for adequate quadrature.


Figure 1. Spatial and material discretization for simulation of penetration of a flat-tip and a conical-tip penetrometer in sand (after Bisht 2021).

Figure 2. Application of tractions to a body in uGIMP MPM: the tractions are first applied on the edges of the material points (rep-resented by thick lines) and then, using finite element-element shape functions, mapped to the nodes of the element containing the material point.

Displacement or velocity boundary conditions are straightforward in MPM: the correct displacement or velocity is directly applied on the outermost grid nodes corresponding to that boundary. Application of traction boundary conditions is more involved, requiring distribution of tractions to the material point boundaries aligned with the boundary of the body for every material point so positioned, and then redistribution of these tractions to the nodes of any element containing any part of the material point (Bisht and Salgado 2018). See Figure 2.

To model a semi-infinite soil medium using a finite grid, silent boundaries are required. Silent boundaries let energy dissipate just as it would by radiation in a semi-infinite medium. Kellezi (2000) proposed a "cone boundary" that assumes that a load applied on a free surface of a half-space would propagate within a volume expanding with increasing depth, which can be approximated as a cone. At the boundary, there is both a viscosity term to simulate the energy dissipation through radiation and a stiffness term. Bisht and Salgado (2018) adapted it for MPM, and it is their formulation that is used here.

MPM formulations for solving the global equation of motion have typically been explicit. The governing equation for a general analysis applicable to simple models and any drained simulation is:

$$\dot{p}_i^{(I)} = f_i^{(I)EXT} - f_i^{(I)INT} \qquad (1)$$

The rate of the momentum $p_i^{(I)}$ $pi(I)$, external force $f_i^{(I)EXT}$ and internal force $f_i^{(I)INT}$ at node I, all appearing in (1), are given by (Bisht et al. 2021a):

$$\dot{p}_i^{(I)} = \sum_P S^{(IP)} \dot{p}_i^{(P)} \qquad (2)$$

$$f_i^{(I)EXT} = \int_\Gamma N^{(I)} t_i d\Gamma + \sum_P S^{(IP)} m^{(p)} b_i \qquad (3)$$

and

$$f_i^{(I)INT} = \sum_P S_j^{(IP)} \sigma_{ij}^{(P)} V^{(P)} \qquad (4)$$

In Equations (2) through (4), σ_{ij} is the Cauchy stress, b_i is the body force per unit mass, $m^{(P)}$ is the mass of the material point, Γ is the boundary of the domain Ω of the problem and $t_i = \sigma_{ij} n_j$ is the traction on an arbitrary point on Γ, with n_j being the unit vector normal to Γ at that point. Also appearing in Equations (2) through (4) are the finite element shape function $N^{(I)}$ at node I, the material point shape function $S^{(IP)}$, which maps the value of a variable at the centroid of a material point P to node I, and its gradient These last two are defined as:

$$S^{(IP)} = \frac{1}{V^{(P)}} \int_{\Omega^{(P)}} N^{(I)} \chi^{(P)} d\Omega \qquad (5)$$

and

$$S_j^{(IP)} = \frac{1}{V^{(P)}} \int_{\Omega^{(P)}} N_j^{(I)} \chi^{(P)} d\Omega \qquad (6)$$

where $\chi^{(P)}$ is the particle characteristic function, usually taken to be uniformly equal to 1 across the MP and zero outside it:

$$\chi^{(P)} = \begin{cases} 1 & r \in \varOmega^{(P)} \\ 0 & r \notin \varOmega^{(P)} \end{cases} \qquad (7)$$

One reason for using an explicit solution scheme in MPM are the difficulties in inverting ill-conditioned stiffness matrices that result when there are only a few material points in some element or elements (Wang et al. 2016).

The Update Stress Last (USL) explicit time integration scheme, in which the stresses in the material point are computed after momentum in the grid is updated (Wallstedt and Guilkey 2008), is used here.

Explicit time integration is conditionally stable, which means that time increments must be less than some limit for the computations to converge. For nonlinear problems, the time step Δt is usually taken as:

$$\Delta t = \kappa \min\left(ele/\sqrt{E_c/\rho}\right) \qquad (8)$$

where κ is the Courant number (Courant et al. 1967), elemin is the minimum element size, E_c is a measure of material stiffness (the Young's modulus or the constrained modulus are common choices, depending on the problem), and ρ is the material density. For dynamic problems, $\kappa \approx 0.4$ yields suitable results for the USL approach, but higher values of κ may be used for quasi-static problems (Wallstedt and Guilkey 2008). For quasi-static problems, such as cone penetration, the time step Δt can be increased by mass scaling to reduce the overall computation time. In mass scaling, the material density ρ is artificially increased by a mass scaling parameter η:

$$\rho_{scaled} = \eta\rho \qquad (9)$$

This allows the use of a larger time step Δt_{ms}:

$$\Delta t_{ms} = \sqrt{\eta \Delta t} \qquad (10)$$

2.3 Volumetric locking

In numerical solutions to problems in mechanics involving incompressible or nearly incompressible materials, a phenomenon known as volumetric locking may occur. Volumetric locking is the insufficiency of variables provided by a grid discretization to allow solution of all equations. This results from the additional equation involving strain tensor components resulting from the imposition of the incompressibility

constraint on an integration point. Incompressibility or near incompressibility appears in Tresca solids in the plastic range and at critical state for any soil model. It often appears as strong spatial oscillations in the values of fundamental variables, such as stress, which appears as a checkerboard pattern when results are plotted as contour plots.

In the finite element method, volumetric locking can be avoided by using higher-order elements, which lead to a sufficient number of variables to overcome any excess equations from the incompressibility constraint. This is not an option in MPM because shape functions for higher-order elements can take negative values for some regions in an element, which in turn can lead to negative mass at the corresponding nodes from a material point located in such regions. The attending complications are discussed in detail in Bisht et al. (2021a).

An effective way to deal with volumetric locking in MPM is the use of the so-called non-linear $\overline{\mathbf{B}}$ method (Hughes 1980). The method is based on the fact that volumetric locking can be prevented by reducing the number of constraints imposed by incompressibility in each element. For example, for Q4 elements, volumetric locking can be prevented if a reduced, single-point quadrature rule is used (see Sloan and Randolph (1982)). The use of single Gauss point in reduced integration for Q4 elements is sufficient to prevent volumetric locking, but this strategy is not applicable in MPM.

For MPM, Bisht et al. (2021a) used a large-deformation formulation of the $\overline{\mathbf{B}}$ method with the deformation gradient $\mathbf{F}$ split into a volumetric and a deviatoric component, with the volumetric component calculated only at the element center. The computational algorithm that results requires that the gradient $S_{,j}^{(IP)}$ of the material point shape functions (material point mapping functions) must be calculated also at the element center. A modified deformation gradient $\overline{\mathbf{F}}^{(P)}$ at the material point P, obtained from combining the deviatoric component of the deformation gradient with the volumetric component of it at the element center, is then used in stress integrations.

2.4 A computation time step in an MPM simulation

During a time step in an MPM simulation, we follow the steps outlined below.

1. Start with initialization of all variables at material points and grid nodes and set the time t to 0.
2. Determine an appropriate time increment Δt using Eq. (10).
3. For each material point P:
   (a) Find every node I around the material point P to which nonzero values of material point variables must be transferred, i.e., nodes for which $\int_{\varOmega^{(P)}} N^{(I)} \chi^{(P)} \mathrm{d}\varOmega \neq 0$
   (b) Compute mapping functions $S^{(IP)}$ using Eq (5) and their gradients $S_{,j}^{(IP)}$ using Eq. (6). If the node is a hanging node, transfer mapping

functions and their gradients to surrounding nodes as explained by Bisht et al. (2021a).

(c) For simulations in incompressible soil, compute mapping function gradients $S_j^{(IP)}(C)$ at element center C.

(4) For each node I:

(a) Compute nodal mass $m^{(I)} = \sum_P m^{(P)} S^{(IP)}$ and momentum $p_i^{(I)} = \sum_P m^{(P)} v_i^{(P)} S^{(IP)}$

(b) Compute nodal external $\overline{f}_i^{(I)EXT}$ (Eq. (3)) and internal forces $\overline{f}_i^{(I)INT}$ (Eq. (4)).

(c) Compute the rate of change of momentum $\underline{p}_i^{(I)}$ using Eq. (1) and update nodal momentum using $p_i^{(I)} \leftarrow p_i^{(I)} + \underline{p}_i^{(I)} \Delta t$

(d) If the node is on a velocity boundary, set $p_i^{(I)} = m v_i^*$, where v_i^* is the prescribed velocity.

(e) Compute contact forces $f_i^{(I)CT}$ using the contact algorithm proposed by Bardenhagen et al. (2000, 2001) and update the nodal momentum using $p_i^{(I)} \leftarrow p_i^{(I)} + f_i^{(I)CT} \Delta t$

(5) For each material point P:

(a) Update material point velocity $v_i^{(P)} \leftarrow v_i^{(P)} + \Delta t \sum_I S^{(IP)} \underline{p}_i^{(I)} / m^{(I)}$ and position $x_i^{(P)} \leftarrow x_i^{(P)} + \Delta t \sum_I S^{(IP)} p_i^{(I)} / m^{(I)}$

(b) Compute the velocity gradient $v_{i,j}^{(P)}$ and deformation gradient $F_{ij}^{(P)}$

(c) For simulations in incompressible soil, compute the velocity gradient $v_{i,j}^{(P)}(C)$ at the element center and compute the modified deformation gra-dient $\overline{F}_{ij}^{(P)}$

(d) Using a suitable objective rate formulation, update the stresses and internal variables using the algorithms proposed in Nazem et al. (2009).

(e) Update the material point volume $V^{(P)} \leftarrow \left(\det F_{ij}^{(P)}\right) V^{(P)}$

(6) Adjust (translate/compress/reset) the background grid.

(7) Update time $t \leftarrow t + \Delta t$. If $t > t_{end}$, go to step 2; otherwise exit.

An objective time rate is required in large-deformation, large-rotation analyses (Lubliner 2008). There is also a specific objective rate formulation that must be used to obtain the correct solution of a bound-ary-value problem (Lim, J., Salgado, R. and Prezzi, M., paper in preparation).

3 VALIDATION OF MPM SIMULATIONS OF RELATED GEOMECHANICS BOUNDARY VALUE PROBLEMS

3.1 *Limit bearing capacity*

If an MPM formulation is capable of modeling cone penetration, then it must be able to also model a bearing capacity problem. The Prandtl punch problem, in which a flat plane-strain punch (a strip footing) is forced into a Tresca half-space from the surface, is a good test of the quality of the formulation because the solution to it is known exactly. But limit analysis solutions also exist bracketing the bearing capacity of footings, strip or square, embedded to various depths D in Tresca soil (Salgado et al. 2004). The values of limit unit bearing capacity qbL are given in Table 1 for strip and Table 2 for square footings. We can see very good agreement between MPM and the benchmark results, including the value for a strip footing on the surface of the half-space, which is known to be $2 + \pi$ times the yield stress c of the Tresca material and is well approximated by the MPM solution.

The MPM analyses were performed for very stiff Tresca soils. This allowed development of the limit bearing capacity for small footing deflection, before any significant change to the geometry of the problem could occur. This is important because this is a feature of the limit analysis solutions used to benchmark the MPM values of qbL.

In only three of the ten cases considered in the two tables was the MPM value outside, and only margin-ally outside, the range defined by the lower and upper bounds from limit analysis.

Table 1. Value of limit unit bearing capacity qbL of a strip footing in Tresca soil from MPM compared to values obtained using formation gradient.

D/B	L	U	MPM
0.0	5.132	5.203	5.213
0.1	5.448	5.548	5.471
0.2	5.696	5.806	5.761
0.4	6.029	6.133	5.977
1.0	6.562	6.657	6.535

B = footing width.

Table 2. Value of limit unit bearing capacity qbL of a square footing in Tresca soil from MPM compared to values obtained using limit analysis.

D/B	L	U	MPM
0.0	5.856	6.227	6.149
0.1	6.491	7.140	7.063
0.2	6.897	7.523	7.426
0.4	7.303	8.104	8.002
1.0	8.771	9.429	9.296

B = footing width.

3.2 *Footing loaded to large settlements*

Rather than simply producing the correct values of limit bearing capacity, the MPM formulation must also reproduce the load response of a footing to large settlements. This problem has been studied using several methods, including sequential limit analysis (da Silva et al. 2011), ALE FEM (Kardani et al.

2015; Nazem et al. 2006, 2009), a form of ALE FEM known as "remeshing and interpolation technique with small strain" (RITSS) (Wang et al. 2013) and MPM (Iaconeta et al. 2019; Sołowski and Sloan 2015; Woo and Salgado 2018).

In the validation simulations, a 1-m wide footing was modeled as a rigid material, and the soil was modeled as a weightless Tresca material with $E = 100$ kPa, $v = 0.49$, $\rho = 1.0 \text{g/cm}^3$ and $su = 1$ kPa (the same parameter values used by Wang et al. 2013). The problem domain was discretized using an irregular background grid with a minimum element size equal to $B/20$ near the base of the footing and a maximum element size equal to $B/80$ away from the footing. Initially, each element contained 4 material points in a 2×2 configuration. The size of the domain was $10B$ in both the horizontal and vertical directions when measured from the center of the base of the footing. The Courant number κ was taken as 0.3. To simulate quasi-static conditions, the vertical penetration velocity increased linearly from 0 to 0.02 m/s over 1 s and then remained constant at 0.02 m/s after 1 s.

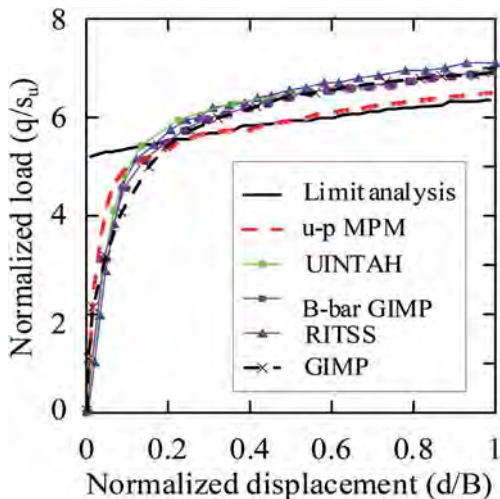
Comparison of the MPM formulation of Bisht et al. (2021a), noted in the legend as "B-bar GIMP," with a variety of other methods is shown in Figure 3. The favorable comparison with the high-quality ALE FEM simulation (labeled "RITSS" in the figure) is an important validation result.


Figure 3. MPM GIMP simulations of a footing pushed to large penetration in an elasto-plastic Tresca soil compared with the solution of various other methods of analysis (after Bisht et al. 2021a).

4 CONE PENETRATION IN SAND

4.1 *Constitutive model*

Simulation of cone penetration in sand using MPM is less complex than in clay largely because drained penetration can be assumed a priori, there being

therefore no need to perform coupled flow-deformation analyses. Coupled analyses are required for clay, as we will discuss later.

To properly simulate penetration in sand, a realistic sand constitutive model is required. The model must be able to accurately reproduce soil element response in triaxial compression, triaxial extension and simple shear loading. A model satisfying this requirement is that of Loukidis and Salgado (2009). The analyses reported here were performed using this model.

Model parameters and the test data required for their determination are listed in Table 3. Also given in the table are the values of model parameters for Ot-tawa sand. It is for Ottawa sand that MPM simulations were performed. Although the number of parameters (22) may seem daunting, only 5 parameters ($h1$, $h2$, $elim$, μ and k_h) are determined using a trial and error approach. The remaining 17 can be directly determined by fitting the model equations to the data. Most parameters can be determined using routine tests such as drained and undrained TXC, while others can be reasonably assumed based on the corresponding values for similar sands.

Table 3. Constitutive model input parameters for Ottawa sand (after Loukidis and Salgado 2009).

	Symbol	Value	Test(s)
Small-strain("elastic") parameters	v	0.15	compression w/unloading
	C_g	611	BE or RC
	n_g	0.437	BE or RC
	γ_1	0.00065	RC or TX
	α_1	0.47	TXCU
Critical state	Γ_c	0.780	TXC
	λ	0.081	TXC
	ξ	0.196	TXC
	M_{cc}	1.21	TXC
Bounding surface	k_b	1.9	TXC
Dilatancy	D_0	1.31	TXC
	k_d	2.2	TXC
Plastic modulus	h_1	2.2	TXC
	h_2	0.240	TXC
	e_{lim}	0.81	TXC
	μ	1.2	TXCU
Stress-induced anisotropy	$c1$	0.71	TXE
	$c2$	0.78	SS
	n_s	0.35	SS
Inherent anisotropy	α	0.31	TXE
	k_h	0.39	TXE
Yield surface radius	m	0.05	-

TXC: triaxial compression; TXE: triaxial extension; TXCU: un-drained triaxial compression; SS: simple shear; RC: resonant column; and IC: isotropic compression.

4.2 *Cone penetration simulation scheme*

A fixed time step size – determined using Eq. (10) – was used for all cone penetration simulations. For us

to use Eq. (10), certain variables and parameters must be evaluated. As will be discussed in detail in the next sub-section, the minimum element size elemin used for the simulations in this study was 5.95 mm, and the relative density DR for all tests was ~90% (implying a dry density $\rho$of 1.72 ton/m3). Using a reasonably high mean stress p' of 10 MPa and a void ratio e of 0.524, corresponding to a relative density DR of 90%, the small-strain shear modulus Gmax is equal to 800 MPa using the Hardin and Richart (1963) correlation. Assuming $\kappa = 0.7$ and $\eta = 25$, a scaled time step $\Delta t_{ms} = 2.0 \times 10^{-5}$s was computed. Simulations performed using smaller κ and smaller ηvalues produced nearly identical results. A fixed time step $\Delta t_{ms} = 2.0 \times 10^{-5}$s was therefore considered acceptable and was used in the simulations.

Penetration was simulated by imposing on the cone penetrometer successive displacement increments. The same rate of penetration is ideally used in computations as in reality, but to reduce computation time, a greater penetration velocity was used in the simulations. This is possible so long as penetration remains quasi-static, so that there is no rate dependence in the value of qc. Table 4 details the parameters for the MPM analyses reported in this paper.

Table 4. General numerical scheme used for the MPM simulations of cone penetration in sand (after Bisht 2021).

Feature	Implementation
Type of MPM	uGIMP
Time integration	Explicit: $\Delta t = 2 \times 10^{-5}$s Mass scaling factor: 25
Mesh	Structured irregular grid divided into moving and compressible regions; Q4 element with initially four material points; element size approximately equal to the width of the shear band
Penetration velocity	$v$cone = 0–10 cm/s for $t \leq 1$s; 10 cm/s for $t > 1$s
Initial stress field	Initial vertical stress known; $K0 = 0.45$ assumed
Contact model	Coulomb friction model with $\mu_f = 0.3$
Stress integration algorithm	Explicit with automatic sub-stepping and error control
Objective stress rate and strain measure	Modified kinematic logarithmic rate; Hencky strain
Volumetric locking	Locking not observed
Constitutive model	Loukidis and Salgado (2009) sand model; Parameters calibrated to Ottawa sand used

ρ: density; Δt = time step size; Q4: linear quadrilateral elements; $K0$: coefficient of lateral earth pressure at-rest; mps.: material points; $v$cone: penetration velocity of cone; and μ_r coefficient of friction.

The grid used to perform the simulations resembles that shown in Figure 1. It has a moving grid region that moves down with the cone penetrometer and a compressible region at the bottom (Woo and Salgado 2015). The nodes at the bottom of the compressible grid do not move, but those above them do. To capture shear bands that develop near the cone base and cone shaft, the smallest element size was chosen to be roughly equal to the shear band width observed in sands (e.g., Alshibli and Hasan 2008; Alshibli and Sture 1999; Desrues and Viggiani 2004; Salgado et al. 2017; Tehrani et al. 2017).

4.3 Validation using calibration chamber tests

The calibration chamber with a viewing window to enable digital image correlation (DIC) analysis of penetration tests was used to perform two cone penetration tests in dense samples subjected to two different levels of vertical effective stress.

The chamber, shown in Figure 4, is a half-cylindrical calibration chamber with a diameter Dc of 1680 mm and a height of 1200 mm. The tests were performed under BC3 calibration chamber boundary conditions (Ghionna and Jamiolkowski 1991; Salgado et al. 1998) by using an inflatable air-rubber bladder at the top of the sample and rigid lateral walls. Three cameras with a resolution of 5 megapixels (SV5M10 complementary metal-oxide semiconductor CMOS cameras, EPIX, Buffalo Grove, Illinois) were used to take images during testing (GalvisCastro et al. 2019; Salgado et al. 2016; TovarValencia et al. 2018).

Figure 4. DIC calibration chamber at COFFEE, Purdue University: front view, showing viewing windows.

Figure 5 shows a comparison of measured q_c with the q_c values computed using MPM for two values of vertical effective stress at the level of the cone. The MPM simulations capture the gradual rise of q_c from the time the cone penetrometer enters the soil, which is also observed in the real experiment, and also the plateau that forms in the q_c versus depth plot once boundary effects are no longer a factor. The experiments have not been repeated for confirmation, but the comparisons of the plots from the

MPM simulation with those obtained from the calibration chamber test are encouraging.
Figure 5. Comparison of MPM simulations of cone penetration tests in a calibration chamber with the results of those tests (modified after Bisht 2021).

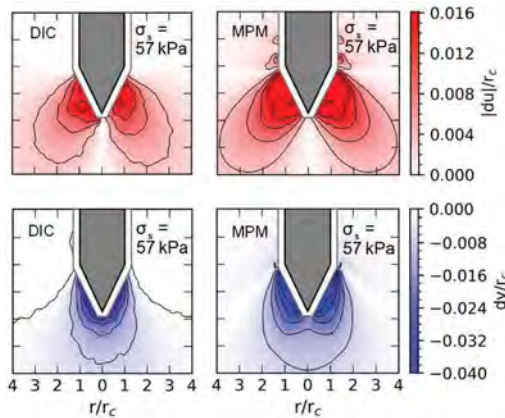
What a DIC calibration chamber enables us to do that a regular calibration chamber does not is the measurement of displacement fields. Figure 6 shows a comparison of the horizontal and vertical displacement increments measured using a DIC analysis of images collected during a small downward move of the cone penetrometer to those computed using MPM. The comparison shows that MPM can effectively capture displacement fields around the advancing cone penetrometers in addition to also approximating closely the cone resistance values.


Figure 6. Comparison of vertical and horizontal displacement increments – du and dv – obtained from DIC analysis of the chamber test and MPM simulations of the same test (modified after Bisht 2021).

5 CONE PENETRATION IN CLAY

5.1 *Formulation*

Simulation of cone penetration in clay requires a coupled, hydro-mechanical, effective stress analysis. Such an analysis allows the calculation of effective stress and pore pressure everywhere in the soil domain as the penetration progresses. It is accomplished in the analysis discussed here using a single material point to represent both the soil matrix and water and an explicit scheme to solve the governing equations, which are in terms of the velocity of the soil matrix and the velocity of water as the primary variables (Bisht et al. 2021b). Incompressibility constraints in the soil matrix are resolved using the non-linear B-bar method, and pore pressures are computed at element centers.

A coupled formulation can be used to handle penetration under partial drainage conditions. Undrained conditions need not be assumed. If we do assume undrained conditions, a simplification of the governing equations is possible. The governing equations are derived from consideration of momentum of the water, momentum of the soil matrix, and interaction of the soil particles and water though a drag resistance between the two due to a relative velocity.

5.2 *Validation*

The MPM formulation has been validated using, among other benchmarks, the one-dimensional consolidation theory of Terzaghi (1943). We show that here for illustration of the quality of the analysis framework, but point readers to Bisht et al. (2021b) for a more extended discussion of the accuracy and robustness of the numerical schemes.

Figure 7(a) shows a soil wall with height equal to 1.0 m and width equal to 0.075 m. An MPM grid was superposed on the wall. The grid is a structured regular grid with linear quadrilateral (Q4) elements with dimensions 0.025 m × 0.025 m. Each element contained four material points initially. The Young's modulus E of the soil is 10,000 kPa, its Poisson's ratio is 0.3, soil particle density is 2.67 ton/m3, the initial porosity is 0.4, and the hydraulic conductivity is 10−3 m/s. The density of water is 2.67 ton/m3 and its bulk modulus is 2.2 GPa. An initial pore pressure of 10 kPa was assigned to the soil. A fixed boundary condition was applied at the bottom, and roller boundaries restricting horizontal movement were applied to the sides. Impermeable boundary conditions were applied at the bottom boundary and the two side boundaries. The consolidation test was performed by applying a 10 kPa traction at the top surface and allowing the water to drain from the top. A fixed time step size equal to 1×10^{-5}s was used in the MPM simulation of the compression of the soil wall.

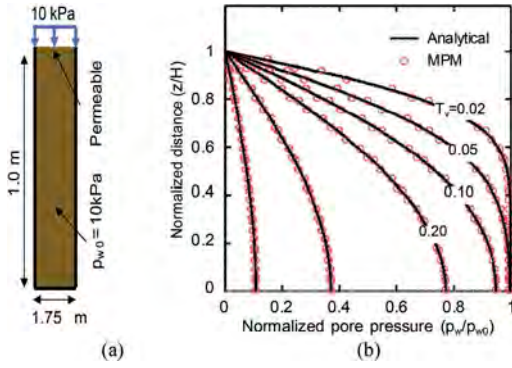
Figure 7(b) shows that the coupled MPM formulation closely matches the results obtained using the traditional Terzaghi solution.


Figure 7. One-dimensional consolidation test: (a) slide of soil undergoing 1D consolidation; and (b) a comparison of the results obtained using the coupled MPM formulation and Terzaghi's solution after (Bisht et al. 2021b).

Figure 8. Grid and material point discretization for simulation of cone penetration at a depth of 9.6 m for the cone penetration tests of Landon (2007) (after Bisht et al. 2021b).

5.3 *Simulation of a real CPT in clayey soil*

We use the two CPTs performed by Landon (2007), which were located approximately 10 m apart, to test the MPM formulation for clay. The cone resistances measured in these two tests at a depth of 9.6 m were approximately 580 kPa and 730 kPa. Soil samples were collected from several depths. Based on testing done on these samples, the soil state at a depth of 9.6 m was estimated to be defined by an initial vertical effective stress $\sigma'_{v0} = 100$ kPa, initial vertical total stress $\sigma_{v0} = 175$ kPa, initial horizontal effective stress $\sigma'_{h0} = 65$ kPa, and overconsolidation ratio OCR = 2.2. The groundwater level was at a depth of 1.7 m. The hydraulic conductivity varied from 10^{-10} to 10^{-9} m/s.

The constitutive model used in the simulations is that of Chakraborty et al. (2013). The model contains a total of 22 parameters, most of which, as in the case of the sand model discussed earlier, can be determined through simple inspection and curve fitting of equations to data obtained from routine laboratory tests. The analyses were performed using the calibrated values of Boston Blue Clay ("BBC") that are given in Chakraborty et al. (2013), except that strain-rate independence is assumed because the problem is quasi-static.

Figure 8 shows both space and material point discretization of the simulations. The default four material points per elements were used. The same general approach followed for the grid in the analysis of cone penetration in sand was repeated for clay. A structured irregular grid with both a moving and a compressible mesh zone was used to discretize the do-main. A standard cone with diameter $d_c = 35.7$ mm and cone tip height $h_c = 30.9$ mm (apex angle = 60°) was assumed. Axisymmetric conditions were assumed, and thus only half the cone was discretized.

The goal of the analysis was not to produce the entire history of penetration from the ground surface, but penetration just into the clay layer. Accordingly, the initial position of the cone for the analysis was $5d_c$ below the upper boundary of the clay layer, which is at a depth of 9.6 m from the ground surface.
The soil was discretized using a mesh of dimensions $20d_c$ in width by $25d_c$ in height. The mesh was built with linear quadrilateral elements, each initially containing 2×2 material points.

Figure 9 shows the results of the MPM simulation compared to the two values measured in each CPT sounding at a depth of 9.6m. The comparison is very encouraging.
Figure 9. Comparison of cone resistance q_c, during a penetration path $5d_c$ long, with the values measured in two CPT soundings (after Bisht et al. 2021b).

6 IMPLICATIONS FOR FUTURE OF CPT INTERPRETATION

6.1 Importance of MPM in future development of CPT interpretation approaches

This paper has shown that MPM, combined with realistic constitutive models, is capable of accurate predictions of cone resistance in both sandy and clayey soils. What does that mean for CPT interpretation in the future? It depends on how far in the future, and it depends on what type of interpretation we are pursuing.

6.2 Limitation of MPM in the present and in the near term

At present, MPM with finite-size material points, and even, to a lesser degree, with material points that are actual points, is computationally expensive if accurate, realistic simulations are desired. It is important to understand that much faster simulations can be done, and can be found in the literature, but not with the level of discretization required for accuracy. At the time of this writing, simulation of an entire CPT starting from the ground surface is cost-prohibitive in an engineering design setting. However, cloud computing is expected to ease the computational burden significantly in the next several years.

This means that routine application of MPM to simulate entire soundings and the richness of interpretation that would result from that lies in the more distant future. However, it is entirely possible to compute cone resistance locally. For example, if the interest is in a specific layer with a certain soil existing with a certain state, then that is a simulation that is practically possible to perform. The computations done earlier for a clay layer illustrate this.

The other use of MPM is to perform simulations ahead of time for various combinations of soil intrinsic and state variables, and then use the results of these simulations to derive correlations of cone resistance with these variables or to feed them to AI tools. There are two types of relationships that can be developed: direct and indirect relationships.

Indirect relationships constitute the basic tool for pure CPT interpretation: from q_c and other measurements made during a CPT, obtain the values of the soil state variables. Direct relationships allow you to obtain estimates of quantities of direct interest in design, such as unit shaft and base resistance of a pile or liquefaction resistance from cone resistance and any other CPT measurements.

6.3 Indirect interpretation of CPT results

In indirect CPT interpretation methods, we are interested in evaluating soil state from CPT measurements. The thinking is somewhat akin to that of solving a system of equations (Salgado 1993). If there are enough equations, the unknown variables can be determined. The "equations" in this case are whatever relationships are available between the knowns (q_c and any other measurement) and the unknowns. The unknowns are, in sands, variables such as the relative density or void ratio, the effective stress state and soil fabric. In other words, the unknowns would be state variables. The relationships would be equations developed based on MPM simulations between cone resistance and the state variables. Parameters in these equations would be the soil intrinsic variables, those related to factors like mineralogy, particle size distribution, and the like, as well as critical state parameters. Intrinsic variables would be determined from routine laboratory tests.

Perhaps the greatest impact of the availability of reliable MPM simulation capabilities will be on interpretation in clay. Relationships already exist relating q_c to relative density and lateral effective stress, for example, in sands (Salgado and Prezzi 2007). However, interpretation of CPT results in clay has remained linked to a Tresca-linked view of clay, with relationships between q_c and s_u instead of between q_c and void ratio, effective stress and fabric. In these traditional relationships, a cone factor N_k is defined to relate q_c to s_u, but how should s_u be defined in such a relationship? Should it be that obtained under triaxial compression, triaxial extension or simple shear loading? Additionally, somewhat awkward relationships must be resorted to relating N_k to a rigidity index defined in terms of a modulus and a shear strength that are again not defined. An interpretation method leading to the values of state variables would be preferable.

6.4 Direct interpretation of CPT results

Direct interpretation occurs in a design application context, instead of a soil mechanics or soil characterization context. To develop a direct CPT method, it is necessary that the soil response for the specific design problem can be correlated with q_c and/or other CPT measurement. If the design problem can be itself simulated numerically, we have an entirely science-based correlation that can be used in design. Otherwise, the correlation will be semi-empirical, as liquefaction potential assessment methods must still be. Table 5 contains three of the most important design problems to which the CPT is routinely applied. Foundation loading can already be effectively simulated using the finite element method to settlement levels of interest in design (see, e.g., Han et al. 2017; Loukidis and Salgado 2011; Salgado et al. 2017). MPM can be used for problems in which significant mesh distortion will render FEM analyses not feasible. Liquefaction cannot as yet be simulated. The main obstacle is the unavailability of a constitutive model that can properly simulate the soil response under repeated cycling, so methods will for now and in the near future remain semi-empirical.

Table 5. Direct interpretation of CPT results.

Design problem	Target variables	Basis of relationships
Shallow foundation design	Limit unit bearing capacity qbL; settlement w in service	Computational simulations using MPM or FEM
Deep foundation design	Ultimate unit base resistance qb,ult; limit unit shaft resistance qsL	Computational simulations using MPM or FEM
Liquefaction potential assessment	Cyclic resistance ratio CRR	Semi-empirical because liquefaction cannot yet be accurately simulated

7 CONCLUSIONS

The main purpose of this paper was to review our ability to simulate the cone penetration process. For realistic simulation of cone penetration in both sand and clay, it is necessary to have (1) realistic, robust constitutive models; (2) realistic, robust constitutive model stress integration schemes; and (3) accurate, efficient, robust numerical schemes for integration of the governing equation for the cone penetration process. The paper focused on prong 3 of the simulation framework: the use of the u-GIMP MPM formulation to simulate the penetration process.

MPM replaces Gauss points in Lagrangian FEM formulations by material points. The material points are not affixed to the finite element constituting the mesh or grid into which a body is discretized but rather can move through the grid, even crossing elements. The material points in fact are the discretization of the body, whereas the grid is the discretization of space.

There are certain consequences from this fundamental difference between the two methods. Two of the most consequential are: (1) integration is not as accurate as in FEM; (2) some techniques used in FEM to avoid pathologies, such as volumetric locking, are not effective in MPM; (3) because the grid can always be reset between computation time increments, mesh distortion does not impact calculations, and MPM simulations can progress to very large displacement levels.

The paper illustrated some of the validation exercises that the MPM computational framework discussed here has been subjected to and successfully passed. These validations have shown that accurate cone penetration simulations are possible. The impact of this capability is yet to come. In the future, the ability to accurately, realistically simulate cone penetration and other processes involved in the direct or indirect interpretation of CPT results will lead to high-quality interpretation methods. Other factors in interpretation, such as spatial variability of soil state variables and soil type, will also be better taken into account with the more advanced command of the mechanics of cone penetration.

Practical use of shear wave velocity measurements from SCPTU in clays

M. Long
University College Dublin (UCD), Ireland

ABSTRACT: The main objective of this paper is to promotes use of shear wave velocity (V_s) measurements from SCPTU testing as a compliment to standard CPTU data. Recent developments in the technique are described. Uncertainties in the methods have been well researched and several methods have been proposed to deal with these uncertainties. Nonetheless V_s measurements seem reliable in isotropic soil conditions. V_s profiles for a range of soft to firm clays world-wide are presented. Clear links between these profiles are identified based on fundamental soil properties. Stiff overconsolidated clays do not follow the same patterns due to pure stress anisotropy and their fissured nature. Correlations between V_s and CPTU data and with a variety of soil properties can be very powerful. However these correlations should ideally be local and only applied to other soils and areas with great caution. An exception might be for correlation between V_s and preconsolidation stress pc'. Use of SCPTU data to help assess sample disturbance and for the prediction of settlement of footings is described. Some future outlooks including dealing with anisotropy are discussed.

1 INTRODUCTION

Shear wave velocity (V_s) is a fundamental measurement in all solids for example steel, concrete, wood, soil and rock (Mayne, 2000). Because of this broad range of application, V_s values are an attractive means of characterising a range of natural geomaterials. Water is not able to tolerate shear waves. Therefore measurements in soil are not influenced by the presence of groundwater (unlike P-waves).

Over the last decades, V_s measurements have gained popularity in geotechnical engineering practice. Advances in cost effective and efficient methods of determination of V_s focused attention on this parameter, which originally was mainly used for seismic hazard assessment or dynamic analyses. However, its use has be extended to general site characterisation studies, ground movement analyses for tunnels and excavation problems, determination of strength and compressibility parameters by empirical correlation, prediction of the behaviour of deep and shallow foundations, assessment of sample disturbance effects and in the quality control of ground improvement schemes among other applications.

V_s can be measured by a wide range of intrusive and non-intrusive methods, see L'Heureux and Long (2017) for example. In this paper the focus will be on the use of the seismic piezocone test (SCPTU) for V_s measurement.

The paper will deal with some basics on shear waves including shear wave anisotropy. The measurement technique will be briefly described together with some recent developments in the method. Uncertainties in the measurement technique will be

considered. The meaning of numerical V_s values will be discussed and typical V_s profiles for various clays will be presented and compared.

Use of V_s profiles for site characterisation will be described. Correlations between V_s and other SCPTU measurements and with a range of soil properties will be considered. An emphasis on estimating preconsolidation stress from V_s. Finally use of V_s for sample disturbance assessment and for prediction of settlement of shallow foundations will be outlined.

The paper will focus on clay soils only (with some comparison made with peat). It will not deal with earthquake problems such as liquefaction.

It is stressed that the objective of the paper is to promote increasing use of SCPTU V_s measurements as a compliment, not as a replacement, to other CPTU measurements. The author supports the suggestion of Mayne et al. (2009), in their Key Note lecture to the 17th ICSMGE in Alexandria, who proposed that in site characterisation studies the standard approach should be in the use of the SCPTU (or seismic dilatometer, SDMT) as up to five separate measurements are captured at each depth tested.

2 SOME BASIC CONSIDERATIONS

2.1 *Shear waves*

Engineer's interest in V_s determination has largely been driven by the need to obtain values of the small strain shear modulus (G_{max}), as this is an important parameter for a range of geotechnical design applications. This usually involves strains of 10-4 to 10-3 % and less.

According to elastic theory G_{max} may be calculated from the shear wave velocity using the following equation:

An example for the well-researched Italian clay site at Augusta (saline area) is shown on Figure 1. The materials below 15 m comprise a medium stiff, overconsolidated (overconsolidation ratio, OCR = 2 to 6) Pleistocene marine clay with low to medium plasticity (Lo Presti et al., 1998). V_{s-vh} values from seismic dilatometer (SDMT) and downhole testing are very similar but they are some 100 m/s less than the cross-hole V_{s-hv} values.

For simplicity in this paper the SCPTU measurement will be denoted as V_s unless otherwise stated.

$$G_{max} = \rho V_s^2 \qquad (1)$$

where: G_{max} is the shear modulus (in Pa), V_s is in m/s, and ρ is the total mass density (in kg/m3).

It is important to remember that for practical use, the G_{max} value needs to be reduced to give the strain level relevant to a particular problem. This point will be addressed later.

2.2 *Anisotropy of shear wave velocity*

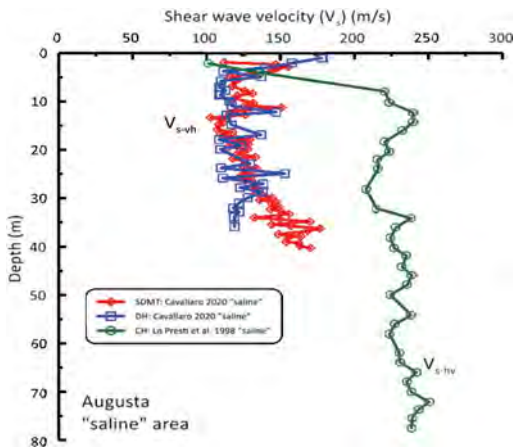
Anisotropy of shear wave velocity/stiffness may be significant in many clays. This is particularly the case for overconsolidated materials. Butcher and Powell (1995) and others have suggested that to distinguish between shear wave velocities with different propagation and polarisation directions, subscripts can be used to donate these. For example V_{s-he} denotes a vertically propagating, horizontally polarised shear wave velocity such as would be measured in a downhole or SCPTU test. Similarly V_{s-hv} or V_{s-hh} would be measured in cross-hole testing.


Figure 1. Anisotropy of shear wave velocity for August (saline area) research site in Italy. Data replotted from Lo Presti et al. (1998) and Cavallaro (2020).

An example for the well-researched Italian clay site at Augusta (saline area) is shown on Figure 1. The materials below 15 m comprise a medium stiff, overconsolidated (overconsolidation ratio, OCR = 2 to 6) Pleistocene marine clay with low to medium plasticity (Lo Presti et al., 1998). V_{s-vh} values from seismic dilatometer (SDMT) and downhole testing are very similar but they are some 100 m/s less than the cross-hole V_{s-hv} values.

For simplicity in this paper the SCPTU measurement will be denoted as V_s unless otherwise stated.

3 SCPTU MEASUREMENT TECHNIQUE

3.1 *Traditional approach*

The SCPTU was first introduced in 1984 at the University of British Columbia, see Rice (1984), Campanella et al. (1986) and Robertson et al. (1986). Some schematics to illustrate the test set-up are shown on Figure 2.
Figure 2. Set-up for CPTU test (a) typical test arrangement (Powell, 2005), (b) details of cone (Mayne, 2000) and (c) schematic for V_s determination (Butcher et al., 2005).

Ideally the test should be carried out according to ASTM (2019) or ISO (2014). Some detailed guidance for the execution of the test is given by Butcher et al. (2005). A standard cone penetrometer is

equipped with one to three horizontally aligned seismic sensors. Originally one sensor was used but most modern equipment has two sets of sensors comprising three component geophones. Butcher and Powell (1996) discuss some problems associated with a single sensor SCPTU. Some commercial companies successfully use equipment with one accelerometer instead of a geophone.

Recordings are made during a pause in the cone penetration typically every 0.5 m. The seismic signals are generated by striking a horizontal beam which is coupled to the ground, usually by the weight of the testing vehicle. Hammers of mass about 10 kg are typically used. The beam should be aligned parallel to the axis of the receivers. Assuming straight ray paths V_s is determined by (Figure 2):

$$V_s = \frac{L_2 - L_1}{t_2 - t_1} \qquad (2)$$

where: t_2 and t_1 are the shear wave travel time from source to receiver

Several methods exist for picking the shear wave arrival time such as manually picking the first arrival time, the first major cross-over method or by use of cross correlation. In a dual array seismic cone, the wave traces from each of the two sensors can be used to get the "true interval" travel time between the sensors. Many authors (Lunne et al., 1997b) have stressed the advantage of the "true interval" set-up stating that it gives more accurate results than the "pseudo interval" method where only one sensor is used. A particular advantage is the same source signal, rather than two successive blows, is used in the calculations.

Similar techniques are used in offshore SCPTU testing, see for example Peuchen et al. (2002), Looijien et al. (2017) or Lunne et al. (2013) with the signal being produced by different techniques such as using a seismic cap (Campanella et al., 1986), hydraulic underwater shear wave box (de Lange et al., 1990) or underwater hammers (Paoletti et al., 2013) or the twin hammers of the PROD system (Nguyen et al., 2015).

3.2 SDMT

The seismic dilatometer (SDMT) is the combination of the standard flat dilatometer (DMT) with a similar seismic module for measuring V_s as employed in the SCPTU (Marchetti et al., 2008, Marchetti, 2015). The SDMT employs two geophones spaced 0.5 m apart and therefore allows a more accurate "true-interval" two-receiver test configuration.

3.3 Recent developments in techniques

Typically modern dual sensors are spaced at between 0.5 m and 1.0 m. The system used by the Norwegian Public Roads Administration allows the

sensors to be set at either 0.5 m or 1.0 m (Valsson et al., 2020).

Typically V_s measurements are made at 0.5 to 1 m intervals, the latter often corresponding to rod breaks. Although the process is more time consuming and expensive, McGillivray and Mayne (2004), (McGillivray and Mayne, 2008), Mayne (2005b) and others advocate the use of frequent interval SCPTU (or SDMT) with measurements taken every 0.2 m. An example of such a set of readings compared to conventional single sensor measurements from the famous Treporti test embankment, Venice are shown on Figure 3 (McGillivray and Mayne, 2004). The site is underlain by a complex mixture of silts, sands and clays (Simonini et al., 2007). These data clearly demonstrates that enhanced depth resolution can be achieved with this technique.

Mayne and McGillivray (2008), McGillivray and Mayne (2008), Ku and Mayne (2012), Ku et al. (2013a) and Ku et al. (2013b) introduce the devel-opment of continuous interval seismic piezocone testing (CiSCPTU). Here V_s is measured at continuously during cone penetration using a specially developed autoseis source. The system employs an electro-mechanical auto hammer to deliver impact type seismic waves that are continuously recorded while the device is penetrating. As well as producing a detailed V_s profile, the significant advantage of this system is that there is no halting in penetration during the SCPTU procedure and therefore no effect on the resulting q_t, f_s, and u_2 readings.

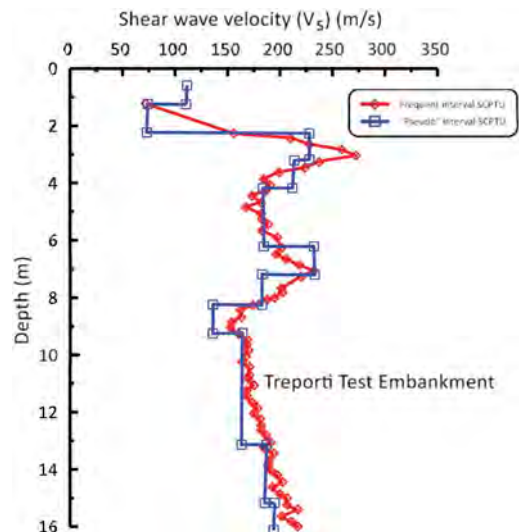
Examples from this system are also given by Agaiby et al. (2016) and Mayne and Woeller (2015).


Figure 3. Frequent interval and "pseudo" interval SCPTU from Treporti test embankment (McGillivray and Mayne, 2008).

3.4 *Uncertainties in measurements*

In engineering practice it is often commonplace to provide a single V_s profile versus depth for a specific location to the design engineer with no description of the uncertainty involved (Stolte and Cox, 2020). There are two types of uncertainty associated with SCPTU measurements, aleatory variability and epistemic uncertainty (Hallal and Cox, 2019).

Aleatory variability is connected to spatial variability of the ground across the site area and can be dealt with by performing multiple tests across a site with perhaps the "gaps" in the data infilled by another geophysical technique such as electrical resis-tivity tomography (ERT).

An epistemic uncertainty refers to the deficiencies by lack of knowledge or uncertainty. Some epistemic uncertainties associated with dual-receiver SCPTU testing are as follows (Peuchen et al., 2020, Stolte and Cox, 2020, Styler and Weemees, 2016, Parasie et al., 2022):

○ choice of signal source,
○ uncertainties related to timing,
○ lateral source offset distance,
○ choice of testing interval,
○ vertical depth control,
○ assumption of isotropic ground conditions,
○ assumption of straight-line ray path of the signal,
○ identification of signal arrival time,
○ external noise (expressed as signal to noise ratio.SNR),
○ near field effects especially at shallow depths (< 5m) e.g. from surface waves or acoustic reflections,
○ conversion of signal arrival time to shear wave velocity,
○ wave interference due to presence of rods/penetrometer.

In offshore SCPT testing some additional uncertainties could be considered (Peuchen and Gomez Meyer, 2021) such as:

○ sea wave interference effects,
○ influence of the physical seabed frame used to support the measuring devices (particularly over the top 5 m of a profile),
○ ambient noise.

With respect to the lateral distance between the source and the receiver it would seem that if the distance is too great the wave form may be closer to that of V_{s-hh} rather than the conventional V_{s-vh} (Personal communication P.W. Mayne). ASTM (2019) suggests the lateral source offset should be in the range 1 m to 6 m. Hallal and Cox (2019) suggest that this distance is limited to a maximum of 1.5 m.

Hallal and Cox (2019) suggest that ideally the testing interval should be less than 1 m and that issues with data reduction may occur of there is a stiff layer close to the ground surface.

The length of the wave path between the source and receiver is often assumed to be a straight line (ASTM, 2019). Alternatively the refracted wave path method has been proposed (Joh and Mok, 1998, Kim et al., 2004). This technique is based on refraction caused by stiffness differences between layers. Bang et al. (2014) propose an improvement on this system which they term the mean refracted wave path method.

Much work has been done on assessing different ways of obtaining shear wave travel times and converting these data into shear wave velocity profiles, see for example Baziw (1993), Baziw (2002) Pidlisecky and Haines (2011), Stolte and Cox (2020) or Valsson et al. (2020).

In engineering practice, for example in seismic response analyses, upper and lower bound estimates of V_s versus depth are often used to account for epistemic uncertainty (Stolte and Cox, 2020). However this approach has recently been criticised especially where uncertainty in V_s is assumed to be depth independent (Teague and Cox, 2016). Several researchers, e.g. Garofalo et al. (2016) have shown that V_s uncertainty is more pronounced nearer to the surface than with depth.

Stolte and Cox (2020) provide a suggested means of quantifying the epistemic uncertainty by involv-ing various wave travel time and velocity analysis methods. These authors also state that, although the conventional single V_s profile may be sufficient for design engineers, any site report should clearly state the assumptions that were made and should report on how the wave travel time was obtained and the report should detail the actual results so the engineer can check the resulting V_s values.

Parasie et al. (2022) suggest a technique for estimating an "uncertainty budget" for V_s/G_{max} based on an inventory of items similar to those listed above. They give an example of two cases for SCP-TU testing in overconsolidated clay and dense sand and determine that the uncertainty budget in both cases is reasonable.

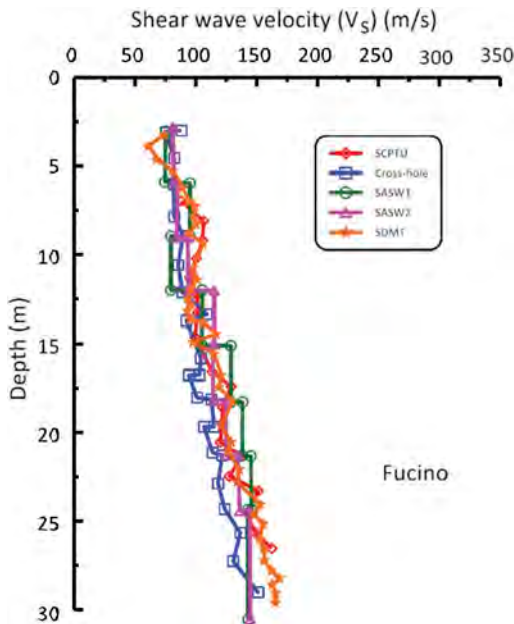
To end this section on a positive note it has been found that, despite the uncertainties discussed above, there have been many published accounts of V_s measurements where different systems were used by different operators but returned very similar output. This is particularly the case for sites which are un-derlain by relatively homogenous, isotropic materials. More care needs to be taken in interpreting data form non-homogenous or layered or highly aniso-tropic soils. The example shown on Figure 4 for the well characterised Fucino site in Italy. The site is underlain by a thick deposit of soft cemented clay (Soccodato, 2003).


Figure 4. V_s profiles for Fucino site, Italy. Data from Burghignoli et al. (1991), Foti et al. (2006) and Soccodato (2003).

V_s measurements by SCPTU, SDMT, cross-hole and SASW (spectral analysis of surface waves) all give similar results, certainly for the purposes of an engineering type analysis.

Table 1. V_s values for clay soil classification.

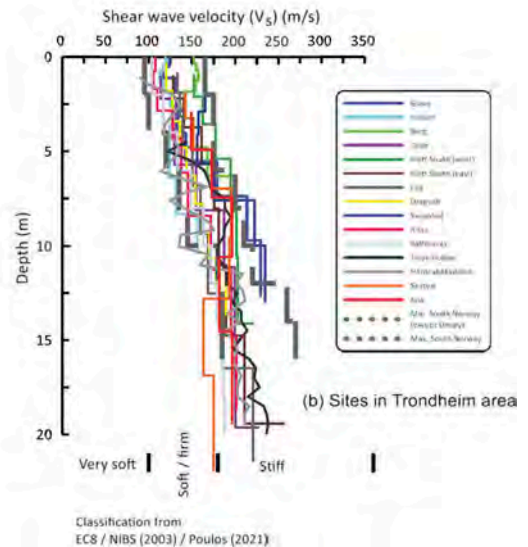
Material	NIBS/EN	Poulos (2021)
	V_s (m/s)	V_s (m/s)
Very soft clay	< 100	85 - 105
Soft clay	{100 to	106 - 135
Medium stiff clay	180}	136 - 185
Stiff clay	180 - 360	186 - 275
Very stiff clay	360 - 800	276 - 365

4 SHEAR WAVE VELOCITY VALUES

Before looking at V_s profiles from various countries in detail it is worth considering the possible meaning/classification of numerical V_s values. For seismic assessments the average V_s over the top 30 m of a site (V_s,30) is often considered.

Both the US (NIBS, 2003) and European (EN, 2004) guidelines quote the same range of V_s values for site classification as summarised on Table 1.

Recently for general engineering classification Poulos (2021) suggested the range of values for site classification also given on Table 1.

The range of values and their allotted meaning is very similar in both cases. For the purposes of this paper an upper bound V_s value for stiff to very stiff clays of 350 m/s will be considered, and all plots will be drawn where possible with this as the maximum value on the x-axis. Similarly the value V_s = 100 m/s will be considered


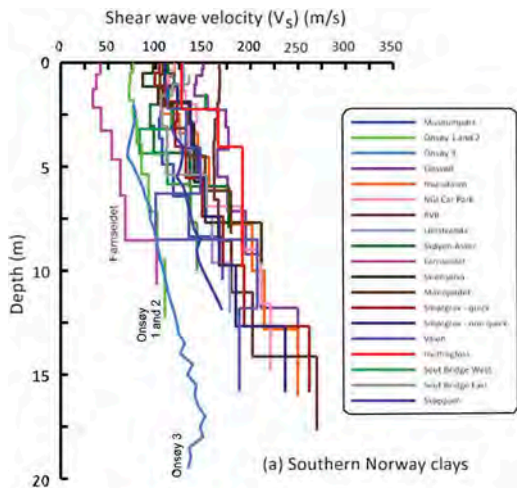


Figure 5. V_s values for Norwegian clays (a) south Norway clays and (b) clays from Trondheim area. Data from L'Heureux and Long (2017) with additional data from Paniagua et al. (2017), L'Heureux et al. (2019) and Dahl and Haugen (2022).

as the upper bound for very soft clays for illustration purposes.

These values need to be treated with caution and can be misleading as will be described later.

5 TYPICAL VS PROFILES FOR CLAYS

5.1 Norwegian clays

A summary of all the available V_s data for Norwegian clays is given on Figure 5, with sites from South-East Norway shown on Figure 5a and those from Mid-Norway/Trondheim area on Figure 5b. The data is mostly taken from L'Heureux and Long (2017) with some additional data as indicted.

Some of the data was obtained using the MASW method (multichannel analysis surface waves) tech-nique. As has been shown in the above paper and elsewhere, the results do not seem to be affected by the technique used or the directions of propagation and polarisation of the waves. This is likely to be due to the largely iso-tropic nature of these materials.

All the Southern Norway sites show a very similar trend between V_s and depth and differ only in the value of V_s close to the surface. Teachavorasinskun and Lukkunaprasit (2004) found a similar pattern for soft Bangkok clay and they expressed the relationship in the form:

$$V_{sz} = V_{sg} + mz \qquad (3)$$

where:
$V_{sz} = V_s$ at any depth z (m/s)
$V_{sg} = V_s$ close to the ground surface (m/s)
m = slope of the line of V_s versus depth (units m/s.m)

Some exceptions are the very soft, high water content and organic, clays at Onsøy and especially Farriseidet which show much lower values of V_s. In general the values increase from about 125 m/s near the surface to 225 m/s at 20 m depth classifying the materials as soft becoming medium stiff to stiff with depth (Table 1) consistent with other measurements on the soils. For example anisotropically consoli-dated undrained triaxial compression (CAUC) tests on the clay from the NGTS (Norwegian GeoTest Site) at Tiller-Flotten show undrained shear strength (su) values increasing from about 25 kPa near the surface to about 115 kPa at 20 m depth (L'Heureux et al., 2019).

Data for the Trondheim and Mid-Norway sites show similar values to those from Southern Norway.

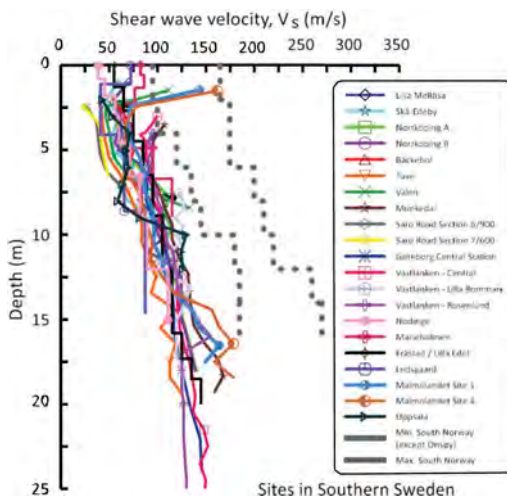
The data fits in a very tight band within the limits for the Southern Norway clays. The fact that the soils have similar values is not surprising given the similar depositional and stress history and mineral-ogy of the sediments.


Figure 6. V_s values for Swedish clays. Data from Long et al. (2017) with additional data from Kania et al. (2000), (Dannewitz et al., 2005), Comina et al. (2017) and Gran-skär (2018).

5.2 Southern Swedish clays

A summary of all the available data from southern Sweden is shown on Figure 6. These data are taken from Long et al. (2017) augmented with additional data as shown.

The data are in general very similar and fall into a relatively narrow band with V_s values typically increasing from 50 m/s at the surface to about 125 m/s at 20 m depth. A similar pat-tern to the Norwegian data can be seen with the values gradually increasing with depth. However the measured values are significantly less than those from Norway. Also the slope of the Swed-ish profiles with depth are not as steep as those of the Norwegian sites. These lower values are compatible with the higher water content, greater organic content and lower unit weight and lower silt content of the Swedish clays compared to the Norwegian sediments as will be explored later.

The range of V_s values encountered suggest that the materials are very soft becoming soft to firm (Table 1), again consistent with the results of other testing.

5.3 Clays from Finland

Only limited data is available for V_s profiles from sites in Finland. SCPTU data has been published for the soft clay sites at Perniö, Lempäälä and Masku from southern Finland These are shown on Figure 7. Two profiles from each site are shown and in general they are very similar.

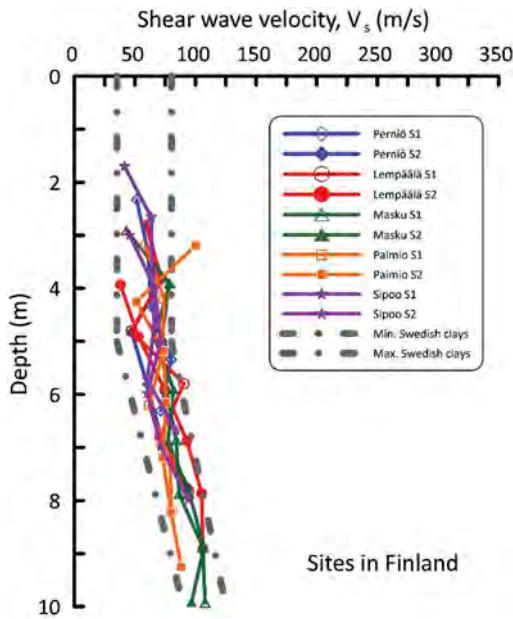
The profiles shown on Figure 7 are compared to the range of values for Swedish clays from


Figure 7. V_s values for Finnish clays (Di Buò et al., 2016, Di Buò et al., 2018, Di Buò et al., 2019).

Figure 6. Overall the range of values measured for the sites in Finland are very like those from Sweden and fall within the range of values measured for the Swedish clays. One possible reason leading to consistent V_s versus depth profiles is to be found in the similarities between the basic clay properties (water content, bulk density and plasticity) (Long and D'Ignazio, 2020).

5.4 *Eastern Canadian clays*

A compilation of some Eastern Canadian data is shown on Figure 8. Note the geology of the Eastern Canadian area is complex and a more detailed discussion of SCPTU data in this area has recently been published by (Salsabili et al., 2022). The profiles chosen here correspond to well-known geotechnical research sites.

Many of the profiles fall within the bounds of the southern Sweden sites. An exception is the profile from the Quyon Landslide site and perhaps the City of Ottawa data.

5.5 *Peats*

Trafford and Long (2020) developed a small lightweight probe for measuring the shear wave velocity in peat. The motivation was to allow testing on site where it would not be easy to gain access with traditional SCPTU equipment.
Figure 8. V_s profiles for Eastern Canadian sensitive clays Data from Bouchard et al. (2017), Lefebvre et al. (1994), Leroueil et al. (2003), Mayne et al. (2019), Fabien-Ouellet etal. (2014), Elbeggo et al. (2021) and Agaiby (2018).

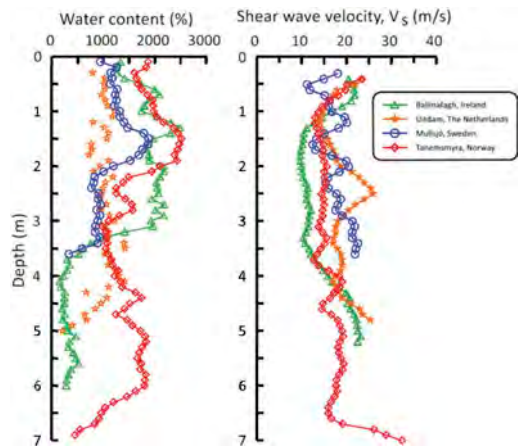
The device is very similar to the "pseudo interval" SCPTU described above. V_s measurements, together with parallel water content measurements, for four peat sites in four different countries are show on Figure 9. Water content values are often in the range 1000% to 2000%. Not surprisingly the V_s values are very low, typically 15 m/s. There seems to be a clear trend of lower V_s corresponding to the highest water content.


Figure 9. Water content and V_s profiles for four peat sies from four countries (x-axis ranged changed from earlier figures).

5.6 *London clay*

Perhaps most well characterised stiff clay in the world is London Clay (Hight et al., 2003). Some profiles for V_s-vh from SCPTU and other testing in London Clay are shown on Figure 10. Due to the stiffness of the clay and the presence of stiff "clay- stone" bands the tests often need to be terminated at relatively shallow depths. The SCPTU data for the Bradwell B nuclear power station, measured by In Situ Site Investigations Ltd., and reported by LessiCheimariou et al. (2019) are particularly interesting as the tests were able to penetrate to the base of the London clay due to use of a technique of continuing the tests in grouted up boreholes once the original tests were terminated.

On Figure 10 the V_s profiles for soft to medium stiff southern Norwegian clays and stiff to very stiff London clay. Intuitively one would expect the London clay V_s values to be much higher than those of the Norwegian soils. However, as can be seen, the range of values recorded are more or less identical.

The reason for the low values in the London clay is likely to be linked to the fissured nature of these soils (Hight et al., 2003) and due to pure stress ani-sotropy with the horizontal propagating waves pass-ing along layers of higher stiffness (Butcher and Powell, 1996, Piriyakul and Haegeman, 2008).

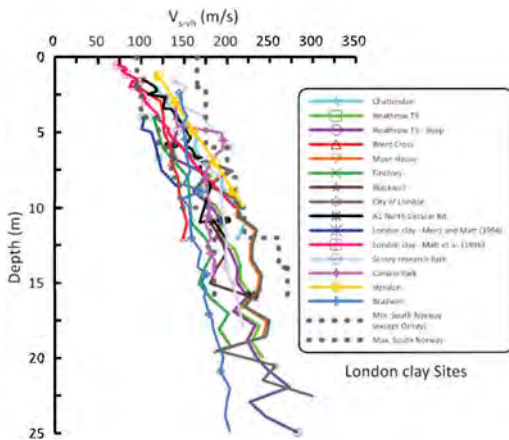
However it is clear that correlations derived for example between V_s and su at one location or for one specific soil type need to be applied only with great caution to another soil type.


Figure 10. Comparison of V_s-vh values for London Clay and range for South Norway clays (L'Heureux and Long, 2017).

London clay data from Powell and Butcher (1991), Butcher and Powell (1995), Gordon et al. (1996), Matthews et al. (1996), Menzies and Matthews (1996), Hight et al. (2003), Hight et al. (2007), Clayton (2011) and Lessi-Cheimariou et al. (2019)

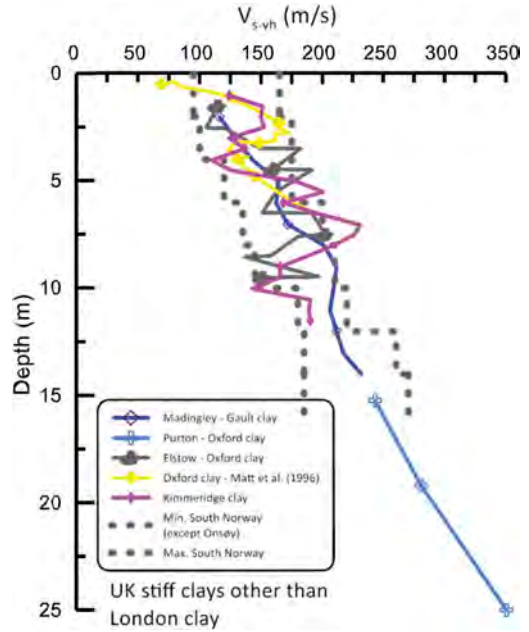
5.7 *Other UK stiff overconsolidated clays*


Figure 11. V_s-vh values for other UK stiff overconsolidated clays (other than London clay). Data from Butcher and Powell (1995), Hosseini-Kamal et al. (2014), Bates and Philips (2000) and Matthews et al. (1996).

Data for UK stiff clays other than London clay are shown on Figure 11. A picture similar to that of London clay emerges with surprisingly low V_s-vh values for these stiff to hard heavily overconsolidated materials. Again the values are similar to those of the South Norway soft to firm clays. Many of these materials have very high V_s-hh values and it is likely that the low V_s-vh values are due to stress anisotropy and possibly also due to fissuring of the materials.

5.8 *Comparison/link between various clay types*

Given the consistence of the V_s profiles for different areas it is worth considering the basic engineering properties of the clays in the attempt to identify the links between the V_s values.

According to Leroueil and Hight (2003) and Hardin (1978) the empirical equation describing the influence of the controlling factors on G_{max} (and V_s) can then be written as follows:

$$G_{max} = SF(e)(\sigma'_v \sigma'_h)^n p_a^{(1-2n)} \qquad (4)$$

where: S is a dimensionless parameter characterising the considered soil; F(e) is a void ratio function; σ_V' and σ_h' are the vertical and horizontal effective stresses respectively; n is a parameter indicating the influence of stress; and pa is atmospheric pressure.

Table 2. Summary of material properties for selected study sites. w = water content, Ip = plasticity index, Org. = organic content OCR = overconsolidation ratio, St = fall cone sensitivity. Main references Gundersen et al. (2019), L'Heureux et al. (2019), Wood (2016), Di Buò et al. (2019) and Trak et al. (1980).

Site	w (%)	Clay (%)	Ip (%)	Org. (%)	OCR	St
Onsøy 3	40-80	50-70	25-50	2.5-4	1.1-2.0	5-8
Tiller-Flotten	30-50	45-70	8-20	Very low	1.5-2.0	up to 350
Göteborg CS	60-90	70-90	27-40	2-5	1.5-2.0	12-30
Perniö	80-110	50-90	30-40	1-2	1.5-2.0	40-60
St. Alban	60-90	45-81	5-30	0.9	2.2	14-22
Peat	1000-2000	Very low	n/a	90-100	Very low	n/a

A summary of the key properties of the clays from well characterized test sites in Norway, Sweden, Canada and Finland are given on Table 2, together with some typical properties of peat. Two sites from Norway were chosen namely the NGTSsites at Onsøy and Tiller-Flotten.

The Tiller-Flotten site is characteristic of many Norwegian clays and is significantly different from the other sites under study. These Norwegian sites have relatively lower water content and plasticity and higher density (1.7 – 1.9 Mg/m3 compared to 1.6 – 1.7 Mg/m3) than the Canadian, Finnish and Swedish sites.
Figure 12. Coefficients $V_s g$ and m (Equation 3) as a function of water content and unit weight for sites in Norway and Sweden.

Also Tiller-Flotten has very low organic content compared to the other sites. The Onsøy site parameters are much closer to those of the Swedish, Finnish and Canadian sites. All sites under consideration have similar clay content and stress history.

In order to explore this further, the coefficients $V_s g$ and m in Equation 3 are plotted against average water content (w) and unit weight (γ) for each site (over the interval where V_s data is available) on Figure 12 (L'Heureux and Long, 2017, Long et al., 2017). It can be seen that both parameters decrease with increasing w and increase with increasing (γ) as would be expected. The trend between the parameters is reasonably good and these relationships could therefore be used for first order estimates of V_s or for controlling site measurements.

6 USE OF V_S IN SOIL BEHAVIOUR TYPE CHARTS

Robertson (1990) introduced the well-known soil behaviour charts based on normalised cone resistance (Qt), normalised sleeve friction (Fr) and the pore pressure parameter (Bq)

$$Q_t = \frac{q_t - \sigma_{v0}}{\sigma_{v0}'} \quad (5)$$

$$F_r = \frac{f_s}{q_t - \sigma_{v0}} \quad (6)$$

$$B_q = \frac{u_2 - u_0}{q_t - \sigma_{v0}} \quad (7)$$

where:
q_t = corrected cone end resistance
fs = sleeve friction
u_2 = pore pressure measured behind cone
u_0 = ambient pore pressure
σ_{v0}/σ_{v0}' = total/effective initial vertical stress

Later Robertson et al. (1995) proposed a complementary SCPTU soil behaviour chart based on Qt and normalised small strain shear modulus (G_{max}/qt). This chart was intended mostly for identifying "unusual" soils such as highly compressible sands, cemented and aged soils and clays with either high or low void ratio.

Robertson (2015) suggested that $I_G = G_{max}/q_t$ can be considered to be a small strain rigidly index as it relates small strain stiffness to a measure of soil strength. He proposed a new chart relating Q_{tn} to I_G which could be used to identify soils with microstructure such as cementation/bonding or aging. Note Qtn is an update to Q_t using a variable stress exponent (Robertson, 2009).
Figure 13. Contours of normalised shear wave velocity superimposed on the normalized Qtn - Fr soil behavior type chart (Robertson, 2009).

Figure 14. $V_s n$ versus $\Delta u/\sigma_{v0}'$ for some Norwegian and UK soft clays. Adapted from Long and Donohue (2010).

Based on 20 years' experience of SCPTU tests in California combined with results from the literature Robertson (2009) also developed a series of contours of normalised shear wave velocity (V_{sn}) and superimposed these on a base of the $Q_{tn} – F_r$ chart as shown on Figure 13. The soils involved were mostly of Holocene age unbonded silica-based soils which tended to plot in the central part of the chart. Some older Pleistocene age soils plot toward the upper right-hand part.

$$V_{sn} = \frac{V_s}{\left(\frac{\sigma_{vo}'}{p_a}\right)^n} \qquad (8)$$

Robertson (2009) and others have chosen the exponent n in Equation 8 = 0.25 and have used the expression $V_s 1$ for V_{sn}. Ku and Mayne (2013) and Moon and Ku (2016a) and others have pointed out that n = 0.25 is based on limited laboratory data on clean quartz and silica sands and suggested n is chosen on site or area specific conditions.

Several authors have suggested that the CPTU u2 measurement is perhaps the most reliable of the normal three sets of data collected (Lunne et al., 2018). Therefore, as V_s is also relatively easy to measure reliably in isotropic material, it seems logical to attempt to develop a characterisation chart based on these two data sets.

On Figure 14 V_{sn} data are plotted against $\Delta u/\sigma_{v0}'(=u_2-u_0/\sigma_{v0}')$ for some Norwegian and UK soft soils.

Here n was chosen to be = 0.5. A tentative division can be made between the lightly overconsolidated material (OCR < 2) and the moderately overconsolidated soils (OCR >3).

Although there appears to be some promise in the use of the charts shown on Figure 13 and 14 and other similar charts, it is felt that some more work, and some more data, is needed to bring these into civil engineering practice.

It is also stressed that these charts are designed to complement the more well-known CPTU soil behaviour charts and not to replace them.

7 CORRELATION BETWEEN V_S AND OTHER SCPTU MEASURMENTS

Various researchers have studied relationships between CPTU parameters and V_s in clayey soils. These studies have explored relationships between in situ V_s and various parameters such as CPTU tip resistance (q_c), corrected tip resistance (q_t), cone net resistance (q_{net}), sleeve friction (f_s), pore pressure parameter (B_q), effective stress (σ_v'), water content (w) and void ratio (e).

Many empirical relationships between V_s and these CPTU parameters have been published. For example L'Heureux and Long (2017) summarise 21 such relationships for clayey soils. Since the publication of the 2017 paper the author is aware of at least ten further newly developed relationships. These include those by Holmsgaard et al. (2016) for silty soils in Denmark, Shahri and Naderi (2016) for clay soils in south-west Sweden, Zhang and Tong (2017), Zou et al. (2017), Tong et al. (2018) and Duan et al. (2019a) all for Jiangsu clays in China, McGann et al. (2015) for silty soils in Christchurch.

New Zealand and Salsabili et al. (2022) for post-glacial sediments in Southern Québec. In addition Ahmed (2017) and Karray and Hussien (2017) derived generalised relationship for a variety of soils.

Robertson (2015) suggests that even though qt and V_s are controlled by the same factors there is no unique correlation between q_t and V_s. However it should be possible to obtain a reasonable relationship if the database used is limited to soils of similar mineralogy, stress history, age and cementation.

An example from the Skatval site in Mid-Norway is shown on Figure 15 (Paniagua et al., 2017). Data from this site was not included in the original Norwegian clay database of L'Heureux and Long (2017). However the correlation developed by these authors, as follows on Equation 9, fits very well with the measured data for this new site.

$$V_s = 8.35(q_{net})^{0.22}(\sigma_{v0}')^{0.357} \qquad (9)$$

In contrast the relationship developed for Southern Swedish clays by Shahri and Naderi (2016), given in Equation 10, significantly underestimates the measured V_s values

$$Vs = 3.839(q_t)^{0.5151}(1+B_q)^{0.174} \qquad (10)$$

The message here is that very good correlations can be developed between CPTU parameters and V_s but these should be used locally and they should only be used with great care for soil types other than those for which they were intended.
Figure 16. (a) Sherbrooke block sampler and (b) mini-block sampler. Image from (Emdal et al., 2016).

8 CORRELATION BETWEEN V_S AND SOIL PROPERTIES

8.1 General

Much work has been done in the past in correlating V_s with various soil properties derived from laboratory testing. An important consideration is that, for the correlation to be reliable, the quality of the soil samples must be very high. To that end in this paper soil samples extracted by high quality samplers such as the Sherbrooke block (Lefebvre and Poulin, 1979), the mini-block sampler (Emdal et al., 2016) (Figure 16) or the Laval sampler (La Rochelle et al., 1981) only are used.

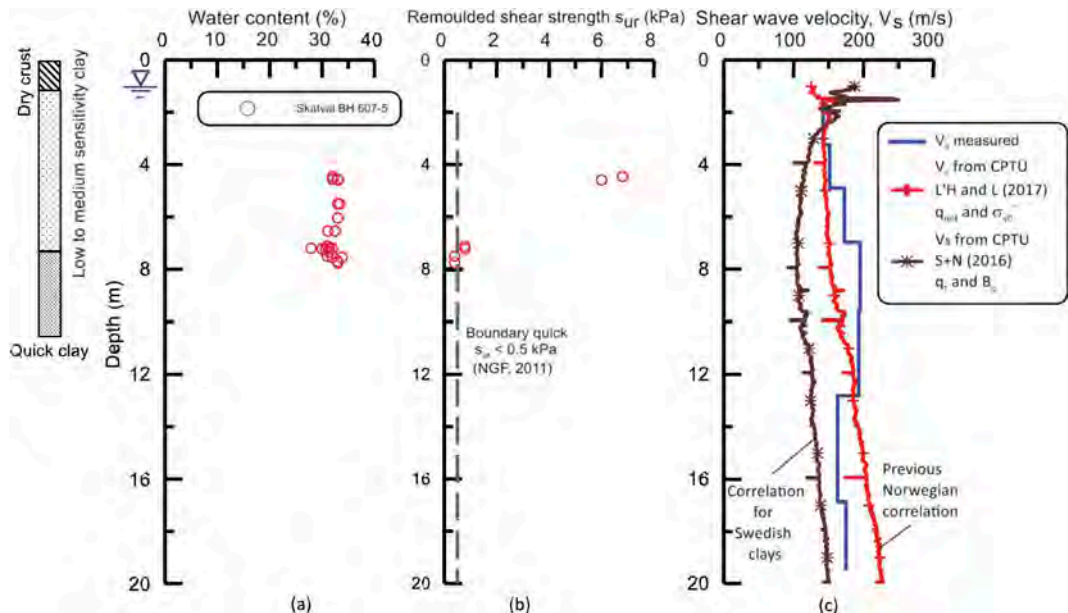
It is also important that the laboratory tests and the derivation of the resulting parameters is carried out in a consistent manner.


Figure 15. Skatval site Norway – predicted and measured V_s.
Figure 17. Unit weight versus V_s for Norwegian clays. Data from L'Heureux and Long (2017).

8.2 Unit weight from V_s

An important relationship between geophysical parameters and soil index parameters is that between V_s and unit weight (γ). Various authors such as Mayne (2007) and Moon and Ku (2016a) have developed relationships between V_s and γ using a world-wide database of soil tests. They have shown how the resulting relationship will depend amongst other factors on soil type, in situ stress and plasticity.

Different equations are suggested for different soil types and the fit between the measured and predicted data can be improved by normalisation of V_s or by introduction of additional parameters such as the plasticity index (Ip) into the relationships. Although these relationships are very useful it is perhaps more worthwhile to develop local correlations. An example of such a correlation for Norwegian clays is shown in Figure 17.

8.3 Undrained shear strength from V_s

Similar to V_s-CPTU relationships much work has been done on deriving empirical relationships between V_s and undrained shear strength su. L'Heureux and Long (2017) summarise 16 such relationships. Since the publication of the 2017 paper the author is aware of at least four other publications on the topic by Powell et al. (2016), Moon and Ku (2016b), Duan et al. (2019a) and Duan et al. (2019b).

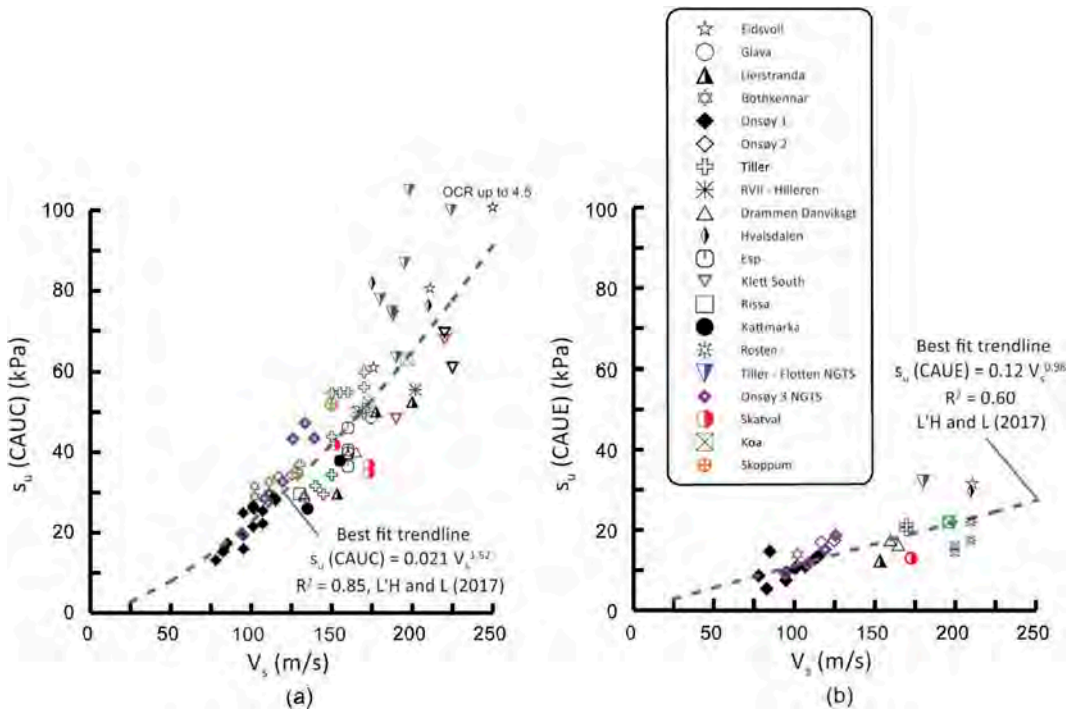
Undrained shear strength has no unique value but depends on the age of the sample, test type, rate of loading and other factors. Therefore comparisons can only be made on results of tests carried out on exactly the same manner.


Figure 18. Norwegian clay relationship between su and V_s for (a) CAUC tests and (b) CAUE tests. Original 2017 data from L'Heureux and Long (2017) is in black and white font. Recent data is in colour font. Recent data is from Gundersen et al. (2019), L'Heureux et al. (2019), Paniagua et al. (2017) and Dahl and Haugen (2022).

39
Figure 19. Norwegian clay relationship between s_u and V_s for DSS tests. Original 2017 data from L'Heureux and Long (2017) is in black and white font. Recent data is in colour font. Recent data is from Gundersen et al. (2019), Long et al. (2019) and Paniagua et al. (2017).

In Norway it is common practice to carry out triaxial testing after the sample has been first consolidated anisotropically to the best estimate of its in situ stress. Shearing can subsequently be by compression (CAUC tests) or by extension (CAUE tests).

The su values obtained from CAUC and CAUE triaxial tests on high quality samples of Norwegian clay are plotted against in situ shear wave velocity in Figure 18a and 18b respectively. A similar set of data for direct simple shear tests (DSS) are shown on Figure 19.

The "best fit" empirical relationship derived in the 2017 study by L'Heureux and Long (2017) is also shown on Figure 18 and 19. The data used in the 2017 study, which was used to derive the empirical relationships, is shown in black and white font. New data available since the 2017 study are shown in colour. It can be seen that in all three cases the new data fit the old relationships very well and it can be concluded that the 2017 relationships still apply.

A similar set of CAUC data but in this case for various world-wide clays is shown on Figure 20. All the samples were of high quality as described above.

In this case the 2017 relationship for Norwegian clays does not work and in fact would underestimate the measured su.

The clear message here is that these V_s-su correlations can be very powerful and useful but they
Figure 20. Relationship between su and V_s for CAUC tests on world-wide clays for testing on high quality samples. Data is from Landon (2007), Tanaka et al. (1998), Tanaka et al. (2001), Di Buò et al. (2019), Lo Presti et al. (2003) and Wood (2016).

should only be used for the test type and materials for which they were originally derived and they should only be applied to other materials/other test types with great caution.
Figure 21. Classical Janbu plot of 1D compression stiffness versus effective stress.

8.4 *Preconsolidation pressure from V_s*

In this and the following sections V_s measurements are compared to the classical 1D compression parameters often used in Scandinavian practice (Janbu, 1963, Janbu, 1969). The classical Janbu plot of 1D compression stiffness against stress is shown
Figure 22. Norwegian clay relationship between pc' and V_s. Original 2017 data from L'Heureux and Long (2017) is in black and white font. Recent data is in colour font. Recent data is from Gundersen et al. (2019), L'Heureux et al. (2019), Paniagua et al. (2017) and Dahl and Haugen (2022).

Figure 23. Swedish clay relationship between pc' and V_s. Data from Wood (2016).

on Figure 21. Janbu (1963) used the resistance concept to interpret one dimensional consolidation in an oedometer test. He defined the tangent modulus (or the constrained modulus), M, as the ratio of the change in stress $(\Delta\sigma')$ to the change in strain $(\Delta\varepsilon)$ for a particular load in increment, i.e.:

$$M = \frac{\Delta\sigma'}{\Delta\varepsilon} \qquad (11)$$

As for su above high quality data preconsolidation stress (pc') for Norwegian clays published by L'Heureux and Long (2017) has been augmented by more recent data (Figure 22). Again, as found for su, the recent data fit the 2017 correlations very well and support the idea that local V_s correlations based on high quality data can be very powerful.

The relationship derived for Norwegian clays is tested against data for high quality samples of Swedish clay on Figure 23. It can be seen that there is a reasonable relationship between the two parameters for Swedish clay but the data falls above the line derived for Norwegian clay.

At the 2017 International Workshop on Landslides in Sensitive Clays (IWLSC) in Trondheim,

Norway, Professor Guy Lefebvre of the University of Sherbrooke suggested to the author that plots similar to that on Figure 22 and Figure 23 could be made more universal by normalising the V_s value by effective stress. This seems a logical suggestion given the clear differences in the basic properties of the two soil types as demonstrated on Table 2.

Data from various countries, where high quality block sample data were available, are shown on Figure 24a. The V_s data were normalised using Equation 8 with a stress exponent n chosen to = 0.5. Var-ious other exponents, including n = 025, were also trailed but no difference in the output was found. Full details of this process are given in a companion paper to this conference by Long and L'Heureux (2022).

The normalisation by effective stress appears to be unsuccessful in unifying the data.

To take the stress history of the materials into account the measured V_s data have been normalised by the preconsolidation stress (pc') on Figure 24b. As can be seen on Figure 24b this form of normalization As for su above high quality data preconsolidation stress (pc') for Norwegian clays published by L'Heureux and Long (2017) has been augmented by more recent data (Figure 22). Again, as found for su, the recent data fit the 2017 correlations very well and support the idea that local V_s correlations based on high quality data can be very powerful. was very successful in harmonising the fifteen sets of data. All fifteen profiles are very similar and show an average $V_s$np value of about 96 m/s. Taking this average $V_s$np value the following equation can be obtained to relate V_s and pc'.

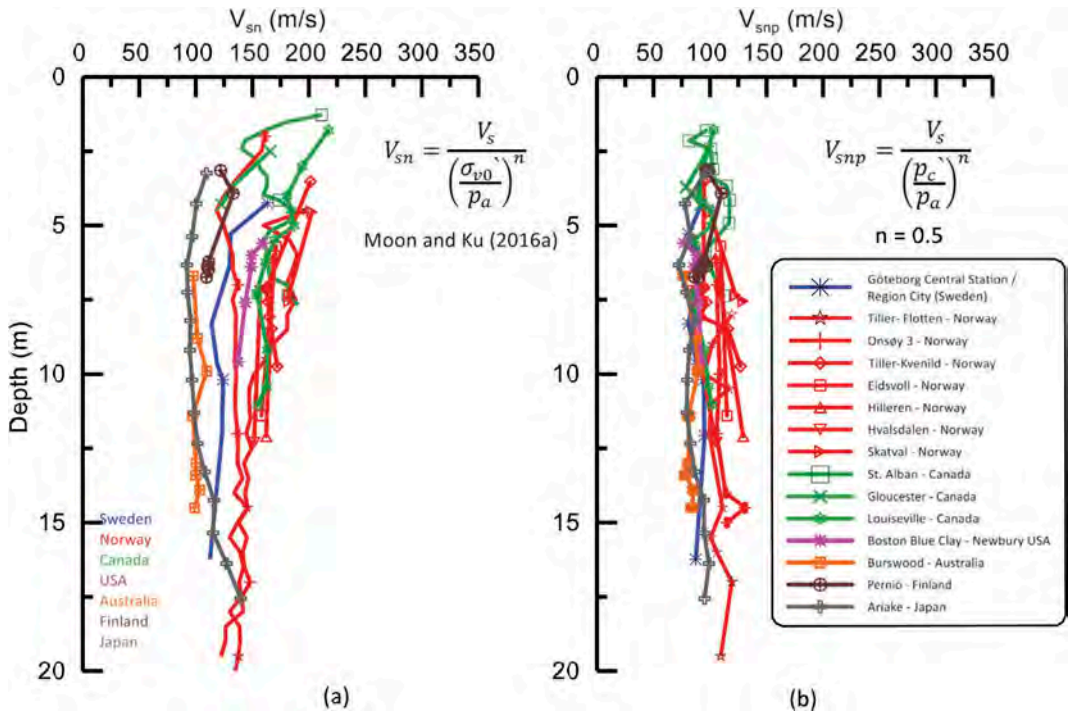
$$p_c` = 0.0108V_s^2 \qquad (12)$$


Figure 24. Normalised V_s profiles (a) by vertical effective stress and (b) preconsolidation stress. Data from Wood (2016), Gundersen et al. (2019), L'Heureux et al. (2019), (L'Heureux and Long, 2017), (Paniagua et al., 2017), Landon (2007), Tanaka et al. (1998), Tanaka et al. (2001) and Di Buò et al. (2019).

$$p_c{'} = 0.106 V_s^{1.47} \qquad (13)$$

$$p_c{'} = 0.00769 V_s^{2.009} \qquad (14)$$

$$p_c{'} = 0.1097 V_s^{1.3575} \qquad (15)$$

Equation 12 is trialed against data for two Italian clays on Figure 25. The mean relationship together with those representing ± 0.5 times the standard deviation are shown. Italian data was not included in the original derivation in Figure 24. The Fucino clay data fits the proposed relationship very well. The fit is reasonable for the complex Pancone clay found beneath Pisa Tower.

Figure 25. Italian clay relationships between pc' and V_s trialed against formulae derived in this paper. Data from Lo Presti et al. (1998), Jamiolkowski and Pepe (2001) and Soccodato (2003).

This form of power equation supports and justifies some previous similar empirical equations that have been developed. These include the general relationship developed by Mayne et al. (1998) as shown on Equation 13, that derived for Norwegian marine clays by L'Heureux and Long (2017) (Equation 14) and by Duan et al. (2019a) for Jiangsu clays in China (Equation 15).

8.5 Other one-dimensional consolidation parameters from V_s

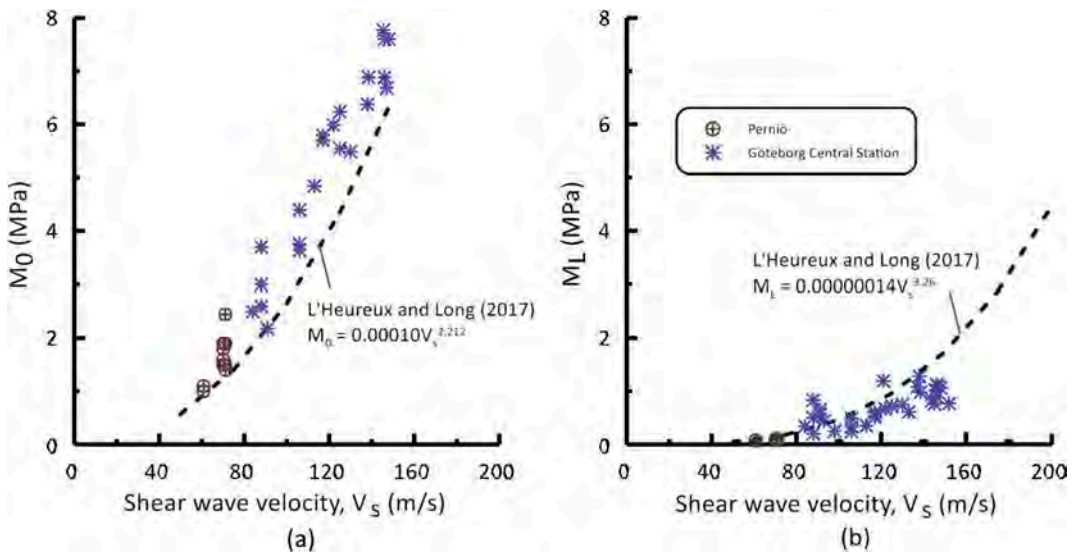
Relationships have also been proposed between V_s and other 1D consolidation parameters, for example M0 and ML (Figure 21). Such data for Perniö clay from Finland and Göteborg Central Station clay from Sweden are compared to relationships for Norwegian clays (L'Heureux and Long, 2017) on Figure 26. In both cases there is a clear relationship between the parameters but the previously published Norwegian clay relationships would underestimate


Figure 26. Relationship between (a) M0 and (b) ML versus V_s for Swedish (Wood, 2016) and Finnish (Di Buò et al., 2019) clays.

and overestimate respectively the values for Finnish and Swedish clays.

9 USE OF V_S FOR SAMPLE DISTURBANCE ASSESSMENT

Various authors have studied the use of shear wave velocity measurements to assess sample disturbance effects. The overall idea is to compare in situ V_s, as measured by SCPTU for example, to V_s measured on soil samples. Some examples of this work, specifically on clay soils, include that of Landon et al. (2007), Ferreira et al. (2011), Ramsey (2020), Gu et al. (2021) and Long et al. (2021). Other authors have used a combination of V_s and suction measurements to assess sample disturbance, e.g. Donohue and Long (2010) and Horng et al. (2010).

Landon et al. (2007) developed a series of criteria for assessing sample disturbance based on the ratio of V_s measured on the sample (in unconfined conditions) to that of the in situ V_s (e.g. from seismic piezocone, SCPTU). However these criteria were based on tests on low sensitivity, relative high water content and high plasticity clays from Onsøy, Norway, Newbury, USA and Burswood, Australia. The specific guidelines and criteria for assessing sample disturbance from this work is summarised on Table 3. They are compared to the well known method of Lunne et al. (1997a) which involves measuring the change in void ratio relative to the initial void ratio ($\Delta e/e_0$) when consolidating a sample back to its in situ stress in the lab.

It is important to note that Landon's criteria were primarily intended to provide a quick technique for assessing sample disturbance and to act as a rapid screening tool for assessing sample disturbance prior to advanced laboratory testing. This is of particular concern in offshore site investigations given the cost of these investigations and the need to maximise data quality. They were not intended to replace the more rigorous techniques.

Table 3. Sample quality designation (SQD) from Landon et al. (2007) and (Lunne et al., 1997a).

SQD	Lunne et al. with OCR 1-2 $\Delta e/e_0$	Lunne et al. with OCR 2-4 $\Delta e/e_0$	Sample quality (SQ)
SQ1	0.6	< 0.04	< 0.03	Very good/ excellent
SQ2	0.6	0.04-0.07	0.03-0.05	Good to fair
SQ3	0.35–0.6	0.07-0.14	0.05-0.10	Poor
SQ4	< 0.35	> 0.14	> 0.10	Very poor

The sample disturbance assessment criteria of Landon et al. (2007) are tested against recently derived data from three Norwegian sites on Figure 27. The data are plotted in the form of $V_s,0/V_s$,insitu against $\Delta e/e_0$ obtained from CAUC or CAUE tests or CRS tests on Figures 27a and 27b. The sample shear wave velocity was measured using bender el-ments at zero confining stress ($V_s,0$).

For both plots it can be seen that although the data under study here is classified as either SQ1 or
Figure 27. Comparison of shear wave velocity ratio and normalised void ratio for (a) CAUC and CAUE tests and (b) CRS tests. Data from Landon (2007), L'Heureux et al. (2019), Paniagua et al. (2017) and Long et al. (2021).

SQ2 by the criteria of Lunne et al. (1997a) consistent with the observations of the stress – strain and stress path plots, it falls well below that of the data of Landon (2007) and would be classified as "poor" according to the latter criteria.

The clays at Tiller-Flotten, Skatval and Koa differ significantly from those studies by Landon (Table 2). These clays have lower water content, lower plasticity and higher sensitivity compared to Landon's clays.

Valsson et al. (2020) and Dahl and Haugen (2022) carried out similar studies on low sensitivity but high plasticity Onsøy clay and low plasticity sensitive clay from Skoppum. Their results are not directly comparable with those presented here as the bender elementtests were carried out after the samles had been consolidated to the best estimate of the-in situ stress. Nonetheless their conclusion were similar

to those found here in that the low plasticity clay from Skoppum showed a significant discrepancy between the field and laboratory tests whereas the results for Onsøy were similar for both techniques.

It is concluded that the criteria Landon et al. (2007) are too of strict for the materials under study here. It is suggested that a lower $V_s,0/V_s$,insitu limit of 0.35 (compared to 0.6) might be more appropriate for low plasticity sensitive clays considered here. However insufficient data exits here to give a definitive recommendation.

10   USE OF V_S FOR SETTLEMENT PREDICTION

Several researchers have used V_s measurements for the purpose of estimating settlement of foundations. The technique has mostly been used for foundations in sandy soils, e.g. Lehane et al. (2008) but has also been used in soft clay Mayne (2000) and Omar et al. (2011) and soft clayey silt (Mayne, 2005a). Small strain shear modulus (G_{max}) can be calculated directly from V_s (Equation 1). For the ground beneath foundations the strains will be larger and therefore the G_{max} value needs to be adjusted downwards to be compatible with the actual strains encountered.

Perhaps the most common technique for this purpose is the use of the hyperbolic stiffness degradation formula suggested by Fahey and Carter (1993) as follows

$$\frac{G}{G_{max}} = 1 - f\left(\frac{\tau}{\tau_{max}}\right)^g \qquad (16)$$

where τ and τ_{max} are the applied shear stress and shear strength respectively and f and g are fitting parameters. The ratio τ/τ_{max} is analagous to the inverse of factor of safety. Values of f = 1 and g = 0.3 appear to give reasonable estimates for unstructured and uncemented geomaterials and provide a general fit to experimental data (Mayne et al., 2009).
Figure 28. Prediction of settlement of footing on soft silt using V_s (Mayne, 2005a).

Some details for the Class "A" footing response prediction on a trial structure founded on soft silt (known locally as "sleech") in Belfast, Northern Ireland are shown in Figure 28. Mayne (2005a) used the measured V_s values (Lehane, 2003) and the stiffness degradation formula describe in Equation 16 above to obtain a Class "A" estimate of the footing settlment. It can be seen that the predicted and measured data are in good agreement, especially to an applied stress of about 80 kPa, at which point the onset of bearing capacity failure occurs.

11 FUTURE OUTLOOKS AND CHALLENGES TO SOLVE

Despite significant developments in the equipment, data acquisition systems and the cumulative experience gained over the past 35 years since the introduction of the SCPTU some significant challenges remain to be solved. Perhaps of these the most significant are (Personal communication from Nico Parasie, Fugro):

- ○ measurement uncertainty,
- ○ spatial variability/aleatory uncertainty,
- ○ anisotropy.

Issues related to measurement uncertainty have been well researched and are dealt with in Section 3.2 above.

11.1 Spatial variability

Spatial variability issues, in sites with widely varying ground conditions, can only be dealt with by carrying out a relatively large number of tests or by introducing another technique to "fill the gaps" between the SCPTU testing.
Figure 29. 2D stiffness profile for Onsøy 2 site in Norway. Image courtesy of Dr. Shane Donohue, UCD. Note horizonatal and vertical scales the same.

An example of such an approach would be to combine SCPTU with a surface wave technique such as MASW. A 2D stiffness profile for the highly uniform Onsøy 2 site in Norway is shown on Figure 29. This profile was produced by "continuous" MASW where a streamer of geophones mounted on wooden blocks were pulled along and repeated hammer shots were imparted to produce regular seismic signals. The resulting series of 1D profiles were then combined to produce the image.

For offshore investigations a recent development has been to produce images similar to that on Figure 29 using fibre optic/distributed acoustic sensing (DAS) techniques, see for example (Trafford et al., 2021).

Another option is to combine SCPTU with ERT as mentioned above.

11.2 Anisotropy

A significant input in the design of engineering systems such as retaining walls and piles subject to lateral loading is the horizontal ground stiffness. In particular for large monopiles, used for example in offshore wind turbine construction, the behaviour of the system is heavily dependent on the horizontal ground stiffness at small strain. A technique for obtaining such input parameters from SCPTU has been described by McAdam et al. (2020) based on work in the PISA project. Wang et al. (2022) have proposed a simple rotational spring model for the design of laterally loaded rigid piles in sand with V_s as a key input parameter.

Strictly speaking the required input parameter in these cases is V_{s-hh}. Unfortunately SCPTU yields V_{svh}. In unform relatively homogenous softer soils V_{s-hh} and V_{s-vh} have the same values. However for more overconsolidated soils this is not always the case as has been illustrated above for example for UK stiff clays and some Italian clays.
Figure 30. V_{s-hh} versus q_t. Data from Powell and Butcher (2004) and Powell et al. (2016) augmented with additional data from Lo Presti et al. (2003), Jamiolkowski and Pepe (2001), DeGroot and Lutenegger (2003) and Ku and Mayne (2014).

Powell and Butcher (2004) and Powell et al. (2016) have studied the relationship between corrected once resistance (q_t) and the various in situ derived shear moduli G_{vh}, G_{hv} and G_{hh} using a database of high quality tests. These authors found

that qt is most strongly influenced by horizontal stiffness and stress in the ground. They proposed that Ghh or V_s-hh could therefore be obtained from correlation with qt.

The data presented by these authors, augmented by some additional results, are plotted using shear wave velocity rather than shear modulus on Figure 30. It can be seen that the relationship between the two parameters is very good and the resulting "best fit" power function has a good R2 value of 0.87. As previously suggested by Powell et al. (2016), a suggestion for future work is therefore that V_s-vh is obtained from SCPTU and V_s-hh is obtained from the same test by correlation with qt.

12 CONCLUSIONS

The main objective of this paper was to summarise the practical and useful application of V_s measurements from SCPTU testing. The intention is to promote the use of SCPTU testing and to highlight the application of V_s data as a compliment to standard CPTU data in future studies and practical projects. It is not intended that V_s measurements replace standard CPTU data. Some conclusions from this work are as follows:

- V_s is a fundamental measure in all solids. Therefore it is an attractive way of characterising a wide range of geomaterials.
- Use of V_s has gained popularity in recent times due to developments in geophysical testing systems and analytical methods.
- Application of the SCPTU testing technique is well covered in guidelines and codes of practice.
- Some descriptions of the equipment used have been given together with some recent developments in the technique including the frequent interval testing and continuous interval testing.
- Uncertainties in the methods have been well researched and understood and several methods have been proposed in the literature suggesting ways of dealing with these uncertainties.
- Despite these uncertainties V_s measurements seem repeatable in isotropic soil conditions using a variety of techniques and methods.
- V_s profiles for sites in southern Norway, mid Norway, Sweden, Finland, Canada and peat have been presented. These data often fall in tight bands.
- There appears to be clear links between these profiles depending on fundamental soil properties such as water content, density, plasticity and also stress history. This has resulted in tentative soil behaviour type charts involving V_s being proposed. This approach seems promising but further work is required on the development and application of these charts.

- An important exception to this is data for stiff overconsolidated clays, such as the UK stiff clays / London clay. For these soils the V_s-vh values are unexpected low. This is due to the natural stress anisotropy and also partially due to the fissured nature of the materials.
- V_s-CPTU correlations can be very powerful. New data for the same soil type in the same area fit the older correlations very well. However these correlations may not work for other areas. Therefore correlations should ideally be locally developed and only applied to other soils and areas with great caution.
- A similar finding was made for soil properties such as su and M0 where once again strong correlations can be developed but these correlations may not apply to other areas
- An exception might be for correlation between V_s and preconsolidation stress pc' where it seems that high quality data from several areas may fit the same trend.
- SCPTU data can also be used to assess sample disturbance effects by comparing in situ V_s values to measurements made on samples. However it would seem that previously published assessment criteria derived for relatively high plasticity clays may not apply to low plasticity clays.
- V_s has been successfully used to directly predict settlement of footings on clays.
- Some future outlooks include further work on understanding test uncertainties and anisotropy. It is suggested that for future studies V_s-vh could be obtained from SCPTU and V_s-hh by correlation with qt.

Uncertainties associated with CPT data acquisition

R. Soage Santos
Ørsted, London, UK

ABSTRACT: Cone penetration test (CPT) and piezocone penetration test (CPTU) are the dominant in situ testing techniques for soil investigations. CPT/CPTU data is used directly in design or used to derive geotechnical properties for design of infrastructure. Occasionally, acquired CPT/CPTU data exhibit anomalies which can cause uncertainties about use in geotechnical design. Consequently, it is very important to understand, and when possible, minimize the uncertainty associated to CPT/CPTU measurements so these can be considered in planning, design, and installation of infrastructure. The practical challenges associated to the quantification of uncertainty and the difficulties of its standardization are discussed. A comprehensive review of uncertainty contributors associated to CPT/CPTU measurements is provided. This document discusses and proposes a standardization approach that combines performance-based cone classification system based on calibration data, with a method-based approach to control and minimize the uncertainty contributions rising from execution of CPT/CPTU.

1 INTRODUCTION

The cone penetration test and piezocone penetration test (CPT/CPTU) are the most dominant in situ testing technique for soil investigations. CPT/CPTU provide valuable input for safe and economical design of many structures and therefore, assessing the representativeness of the CPT/CPTU results is essential.

This document broadly reviews the challenges related to the assessment of CPT/CPTU results quality. Most often, the CPT provides reliable data with depth, particularly the independent parameters q_c (cone resistance), f_s (sleeve friction), and u_2 (pore pressure). Occasionally, acquired CPT/CPTU data exhibit anomalies which can cause uncertainties about applicability in geotechnical design of offshore structures. Peuchen *et al.* 2020 provides detailed examples of data anomalies and discusses how to avoid them.

CPT/CPTU are among the most fundamental datasets used to define soil layers and infer parameters for safe geotechnical design of infrastructure and is often used directly in design of foundations (for instance pile capacity calculations). Thus, it is very important to understand the quality and therefore the uncertainties associated to CPT/CPTU results that are to be applied in design. The term uncertainty of measurement intends to express the doubt regarding the validity/representativeness of the results. Quantification of uncertainty is very important, because ignoring uncertainty may result in the choice of non-optimal geotechnical design and decision making which could lead to costly and unsafe infrastructure development. Understanding

uncertainty is even more important when using the CPT/CPTU measurements directly in design. Note that additional uncertainty is introduced when inferring geotechnical parameters from CPT/CPTU data. Additional uncertainties associated to data interpretation is out of the scope of this document.

The objective of this document is to propose a way forward for maximizing the quality and representativeness of the CPT/CPTU results by controlling and reducing of the uncertainties.

Before proposing a new approach and methodology, it is necessary to understand and review potential sources of uncertainty (uncertainty contributors) and previous standardization efforts aimed to control and minimize uncertainty. The following sections will review standardization efforts and discusses the challenges associated to standardization.

2 CPT/CPTU STANDARDS

2.1 *Development in requirements*

There have been several documents describing requirements and recommendations for the cone penetration test. Before 1980s only cone penetrometers without pore pressure measurements were included. But, in later years the CPTU, or piezocone, has also been covered. In 1977 the Society of Soil Mechanics and Foundation Engineering (ISSMFE) issued a document that included recommendations regarding cone geometry and provided some requirement to precision: *The precision to be obtained should not be*

worse than the larger of the following values: 5 % of the measured value or 1 % of the measuring range of the sensor used. Later documents have left out such references to the measuring range.

The Swedish Geotechnical Society Guideline in 1993 (SGF, 1993) introduced the concept of accuracy classes where the requirements were related to what the results were to be used for. ASTM released, in 1979, the first CPT standard publish by a national standardization institute. ASTM did not embrace the accuracy class approach but just included reference to estimates of precision of cone resistance (q_c) and sleeve friction (f_s). Later updates in ASTM 5778-12 (ASTM, 2012) and ASTM 5778-20 (ASTM, 2020) follows the same approach providing estimates of expected precision for q_c, f_s, and u_2 and providing requirements for the calibration errors expressed as maximum allowable errors as percentage of full-scale output (FSO).

In 2012, the first CPT/CPTU standard was published by an international standardization institution. ISO 22476-1:2012 (ISO 2012) opted for an application class scheme, defining four classes for given soil profiles and the use of CPT results. Each application class specifies minimum accuracy requirements for q_c, f_s and u_2 with an associated degree of uncertainty. In the ISO standard for Marine Soil Investigations 19908-1:2014 (ISO 2014) a simplification was made to accommodate offshore practice resulting in three application classes.

2.2 Present status

Two principal CPT/CPTU standards widely used are ISO 2012 and ASTM 2020. While the overall procedural approach is rather aligned between these two standards, there are still some fundamental differences regarding the uncertainty requirements of the CPT/CPTU results.

ISO 2012 and ISO 2014 propose a performance-based approach to classify CPT/CPTU results into application classes defined by limiting values of accuracy. Thus, these standards expresses the uncertainty requirements in terms of accuracy: *"If all possible sources of errors are added, the minimum accuracy of the recorded measurements should be better than the largest of the values given in Table 1. The uncertainty analysis should include internal friction, errors in the data acquisition, eccentric loading, temperature (ambient and transient) effects, pore pressure effects in gaps below and above the friction sleeve, and dimensional errors. "*

While the statement has the right intention it is challenging to implement in practice. Using the term accuracy implies the knowledge of the true value. It is not possible, to prove and document, with 100% confidence, how accurate the CPTU measurements are, since the true values are not known. The standard provides little guidance as to how errors and accuracy can be calculated. In practice, identifying and quantifying '*all possible sources of error*' is near impossible and this presents a fundamental problem with the demonstration of compliance.

The ASTM, 2020, approach avoids the intrinsic difficulties associated with expressing requirements in terms of uncertainty, by expressing requirements in terms of repeatability or precision. ASTM, 2020 states: *"There are little direct data on the precision of this test method, in particular because the natural variability of the ground"* and merely provides informative and generic estimates of the precision of q_c, f_s and u_2 from experience in uniform deposits. ASTM, 2020 clearly attempts to mitigate or diminish the uncertainty associated with the CPT/CPTU measurements by providing procedural requirements regarding the calibration of cone penetrometer in a laboratory environment and sets minimum requirements for the precision of q_c, f_s and u_2 in relation to a series of potential sources of uncertainty, although omits some important contributors. The most obvious omission is the requirement for the minimum uncertainty (or precision) of the reference source used in calibration. ASTM, 2020 states: *"In cases where higher level of precision is required, stricter calibration requirements would be required"* however not further advice is provided regarding the cases where higher precision is required or how to make the calibration requirements stricter. In summary ASTM, 2020, focuses on providing requirements for the calibration of cone penetrometers and for field methodology but does not provide requirements for assessing performance in the field.

None of these standards provide unequivocal guidelines on how to evaluate data quality. They only discuss some of the factors that could influence the data quality. A number of methods are used throughout the industry, and the approaches vary from company to company. This makes it very difficult to compare the quality of CPT/CPTU results from various systems and providers and creates difficulty for geotechnical practitioners, who may often need to take conservative judgements for design. The practical challenge related to this topic is setting up robust and detailed guidelines for the assessment of data quality of a performed test more or less immediately upon completion of the CPTU, so it can be repeated if necessary.

2.3 Present challenges using standards

Recent publications discussed in depth the difficulties of using ISO 2012 and ISO 2014 to assess the quality of CPT/CPTU results (Peuchen and Terwindt 2014 and 2015, Lunne et al 2017). The main difficulty arises from the definition of application class and the lack of procedural detail for the classification of CPT/CPTU results in practise. The vague nature of the recommendations opens up for different interpretation and can cause contractual disputes. Some of the practical questions that CPT/CPTU data providers and users are facing are listed here:

- How to determine and document that a certain Application Class can be obtained before the start of field work, for instance in the tender phase?
- Regarding the CPTU parameter accuracy requirements: is it an absolute requirement that all three parameters (q_c, f_s and u_2) shall fulfill the limiting values given in Table 1? Should the main emphasis be given to the measured parameters, which are most crucial for the interpretation methods?
- ISO 2012 Annex D, clause D2.1 refers to zero readings before and after a test: For CPTU's, a first attempt at recommendations for limiting values is to follow the minimum accuracy according to the applications given in Table 1. How reliable are the zero readings before and after for this evaluation? How does cleaning of the cones etc. play a role?
- What is the overall best approach for the evaluation of the resulting Application Class after a test has been completed?
- If a test is evaluated to be in a lower Application Class than required in the project specifications, how shall the results be treated in the definition of representative parameters for design?
- From a client's point of view: Which Application Classes and default values are reasonable to require in the project specifications? What is achievable in which conditions?

3 CHALLENGES ASSOCIATED WITH THE QUANTIFICATION OF UNCERTAINTY

The term uncertainty of measurement intends to express the doubt regarding the validity of the results. It follows, from the discussions in previous sections, that a detailed and robust methodology for the quantification of the uncertainty associated with CPT/CTU profiles is desired and necessary to resolve the challenges associated with the assessment of quality. Unfortunately, the quantification of measurement uncertainty for CPT/CPTU results is not trivial.

The formal definition of the term uncertainty of measurement is, in accordance with the International Vocabulary of Metrology (VIM:2012), as follows:" *non-negative parameter characterizing the dispersion of the quantity values being attributed to a measurand, based on the information used"*. ISO/IEC Guide 98-3:2008 adopt the use of uncertainty of measuring in the operational sense. This is to avoid the previous issues associated to terms like accuracy and error, which implies by definition the true value needs to be known in order to calculate accuracy.

ISO/IEC Guide 98-3:2008 and JCGM 100:2008 provides guidance for the estimation of uncertainty of measurement. Measurement uncertainty comprises, in general, many components or uncertainty contributors. The combined standard uncertainty of a measurement can be expressed as the positive square root of the sum of the uncertainty contributors. The expanded standard uncertainty can then be used to express the probability or level of confidence of the estimations of uncertainty by using a coverage factor.

Some of the uncertainty contributors may be evaluated by "Type A" evaluation of measurement uncertainty. Where the statistical distribution of the quantity values from series of repeated measurements under the same conditions are compared against a reference and can be characterized by standard deviations. Other uncertainty contributors may be evaluated by "Type B", which are evaluations based on scientific judgement considering probability density functions based on experience, theoretical modelling, manufacturers specifications or other information.

It is not possible to apply "Type A" approach to field measurements given the difficulties associated in finding a perfectly uniform site that removes soil variability from the uncertainty equation. In addition, the uncertainties may also depend on the soil type, and this make this approach unpractical.

Peuchen and Terwindt (2014, 2015) proposed a model that applies a "Type B" evaluation of uncertainty of CPT/CPTU profiles. Their work really represents an in-depth evaluation of the factors that can influence the various measurements during a CPTU. The analyses of uncertainties are based on input parameters found in literature, own investigations, some general knowledge on transducers, etc. The uncertainty analysis proposed becomes rather subjective and hazy when weighting coefficients are applied to the uncertainty calculation model for representing poor operational procedures and adverse soil conditions. Peuchen and Terwindt concluded that the approach proposed can be considerable conservative and that further studies were required.

In current practice the implementation of "Type B" evaluations for estimating the uncertainty of CPTU measurements is cumbersome and inevitably involves making conservative assumptions to fill the gap of knowledge regarding the uncertainty distributions of certain components. An added challenge is to reach consensus between all sectors, contractors, design engineers, consultants, certifiers, and researchers may have different interest from enterprises involve in manufacturing or those involve in the distribution of services.

Modelling uncertainty using a "Type B" is difficult to implement without adding excessive conservatism. It requires deep knowledge on the behaviour of each particular measurement system and this in turn requires substantial research from geotechnical practitioners, equipment operators and manufacturers. In particular research effort is required to gain sufficient understanding on:

- Development of standard methodologies and requirements to test and measure the behavior of

a particular cone penetrometer design to minimize or eliminate subjective judgement when selecting uncertainty probability distributions and sensitivity coefficients.

- Development of an unambiguous methodology for reporting uncertainty probability distribution and sensitivity coefficients.

In summary, modelling uncertainty using a "Type B" evaluation can be a viable option for determining uncertainty of CPTU measurement, further maturation and consensus for calculation methodologies are required, before this approach can be incorporated into a standardization document.

4 CHALLENGES ASSOCIATED WITH STANDARDISATION

ISO Working Groups are responsible for the development of standardisation documents. Working groups are generally composed by technical experts and delegates appointed by the national standardisation participating in the standard. The main objective of a working group is delivering the minimum requirements to minimise the level of uncertainty associated to results and to deliver sufficient methodology descriptions to ensure consistent and repeatable results.

Working Groups are generally composed by diverse experts with different areas of competence and with specific experience on the local practise in their countries. Generally, the most important challenge is reaching agreement and consensus within the working group to ensure that the draft standard document is supported by the majority of countries during the balloting stages. Reaching consensus often requires long discussions, preparation and revision of formulations, datasets and evidence to demonstrate the scientific or operational rigor of a position or opinion.

Whenever possible, requirements should be expressed in terms of performance criteria, leaving maximum flexibility to technical development and innovation.

An important consideration for the Working Group is to use clear and concise language, well define terminology, clear unambiguous requirements to reduce the possibility of multiple interpretations. In this regard the provision of informative material in the form of examples, explanations and figures is very valuable to improve understanding and ease implementation.

Working Groups must consider the needs and the challenges from the industry and reach stakeholders to ensure key objectives, needs and challenges are served. During preparation of the standard the Working Group must take into consideration the cost of implementation of the standard in the industry against the value added and ensure, that the new requirements are practical and cost effective. Finally,

the extent of the implementation period must be considered to ensure that the industry is able to react to requirement changes. In this regard Working Groups have often to consider the standard document as "work in progress" and consider a staged approach particularly when large changes in requirements are needed.

5 UNCERTAINTY CONTRIBUTORS

Whether a series of equations for quantifying the uncertainty associated with the CPT/CPTU measurements are formulated, or whether a series of effective testing methodology requirements are established to minimise the level of uncertainty, it is fundamental to start by mapping out the potential sources of uncertainty and classifying their relative weight on the overall CPT/CPTU quality.

The tables presented below shows the main uncertainty contributors associated to CPT/CPTU results grouped into three categories. Tables provide a subjective qualitative assessment of the impact on uncertainty, as function of the maximum cone resistance registered in the test. Additional commentary describing the contributors and the potential mitigation measures are included. Table 1A describes contributors associated with the measurement system; Table 1B lists the contributors linked to testing methodology (including procedure, equipment and operator dependency) and Table 1C presents the contributors intimately associated the effects, caused by the interaction between cone penetrometer and soil, during the penetration phase.

From the varied list of uncertainty contributors, it is clear, that the measuring system uncertainties are easier to measure with robust laboratory testing procedures. Soage Santos *et al.* (2022) discuss in detail the quantification of calibration uncertainty.

The uncertainties associated with testing methodology are described in detail in recent publications (Peuchen and Terwindt, 2014, Lunne *et al*, 2017, Kardan *et al.* 2016). Testing methodology related uncertainties can be minimised or fully removed by implementing best practise guidance and prescriptive procedures.

Uncertainties associated with the effects derived from cone penetrometer-soil interaction are more difficult to measure and control. The most important contribution to uncertainty during testing is temperature variations. The importance of temperature changes is widely discussed in literature (Boylan, 2008, McCallum, 2010, Peuchen, 2014). Transient temperature gradients resulting from frictional heat during cone penetration and from thermal flux through push rods causes heating of a cone penetrometer. Temperature-induced drift under in situ stress and axial loading is without a doubt the larger error contributor on CPTU results. Figure 1 shows an example of the magnitude of the drift and the behavior of the measurement system when a cone is

Table 1A. Uncertainties associated with the CPT/CPTU measurement system.

Uncertainty contributors	Potential impact to uncertainty of CPT/CPTU results			Comments	Potential mitigation
	Profiles with q_c<1MPa	Profiles with 1<q_c<3MPa	Profiles with q_c>3MPa		
Reference	High	Medium to high	Medium to high	Refers to the measurement of uncertainty or the reference used for the calibration of a sensor. The reference uncertainty should be several times lower than the instrument that is under calibration.	Introduction of a robust standard procedure for calibration of cone penetrometers. Definition of standard methodology for type A evaluation of uncertainty (in accordance with ISO/IEC Guide 98-3:2008 and JCGM 100:2008 recommendations) specific for the calibration of cone penetrometers under laboratory conditions
Reproducibility	High	Medium to high	Medium to high	Refers to the extent, to which consistent results are obtained when an experiment is repeated under a set of different conditions	
Repeatability	High	Medium to high	Medium to high	Refers to the closeness of successive measurements when carried out under as set repeatability conditions	
Resolution	High	Medium to high	Medium to high	Refers to the ability of a measurement system to detect small changes. The resolution indicates the smallest change in the measurand that a measurement system can detect.	
Zero drift	High	Medium to high	Medium to high	Refers to the difference in the measurement at zero load or pressure before and after applying a load or pressure increment	
Interpolation	High	Medium to high	Medium to high	Refers to the difference of the values given by the calibration interpolation equation and the actual measurements taken during the calibration	
Reversibility	High	Medium to high	Medium to high	Refers to the difference between two separate measurements taken at the same point, the first is taken during a series of increasing measurement values, and the other during a series of decreasing measurement values	
Apparent load transfer	High	Medium to high	Medium to high	Refers to the undesired influence experienced by a sensor caused by another sensor. For instance, when in compression type cone penetrometers sleeve friction strain gauge perceives changes, when the cone resistance sensor is loaded or vice versa.	
Normalised net area ratio	High	Medium to high	Medium to high	Applying a correct net area ratio for cone resistance corrections is of importance specially in clays. Best practise recommendations suggest the determination of net area ration in a in a pressure cell during calibration. It should be noted that the net area ratio varies with applied pressure and there is some variance along the measurement range.	
Dimensions and geometry	High	Medium to high	Medium	CPT/CPTU measurements are highly dependent on geometry and deviation from the standard recommended geometries will compromise the representativeness of the results. In addition, cone resistance and sleeve friction are reported in units of pressure thus the uncertainty associated to the determinations of cone and sleeve friction area will have an important impact on the CPTU reported measurements	

Table 1B. Uncertainties associated with testing methodology.

Uncertainty contributors	Potential impact to uncertainty of CPT/CPTU results			Comments	Potential mitigation
	Profiles with $q_c<1$MPa	Profiles with $1<q_c<3$MPa	Profiles with $q_c>3$MPa		
Temperature	High	Medium to high	Medium	Changes in temperature will affect the results of the test due to sensors do not readily compensate for transient temperature changes. Prior to testing, the penetrometer should be brought to a stable temperature as close as possible to the expected ground temperature. This is particularly important when the penetrometer temperature is significantly higher or lower than the ground temperature.	Introduction of robust methodology, equipment and reporting requirements to prevent or minimise the error caused by these potential contributors.
Zeroing	High	Medium to high	Medium	Loads caused by trapped soil, or any other loads influencing the cone (handling, embedment in soil) can result in offsets being wrongly introduced while zeroing the measurement system and adding unnecessary uncertainty to CPTU datasets. In addition, unrepresentative zero reference values are likely to penalise the cone performance assessment after testing by comparing reference readings before and after the test	
Saturation	High	Medium to high	Medium	Gas or air trapped in the pressure chamber will cause delays in the sensor response (sluggish response) resulting in unrepresentative data. The pore pressure data will be invalid. This has a direct impact on the representativeness of the cone resistance, as cannot be corrected for pore pressure effects. Careful selection of filter elements, saturation fluid and saturation method are required to minimize the adverse effects on uncertainty.	
Rate of penetration	High	Medium to high	Medium	CPT/CPTU measurements are highly dependent on the penetration rate and deviations from the standardised rates will compromise the representativeness of the results.	
Placement of CPT rig at ground surface	Medium-high	Medium	Low-medium	The weight of the CPT rig can cause changes in the natural stresses in the ground. Placement of the weight need to be considered to avoid influencing the soil to be tested.	
Stops in penetration	Medium	Low to medium	Low	May cause adherence of soil to cone penetrometer body and thus false increase in cone resistance and sleeve friction. The acceleration and deceleration required for starting and stopping a test will inevitably cause local change in cone sensor readings	

Table 1C. Uncertainties associated with effects caused by cone penetrometer-soil interaction.

Uncertainty contributors	Potential impact to uncertainty of CPT/CPTU results uncertainty			Comments	Potential mitigation
	Profiles with $q_c<1$MPa	Profiles with $1<q_c<3$MPa	Profiles with $q_c>3$MPa		
Temperature	High	Medium to high	Medium	Frictional heat developed during penetration can be significant and the consequence is large drifts will occur during testing. This is perhaps the most important source of uncertainty	Introduction of additional sensors to monitor temperature and bending changes and applied sound correction methods based on laboratory studies. Introduction of robust methodology, equipment and reporting requirements to prevent or minimise the error caused by these potential sources
Loss on saturation	High	Medium to high	Medium	It is sometimes difficult to maintain filter saturation during testing, particularly when pushing through a desiccated crust or through dilatant soils. Loss of saturation leads to sluggish pore pressure response and reliable fluid pressure data may not be consistently obtained. In instances testing approach need to be adjusted, for example by applying predrilling though a partially saturated soil to avoid losing saturation before reaching the saturated zone.	
Dimensions and geometry	Medium to high	Medium	Low to medium	As discussed, early variations dimensions and geometry of a cone can significantly contribute to uncertainty. Even when the dimensions and geometry are well known at the commencement of a test, the high frictional forces, and the abrasive nature of some soil types of my cause small variations on cone penetrometer dimensions and therefore affect the results. This is most likely to occur in sandy profiles and will have a significant effect on soft and loose sediments underlaying the sand layer.	
Bending	Medium	Low to medium	Low	During penetration the cone can be subjected to bending moments. This influence is generally small for q_c and f_s (error <10kPa and <1kPa respectively) for cone penetrometers using double bridge strain gauge.	
Inclination	Medium	Low to medium	Low	Control of inclination is of particular importance contributor to depth uncertainty. In addition, larger inclination will affect the cone resistance and sleeve friction readings. Cone resistance can be affected significantly (10%) in anisotropic soils when inclinations exceed 30 degrees	
Soil trapped or adhered	Low to medium	Low	Low	Trapped soil and dirt on gaps and seals can cause undesirable resistance that will impact the measurements specially when testing soft clays. Soils can also stick to the cone penetrometer surfaces effectively increasing the projected area and providing overestimates of q_c and f_s.	

submerged into a water bath at different temperatures in laboratory conditions.
Figure 1. Example of verification data for temperature influence.

Additional uncertainty is introduced when inferring geotechnical parameters from CPT/CPTU data. These additional uncertainties associated with data interpretation is out of the scope of this document. Powell and Dhimitri, 2022 provide detailed discussion and advice for avoiding introduction of undesired uncertainty when deriving geotechnical parameters from CPT/CPTU results.

6 RECOMMENDED WAY FORWARD

The implementation of a rigid performance-based approach for quantifying CPT/CPTU uncertainties using modelling techniques ("Type B" uncertainty analysis) is complex and not fully developed. Modelling uncertainty requires maturation and large amount of research effort. Peuchen and Terwindt 2014 work has shown good potential for the application of this type of analysis, but currently it is not considered a feasible approach in practise as discussed in section 3. In this section a recommended methodology for standardising quality control is proposed.

There is ample opportunity to improve the overall quality of the CPT/CPTU results by implementing standard requirements with the objective of minimising the sources of uncertainties presented in Table 1. Different approaches can be followed to target the three main uncertainty groups:

1. Performance-based approach: Uncertainty analysis (Type A) to quantify uncertainty on measuring systems.
2. Method-based approach. Provide unequivocal procedures and equipment specifications to reduce uncertainty caused by operator and equipment bias.

3. Technological enhancement: Incorporating new technology that facilitates deeper understanding of the uncertainties rising from soil-equipment interaction.

6.1 *Application of uncertainty analysis to cone penetrometer calibration results*

The uncertainty contributions intrinsically associated to the CPT/CPTU measurement system can be better understood and quantified by conducting a series of well design and robust procedures for the calibration of cone penetrometers. Uncertainty analysis "Type A" is applied to the calibration results, allowing systematic quantification of the cone penetrometer ability to produce repeatable results under laboratory conditions.

Requirements for calibration of cone penetrometers and verification of cone penetrometers and uncertainty calculations are incorporated in (draft) standards published by ISO, particularly ISO/DIS 22476-1:2021 and ISO/DIS 19901-8:2022. The use of uncertainty analysis on calibration results implies the departure from the existing application class type approach and the inevitable implementation challenges discussed earlier. Instead, a series of "cone penetrometer classes" can be established using limiting values that defines the minimum uncertainty requirements to satisfy a given cone class. This provides a cone penetrometer classification framework that allows transparent comparison between systems, regardless of manufacturer or supplier. And facilitates the selection of cone penetrometers to match the project and design sensitivity requirements.

Calibration uncertainty analysis and performance indicators based on verification tests defines the best cone class that a particular system can obtain under laboratory conditions. Soage Santos *et al.* 2022 describes this scheme in some detail and provides example of the results.

6.2 *Improving and controlling quality by implementation of testing methodology requirements*

Most of the uncertainties associated to testing methodology (listed in Table 1B) can be greatly reduced by prescribing detailed methodologies and equipment requirements. For instance, zeroing the cone penetrometer acquisition system is critical. If zeroing is performed while the cone penetrometer is undergoing temperature changes or when the cone is embedded or covered in soil, the cone will experience significant drifts affecting the representativeness of the data. Thus, clear requirements regarding temperature stability and presence of undesired loads while zeroing the measurement system are necessary.

Significant uncertainty, up to 4% on cone resistance, can rise from using the default areas (cone

design areas) in the conversion of force to pressure measurements rather than the actual measured areas. This can be readily prevented by ensuring that cone geometry is measured in a calibration laboratory and monitored in the field. Powell and Lunne 2005 and Powell et al. 2021 showed the impact of cone dimensions and geometry on CPTU results.

While CPT/CPTU measurement systems are generally reliable and robust, experience shows that every single component of the CPT/CPTU measurement system may deteriorate, suffer damage, or experience drifts during operations (transport, system set up or testing). Consequently, it is imperative to monitor the integrity of the system during field operations. A diagnostic check scheme can be introduced to classify the CPT/CPTU test results.

Reference readings and output stability are non-subjective diagnostic checks that can be measured and quantified. For instance, observed differences of reference readings taken before and after a test will indicate if the measuring system has experienced a drift during the penetration or retraction of the cone from the ground. The absolute difference of values observed can be used for classifying the CPTU results in accordance with prescribed limits to assign a "performance category" to the test.

CPT/CPTU "performance categories" does not provide quantification the uncertainty of a particular test but allows identification of results that may have been affected by equipment malfunction or procedural error. Certain CPT/CPTU applications, like the characterisation of soft clays for foundation design, may require highly representative and repeatable results and consequently better performance is required. The CPT/CPTU category scheme can accommodate this by defining allowable limits for a given soil profile or for a range of soil conditions. In order to avoid potential conflicts caused by interpretation, the soil categories can be linked to prescribed ranges of cone resistance, for example profiles showing q_c<1MPa can be use instead of using terms like "Very soft to firm clays".

It is important to highlight those changes such as ambient temperature, ambient pressure, the presence of dirt in the cone seals and adhesion of clayey soils can cause reference readings differences, that are not directly related to the changes that the measurement system may have experienced in the ground. For a performance category scheme to work as intended, it is fundamental, that reference readings are taken under similar conditions every time so that a meaningful comparison can be made. This challenge can be addressed by the incorporation of very clear testing methodology requirements.

Not all the uncertainty contributors associated to test methodology can be easily quantified and included in a CPT/CPTU performance classification scheme due to the impossibility to quantify them. However, qualitative assessment of test performance is very valuable and relevant information to the users and interpreters of the CPT/CPTU datasets. The introduction of rigid reporting requirements for capturing qualitative performance assessment can be a suitable approach to deal with this challenge. Some examples of qualitative performance observations are listed below:

- Information related to the responsiveness of sensor to soil changes
- Pore pressure sluggish responses
- Sleeve friction or cone resistance insensitivity caused by dirt trapped in cone seals and gaps.
- Pore water pressure cavitation effects experienced during testing
- Qualitative indication of the soil disturbance caused by the seabed frame or drilling activities

Draft ISO/DIS 22476-1:2021 and ISO/DIS 19901-8:2021capture quality monitoring by means of test categories, as discussed above, and provide highly detailed normative procedures ranging from field operations preparations to test termination and reporting activities.

6.3 *Improving and controlling uncertainty by encouraging technological development*

The uncertainty contributors resulting from the effects of the interaction between cone penetrometer and soil (see Table 1C) are especially challenging to quantify, control or correct. The introduction of additional technical requirements targeted to reduce and understand the uncertainty caused by the development of temperature variations and bending moment during testing will be greatly beneficial to improve the quality of CPT/CPTU results, especially in unfavourable soil profiles (i.e., dense sands, stiff to hard clays and interbedded soils profiles). Temperature changes of 10 degrees are not uncommon in unfavorable soils (i.e., Dense sands) and can cause drifts on q_c in the order of 300kPa, which is a very large error when trying to characterize a clay unit underlaying a dense sand unit.

Laboratory verification tests, designed to measure how temperature or bending moment variations affects the performance of q_c, f_s and u_2 sensors can be introduced. Performance indicator limiting values (expressed in terms of kPa/°C and kPa/N) can be included as part of the cone classification scheme described in section 6.2 such that cone penetrometer classes are defined by the combination of the uncertainty associated to the calibration and the test verification results.

Further, the inclusion of temperature sensors in cone penetrometers can additionally provide valuable information on sensor performance during field testing. As the effect of temperature changes on a particular cone design can be measured under laboratory conditions it is relatively straight forward to develop correction algorithms based on the variations of temperature recorded by the temperature

sensor. The application of this technology can greatly reduce the uncertainty of CPT/CPTU results in unfavourable conditions where temperature changes dominate the uncertainty of the results.

Draft ISO/DIS 22476-1:2022 and ISO/DIS 19901-8:2022 introduces a cone penetrometer class that requires the inclusion of a temperature sensor. This clearly promotes technological development targeting the reduction of the uncertainties caused unavoidable temperature changes during testing in unfavourable conditions. It should also be noted that the required presentation of results of the ISO verifications covers the influences of temperature and bending on the parameters q_c, f_s, and u.

7 SUMMARY AND CONCLUSIONS

CPT/CPTU provide fundamental input for safe and economical design of many structures. Assessing the representativeness of the CPT/CPTU results is essential. Consequently, it is important to understand, and when possible, minimize the uncertainty associated to CPT/CPTU measurements, so these can be considered in planning, design, and installation of infrastructure.

The practical challenges associated to the quantification of uncertainty and the difficulties of its standardization have been discussed in depth in this document.

Uncertainty contributors associated to CPT/CPTU measurements have been categorized into three main groups: (1) Uncertainties associated with the measuring system, (2) Uncertainties resulting from testing methodology (including procedure, equipment and operator dependency) and (3) Uncertainties intimately associated with the effects caused by the interaction between cone penetrometer and soil. This classification of uncertainty contributors allows proposing a standardization approach that addresses each group with a combination of performance-based and method-based requirements, aiming to control and minimize the uncertainty contributions rising from execution of CPT/CPTU.

Uncertainties associated with the measurement system can be reduced by the introduction of a detailed calibration and verification procedures and prescribed methodology for uncertainty quantification. This also enables the development of a performance-based cone penetrometer class scheme. The approach allows for easy comparison of cone penetrometers, regardless of manufacturer or supplier, and assists the appropriate selection of cone penetrometer for specific applications.

Uncertainties resulting from test methodology can be addressed by implementing a quality monitoring scheme defining test categories based on quantitative performance indicators such as reference readings differences and output stabilities. In addition, detailed normative procedures ranging from field operations preparations to test termination and reporting activities will also improve repeatability and representativeness of the results.

Uncertainties intimately associated the effects caused by the interaction between cone penetrometer and soil are often unavoidable. The introduction of new technology that allows measurement of these uncertainties and enables the development of suitable corrections improving the quality and therefore the overall certainty of the CPT/CPTU measurements even in unfavourable conditions.

CPT equipment: Recent advances and future perspectives

D.J. White
University of Southampton, UK

ABSTRACT: The basic configuration of the cone penetrometer test (CPT) has remained constant for half a century since the electric piezocone became widespread in the 1970s and the dimensions and test protocols were standardized soon after. The results of a conventional CPT performed today might be indistinguishable from a test conducted at the same location in 1972, aside from improved data logging and presentation. This discussion reflects on advances in CPT and other penetrometer equipment presented at this conference and in the recent literature, and presents discussion points to be considered during the event. Two general observations emerge: (i) advances in instrumentation, sensing and mechanical engineering have created a vast range of variations on the conventional CPT, providing excitement for technologists, researchers and a small subset of users; (ii) the conventional CPT is heavily standardized, commoditized and automated, and is progressively replacing the SPT in onshore practice. The result is a dispersion of practice: the majority of civil engineers base their ground characterization on a durable 1970s technology, updated with automation and improved data quality, while a minority are enjoying exploration of non-standard innovations – with mixed levels of impact. This conference provides a chance for us to (i) reflect where our activities sit in this spectrum, (ii) enjoy learning about recent advances, and (iii) debate how we will characterize the ground in another 50 years.

1 INTRODUCTION

1.1 *Purpose and scope of this discussion paper*

I was invited by the organisers of this conference to prepare a presentation for the start of the discussion session on the subject of CPT and other penetrometer equipment. This written contribution is to provide a record of the presentation in advance, and the presentation is intended to set the scene for a productive discussion.

The paper draws on the manuscripts presented at this event related to penetrometer equipment, as well as recent literature on the subject, and I have also tried to draw in wider context from the civil engineering industry, and other relevant industries, to give context to the drivers of CPT equipment developments.

The discussion that follows sets current developments in the context of the history of the CPT. This short contribution cannot comprehensively cover the full history and range of this technology, which is properly described by other keynote and review papers such as Broms & Flodin (1988), Lunne et al. (1997), Lunne (2012) and Massarch (2014).

Many of the advances described in the papers of CPT'22 are non-mainstream – relating to specialized modifications or applications of the CPT – so this review is a journey mainly through the exotic. However, there are contributions that provide incremental but useful improvements to traditional CPT equipment, which are suited to widespread adoption.

1.2 *Elements of penetrometer equipment*

To review advances in CPT equipment it is useful to define a baseline starting point, which is taken by defining a 'conventional' CPT. Also, it is useful to divide CPT equipment into the various functional elements of the test and examine the advances in each. Table 1 lists the adopted set of functional elements.

Table 1. Functional elements of CPT equipment.

Element	Description
Delivery	How the CPT equipment reaches the site location (at the soil surface)
Deployment	How the CPT advances into the subsoil, to the test location
Sensing	The instrument types and measurements taken during the test
Motion	The applied movement during the test
Scale	The size of the instrument

For the baseline case of the conventional CPT, these functional elements are shown in Figure 1. They are essentially unchanged since the 1970s,

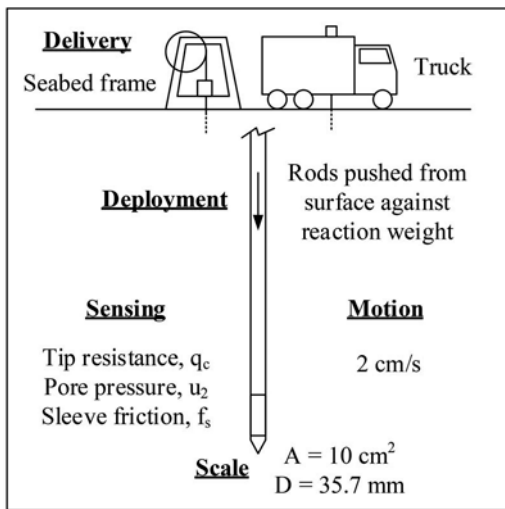
when standard dimensions and penetration rates emerged from early standardization work.


Figure 1. Conventional CPT systems – onshore and offshore.

2 CPT EQUIPMENT ADVANCES

2.1 Introduction

The following sub-sections discuss advances related to each functional element. The advances that feature in this review are summarized in Figure 2, which can be compared to the baseline of Figure 1. However, Figure 2 is not an exhaustive record of CPT equipment innovations, and many more can be found in the earlier CPT and ISOPT/ESOPT conferences.

2.2 Delivery

For *delivery* to onshore sites, early CPT rigs were mounted on rugged vehicles and today's fleets of commercial CPT rigs includes large and small wheeled or tracked vehicles, driven by people sat in a driving seat.

Recent onshore *delivery* advances have eliminated the wheels and tracks and in some cases the driver, to allow CPT testing in situations where these may not be used. This may, for example, be due to (i) extremely soft ground (e.g. tailings or marsh), (ii) hostile locals (e.g. for military trafficability assessments) or (iii) the lack of oxygen (e.g. on Mars) (Figure 3).

Uncrewed and remote-controlled onshore CPT delivery systems that have been trialled include aerial drones (Baez et al. 2020) and uncrewed wheeled or tracked vehicles (e.g. Scholz et al. 2014, Olmedo & Lipsett 2020). These technologies allow soil consistency assessments in wetlands, agricultural land and tailings ponds (Figure 3a-c). Robotic vehicles with advanced manipulators are widely used in agriculture

for sowing, weeding and harvesting, and these carry soil condition sensors. It is a simple extension to add a penetrometer system to these vehicles. Interplanetary landers have also conducted penetrometry.

For *delivery* to offshore underwater sites, the remote-controlled CPT vehicle is not as esoteric as onshore. Trials of ROV-mounted CPT systems were reported in the early 1980s by Geise & Kolk (1983) and the GeoROV CPT system (Edmunds 2014) has found widespread use as a lightweight seabed penetrometer system over the past decade (Figure 3d).

During an ROV-based CPT test, the crew is above the apparatus, on the vessel that the unit is tethered to. A logical extension, aligned with trends in other offshore survey technologies, is for the crew to remain on land, and the vessel to be uncrewed. Autonomous (or uncrewed) surface vessels are now used for geophysical surveys, and an uncrewed geotechnical survey is a realistic prospect.

Compared to sampling operations, penetrometer testing is easier to perform in an uncrewed situation due to the complexity of sample handling and storage. Penetrometer testing will therefore be a central element of future uncrewed geotechnical surveys, both offshore and onshore. This likely increase in reliance on penetrometry is a driver of more advanced test types, as discussed in Section 2.5, to replace the reduction in data if sampling is eliminated or reduced.

2.3 Deployment

2.3.1 Introduction

For *deployment* of the cone penetrometer into the subsoil, a conventional onshore CPT rig usually has a hydraulic pushing system, with rods of 2.5--3.0 m length, that are connected after each push by the operator. Some offshore systems use coiled rods (e.g. Power & Geise 1994, Meunier et al. 2004), or a robotic drilling system (e.g. Kelleher & Randolph 2005). The vertical reaction force is provided by the vehicle weight, sometimes supplemented by ground anchors, or by the skirts of a suction-type foundation on the base of the unit (e.g. Boggess & Robertson 2010).

Advances in deployment of the penetrometer fall into two primary categories: (i) techniques to speed-up the deployment process and (ii) techniques to reduce the vertical required reaction force and therefore increase the potential depth of penetration.

2.3.2 Speeding up deployment

In this conference, Storteboom et al. (2022a) describe a new trademarked 'SingleTwist' rod connection system, which allows a long CPT string to be compactly stored and quickly assembled by robotics (Figure 4a). The rods are held together with a flexible ball joint, for storage on a reel, but require only 1/6th of a turn to become rigidly connected for deployment. The ball joint connection
Figure 2. CPT equipment advances: selected from this conference and recent literature – as discussed in Section 2.
Figure 3. Advances in *delivery* of CPT equipment: uncrewed vehicles, (a) aerial (Baez et al. 2020), (b) land (Olmedo & Lipsett 2016), (c) land/water (HELIX25: www. copperstonetech.com) and (d) underwater (ROVcone www. bluefieldgeo.com).

features a protected data cable running through the joint.

An alternative speed-up technique, which also removes the need for any vertical reaction force, is to use a free-falling penetrometer (FFP). These systems are gaining wide use in research for shallow seafloor characterization (e.g. Stark et al. 2009, Steiner et al. 2014, Stark 2016) and their interpretation methods are evolving in parallel with free falling anchor research (Chow et al. 2017). Commercial FFP systems are also used for deepwater soft soils, sometimes with combined free-falling and static push test stages (e.g. Young et al. 2011).

In this conference, Kang et al. (2022) present sea trials in a relatively lightweight FFP, weighing 38 kg (Figure 4c). Studies such as this demonstrate how a self-contained low cost FFP data system (e.g. Randolph et al. 2018) allows multiple rapid CPTs to be performed.

However, these studies, and others (e.g. Stephan et al. 2015, Peuchen et al. 2017) show the challenge of achieving sufficient penetration in sands to reach the depth required for typical designs – such as assessing trenchability for cable route surveys. FFP penetration

Figure 4. Advances in *deployment* of CPT equipment: (a) SingleTwist[TM] connectors (Storteboom et al. 2022a), (b) water lubrication (Yetginer-Tjelta et al. 2022), (c) free falling system (Kang et al. 2022) and (d) self-driving system (HP[3] Spohn et al. 2018).

of up to 15-20 m is reported in soft clays by the 'CPT stinger' (Jeanjean et al. 2012). However, the reported trials in sandy or stiff clay soils have achieved only 1--3 m penetration in some situations, even with a heavy 250-500 kg FFP unit. The challenge of achieving sufficient penetration may be exacerbated in dilatant sands by the undrained response. This effect also complicates the data interpretation, due to the change in drainage conditions relative to a standard CPT as well as the viscous rate effect (White et al. 2018). The depth range can be extended by a static push unit in the FFP (e.g. Jeanjean et al. 2012, Peuchen et al. 2017). This approach requires the embedment from the initial free fall stage to provide sufficient reaction.

2.3.3 *Reducing reaction force, raising depth range*

Twin advances of a lighter CPT system and an increased depth range can be achieved through methods that reduce or eliminate the external force required to push the rods through the ground.

A simple modification to reduce the pushing force that can form an addition to a conventional CPT system is a lubrication system to inject water or drilling mud around the rods (e.g. Jefferies & Funegard 1983.

In this conference, Yetginer-Tjelta et al. (2022) report a systematic investigation into different methods of water injection at the tip and rods of a seafloor CPT system (Figure 4b). This was part of a long term campaign on the Dogger Bank in the North Sea, with more than 500 CPTs. These improvement to the equipment have led to an

approximate doubling of the depth achieved, including penetration through sands with $q_c > 100$ MPa.

2.3.4 *Bypassing reaction force: Self-burrowing*

An alternative to eliminating rod friction is to eliminate the rods themselves, and transform the CPT unit into a burrowing robot. Setting aside questions of navigation and power, this concept relies on the sleeve friction to provide a reaction force to overcome the cone tip resistance. Natural burrowers such as razor clams, earthworms and roots have been used as bio-inspiration for robots that could evolve into a rod-free CPT (e.g. Winter et al. 2014, Tao et al. 2020, Naclerio et al. 2021). Martinez et al. (2020) show that a roughened sleeve with a length-diameter ratio of L/D = 4-6.5 is required in dense sands – the most difficult conditions – to provide the required reaction.

An additional strategy to ease burrowing is to reduce the tip resistance by fluidizing the soil ahead of the robot, or in dry sand by aerating it. The approach has been successfully demonstrated in the laboratory by a steerable robot using an externally-provided air supply to fluidise the soil ahead (Naclerio et al. 2021).

The rise of robotics has led to many proposals for burrowing robots to be used across civil engineering applications. Perhaps self-burrowing CPTs will feature in future versions of this conference.

2.3.5 *Bypassing reaction force: Self-driving*

An alternative to self-burrowing is self-driving, in which the CPT is advanced by a driving mechanism that is incorporated within the machine itself. This concept was adopted by the Heat Flow and Physical Properties Package (HP[3]) of the Insight Mission that took a lander to Mars during 2018.

The HP[3] system featured a CPT-like 'Mole' device, 400 mm long, 27 mm in diameter, with a mass of 860 g. The Mole was designed to pull a 5m-long Science Tether into the subsoil to a depth of 3 – 5m (Spohn et al. 2018, Kromer et al 2019) (Figure 4d).

The driving mechanism was designed to achieve 0.1-1mm of set per blow, at a rate of 0.28 blows/sec. Laboratory trials show this probe self-driving to 5 m depth in a sandy Mars-simulant soil of crushed basalt sand. Comparisons with conventional CPTs in the same bed showed that penetration at around 20 mm/min was possible in soil with $q_c \sim 1$ MPa (Spohn et al. 2018, Wippermann et al. 2020).

However, attempts to penetrate the surface of Mars were unsuccessful, despite the Mole operating correctly. The probe failed to overcome the initial penetration resistance of the shallowest few centimetres and created a wide hole around the probe. This prevented the shaft resistance on the Mole from providing resistance against the hammer recoil, contributing to the failure to penetrate. Despite various attempts over a period of two years, the Mole remained stuck in a shallow open hole on the surface

of Mars (Spohn et al. 2021). Despite these difficulties on Mars, the project demonstrates the feasibility of self-burial by a CPT-like device using an internal hammer system.

2.4 Sensing

2.4.1 Introduction
The *sensing* on a conventional cone comprises primarily the three CPT parameters, tip and sleeve resistance, and pore pressure (i.e. q_c, f_s and u_2) with additional measurements of depth and tilt. The seismic piezocone test also provides measurements of shear wave velocity, V_s, at discrete depths.

A wide range of additional sensors have been incorporated within the cone, some of which are illustrated in Figure 2, based on contributions to this conference and other recent publications. These are discussed under the following headings of (i) mechanical, (ii) hydraulic and (iii) thermal.

2.4.2 Advances in mechanical sensing
It is well recognized that the fundamental strength and stiffness properties of a soil, in whatever constitutive framework is considered, do not uniquely correlate with the three basic cone parameters. This uncertainty can be reduced by taking one or more further mechanical readings, such as normal or shear stress values, by testing with a modified instrument equipped with additional sensors. These additional sensors are commonly mounted in further sleeves behind the conventional single friction sleeve.

For example, Isaev et al. (2022) describe in this conference a lateral stress cone, which is equipped with three pairs of lateral total stress and pore pressure sensors in successively larger diameter sleeves (Figure 5a). This type of 'lateral stress cone' provides data 'on-the-fly' (i.e. during steady penetration) that is analogous to a dilatometer or three points on a pressuremeter expansion curve. Correlations are explored to link these measured stresses, via their ratios or differences, to the in situ stress state and OCR.

A similar theme of multiple sleeves was proposed by DeJong & Frost (2002), using different values of roughness. In this case the multi-sleeve approach allows rough and smooth interface strengths to be measured, and the CPT sleeve to be tailored to the interface for which a design friction is required. By measuring sleeve friction at two positions, a new normalized friction parameter related to the degradation of friction can be calculated, and used as a fourth non-dimensional CPT parameter, to augment Q_t, F_r and B_q. This multi-friction parameter, MFP, allows the conventional range of CPT soil classification charts (e.g. Robertson 2009) to be supplemented by an extra chart using a derivative of MFP (Hebeler et al. 2018).

Friction sleeve data is sometimes treated with caution, due to potential unreliability from two sources: (i) errors in measuring the applied shear stress due to load leakage through the seals and/or low load cell sensitivity in subtraction cones and (ii) variations in the applied shear stress due to the sleeve roughness or minor differences in diameter or alignment of the sleeve. A review of these difficulties is presented in this conference by McConnell & Wassenaar (2022), who describe a new cone with improved load cell design to overcome these limitations and provide more reliable friction sleeve data in soft soils.

2.4.3 Advances in hydraulic sensing
Multiple contributions to this conference focus on the reliable measurement of hydraulic properties. Lunne et al. (2022) report on a revival of multiple pore pressure measurements – a review of early data that used the u_1 (tip and face) and u_3 (top of sleeve) sensors, alongside the conventional u_2 (shoulder). They show that normalized parameters using the difference or ratio between u_1 and u_2 can provide a reasonable correlation with OCR on a site-by-site basis, but the correlation with the conventional Q_t remains stronger.

One of the difficulties with CPT pore pressure data is the potential for unreliability due to poor saturation of the sensor filter element, air trapped elsewhere in the tip and cavitation. In this conference, Rocchi et al (2022) describe a new device that can be used to rapidly assure the saturation of a piezocone tip (Figure 5b). This device is used to test the saturation level by applying an impulse of pressure to the sensor, and then checking Skempton's B-value for the response.

Saturation is especially important when performing CPTs in unsaturated soils, where negative pore pressures are to be measured. In this conference, Tarantino et al. (2022) describe the development of a Tensiocone – a CPT attachment incorporating a high capacity tensiometer (HCD). They describe the laboratory validation of a new adapter that sits between the cone tip and friction sleeve, equipped with a surface-mounted tensiometer. Field trials did not show agreement between in situ tensiometers and the tensiocone measurements. This was traced to a cross-sensitivity between CPT axial load and tensiometer reading, which will be rectified in a new design of the sensor.

A further development of hydraulic measurement using the CPT is to impose a flow of water from the tip or shaft of the cone, and measure the associated pressure, in order to determine the local permeability. This adaptation is analogous to the conventional constant head borehole flow test (Hvorslev 1951). A similar adaptation has been applied to the pressuremeter, by withdrawing the device to create a test 'well' and applying controlled flow (Ratnam et al. 2001).

Gundersen et al. (2022), in this conference, describe trials using a 'flow cone' equipped to release water through a porous sleeve located
Figure 5. Advances in *sensing* on CPT equipment: (a) Tensiometer (Tarantino et al. 2022), (b) saturation verification (Rocchi et al. 2022), (c) the 'flow cone' (Gundersen et al. 2022), (d) Tensiometer adaptor (Tarantino et al. 2022) and (e) a parallel thermal probe element (www.datem.co.uk).

1.23 m above the shoulder of the cone, which is also equipped with pressure measurement (Figure 5c). Tests are reported from NGI's Halden test site, which comprises of silt. In these conditions, the sleeve measurement indicates an excess pore pressure remaining from the cone penetration process, and the dissipation response at the porous sleeve is used to infer the soil permeability. Prior studies using the same device at a sand site reported by Gundersen et al. (2019), show accurate direct measurement of permeability through constant head or falling head tests at the sleeve.

2.4.4 *Advances in thermal sensing*
CPTs are usually equipped with a temperature sensor within the tip, which can be used to check for temperature-induced drift of any sensors, and to also indicate the ground temperature – which may feature a step change at the depth of the water table.

More advanced use of the temperature data is described by Vardon et al. (2018, 2019). They describe the use of passive temperature responses to evaluate the thermal conductivity of the soil surrounding the CPT. The passive approach relies on the dissipation of heat generated by the penetrometer-soil friction during the installation process. This is a simplification of the active approach, which was developed earlier for geophysical research, which relies on an internal heating element to provide a pulse of heat that is recorded at other locations along the device. This type of 'thermal needle probe' can involve a thin extension from the front of a conventional CPT, or a parallel thinner element behind the friction sleeve, such as the example shown in Figure 5e produced by Datem.

These advances in the use of CPTs for thermal measurements reflect new markets related to ground heat energy systems and buried cables for offshore wind. Both of these applications relate to the energy transition and are rapidly growing markets.

2.5 *Motion*

2.5.1 *Introduction*
The *motion* in a conventional CPT is continuous penetration, usually at a rate of 2 cm/s, with intermittent pauses for rod changes or dissipation phases.

There have been many attempts to expand this motion through different speeds, patterns and directions of movement, some of which are the subject of papers in this conference. Changes in the pattern of vertical movement are made possible by advanced drive systems, which allow specific patterns of movement or load to be applied to the top of the cone rods. Meanwhile, modern miniature robotic technology has allowed miniature actuators to be incorporated in sleeve elements located behind the cone tip. This allows elements to be displaced relative to the main cone rod, with the corresponding soil response measured. The extensions can be summarized as follows:

1. Novel vertical movement: (i) different speeds, (ii) large amplitude cycles, (iii) small vibratory cycles;
2. Separate elements for other movements: (iv) expansion – i.e. the cone-pressuremeter, (v) rotation or (vi) lateral translation

Recent contributions to each of these test variations are briefly discussed below.

2.5.2 *Variations in the vertical movement*
Studies of large-amplitude cyclic CPTs – with vertical movement by several cone diameters – were prompted by similar testing of flow-round penetrometers (such as the T-bar or ball). For these devices, the cyclic penetration process is symmetric, with soil flowing in reverse around the protrusion. Cyclic T-bar or ball penetrometer tests provide a measure of soil sensitivity (e.g. Randolph 2004).

For a CPT, cyclic vertical movement may lead to a hole opening beneath the CPT, but if this does not occur the process can be similarly symmetric. Regardless of the flow at the cone tip, the cyclic movement on the friction sleeve also provides data that can support estimates of sensitivity or the degradation of friction on piles (e.g. Hebeler et al. 2005, Diambra et al. 2014, Shonberg et al. 2019).

Small amplitude high-frequency vertical cycles can also be applied concurrent with the standard installation push. This type of test and device is known as a Vibro-CPT (VCPT) or Vibropiezocone

(e.g. McGillivary et al. 2000, Jorat et al. 2014, Al-Sammarraie et al. 2018). These vibrations can be imposed by an oscillating mass attached to the rods, or by control of the hydraulic actuator. VibroCPT installations typically feature 10-15 Hz vibrations on top of the standard 2 cm/s penetration, creating a vibratory amplitude on the order of 1 mm at the cone tip. Due to rod compression, accelerometer data from the tip is double integrated to find the tip motion.

The simplest interpretation of the VCPT is as the reduction ratio between q_c in a VCPT and an adjacent conventional CPT. This has been used as an indicator of liquefaction potential (e.g. McGillavary et al. 2000). In this conference, Al-Sammarraie et al. (2022) describe recent VCPT studies that have investigated more detailed interpretation of the q_c response within individual VCPT cycles. The aim is to link the measured response to pile-soil interaction models used for vibratory pile driving.

In softer soils, a further variation in vertical movement is to apply varying rates of penetration, altering the rate in steps – a so-called 'twitch' test (House et al. 2001, Randolph & Hope 2004, Silva et al. 2006). This test provides a basis to estimate the consolidation coefficient, albeit taking approximately the same time as a conventional dissipation test. However, a further benefit is that twitch results provide a ratio between the slow (drained) and fast (undrained) resistance, which can be linked to strength, stiffness or state (e.g. OCR) parameters (Schneider et al. 2007, Suzuki & Lehane 2015, Dienstmann et al. 2017, White et al. 2018, Mo et al. 2020).

Penetrometer tests that span a range of motion rates and also involve periods of cyclic movement and dissipation periods allow a wide range of soil strengths to be mapped out (e.g. Chow et al. 2019). These tests can mimic the loading history applied by infrastructure to the ground. The results may therefore be suitable for scaling to the changing capacity of a foundation system under 'whole life' loading (e.g. Zhou et al. 2020, Gourvenec 2020).

2.5.3 *Pressuremeter elements*
The earliest example of an additional actuated element combined with the CPT is the cone pressuremeter. Early studies using a pressuremeter incorporated above the cone led to interpretation solutions that focused on the cyclic and unloading stages, acknowledging that the initial penetration of the cone will have disturbed the in situ stress state (e.g. Houlsby & Withers 1988, Withers et al. 1989, Bellotti et al. 1989, Ferreira & Robertson 1992, Bolton & Whittle 1999, Whittle & Liu 2013).

Recently the cone pressuremeter has found new usage in relation to offshore wind, for the determination of soil stiffness for monopile foundations (e.g. Whittle et al. 2017). In this conference Vinco & Sachetto (2022) describe a new cone pressuremeter

system designed particularly to verify the results of ground improvement activities (Figure 6a). For this application the system must be small, portable and suited to use within existing buildings, and requires only a low penetration force and depth capability. This system uses water as the control fluid, in common with another recently-developed pressuremeter described by Lopes dos Santos et al. (2019).

These new systems could support wider adoption of the cone-pressuremeter, taking advantage of the use of unload-reload loops and the unloading phase to gather strength and stress-strain or stiffness degradation curves from the measured data. It has also been demonstrated that pressuremeter tests can include large numbers of constant pressure-amplitude cycles, which may allow insights into the cyclic response, that can be translated into lateral p-y response models (e.g. Briaud et al. 1984, Lopes dos Santos 2020).

2.5.4 *Torsional or lateral motion elements*
Miniaturization of electromechanical systems allows actuators to be located within the cone sleeve. This allows concepts such as a torsional (t-θ) sleeve element (Frost & Martinez 2013, Figure 6b) and a laterally-moving p-y-type element (Diambra et al. 2022, in this conference, Figure 6c). These concepts offer the potential to provide more detailed soil characterization, by measuring load-
Figure 6. Advances in *motion* during CPT-type testing: (a) pressuremeter module (Vinco & Sachetto 2022), (b) Torsional sleeve (Frost & Martinez 2013), (c) lateral (p-y) sleeve (Diambra et al. 2022) and (d) rotational shallow penetrometer tests (White et al. 2022).
Figure 7. Shallow penetrometer system – a combination of CPT, T-bar and ball strength profiling tools and the shallow ring, toroid and hemiball devices for near-surface soil strength, interface strength and consolidation property measurement (White et al. 2022).

displacement responses for modes of soil deformation that are different to the cylindrical expansion of the pressuremeter.

For example, laboratory torsional shear tests indicate differences in the rate of pore pressure generation compared to axial shearing. Meanwhile, lateral deformation is more closely linked to pile p-y loading than cylindrical expansion. These locally-actuated sleeve concepts remain to be proven beyond trial prototype devices, but such robotic cones (or ROBOCONEs, to use the term coined by Diambra et al. 2022) could create exciting possibilities for complex in-situ tests.

The introduction of more complex dual-directional actuation in a penetrometer test has been successful for shallow devices, such as the ring, toroid and hemiball penetrometers. These tests involve penetration of the device by a fraction of a diameter, followed by phases of dissipation (on clay soils) and rotation (Figure 6d).

In this conference, we present test execution and interpretation procedures for a rotational penetrometry system that has been used for more than 300 tests over the past 6 years, including for

several commercial projects (White et al. 2022). The system features electromechanical drives with feedback control, so a vertical load can be maintained while the device rotates and settles. Drained and undrained interface strength parameters, as well as consolidation properties, are derived from the tests.

3 HOW DOES CPT EQUIPMENT ADVANCE?

3.1 *Are equipment advances led by new ideas?*

This discussion and the wider CPT'22 conference feature numerous advances in CPT equipment, some of which will influence future practice, and many of which will not. So this closing part of the discussion offers some views on how the CPT equipment used in practice becomes more advanced. Hopefully this will prompt the sharing of wider views during the conference, and I look forward to learning from these.

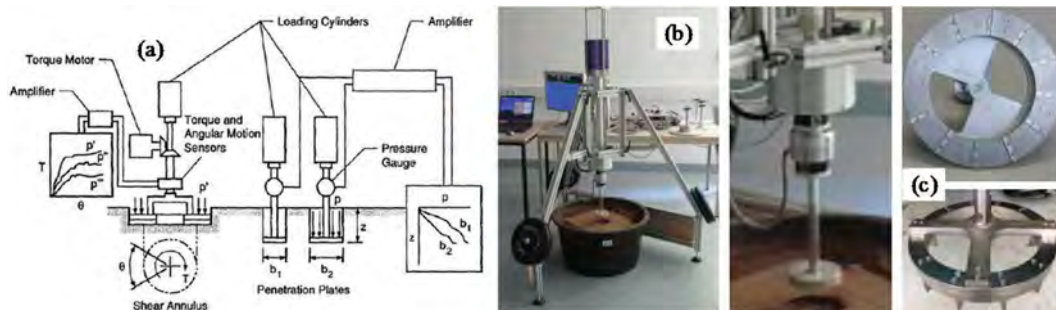
The last equipment example discussed above – rotational testing using shallow penetrometers (Figure 7) – is an example that I have been heavily


Figure 8. The bevameter – the original shallow penetrometer? (a) Bevameter principles (Bekker 1969), (b) Laboratory Bevameter system (Apfelbeck et al. 2011), (c) Shear plates for torsional Bevameter tests (top: Apfelbeck et al. 2011, bottom: Kim et al. 2021).

involved in, so I will use this as a living case study of an advance that might or might not have a future life.

These shallow penetrometers emerged from research at UWA at a time when we were heavily focused on seabed pipelines, and their friction on the seafloor. Centrifuge model testing of short pipeline elements was being used to assess design friction coefficients (White & Gaudin 2008). This led to the idea of a 'pipe-like' in situ test, but using rotation to allow longer distances of interface sliding. Prof. Mark Randolph and I proposed this concept as Dr Yue Yan's PhD topic and she developed the shallow penetrometer concept (Yan 2013). Dr Sam Stanier took the topic further in the RIGSS Joint Industry Project, with close support from industry, and co-supervising Dr Mark Schneider's PhD on this topic. The devices worked well, we devised rigorous interpretation methods, and the devices appeared to meet an industry need.

But was this type of test a new idea? It turns out not. After the PhD studies and the RIGSS JIP were completed, we discovered parallel research in the world of terramechanics and agriculture that involved a similar type of test – the bevameter (Bekker 1969, Wong 2010). This device was developed in the 1950s and resembles the ring penetrometer and the torsional plate penetrometer (Watson & Randolph 1998).

A bevameter test involves penetration and rotation of a ring-shaped device, with the pressure-sinkage and torque-rotation results being used to characterize the soil for assessment of trafficability (Figure 8). Bevameters have been developed for attachment to lunar landers and Mars rovers (Bekker 1969, Apfelbeck et al. 2011, Edwards et al. 2017). Their interpretation is rarely rooted in the same soil mechanics principles as are familiar for CPTs and our shallow penetrometers, but the test concept is similar.

So – shallow penetrometers might deserve to be counted as an advance, but they are not a new idea. The message is perhaps that (i) a new idea may

create an advance but (ii) there may be plenty of old ideas that we are yet to develop into a suitable form that can be brought into the geotechnical market.

3.2 Are equipment advances led by new markets?

3.2.1 Introduction
The shallow penetrometer story leads to the question of markets for advances in penetrometer testing. Many of the advances reviewed in this paper target a particular market that requires additional information from a penetrometer test – through an additional *sensor* or *motion* stage. Or, the advances relate to a new market where conventional *delivery* and *deployment* methods are unsuited.

The offshore engineering examples discussed below illustrate three market pulls that have supported recent penetrometer equipment advances.

3.2.2 High temperature high pressure pipelines
The emergence of high temperature high pressure (HTHP) seabed pipelines around 20 years ago led to an increased focus on near-surface seabed strength. Engineered lateral buckling schemes for HTHP pipelines require reliable estimates of the embedment and the subsequent axial and lateral soil resistance (Bruton et al. 2007).

This market led to innovations such as miniature box-core-based CPT, T-bar and ball penetrometer systems (Low & Randolph 2010, Puech et al. 2010) and the shallow penetrometer systems (Yan et al. 2010, Boscardin & DeGroot 2015, White et al. 2017). These devices are designed to characterize only the shallowest half metre or so of the seafloor, by conducting tests in box core samples. There is a particular emphasis on remoulded properties, which control pipeline embedment, and interface strength, which controls axial pipeline friction.

3.2.3 Subsea power cables
The offshore wind industry has created a major market for cable route surveys, which has

similarities with the on-bottom pipeline survey market. However, a particular feature of subsea cable design is the importance of thermal properties. The thermal insulation created by the trench backfill can have a strong influence on the cable rating and operating temperature (Dix et al. 2017).

A response to this market has been the development of new in situ thermal tests, that can be integrated within a conventional CPT-based route survey. Some of these devices (e.g. Figure 5e) use the violin bow-type design of thermal probe that has been used by the earth science community for studying heat flow from the deep earth into the oceans (e.g. Lister 1979). Once again – the idea is not new, but the concept has recently entered geotechnical survey practice in response to a market pull.

Another approach to a thermal measurement is the passive thermal CPT (T-CPT) system, which is easily added to a standard cone test. In this test the decay of the heat developed by the penetration process is used to infer the thermal conductivity. This simplicity has allowed the T-CPT to rapidly enter geotechnical survey practice.

A further driver for adoption of the T-CPT is the evidence that thermal conductivity measurements from samples are biased compared to in situ data. A review of hundreds of in situ and ex situ thermal conductivity measurements by Vardon et al. (2019) showed that the thermal conductivity measured in laboratory tests is consistently lower than in situ data. This is attributed to slight de-saturation and a reduction in density of the samples (Vardon et al. 2019).

3.2.4 *Project acceleration: Reliance on in situ data*

A further example of a market pull that is motivating advances in CPT equipment, is the need to accelerate the maturation of projects, from planning to operation. This is linked to the energy transition, with wind projects aiming for faster progression from planning or final investment decision (FID) to the beginning of energy production, compared to oil and gas projects.

As an illustration, offshore wind projects in Europe typically take 7-10 years to progress from initial planning to operation and in China the process is compressed into 2-4 years. In the past, major oil and gas projects often had a longer timeline than European offshore wind, and also a smaller footprint to survey.

The rest of the world needs to approach Chinese rates of project maturation if net zero targets are to be met. DNV (2021) predict a global wind capacity of 5.9 TW by 2050, which will require around a quarter of a million turbines to be installed in the next 30 years, with the annual rate of installation increasing by a factor of 10 compared to now.

One method to compress the project timeline is to increase the use of in situ geotechnical test data for determining design parameters. This can eliminate or reduce the importance of the period required for samples to reach the testing laboratories, be tested, and an interpreted set of design parameters be generated.

If in situ testing takes a larger role in determining design parameters, then there is a strong market pull for new types of in situ test, or extensions of the CPT, which can explore the detailed aspects of soil response that are conventionally determined from laboratory testing – such as cyclic behaviour, and stiffness parameters.

This market pull has created the driver for cyclic and small strain components of CPT-type tests such as the seismic CPT, the VCPT, the cone-pressuremeter and the locally-actuated lateral and torsional sleeves. The ability to determine thermal properties in situ, rather than relying on laboratory tests, also allows compression of the project timeline.

3.3 *Are equipment advances led by new technology?*

A final driver of equipment advances is the emergence of new technologies across mechanical and electronic engineering, as well as new types of vehicle. Over the past twenty years, the emergence of low cost sensors, data acquisition systems, actuators and communication technologies have permitted new types of sensor and testing protocol to be devised. Miniaturization has allowed additional equipment to be packed into the shaft of the CPT.

Also, the low cost and wide availability of mechatronic devices has opened up and democratized the process of equipment development. Small companies or individuals can now prototype sensors and devices that could previously only be produced and trialled by major organisations.

Massarch (2014), in his comprehensive review of the CPT, past and present, discussed a future in which sensors are so cheap that the device can be left in situ after the penetration test. This idea opens up the possibility that penetration tests are not a snapshot of the ground condition at a moment in time, but implant a sensor in the ground, that continues to operate, relaying back the condition of the ground through the life of the surrounding infrastructure. The boundary between in situ testing and field monitoring thus becomes blurred.

Automation technology also means that the execution of a CPT is becoming an 'office job'. In this conference, Storteboom et al. (2022b) describe a new hybrid CPT truck that operates using battery when on site. A carousel system automatically connects the CPT rods so the operator has minimal mechanical activities to perform. Storteboom et al. (2022b) report that *"the workplace of the CPT operator is turned into an office environment"*. They describe an improvement in working conditions, reduced absenteeism and higher productivity.

A final example of emerging technology is the digital environment used to hold and process CPT data, and the integration of this into the geotechnical design workflow and the digital model of the resulting construction. The geotechnical survey industry in the UK was an early adopter of standardized data formats, through the AGS standard, which is named after the Association of Geotechnical and Geoenvironmental Specialists, who are custodians of the standard. Version 1 of this data format was released in 1992, and version 4.1.1 is the current edition (AGS 2022).

The AGS format is widely used in the UK and worldwide, and improves the workflow and assurance of geotechnical data, as well as simplifying the sharing and public release of geotechnical data. For example, the Crown Estate (England and Wales) requires wind farm operators to release survey data to the Marine Data Exchange portal. This data commonly takes the form of reports, but for geotechnical in situ testing the data is often held in the AGS format, where it can be rapidly assimilated into other software for wider use.

A common software platform for storing and interpreting in situ data is gINT, which is owned by the Bentley software house. Bentley also own PLAXIS, and the two programs have growing interface capabilities. A consequence of this connectivity from raw CPT data to geotechnical numerical modelling software is that there is a single digital workflow from site measurements to design output.

This connectivity can be used to allow more rapid progression from survey to construction. It can also eliminate the human attention given to geotechnical data that is often held dear in our discipline. For example, the progression of data through factual reporting, interpretive reporting and ground model development involves detailed evaluation and thought processes that support geotechnical risk analysis, as well as design parameter choices.

On the other hand, we could take the counter view, which is that a smooth processing pipeline from in situ data towards design will liberate geotechnical specialists. We can spend more time assessing the information created by the data, rather than passing data between spreadsheets and different types of software.

3.4 Equipment advances: Does standardisation help or hinder?

Standardisation of the CPT emerged in the 1970s and has more recently been set out in various international standards produced by the ISO, CEN and others (e.g. ISO 2012, 2014).

Many advances in CPT equipment remain 'within standard', such as methods for efficient deployment of the rod string or improvements to load cells or data transfer. However, many advances in penetrometer equipment are 'non-standard',

which creates difficulties when clients wish to assure data quality or set contract specifications and develop a competitive supplier market.

Two key challenges are therefore faced by developers of any new equipment that deviates from the standards:

1. *The need for a specification:* a test specification is required to define and allow assurance that any testing is conducted according to an appropriate procedure, agreed between client and contractor. A hierarchy of specification types, listed by the strength of their basis, might be: (i) a publication by the system developers, (ii) a guideline emerging from a Joint Industry Project, or developed with a verification agency, (iii) a guideline developed more openly by an industry technical committee or association (e.g. CFMS, CIRIA and the ISSMFE have supported guidelines on in situ testing) (iv) a recommended practice or standard produced by an international standards body (e.g. ISO, CEN, API).

   In practice, procedures generally evolve upwards through this hierarchy over a period of perhaps a decade – as seen by the procedures adopted for flow-round penetrometers that have now reached ISO 19901-8.

2. *The need for market competition.* A second challenge facing proponents of an advance in penetrometer equipment is that new test types will rarely be specified by clients if there is only one supplier. This places developers of new equipment in the difficult position of requiring a competitor to come into existence in order for demand to be created. This situation does not apply to equipment advances that are 'within standard', since the specification is unaffected.

   However, using the example of the shallow penetrometers for a final time, research funding for the RIGSS JIP from owners/operators was conditional on more than one contractor also being part of the project, in order to ensure that a competitive supply chain could emerge.

The heading for this final sub-section was perhaps a little frivolous. Standards are invariably beneficial for industry and should not hinder innovation. However, innovators of new 'non-standard' in situ test equipment need to be prepared to address the two challenges set out above. Developing reliable equipment that offers a technical benefit over standard test methods will not necessarily lead to industry adoption. Time and effort must be spent 'socialising' the technology among the community of practice, for example at events like this conference. It is then necessary to develop open guidance and specifications for execution and interpretation of non-standard tests. Finally, it might even be necessary to support open competition in the marketplace to avoid the technology being from a sole source.

4 CONCLUDING COMMENTS

The basic configuration of the cone penetrometer test (CPT) has remained constant for around 50 years. This discussion has reviewed recent advances in penetrometer equipment presented in this conference and elsewhere, considering separately the (i) delivery, (ii) deployment, (iii) sensing and (iv) motion aspects of the penetrometer test.

It is evident that new innovations in instrumentation, electronics and mechanical engineering have created a vast range of variations on the conventional CPT equipment. In some cases these advances provide a small but widespread improvement in penetrometer testing, such as improved rod connection systems, hybrid-powered CPT trucks and better saturation and calibration systems. In other cases the advances are more ambitious, aiming to incorporate new sensors and motion systems within a penetrometer, to allow new types of measurement to be incorporated in the testing process.

The result is a dispersion of practice: the majority of civil engineers base their ground characterization on a durable 1970s technology, updated with automation and improved data quality, while a minority are enjoying exploration of non-standard innovations – with mixed levels of impact.

This discussion, and the wider conference, is an opportunity to reflect, learn and debate how we will characterize the ground in another 50 years.

Non-deterministic interpretation and applications of CPT testing data

M. Uzielli
Department of Civil and Environmental Engineering, University of Florence, Italy
Georisk Engineering S.r.l., Florence, Italy

ABSTRACT: The evolution of geotechnical design codes towards reliability-based and probabilistic concepts, the growing global awareness towards risk management for engineered and natural systems, and the global digital transition are steering geotechnical research and practice towards non-deterministic and data-centric approaches to geotechnical characterization and design. The quasi-continuity and high repeatability of CPT measurements inherently endow this testing method with a central role in the momentous shift in paradigm. This paper contributes principles and selected examples which exemplify the nature and use of non-deterministic CPT-based methods for geotechnical site characterization, design, and geohazards risk management. Current cautions and limitations to the development, dissemination, and implementation of these methods are arguably surmountable and provide stimulating opportunities for a collective effort on the part of the CPT community to meet the evolving requirements and trends in geotechnical practice, research, and education.

...ἔοικα γοῦν τούτου γε σμικρῷ τινι αὐτῷ τούτῳ σοφώτερος εἶναι, ὅτι ἃ μὴ οἶδα οὐδὲ οἴομαι εἰδέναι.

"... I seem, then, in just this little thing to be wiser than this man at any rate, that what I do not know I do not think I know either."

- Plato, Apology

1 LEVERAGING THE UNAVOIDABLE

"As far as laws of mathematics refer to reality, they are not certain; and as far as they are certain, they do not refer to reality."

- Albert Einstein, "Geometry and experience" (1921)

The variability in testing data and derived design parameters is a distinctive trait of the geotechnical discipline with respect to other engineering disciplines which deal with artificial materials. Measured properties effectively vary due to the natural heterogeneity and complexity of soils, which are generated and continuously modified by natural geologic and geomorphologic processes. In-situ effects due to stress state and stress history lead to spatially variable measurements even for compositionally homogeneous deposits. The spatial and temporal variability of geotechnical properties can be especially appreciated in the results of geophysical testing and geotechnical in-situ testing, which involve larger volumes of soils than laboratory tests. Moreover, the same test conducted at the same spatial location may produce different results due to the temporal variability of the natural environment (e.g., seasonal fluctuations in water content,

groundwater level, etc.) and to imperfect measurement capability. Some degree of inaccuracy and imprecision is always present in testing operations.

The variability in measured values thus stems from inherent soil variability and measurement uncertainty. When transposed in quantitative engineering analyses, these variabilities result in uncertainty. When representative values are calculated from measured data (e.g., the mean value over a depth interval), additional statistical estimation uncertainty arises from the limited number of values used to calculate these values. Moreover, when testing data are used to calculated engineering design parameters, a further source of uncertainty is introduced due to transformation models which are always approximate and imperfect models of the physical world.

Given the evident existence of considerable uncertainties in geotechnical engineering, the question arises as to "whether" and "how" to address them. The complete neglect of uncertainty is unacceptable from both the ethical and technical viewpoints. Failing to acknowledge the existence and relevance of uncertainty would imply that basic geotechnical notions and geotechnical code prescriptions are not adhered to, since these do address uncertainty (either implicitly or explicitly, as discussed later). This paper focuses on how the geotechnical discipline has evolved from the primordial "deterministic" paradigm, in which the modeling of uncertainty is implicit, to the currently trending "non-deterministic" paradigm, in which uncertainties are modelled, processed, and reported explicitly, and is continuing to evolve towards a "data-centric"

mode which fosters the synergy between engineering judgment and the increased availability of data, facilitating the treatment of uncertainty in characterization and design.

Through a specific focus on cone penetration (CPT) testing, this paper attempts to provide examples from research and case-study applications of the pivotal role of CPT testing in accompanying the geotechnical discipline towards an emerging non-deterministic and data-centric paradigm. Far from aiming to provide a structured theoretical treatment of non-deterministic and data-centric approaches and from contributing an exhaustive review of available examples, this contribution wishes to spark both an interest and the willingness, on the part of researchers and practitioners, to contribute proactively to the continued development, refinement, promotion, and dissemination of uncertainty-based and data-centric methods relying on CPT. Lastly, it aims to stimulate a constructive discussion focusing on how some current aspects requiring attention actually represent opportunities for the further refinement of methods for interpretation and use of CPT results in characterization and design.

While this paper advocates the increased use of non-deterministic, data-centric methods, it wishes to convey the awareness that such methods largely rest on the broad shoulders of the ingenious, pioneering deterministic methods which have laid the foundations of the geotechnical discipline, and which have nurtured its growth and evolution.

2 A HISTORY OF CHANGE

"The quest for certainty blocks the search for meaning. Uncertainty is the very condition to impel man to unfold his powers."

- Erich Fromm

The concepts of "determinism" and "non-determinism" stem from the fundamental question regarding the cause behind the occurrence of events, which has engaged philosophers in the East and West since ancient times. The deterministic approach prevailed over the stochastic approach in the technical community for many centuries. In the past decades, led by the high-energy physics community and facilitated by advancements in statistical-probability theory, enhanced data analysis capabilities, and increased computational power, the non-deterministic approach has replaced the deterministic one in many scientific and technical disciplines, and is progressively gaining momentum in others, including geotechnical engineering. Moreover, improved data collection technologies and computational power increasingly advocate the adoption of approaches making use of big data, which can further boost the performance of non-deterministic approaches. While a brief account of the transition from the deterministic to the non-deterministic and

data-centric paradigm is provided below, readers are referred to Baecher & Christian (2003), Phoon (2020) and Tang & Phoon (2021) for further insights into the philosophical, conceptual, and operational evolution of the geotechnical discipline.

2.1 The past: The illusion of certainty

Geotechnical engineering, as all engineering disciplines, originated and developed speaking the deterministic language, in which uncertainties are neither modelled, processed, nor reported explicitly, but are lumped together and represented implicitly in design methods, for instance through factors of safety. Numerous research contributions and real-world cases continue to provide new evidence that deterministic approaches are prone to overestimating or underestimating the performance of geotechnical systems because they are unable to parameterize the "real" complexity in soil-structure systems and the inevitable approximation in the models used to obtain design parameters from testing data. For instance, neglecting to model the spatial variability of design parameters prevents the identification of relevant failure modes (e.g., non-symmetric failure modes foreseeable even in presence of symmetric foundations and axial loading conditions, see Figure 1).

Overconservatism and unconservatism are both to be avoided: while the first entails the excessive use of resources to attain a target level of performance, the second, more seriously, fails to achieve performance and can result in failures which bring human and economic losses.

2.2 The present: Embracing uncertainty

In the context of engineering disciplines, the adjective "non-deterministic" refers to a broad range of methods and techniques relying most frequently – but not exclusively – on statistical and probability theory.

The development of ingenious approaches based on concepts such as reliability-based and performance-based analysis and design, along with increased computational power and efficiency, have allowed civil engineering to embark on the evolution from the primordial deterministic paradigm towards the non-deterministic one. The latter is characterized by the explicit consideration of uncertainty. The adoption of the non-deterministic approach allows to exploit powerful mathematical tools such as statistics and probability to model, process, and report uncertainties quantitatively.

While all engineering disciplines originated within the deterministic framework, geotechnical engineering has been delayed in initiating its transition, probably due to the greater inherent difficulty in quantifying and modelling its uncertainties. The geologic environment is made up of two- or even three-phase natural materials and is thus inherently
Figure 1. Comparison of failure modes for a surficial footing on uniform and spatially variable soils (from Li et al. 2014).

more complex and less easily characterized and modelled than structural materials such as steel, concrete, or timber. Nonetheless, in the past decades seminal research contributions and increased computational power have fostered and accelerated the development of non-deterministic methods.

The progressive shift towards non-deterministic methods is perhaps the most distinctive trait behind the development of evolutionary geotechnical design codes which are based on statistical, probabilistic, and performance-based concepts and which are gradually replacing the traditional deterministic design codes. Notable examples are Eurocode 7, Eurocode 8, the AASHTO (American Association of State Highway and Transportation Officials) LRFD Bridge Design Specifications, CHDBC (Canadian Highway Bridges Design Code), and JSHB (Japanese Specifications for Highway Bridges). The adoption of the non-deterministic paradigm enables the conceptual and formal harmonization between geotechnical and structural design, thus contributing to enhanced homogeneity and effectiveness in the design of soil-structure systems. Embracing non-determinism for geotechnical practice is no longer a choice in many parts of the world and is becoming less and less so at a global level. Despite the above, the transition to the non-deterministic paradigm is far from complete.

2.3 The future: Data meets knowledge

The momentous global process of digital transition which characterizes our time brings unprecedented possibilities. A new "data-centric" paradigm is emerging involving the synergy between the increased availability of data, evolutionary approaches such as machine learning, and expert engineering judgment (e.g., Phoon 2020). Such paradigm is extremely well-suited to synergize with non-deterministic approaches in defining the new identity of the geotechnical discipline.

Comprehensive compendia of literature estimates of uncertainties in soil parameters are available in the geotechnical literature (e.g., Uzielli et al. 2007; ISSMGE 2021). However, most estimates refer to

total uncertainty. Prior to the introduction of the data-centric paradigm, soil property statistics determined from total uncertainty analyses could only be applied reliably to the specific set of site conditions, measurement techniques and procedures, and correlation models for which the design soil properties were derived. The site-specificity of variability parameters had thus constituted a long-standing limitation and an obstacle to the diffusion of non-deterministic approaches. A main strength of the data-centric paradigm thus lies in the provision of quantitative probabilistic methods to allow the integration between site-specific data collected for a given project and "big indirect data", i.e., existing data of any type collected from past stages of the same project or past projects at the same site, neighboring sites, or beyond.

The progressive surge of the data-centric paradigm is arguably entwined with the increasing centrality of the Bayesian approach in geotechnical engineering. Bayesian statistical analyses, differently from "frequentist" statistical analyses, provide analysts with the tools to update a "prior" probability model through the availability of new evidence (e.g., data observations) to obtain a "posterior" model. This approach is particularly suited for the geotechnical engineering discipline, in which it is often necessary to supplement site- and case-specific data (or aprioristic engineering judgment) with data from other sites, or to update characterization and design values as new data become available. The use of Bayesian methods in the data-centric approach promises to be useful in circumventing the limitations of site-specificity of geotechnical variability estimates, and in actually leveraging the availability of "indirect" data from other sites (see, e.g., the outcomes of Project DeepGeo at http://yo-1.ct.ntust.edu.tw/jge/files/articlefiles/v16i2202106031836319463.pdf) The data-centric paradigm arguably provides the natural evolution of the geotechnical discipline, provided that researchers and practitioners are provided with the necessary simple knowledge required to correctly interact with data (Tang & Phoon 2021).

"Data-centric" and "non-deterministic" are not synonymous. While the data-centric approach does not imply *per se* resorting to non-deterministic methods, the former clearly fosters the latter. Increased data numerosity increases the applicability, meaningfulness, and reliability of non-deterministic techniques. Many statistical and probabilistic analyses, for instance, rely on the availability of sufficient quantities of data, and the level of confidence of their outputs increases with increasing numerosity of data samples. As the quantity and quality of data are expected to continue to increase over time, failing to proactively confer further centrality to the data-centric approach in both geotechnical research and practice would be nothing short of a wasted huge opportunity.

In their illuminating treatment of geotechnical uncertainty, Baecher & Christian (2003) opined that a hybrid approach involving both deterministic and non-deterministic methods is "proper to the geotechnical engineering discipline". This statement is increasingly and fully supported by a conspicuous, growing corpus of research and real-world applications, in which some aspects of a specific geotechnical analysis can be sufficiently well-described deterministically for practical purposes, while for others it is *convenient* to describe and model phenomena and variables as if they behaved, at least to some degree, in a random manner. A typical example is found in the quantitative modeling of spatial variability of soil properties, which is often pursued through the decomposition of data into a deterministic trend and a fluctuating, supposedly random component. The hybrid approach is fully compatible with the data-centric paradigm since the availability of more and better data is beneficial to both deterministic and non-deterministic analyses.

3 THE COMPETITIVE ADVANTAGES OF CPT TESTING

CPT testing has long been known to surpass other in-situ testing methods with respect to the high numerosity, quasi-continuity, and accuracy of its measurements. Moreover, CPT testing is highly standardized. Such features endow this testing method with several relevant "competitive advantages" in the light of the emerging data-centric, non-deterministic approach to geotechnical site characterization, geotechnical design, and geohazards risk analysis.

The small measurement interval which is unique to CPT testing among in-situ testing methods results in significantly higher data numerosity, i.e., in a higher number of measurements obtained for any given depth interval. Sample numerosity plays a decisive role in the applicability and significance of non-deterministic analyses. In most general terms, higher data numerosity is beneficial at least in terms of: (a) reduced statistical uncertainty; (b) improved modelling of inherent spatial variability and estimation of spatial averaging effects; and (c) improved estimation of transformation uncertainty. Ultimately, increased data numerosity contributes to the optimization of cost-performance optimization in geotechnical characterization and design by reducing the likelihood of unconservatism and the degree of over-conservatism. Data-centric approaches relying on machine learning also enhance their performance (when not outright requiring) large data sets. Phoon et al. (2021) opined that CPT data is the only practical source of data for data-driven site characterization (DDSC).

The concepts of testing repeatability and accuracy is related to measurement uncertainty. The latter is due to equipment, procedural-operator, and random testing effects. Previous research (e.g., Kulhawy & Trautmann 1996) indicates that CPT testing repeatability is higher in comparison to that pertaining to other testing methods. Peuchen & Terwindt (2014) provided an extensive insight into CPT measurement uncertainty and affirmed that piezocone testing is closest to an ideal penetration tool than any other in-situ testing method. In principle, high accuracy is desirable in non-deterministic analyses because low epistemic measurement uncertainty contributes to a lower total uncertainty. High standardization allows more stringent control on testing data quality. Peuchen & Parasie (2019) highlighted the ongoing technical and normative activities aimed at the continued pursual of high CPT testing standardization.

The innumerable possible ramifications stemming from these virtuous attributes of CPT testing do not allow their exhaustive enumeration. Selected examples are provided in the following among the many ingenious available in the geotechnical literature.

4 NON-DETERMINISTIC CPT-BASED SITE CHARACTERIZATION

"Exploring the unknown requires tolerating uncertainty."

- Brian Greene

Non-deterministic approaches have been proposed for fundamental activities related to CPT-based geotechnical site characterization including soil behavior classification, stratigraphic profiling, and spatial variability modeling. Selected examples are presented in the following, and readers are referred to Cao et al. (2017) for a more comprehensive treatment of such topic.

4.1 *Soil behavior classification*

CPT testing is frequently used for soil behavior classification through approaches which link the quantitative measurements of the mechanical resistance to cone penetration to likely corresponding soil types. The association between mechanical resistance and soil type is pervaded by significant uncertainties stemming from in-situ state effects (e.g., cementation, overconsolidation), by the inter-site and intra-site variability in compositional and mechanical properties of soils, and by the complexity of soil behavior.

CPT-based soil behavior classification methods routinely used in geotechnical practice are overwhelmingly deterministic. While their use worldwide and in many different soil and site conditions attests to their high performance, these methods are inherently unable to quantify explicitly the degree of uncertainty in their outputs. Methods for the non-deterministic CPT-based soil classification have nonetheless been made

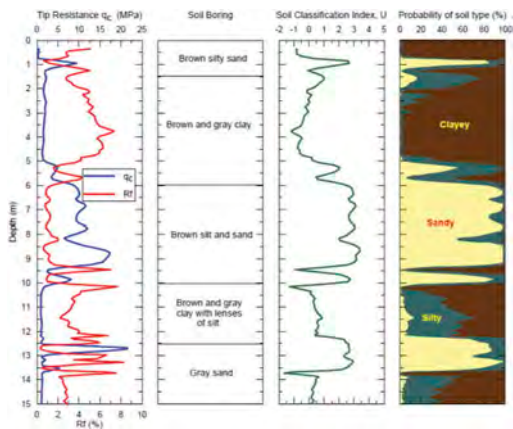
available in the geotechnical literature since many years. Zhang & Tumay (2003) proposed the probabilistic region estimation method. Such approach provides a depth-wise profile of the probability that a set of CPT measurements (more specifically, cone resistance and friction ratio) correspond to cohesive-, intermediate-, or cohesionless-behavior soil type (see Figure 2).


Figure 2. Non-deterministic depth-wise soil behavior classification (Zhang & Tumay 2003).

4.2 Stratigraphic profiling

Stratigraphic profiling is one of the main applications of CPT testing. Such process involves the identification of interfaces between soil units which can be considered sufficiently homogeneous and/or significant for specific purposes. Reliable stratigraphic profiling is also relevant to geotechnical design. For example, in CPT-based pile design, the identification of a stratigraphic interface between a layer with low bearing capacity and one with high bearing capacity and stiffness is fundamental in the definition of design pile length. Cone resistance in layered soil is affected not only by the layer currently being traversed but also by the underlying and, under certain conditions, overlying layers, depending on the position of the cone relative to such layers.

Several non-deterministic approaches for CPT-based stratigraphic profiling have been proposed. Wang et al. (2019), for example, developed a Bayesian unsupervised learning approach for automatic layer detection and soil classification with an explicit quantification of uncertainty, using CPT-based parameters (i.e., normalized sleeve friction F_R and normalized cone resistance Q_t) commonly used in the well-established soil behavior classification system by Robertson (1990). Figure 3 provides a visual representation of the approach, highlighting the capability of the method to simultaneously provide both soil

behavior type and stratigraphic profiling from CPT testing data.

4.3 Spatial variability modeling

In-situ testing typically reveals that engineering properties of geomaterials vary spatially both in the horizontal and vertical directions (most often with higher variability in the latter case due to layering- and stress-related effects). In absence of geological, geomorphological, or geotechnical macro-discontinuities (e.g., layer interfaces) which should be accounted for by separating data by homogeneous soil units through stratigraphic profiling and soil behavior classification, soil properties (as parameterized, for instance, in CPT data) can be expected to vary gradually in conformity with the conceptual principle stated by Leibniz (1704) by which "*tout va par degrés dans la nature, et rien par saut*" ("everything occurs gradually in nature, and nothing by jumps"). Spatial variability can never be estimated with full precision and accuracy at any scale, from the micro-scale to the macro-scale, due to the finite number of tests and measurement uncertainty.

The importance of the quantitative modeling of spatial variability is increasingly acknowledged in research and practice as: (1) it is necessary for the conduction of simulation-based analyses based on techniques such as random field modeling; (2) it allows the spatial interpolation of in-situ testing measurements and of derived parameters and the quantification of uncertainties in interpolation estimates at unsounded locations, thereby providing support in the planning and integration of geotechnical investigation campaigns and optimizing their cost-performance ratio; (3) allows the quantitative estimation of the spatial averaging effect, by which the effects of variability on geotechnical design can be rationally calibrated with respect to the spatial extension of geotechnical structures (typically, pile foundations).

Multiple approaches and techniques have been used to the purpose of geotechnical spatial variability modeling. In many of these techniques, variability is often modeled most efficiently through the integration between deterministic and non-deterministic approaches, i.e., through the decomposition of data into a trend which is expressed deterministically (for instance through a polynomial function) and a fluctuating component, which is assumed to be a random variable, and which is investigated using statistical, probabilistic, geostatistical, and random field theory among others.

Regardless of the specific technique used, CPT is particularly suited for the modeling of spatial variability because of its small measurement interval, which allows, jointly with its high testing repeatability, more reliable estimation of small-scale variability in the vertical direction with respect to other in-situ testing methods. Moreover, higher data numerosity reduces statistical uncertainty in non-deterministic analyses such as the modeling of semivariograms for the modeling of spatial correlation.

5 NON-DETERMINISTIC CPT-BASED GEOTECHNICAL DESIGN

Non-deterministic approaches are available for the utilization of CPT data in geotechnical design, both in the derivation of design parameters and in design methods. As shown in the following selected examples, such approaches allow improved and more rational calibration and assessment of the performance of geotechnical design. Readers are referred to Tang & Phoon (2021) for a more comprehensive insight into geotechnical transformation uncertainty.

Engineering models which relate in-situ and laboratory testing measurements to geotechnical design parameters, whether theoretical, empirical, experimental, or a combination thereof, are always approximate simplifications of physical soil-structure systems. Geotechnical models are thus invariably affected by bias (which relates to the model's precision) and/or dispersion (which refers to the model's accuracy). Empirical correlations have been made available to estimate numerous geotechnical design parameters from CPT testing results. Lunne et al. (1997) tabulated comparatively the degree of applicability of a wide range of in-situ testing methods to the estimation of geotechnical parameters, assessing that CPT testing overall outperformed other methods. Robertson & Cabal (2015) tabulated the perceived applicability of piezocone testing to the estimation of soil parameters for coarse-grained and fine-grained soils (Table 1), once again assessing the overall utility of CPT for geotechnical parameter estimation.

Table 1. Perceived applicability of CPTU for deriving soil parameters (from Robertson & Cabal 2015).

Parameter	Coarse	Fine
Relative density	2-3	-
State parameter	2-3	-
Young's and shear moduli	2-3	2-4
Overconsolidation ratio	5	1
Undrained strength	-	1-2
Coefficient of consolidation	3-4	2-3
Peak friction angle	2-3	4
In-situ stress ratio	5	2
Small-strain shear modulus	2-3	2-4
1-D Compressibility	2-3	2-3
Sensitivity	-	2
Permeability	3-4	2-3

Note: 1=high; 2=high to moderate; 3=moderate; 4=moderate to low; 5=low.

$\phi' = 17.6 + 11.0 \log[(q_c/p_a)/(\sigma'_{v0}/p_a)^{0.5}]$
$(n=633, r^2=0.640, S.D.=2.8°)$

$p_a = 100$ kPa

Normalized Cone Tip Resistance $q = (q_c/p_a)/(\sigma'_{v0}/p_a)^{0.5}$
Figure 4. Source data and deterministic correlation for estimating friction angle from CPT (Kulhawy & Mayne 1990).

In the light of the non-deterministic insight into CPT testing, the "degree of perceived applicability" could be related conceptually to the reliability of the transformation models, i.e., to the magnitude of transformation uncertainty. However, this qualitative assessment can hardly be translated into quantitative probabilistic formulations which can be seamlessly used in new geotechnical design codes. Available CPT-based correlations are overwhelmingly deterministic. They are typically obtained as "best-fit", central tendency models from scattered data, and are thus amenable to an "intermediate" degree of conservatism.

An example of the transition to non-deterministic CPT-based estimation of geotechnical parameters is

related to the estimation of effective friction angle of sands from stress-normalized cone resistance. Figure 5 shows the data used by Kulhawy & Mayne (1990) to develop their well-known deterministic model

$$\phi' = 11.0 \cdot \log_{10}(q_{t1}) + 17.6 \qquad (1)$$

While goodness-of-fit statistics (typically, the coefficient of determination R^2) or descriptive second-moment dispersion statistics (e.g., standard deviation, variance) are provided together with the regression model in best-practice cases such as this one, these are in principle not sufficient to allow the model-based estimation of properties for different levels of conservatism. Moreover, the statistical distribution of data around the best-fit model cannot be characterized statistically beyond second-moment description.

Uzielli & Mayne (2019) proposed a probabilistic transformation model using a high-quality database comprising CPT and triaxial tests. The logarithmic formulation

$$\phi' = p_1 \cdot \ln(q_{t1}) + p_2 \qquad (2)$$

has the same ease of practical applicability as the previous deterministic model while allowing the estimation of ϕ' for varying levels of conservatism (i.e., for different probabilities of exceedance P_{exc}) by varying model coefficients p_1 and p_2 as shown in Table 2. Figure 5 plots the curves corresponding to probabilities of exceedance 0.05, 0.50, 0.75, and 0.95 of effective friction angle in comparison with the deterministic model by Kulhawy & Mayne (1990). While the performance of the deterministic methods is overall comparable to the probabilistic method for a "median" probability of exceedance, it is apparent that the latter allows the fuller exploitation of the experimental dataset. It is also apparent that the deterministic model does not refer uniformly to a probability of exceedance for increasing values of q_{t1}. Thus, the degree of conservatism in the deterministic model is not established univocally.

The transition to a data-centric paradigm can further enhance the quality and utility of new-generation geotechnical transformation models. Site-specific data are typically sparse and incomplete. The geotechnical discipline has adapted to this fact by providing transformation models which are

Table 2. Coefficients of the logarithmic CPT-based model for the estimation of friction angle for various probabilities of exceedance (Uzielli & Mayne 2019).

P_{exc}	0.95	0.75	0.50	0.05
p_1	4.27	4.00	3.81	1.70
p_2	18.1	20.3	22.2	35.1
Figure 5. Comparison of probabilistic (Uzielli & Mayne 2019) and deterministic (Kulhawy & Mayne 1990) models for the estimation of effective friction angle from stress-normalized cone resistance.

founded on data from multiple sites. While geotechnical engineers are trained to operate the transition between "indirect" data (i.e., from other sites) to "direct" (i.e., local) data by applying transformation models and assessing the results critically using engineering judgment, non-deterministic approaches based on the data-centric paradigm allow an improved synergy between indirect and direct data. Through Bayesian approaches relying on the data-centric paradigm, it is possible to quantify the reliability of indirect data with respect to direct data and to provide a "hybrid" transformation model which relies on both datasets, and in which the weight of the "indirect" model is determined on the basis of objective criteria such as the "similarity" between indirect sites and the target site, e.g., in terms of soil types. For example, Ching et al. (2021) used a hierarchical Bayesian modelling framework to apply hybridization to the estimation of undrained strength of clays from CPT testing. Figure 6 illustrates indirect site-specific models as well as the hybrid model for the target site-specific model. Ellipses represent the uncertainties associated with the respective models, which are quantified explicitly.

An increasing set of non-deterministic CPT-based design methods are also available in the geotechnical literature. Cai et al. (2021) provided a framework for the CPT-based calculation of axial pile capacity in spatially variable soil. The study relied on the simulation of CPT profiles through random field modeling and on the statistical-based calculation of pile capacity for varying target levels of conservatism. Figure 7 provides a comparative visual representation of simulated profiles of cone resistance at preset

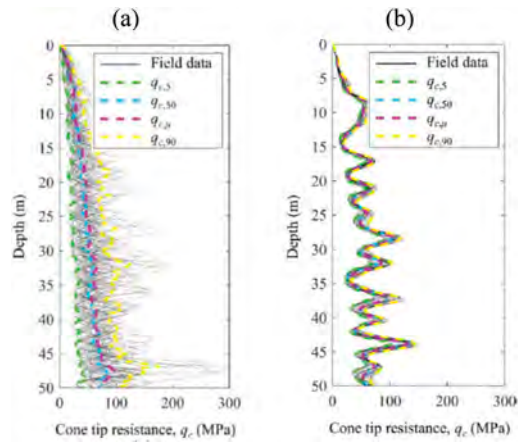
spatial separation distances within the design site for smaller and larger horizontal correlation distances. Random field modeling also allows to refer explicitly to the scale of fluctuation, thus allowing the quantification of the spatial averaging effect by which the influence of the variability in soil properties is smoothed out along the shaft. The rigorous inclusion of the spatial averaging effect contributes to calibrating the effect of inherent soil variability and to reconduct rationally the degree of conservatism in design to its target level. CPT testing data are particularly suited for simulation purposes because of the higher reliability in the estimation of vertical spatial variability parameters stemming from the quasi-continuity of measurements in comparison to other in-situ testing metods.


Figure 7. Simulation of horizontal site-scale variability of cone tip resistance for: (a) lower; and (b) higher horizontal correlation distance (adapted from Cai et al. 2021).

6 NON-DETERMINISTIC CPT-BASED GEORISK ANALYSIS

In-situ testing results are frequently used in the increasingly relevant contributions of geotechnical engineering to geohazards risk analysis. Methods have been made available for various hazards and related phenomena including the prediction of triggering of seismic liquefaction, seismically induced soil densification, lateral spreading, and slope stability, among others. The prediction of seismic liquefaction triggering has arguably received most attention. Numerous simplified liquefaction evaluation approaches based on the results of in-situ tests (SPT, CPT, DMT, seismic testing) have been made available over the past decades. Among these, CPT-based methods have been shown to provide significant advantages over others due to: (a) the capability to detect thin layers; (b) the repeatability of measurements; (c) the relative speed and economy.

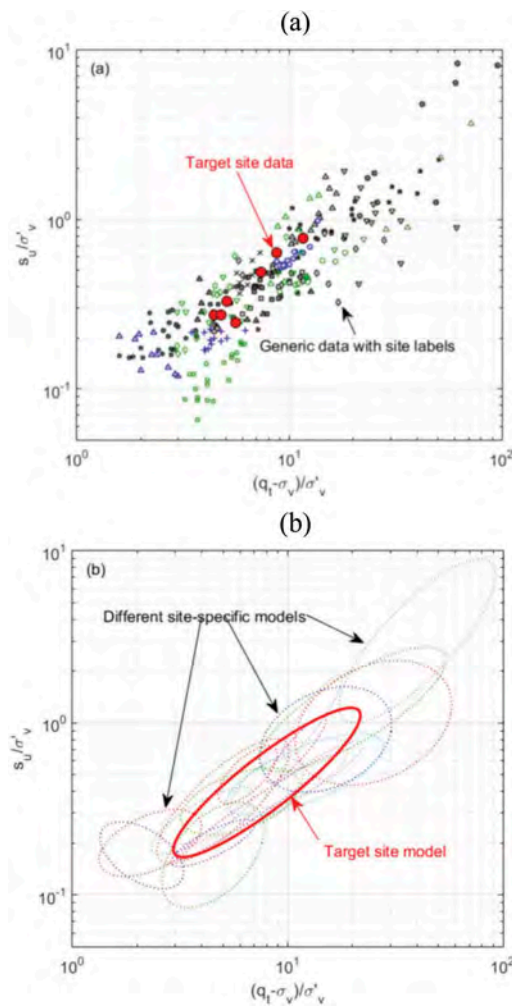
As in all ramifications of the geotechnical discipline, deterministic methods for liquefaction assessment have preceded non-deterministic methods chronologically and are still today predominant even though literature findings increasingly indicate that non-deterministic methods provide multiple significant advantages. First, they allow users to define liquefaction boundary curves for target levels of conservatism, thereby contributing to cost-performance optimization with respect to the vulnerability and value of elements at risk in a specific area. Second, they explicitly include uncertainties in the estimation of the parameters and models used to estimate seismic demand and soil resistance parameters. Third, they allow a more realistic and physics-based modelling and treatment of geotechnical phenomena. The latter point can be well exemplified by the following.


Figure 6. Hybridization of direct and indirect data-driven models for undrained strength from CPT: (a) target site and generic data; (b) resulting site-specific and target site models (Ching et al. 2021).

A vast bulk of research and experimental evidence indicates that seismic liquefaction typically occurs in loose or medium-density, saturated cohesionless soils, while high-plasticity, fine grained soils are inherently "non-liquefiable" due to the relevance of the cohesive component of shear strength. A fundamental step in the implementation of simplified CPT-based methods lies in the assessment of inherent soil liquefiability. Such methods are developed from databases pertaining to soils which are expected to be inherently liquefiable based on prior knowledge, and are thus applicable solely to such soils, i.e., the calculation of the cyclic resistance ratio CRR, which parameterizes the cyclic resistance of soils to liquefaction, is pursued solely at depths corresponding to soils preliminarily assessed to be liquefiable. The applicability of simplified methods must be assessed depth-wise, as stratigraphic profiles can be very heterogeneous in terms of soil types and can include both liquefiable and non-liquefiable soil.

All simplified CPT-based liquefaction evaluation methods include quantitative approaches to the depth-wise assessment of the liquefiability or non-liquefiability of soils. Such assessment typically relies on the definition of deterministic threshold values of the soil behavior classification index I_c (typically varying between 2.4 to 2.6 among methods) which provide a strict boundary between liquefiable and non-liquefiable layers. The assessment resulting from the adoption of deterministic thresholds is invariably binary, i.e., a set of CPT measurements corresponds to either a "fully liquefiable" or "fully non-liquefiable" measured soil volume interval. The hypothesis of an abrupt discontinuity between non-liquefiability and full liquefiability is hardly compatible with well-established geotechnical knowledge and evidence by which liquefiability can be expected to decrease gradually with increasing percentage of fines in a soil. Incidentally, the non-binary effect of varying fines content is already included in simplified methods through the calculation of fine-sand equivalent stress-normalized cone resistance (usually denoted by $q_{c1N,cs}$), which takes continuous (albeit usually inferiorly and superiorly bounded), values, but does not intervene in the preliminary assessment of liquefiability. Moreover, calculated values of I_c are pervaded by uncertainty stemming from measurement depth offset effects, layering effects, and uncertainty in measurements of q_c and f_s. The progressive variation of the degree of liquefiability should be accounted for quantitatively.

Non-deterministic approaches to susceptibility evaluation can contribute to improving deterministic methods. Maurer et al. (2017) proposed deterministic and probabilistic correlations relating I_c to liquefaction susceptibility as defined by four well-established published criteria. Figure 8 shows the respective liquefaction susceptibility probability curves. Such curves, if duly integrated into existing deterministic
Figure 8. Probability of liquefaction susceptibility as a function of the soil behavior type index (from Maurer et al. 2017).
Figure 9. Probabilistic liquefaction boundaries (Schmidt & Moss 2021).

methods, could provide a useful means to quantify liquefiability as a continuous (as opposed to binary) variable and to partially circumvent the limitations which are inherent to deterministic approaches.

"Fully" non-deterministic CPT-based approaches, mostly relying on Bayesian methods for the prediction of liquefaction triggering, are available in the geotechnical literature and are being increasingly used in practice. In comparison with deterministic approaches which provide a single liquefaction boundary curve, these allow the selection of liquefaction boundaries for varying degrees of conservatism while accounting explicitly for uncertainties. Figure 9 provides an example of probabilistic

liquefaction boundaries for varying probability levels as calculated from normalized cone resistance using the approach proposed by Schmidt & Moss (2021). This approach addresses and processes uncertainties in the parameters used in the estimation of cyclic resistance and cyclic stress, as well as uncertainties stemming from intra-event correlation in loading variables and differences in event sample sizes.

Non-deterministic methods can also be used to spatialize the outputs of deterministic simplified CPT-based methods. For example, Guan & Wang (2022) developed a probabilistic method for characterizing the horizontal spatial distribution of the deterministically calculated cyclic resistance ratio, cyclic stress ratio, and factor of safety against liquefaction in data from CPT soundings using Bayesian compressive sampling and Monte Carlo simulation. The method relies on the generation of random field samples and allows the modeling and quantification of spatial variability, interpolation uncertainty, and model uncertainty. Example outputs of the methods include spatial distributions of statistics of the factor of safety resulting from the interpolation of deterministic values obtained at 6 CPT sounding verticals. Figure 10a refers to the mean values of the factor of safety calculated from 10,000 realizations of random fields, while Figure 10b plots the spatial distribution of the coefficient of variation, which provides a quantitative measure of the level of uncertainty in the spatialized values of the factor of safety.

The availability of quantitative measures of uncertainty associated with interpolated values provides a fundamental advantage over deterministic characterization methods, at least because: (1) the parameter is defined probabilistically for direct use in reliability-based methods; and (2) it becomes

Figure 10. Example statistical outputs of the horizontal spatialization of the factor of safety against liquefaction: (a) mean; (b) coefficient of variation (from Guan & Yang 2022).

possible to assess where estimation uncertainty exceeds thresholds of tolerability/acceptability, thus providing direct indications for the conduction of supplementary tests. The visual representation of the spatial variability of the interpolation estimates of the factor of safety allows rational decision-making regarding possible supplementary investigations.

7 TURNING CAUTIONS INTO OPPORTUNITIES

The adoption and implementation of methods such as those presented in the previous sections should never occur in absence of engineering judgment and geotechnical knowledge. Cautions should be adopted at all stages of CPT-based analyses to ensure the geotechnical significance and formal correctness of the quantitative procedures relying on uncertainty modeling. This paper argues that current cautions can be successfully addressed through synergies between research and practice.

7.1 *Interpretation in layered soils.*

Previous studies explored the problem of cone penetration in layered soils analytically (e.g., Yu 2006) or experimentally, either in calibration chambers (e.g., Tehrani et al. 2017) or centrifuges (e.g., Mo et al. 2017). Some of these studies define "sensing distance" as the distance from a layer interface at which the cone resistance first starts changing because the cone is approaching it, and "development distance" the distance from a layer interface at which the cone resistance ceases to be affected by the interface as it moves away from it.

A further complication is given by the fact that the three fundamental CPT parameters pertain to different depths and to different volumes of soil. This fact stems from the physical geometry of the cone and by the inherent differences between the volumes of soils and the physical phenomena affecting cone resistance, sleeve friction, and pore pressure. These three measurements, involving different volumes of soil during penetration. Theoretical modeling of cone penetration has shown that such extent may depend on cone size, geometry, and soil type and stiffness. Thus, the volumes of soil involved in cone tip resistance and sleeve friction measurements are variable. The existence of a measurement depth offset between cone resistance, sleeve friction, and pore pressure is well-known. Approaches relying on statistical techniques such as cross-correlation have been proposed and are implemented in widely used commercial CPT interpretation software.

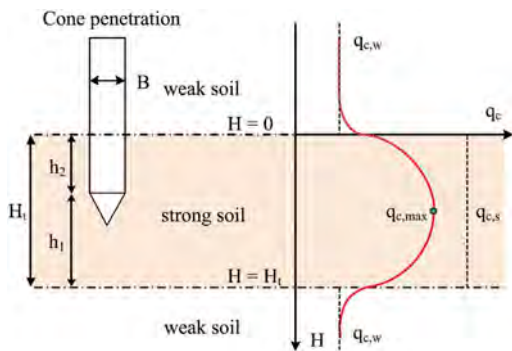
While CPT measurements ultimately reflect the true mechanical behavior of the in-situ soil volume in terms of its resistance to cone penetration, they do not provide fully reliable information if data are not corrected for layering effects, and measurement


Figure 11. Schematic of cone penetration in multilayered soils: strong soil embedded in weak soils (Mo et al. 2017).

offset prior to being used for stratigraphic profiling, soil classification, and in the calculation of geotechnical design parameters. This is because depth-wise measured values do not correspond to the true values at the same depth. CPT-based approaches relying on the depth-wise processing of measurements should in principle be preceded by a pre-processing of data to account for layering effects and for the inherent depth offset between measurements. If such pre-processing is not conducted, these approaches will be pervaded by additional epistemic uncertainty, however sophisticated they may be. The magnitude of the epistemic uncertainty related to layering effects and depth offset tend to increase with stratigraphic complexity.

Despite the inherent complexity in physical phenomena involving cone penetration in layered soils, studies such as those mentioned above have provided ingenious analytical models for the estimation of sensing distance and development distance and for the correction of raw measurement data. The development of efficient algorithms for the translation of the results of these studies into software applications provides a stimulating challenge and an opportunity for considerable improvement in the significance of CPT data interpretation for routine implementation in non-deterministic methods for geotechnical site characterization and design. Operating in the light of the non-deterministic paradigm provides an ideal scenario as uncertainties in the "true" values of CPT measurements in layered profiles can be expressed explicitly.

7.2 *Improved quantification of measurement uncertainty*

The separation of the components of total uncertainty may prove to be a complex process depending on the quality and quantity of data from a specific case. The relative contribution of total uncertainty is also highly case-specific, and depends on site conditions and inherent spatial variability, and degree of

equipment and procedural control in testing data. Geotechnical uncertainty models are typically additive (e.g., Phoon & Kulhawy 1999). The magnitude of individual uncertainty components can thus be estimated in reverse-mode, i.e., by subtracting known uncertainty terms from the total uncertainty which is observed. Consistent approaches to the quantification of measurement uncertainty would result in the availability of more reliable parameterization of measurement uncertainty, leading to more confident subtractive-mode implementation of uncertainty models to estimate aleatory and other epistemic uncertainties from total uncertainty. To this purpose, Peuchen & Terwindt (2014) advocated the development of a shared, less ambiguous glossary (e.g., "repeatability" is strictly not synonymous to "accuracy") and the compilation of a reference measurement uncertainty dataset from real cases (as opposed to "ideal" cases referring to unrealistically controlled conditions).

7.3 *Upgrading of geotechnical correlations*

While new, non-deterministic transformation models yielding design properties from CPT data such as the ones presented in this paper are progressively being made available, the vast majority of geotechnical correlations (including CPT-based correlations) remain deterministic. The full migration of the geotechnical discipline to the non-deterministic paradigm cannot prescind from the upgrading of geotechnical correlations to formats which are compatible with new paradigms. This could be aided by, for instance, through: (a) specific and systematic focus of new research on the development of non-deterministic correlations; and (b) a collective effort on the part geotechnical researchers and practitioners to contribute existing data for the non-deterministic reformulation of existing literature correlations.

8 CONCLUDING REMARKS

This paper has hopefully provided a meaningful insight into the possible benefits of non-deterministic methods for the interpretation of CPT data and its utilization in many and diverse aspects of geotechnical engineering. It has also aimed to highlight the inherent competitive advantage of CPT over other in-situ testing methods in meeting the demands of the new non-deterministic, data-centric paradigm of the geotechnical discipline.

The progressive migration of geotechnical design codes towards non-deterministic formats and the ever-strengthening global digital transition indicates that embracing and implementing such paradigm in practice is no longer a choice for the geotechnical community at large, but rather a beneficial, convenient obligation. Providing students, practitioners, and researchers with sufficient theoretical knowledge and practical tools to understand and implement

non-deterministic methods and approaches is a necessity. ISSMGE TC304 "Engineering Practice of Risk Assessment & Management" recently exerted a formidable effort resulting in a state-of-the-art report containing a conspicuous bulk of quantitative estimates of inherent variability parameters as well as statistics for geotechnical design model factors, random field parameters of geotechnical properties, statistics for transformation uncertainties, and characteristic values of geotechnical parameters for use in non-deterministic design methods.

To further exploit the opportunities offered by the global digital revolution and improved measurement technologies, and to meet the requirements of evolutionary design codes, the geotechnical community must persist in the transition towards the data-centric approach, which is fully compatible with the non-deterministic paradigm. To facilitate and stimulate this transition, new geotechnical databases providing high-quality, validated information are made publicly available. An example database including CPT testing outputs is the ISSMGE TC304 database – 304dB at http://140.112.12.21/issmge/tc304.htm. This paper wishes to encourage the CPT community to actively contribute to this database.

The surge of data-driven approaches does not undermine the central role of geotechnical expertise and engineering judgment. Rather, new engineering paradigms and technological evolutions now require that geotechnical engineering judgment also rely on skills allowing the comprehension of uncertainties and the enhanced analysis of the data which geotechnical testing provides. A modern geotechnical engineering education would thus greatly benefit from structured training in statistical and probabilistic methods, specifically including Bayesian approaches, along with data analysis and machine learning methods. Current practitioners could receive these contents through high-quality professional development initiatives. On the academic side, geotechnical researchers focusing on non-deterministic and data-centric methods should continue striving to make their promising findings increasingly accessible through open-source sharing, free software, and on an improved communication skills to allow a more immediate comprehension of new findings on the part of the geotechnical community at large. ISSMGE-related initiatives focusing on these topics could be disseminated through structured protocols with academia and professional bodies.

The translation of non-deterministic mathematical frameworks of varying complexity and sophistication into practically utilizable executables for the interpretation of CPT data may further foster the transition of the geotechnical community towards cost-performance optimization in geotechnical site characterization, design, and in the analysis and management of georisks, in full accordance with current global trends aimed at sustainability, circularity, and community participation.

Combined use of CPT & DMT: Background, current trends and ongoing developments

P. Monaco
University of L'Aquila, L'Aquila, Italy

ABSTRACT: This paper aims to introduce and stimulate the discussion on the use of CPT & DMT and on the potential of their mutual integration for enhanced site characterization and geotechnical design. It provides a brief overview of background information, current trends and ongoing developments on the combined use of CPT & DMT testing. Specific issues addressed in the paper include: (a) CPT-DMT comparisons and interrelationships; (b) derivation of soil parameters from combined CPT & DMT data; (c) applications based on combined CPT & DMT data.

1 INTRODUCTION

The use of in-situ testing for geotechnical site characterization has continued to expand over the past few decades, gaining an increasing role over the traditional practice based on drilling and sampling for laboratory testing. Often today in-situ tests represent the major part of a site investigation, particularly in geomaterials that are difficult to sample and test using conventional methods (e.g., sands, tailings, semi-liquid soils). Mayne et al. (2009) summarized the key advantages of in-situ tests: (a) they can be done relatively quickly as compared with laboratory tests, (b) results are available immediately, (c) large numbers of data are obtained, and (d) vertical and lateral variability can be assessed over the site.

In this context, the cone/piezocone penetration test (CPT/CPTu) and the flat dilatometer test (DMT) have proven to be particularly efficient and expedient for routine site investigations. In fact: (a) both are direct-push probes, which do not need a borehole for advancement, (b) multiple measurements are collected from a single sounding, (c) the data are obtained digitally and can be accessed for use immediately after completion of the sounding or even in real-time during advancement of the probe, (d) their instrumental accuracy is high, unlike "older" techniques such as the standard penetration test (SPT), (e) technological upgrades, such as additional sensors or full automation (e.g., Medusa DMT, Marchetti et al. 2019), can be easily implemented.

The use of direct-push in-situ tests providing multi-measurements was emphasized by Mayne et al. (2009) as a more efficient approach to geotechnical site characterization. Particularly beneficial and versatile is their "hybrid" configuration that combines the advantages of full-displacement penetrometer probes with downhole geophysics (seismic piezocone SCPTu, seismic dilatometer SDMT), capable to provide information on soil behavior from the small- to the large-strain range.

A single SCPTu sounding provides up to five independent measurements: the basic CPTu measurements (cone resistance q_t, sleeve friction resistance f_s, pore pressure u_2), the shear wave velocity V_S, and information on soil consolidation/permeability parameters if dissipation tests are performed by monitoring the u_2 decay with time (e.g., time to reach 50% degree of consolidation, t_{50}). A single SDMT sounding provides a comparable number of independent measurements: the basic DMT pressure measurements (A, B and optional C corrected to p_0, p_1, p_2 respectively), the shear wave velocity V_S, as well as the compression wave velocity V_P when using the SPDMT configuration equipped with two pairs of receivers for S- and P-wave (Amoroso et al. 2020), and information on soil consolidation/permeability parameters if dissipation tests by monitoring the A-pressure decay with time are performed (e.g., reference time in the A-decay curve, t_{flex}).

For these reasons, Mayne et al. (2009) suggested that the SCPTu and SDMT direct-push tests should serve as the basis for the minimum required level of effort in routine and daily site investigation practices by the profession, in order that adequate amounts and sufficiently different types of data are collected for a given project. These data are complemented with sampling and laboratory testing.

The CPT and the DMT have in common the same equipment for insertion (push rig, rods) and a similar range of soil type applications (clays, silts, sands). Both tests are utilized in site investigations to obtain

information on stratigraphy, soil types and parameters to be used with general or dedicated design methods. However, each test has advantages and limitations and may prove more adequate in specific applications. E.g., the CPT is commonly used for pile design and liquefaction assessment, the DMT generally provides good predictions of settlements of shallow foundations.

In common practice, the CPT is often the preferred primary in-situ test, supported by a much larger consolidated use. On the other hand, the DMT can provide distinctive contributions in a routine site investigation: (1) information on stress history, which has a dominant influence on soil behavior; (2) being an in-situ pressure-displacement test, the DMT results are more closely related to "working strain" soil stiffness than penetration tests.

Some questions that may arise are then: are the two in-situ tests equivalent? Is one test (CPT or DMT alone) self-standing and sufficient for exhaustive geotechnical site characterization? Are there any advantages in the combined use of CPT & DMT?

One notable emerging trend (Marchetti 2015, Marchetti & Monaco 2018) is the increasing diffusion in site investigation practice of a "multi-parameter/multi-test" approach, based on the combination of CPT & DMT. This approach benefits, besides from the multiple measurements provided by a single CPT or DMT sounding, also from the combination of the different measurements obtained from nearby CPT and DMT soundings. Examples of application of a multi-parameter/multi-test approach based on the combined use of CPT & DMT are illustrated in this paper, aiming to stimulate the discussion on the potential of the mutual integration of these two in-situ tests for enhanced site characterization and geotechnical design. The terms 'CPT' and 'DMT' are herein intended in a general sense, referring to any equipment configurations (i.e., CPT(u), SCPT(u); DMT, SDMT, Medusa (S)DMT).

2 CPT-DMT CORRELATIONS

Interrelationships between CPT & DMT parameters can be helpful to expand and improve correlations and applications by using existing experience and databases from one test and extrapolating to the other (Robertson 2012).

Robertson (2009a) reviewed published records of data from nearby CPT and DMT soundings, as well as existing correlations for geotechnical parameters, in an effort to identify possible intercorrelations. The key in this approach was the recognition that, since the main DMT interpreted parameters are normalized, they should be correlated with normalized CPT parameters. Correlations were tentatively established between the three "intermediate" DMT parameters, i.e., the material index I_D, the horizontal stress index K_D and the dilatometer modulus E_D (Marchetti 1980), and the CPT normalized cone resistance Q_{t1},

normalized friction ratio F_r and Soil Behavior Type (SBT) Index I_c, defined as follows:

$$I_D = \frac{p_1 - p_0}{p_0 - u_0} \tag{1}$$

$$K_D = \frac{p_0 - u_0}{\sigma'_{v0}} \tag{2}$$

$$E_D = 34.7(p_1 - p_0) \tag{3}$$

$$Q_{t1} = \frac{q_t - \sigma_{v0}}{\sigma'_{v0}} \tag{4}$$

$$F_r = \left[\frac{f_s}{(q_t - \sigma_{v0})} \right] 100(\%) \tag{5}$$

$$I_c = \left[(3.47 - \log Q_{t1})^2 + (\log F_r + 1.22)^2 \right]^{0.5} \tag{6}$$

where p_0 = corrected first DMT pressure reading, p_1 = corrected second DMT pressure reading, q_t = corrected cone resistance, f_s = sleeve friction resistance, u_0 = pre-insertion in situ equilibrium pore pressure, σ_{v0} = in situ total vertical stress, σ'_{v0} = in situ effective vertical stress.

Robertson (2009a) explained that in most of the available published records the DMT K_D is normalized by σ'_{v0} as in the original formulation (Eq. 2) proposed by Marchetti (1980). Therefore, the CPT cone resistance Q_{t1} was normalized by σ'_{v0} in a consistent manner, i.e., assuming the exponent for stress normalization $n = 1$, as originally proposed by Robertson (1990), although currently used updated formulations (e.g., Robertson 2009b) refer to a normalized cone resistance Q_{tn} that uses a variable n:

$$Q_{tn} = \left[\frac{(q_t - \sigma_{v0})}{p_a} \right] \left(\frac{p_a}{\sigma'_{v0}} \right)^n \tag{7}$$

where p_a = atmospheric pressure in same units as q_t and σ_v, n = stress exponent that varies with SBT I_c (for $n = 1$, $Q_{tn} = Q_{t1}$).

In addition, stress normalization for K_D is a debated issue. Robertson (2009a, 2015) suggested that a more complex normalization for K_D, similar to Q_{tn}, would likely be more appropriate, especially in sands, and future CPT-DMT correlations could use more suitable normalized parameters. However, for typical stress levels in geotechnical engineering of about 65-200 kPa (i.e., $\approx$ 4-20 m) the normalization method has little influence on the normalized parameters, hence updated CPT-DMT correlations using a different normalization may not change significantly. On the other hand, Marchetti (2015) remarked that a linear increase with depth of the DMT p_0 (i.e., a nearly constant K_D calculated using $n = 1$) is observed to large depths at

various test sites. In contrast, the increase of the CPT q_t with depth is generally less than linear, corresponding to $n < 1$. Such a different trend was attributed by Marchetti (2015) to the fact that the DMT blade, having a rectangular cross section with a width/thickness ratio ≈ 6, is less affected by arching than a conical probe, resulting in a more linear trend of p_0 with depth which justifies $n = 1$ for K_D.

The preliminary set of average CPT-DMT correlations proposed by Robertson (2009a) is:

$$I_D = 10^{(1.67-0.67I_c)} \qquad (8)$$

When $I_c \leq 2.60$ (i.e., for sand-like soils):

$$K_D = \frac{0.144Q_{t1}}{[10^{(1.67-0.67I_c)}]} \qquad (9a)$$

When $I_c > 2.60$ (i.e., for clay-like soils):

$$K_D = \beta(Q_{t1})^{0.95} + 1.05 \qquad (9b)$$

$$E_D/\sigma'_{v0} = 5Q_{t1} \qquad (10)$$

where the constant β varies with soil sensitivity ($0.30 < \beta < 0.7$), with an average value $\beta = 0.3$.

The correlations for I_D, K_D (Eqs 8, 9a, 9b) depend on soil type, reflected in the CPT index I_c, which is a function of both Q_{t1} and F_r. These correlations are shown in Figure 1 in the form of contours of DMT I_D, K_D on the CPT normalized SBT chart $Q_{t1} - F_r$.

The relationship between DMT I_D and CPT I_c (Eq. 8) was established considering that both parameters are used to identify soil type. It is noted that I_D, likewise I_c, is a parameter reflecting the mechanical soil behavior, not a soil classification index based on real grain size distribution (Marchetti 1980). Robertson & Wride (1998) suggested that $I_c = 2.60$ can be assumed as an approximate boundary between sand-like and clay-like soils. Based on Eq. 8, $I_c = 2.60$ corresponds roughly to $I_D \approx 1$. In a general sense, CPT and DMT results are drained in sand-like soils ($I_c \leq 2.60$, $I_D > 1$) and undrained in clay-like soils ($I_c > 2.60$, $I_D < 1$). The correlation for K_D (Eqs 9a, 9b) can be sensitive to the cut-off $I_c = 2.60$ when CPT data fall close to the boundary between clay-like and sand-like soils. DMT results in the transition region of silt-mixture soils may also be influenced by partial drainage.

Robertson (2015), based on additional pairs of CPT & DMT (e.g., Togliani et al. 2015), suggested a more simplified link between CPT Q_{t1} and DMT K_D, I_D for young uncemented soils (i.e., soils with little or no microstructure):

$$Q_{t1} = (1.5\log I_D + 7.5)I_D K_D \qquad (11)$$

The (smoother) contours of DMT K_D corresponding to Eq. 11 are also plotted in Figure 1 (red dashed lines) on the CPT normalized SBT $Q_{t1} - F_r$ chart.
Figure 1. Contours of DMT K_D, I_D on the CPT normalized SBT $Q_{t1} - F_r$ chart for young uncemented soils (from Robertson 2017).

To stimulate a discussion on this topic, it is worth recalling what was observed by Robertson (2009a, 2015), i.e., the proposed CPT-DMT correlations are approximate and influenced by variations in in-situ stress state, soil density, stress and strain history, age, cementation, soil sensitivity. These correlations are unlikely to be unique for all soils, but they may form a framework for possible future refinements. Moreover, they may provide further insight into possible future correlations for the DMT with other geotechnical parameters and design applications, since the CPT has a somewhat more extensive theoretical background compared to the DMT, as well as a larger database of documented case histories for certain applications (e.g., liquefaction assessment). Marchetti (2011) recognized that procedures helpful for extracting as much information as possible from the field data represent a precious contribution since soil information is vital for the determination of reliable soil parameters for design, but costly to obtain. Correlations interconnecting CPT & DMT are useful in that translation formulas permit: (1) the use of interpretation methods or charts developed for one test with the results of the other test, (2) converting a database available for one test to a database for the other test. However, Marchetti (2011) stressed that intrinsic limits exist to the accuracy of the CPT-DMT translations, which, despite further refinements, are bound to remain of an approximate nature. These limits are mostly due to the different sensitivity to stress history

of the representative normalized CPT and DMT parameters, as will be discussed in the following.

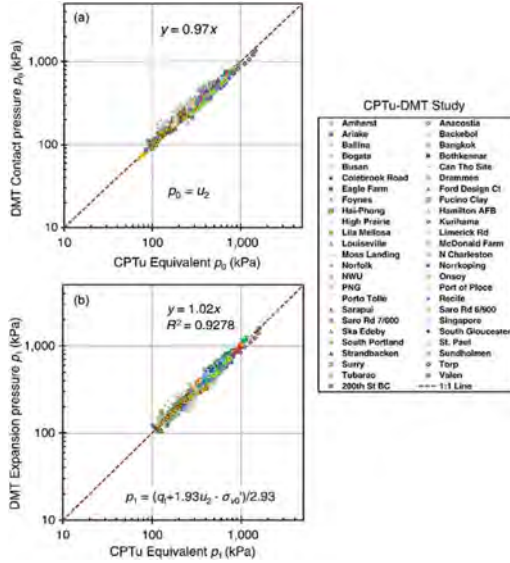
A different theoretical approach for establishing interrelationships between the CPT and the DMT in soft clays has been explored by Mayne (2016), Ouyang & Mayne (2017, 2018) and earlier studies, based on a CPT-DMT compiled database in clays that progressively expanded over the years.


Figure 2. Comparison of DMT and CPTu-equivalent pressures p_0 (a) and p_1 (b) for 49 clays (adapted from Ouyang & Mayne 2018).

Mayne (2016) and Ouyang & Mayne (2017) established a theoretical nexus between CPTu readings (q_t and u_2) and DMT pressures (p_0 and p_1) based on spherical cavity expansion solutions for undrained penetration of both probes in soft to firm clays. This nexus would permit an exchange of interpretations between the two tests, offering a complementary extension of methodologies. Data from paired sets of CPTu-DMT results in a variety of clays were used to support and validate the theoretical links. The net cone resistance, q_{net}, defined as:

$$q_{net} = q_t - \sigma_{v0} \qquad (12)$$

was linked to the DMT pressure readings p_0, p_1 by the following relationship:

$$q_{net} = 2.93p_1 - 1.93p_0 - u_0 \qquad (13)$$

Ouyang & Mayne (2018) further expanded this concept and suggested that q_t and u_2 measured from the CPTu can be utilized to duplicate equivalent DMT pressures p_0 and p_1, and vice versa, according to the relationships:

$$p_0 = u_2 \qquad (14)$$

$$p_1 = \frac{(q_t - 1.93u_2 - \sigma'_{v0})}{2.93} \qquad (15)$$

Eq. 14 is in agreement with earlier studies (Mayne & Bachus 1989, Mayne 2006) that found the p_0 from DMT very similar to the pore pressures u_2 measured by CPTu in intact clays and clayey silts. Figure 2 shows a good agreement between the pressures p_0, p_1 measured by DMT and their CPTu-equivalent p_0, p_1 estimated by Eqs 14 and 15, based on 49 paired CPTu-DMT data sets in a variety of natural soft to firm clays and silts worldwide, having an overconsolidation ratio OCR between 1 to 2.5.

The approach proposed by Ouyang & Mayne (2017, 2018) is valid only for undrained penetration conditions, which are generally accepted to occur for both CPTu and DMT in low permeability clays at a standard penetration rate of 20 mm/s. The approach could be invalidated in intermediate permeability soils, such as silts, where drainage conditions may be different. The CPTu readings q_t and u_2 are taken during penetration (at time $t = 0$), whereas the DMT readings p_0 and p_1 are obtained at approximately $t = 15$ s and $t = 30$ s after penetration respectively, hence some pore pressure dissipation may have occurred prior to obtaining the DMT readings.

3 CPT VS. DMT DATA COMPARISONS

3.1 *Sensitivity to stress history of DMT vs. CPT*

The horizontal stress index K_D is a key parameter obtained from DMT interpretation. K_D reflects cumulatively various stress history effects (overconsolidation, aging, in-situ horizontal earth pressure, K_0), as summarized by Marchetti (2010).

Numerous researchers have observed that the DMT K_D is considerably more sensitive than the CPT cone resistance q_c in monitoring compaction in the field. The higher sensitivity of the DMT to stress history is confirmed by comparisons CPT-DMT in controlled calibration chamber (CC) testing conditions. Jamiolkowski & Lo Presti (1998), in CC tests in Ticino sand, found the DMT K_D much more sensitive to stress-strain history (including aging-like effects) than the CPT q_c. Lee et al. (2011) investigated the effects of stress history on CPT and DMT in CC testing on 40 large specimens of Busan sand having different relative density D_r and OCR in the range 1 to 8. The overconsolidation produced an almost negligible increase in the normalized cone resistance $q_c/(\sigma'_v)^{0.5}$ (Figure 3a), but a substantial increase in K_D (Figure 3b). It appears

that, while the normalized q_c reflects essentially D_r and only to a minor extent OCR,
Figure 3. Effect of stress history on (a) normalized q_c from CPT, and (b) K_D from DMT in CC testing on Busan sand (modified from Lee et al. 2011).

K_D reflects not only D_r, but also stress history effects. The higher reactivity of K_D to OCR indicated by Figure 3, in agreement with other available experiences, implies that to the same normalized q_c may correspond different values of K_D (Marchetti 2016). In Figure 3a the coefficient of determination r^2 close to 1 for data points of any OCR suggests poor ability of the normalized q_c to distinguish OC from NC sands, hence estimating OCR from CPT alone appears problematic. This example supports the necessity of a multi-parameter/multi-test approach based on both DMT & CPT for estimating OCR in sand, as will be discussed in the following.

3.2 Soil parameters estimated from DMT vs. CPT

Many indirect correlations exist between DMT and CPT results, since both tests are used to estimate various geotechnical parameters.

The DMT interpretation is commonly based on the original correlations developed by Marchetti (1980) for "textbook" soils, although several updates, reviewed by Marchetti et al. (2001), have been proposed. Among the various parameters obtained from DMT, the 1-D constrained modulus M (M_{DMT}) is the most generally appreciated. According to Marchetti (1980) M_{DMT} is obtained from E_D (Eq. 3), which links soil stiffness to the p_0 and p_1 measured during membrane expansion (a "mini load test"), corrected as a function of I_D (soil type) and K_D (OCR). Several favorable comparisons in terms of both M_{DMT} vs. reference M and DMT-predicted vs. measured settlements have shown that, in general, M_{DMT} is a reasonable estimate of the "operative" or "working strain" modulus.

Numerous correlations have been proposed to estimate the constrained modulus M from CPT in various soil types. Typically, M is obtained by multiplying the cone resistance (q_c or q_t), or the net cone resistance ($q_t - \sigma_{v0}$), by an empirical coefficient α which depends on soil type and other soil properties, and may vary in a rather large range (e.g., 1 to 10).

Comparisons of moduli M estimated from DMT vs. CPT have been published by several authors. As an example, Amoroso et al. (2022a) compared the depth profiles of M estimated from DMT and CPTu before/after ground improvement with Rammed Aggregate Piers (RAP) in silty and sandy soils at the Bondeno test site, Italy. In natural soils they found a rather good agreement between M estimated from DMT (Marchetti 1980) and from CPTu using the correlations proposed by Robertson (2009b), as shown in Figure 4, while other CPT-based correlations (Lunne & Christophersen 1983, Senneset et al. 1988) provided M equal to about half the values of M obtained from DMT and from Robertson (2009b). The agreement between the latter two methods is not surprising. In fact, the development of the CPT correlations for M by Robertson (2009b) was partly "guided" by the author's correlations between normalized DMT and CPT parameters (Robertson 2009a), based on the recognition that M estimated from DMT has often been shown to provide excellent estimates of settlement (e.g., Monaco et al. 2006). However, Figure 4 also shows that in treated soils, using the same correlations, the increase in M from DMT was found much more evident than the increase in M from CPTu, suggesting higher ability of M_{DMT} to reflect the benefit of soil treatment.

As to the undrained shear strength (s_u) in clay, available comparisons of s_u from DMT vs. other tests at well-documented sites have often found that the depth profiles of s_u estimated from DMT (Marchetti 1980) plot in an intermediate position, in particular in between the s_u profiles obtained from CPT(u) assuming variable values of the cone bearing capacity factor (N_k or N_{kt}). An example is shown in Figure 5 (Marchetti et al. 2022), where the s_u values obtained in Fucino clay by Medusa DMT are compared with the s_u from CPT(u) and from other tests.

Comparisons CPT-DMT are also available in terms of pore pressure index and consolidation/drainage parameters inferred from dissipation tests. The DMT, though non provided with a pore pressure sensor as the CPTu, permits to determine the pre-insertion in-situ equilibrium pore pressure u_0 in sand and to discern layers of different permeability based on the closing pressure p_2. As described by Marchetti et al. (2001), in sand $p_2 \approx u_0$, while in clay $p_2 > u_0$ due to some excess pore pressure induced by penetration persisting at the time of the p_2 measurement. The pore pressure index U_D (Lutenegger & Kabir 1988) is defined as:

$$U_D = \frac{(p_2 - u_0)}{(p_0 - u_0)} \qquad (16)$$

The parameter U_D is the DMT equivalent of the pore pressure ratio B_q from CPTu:

$$B_q = \frac{(u_2 - u_0)}{(q_t - \sigma_{v0})} \qquad (17)$$
Figure 4. Comparison of constrained moduli M estimated from CPTu (Robertson 2009b) and SDMT (Marchetti 1980) in natural and treated soils at the Bondeno test site (modified from Amoroso et al. 2022a).

Figure 5. Comparison of profiles of the undrained shear strength s_u from standard/Medusa DMT, CPT/CPTu and other in-situ and laboratory tests (data from Burghignoli et al. 1991) at Fucino-Telespazio (Marchetti et al. 2022).
Figure 6. Comparison of U_D from DMT and B_q from CPTu (Benoit 1989, from Marchetti et al. 2001).

Similar to B_q, U_D may help delineate soil stratigraphy, particularly in highly stratified deposits. In free-draining soils $U_D \approx 0$, in non free-draining soils $U_D > 0$. The example in Figure 6 (Benoit 1989) shows a good agreement between DMT U_D and CPTu B_q.

The use of the DMT in intermediate soils (silty sands, silts, sandy silts) is being increasingly Monaco et al. (2014) as part of an extensive investigated (Schnaid et al. 2016, 2018). Monaco et al. (2021) presented preliminary results of tests carried out using the Medusa DMT adopting variable pressurization and penetration rates in intermediate soils in the Po river valley, Italy, combined with CPTus at variable penetration rates. In these soils, the highly accurate and repeatable time-for-reading facility of the Medusa DMT permitted to identify some trends in the variation of DMT pressure measurements in response to variable-rate testing conditions, i.e., a slower penetration/pressurization rate 'shifts' the interpretation towards drained behavior, while a faster penetration/pressurization rate 'shifts' the interpretation towards undrained behavior. In sand, a fully drained response was found for any penetration/pressurization rate. U_D appears as a suitable independent parameter to discern between drained, undrained or partially drained soil behavior and may be usefully combined with I_D to obtain some 'soil behavior type'. Ongoing research investigates the potential of combining variable-rate Medusa DMT and CPTu tests as an innovative approach for characterizing the in-situ behavior of intermediate soils.

The DMT is also used to estimate in-situ consolidation/permeability parameters by means of

dissipation tests. Differently from CPTu, the decay with time monitored by the DMT is not that of the pore pressure, but of the total contact A-pressure. This involves lack of worry over desaturation or poor saturation of a porous element, which may affect the u_2 measurement in CPTu dissipation tests. The Medusa DMT technology, which permits to acquire up to 3 repeated A-pressure readings per second, has extended the range of soil types in which A-dissipations are feasible from low permeability soils (clays, silty clays) to intermediate permeability soils (silts, silty sands).

4 DERIVATION OF SOIL PARAMETERS BY COMBINED USE OF CPT & DMT

4.1 *Estimating OCR in sand from DMT & CPT*

The combined use of DMT & CPT may provide estimates of the *OCR* in sand. Marchetti et al. (2001) suggested to use the ratio between the constrained modulus from DMT M_{DMT} and the cone resistance q_c from CPT as an indicator *OCR* in sand:

$$M_{DMT}/q_c = 5 - 10 \text{ in NC sands} \qquad (18a)$$

$$M_{DMT}/q_c = 12 - 24 \text{ in OC sands} \qquad (18b)$$

The above preliminary indications were based on available CPT-DMT data before/after compaction of sand fills (e.g., Jendeby 1992), where M_{DMT}/q_c was found to increase with the overconsolidation achieved by compaction, combined with data from CC research and from other tests.

The possibility to estimate *OCR* in sand by the combined use of DMT and CPT was investigated by Monaco et al. (2014) as part of an extensive experimental study carried out at the Treporti Test Site, Venice, Italy. At this site, a full-scale cylindrical trial embankment (40 m diameter, 6.7 m height, applied pressure 106 kPa) was built and monitored from the beginning of its construction until its complete removal, four years later. Using same-depth values of M_{DMT} and q_t obtained in sand layers from paired DMT and CPTu soundings carried out at the times when reference "imparted *OCR*" were known, i.e. at end-of-construction and post-removal, Monaco et al. (2014) derived the correlation (Figure 7):

$$OCR = 0.0344(M_{DMT}/q_t)^2 - 0.4174(M_{DMT}/q_t)$$
$$+ 2.2914$$
$$(19)$$

Using the same data set, Monaco et al. (2014) also constructed a correlation *OCR*-K_D based only on DMT. However the *OCR*-K_D correlation is not
Figure 7. Correlation OCR-M_{DMT}/q_t in sands obtained from paired DMT-CPTu data at the Treporti trial embankment test site (modified from Monaco et al. 2014).
Figure 8. Chart for evaluating $K_0 = f(K_D, q_c/\sigma'_v)$ proposed by Marchetti (1985).

unique, but likely depending also on the relative density D_r. In fact, going back to the CC results shown in Figure 3b (Lee et al. 2011), it can be deduced that for a given D_r there is a one-to-one correspondence between K_D and *OCR* values (i.e., a vertical line having constant D_r in the diagram intersects each *OCR* curve for a unique K_D value), but if D_r is not constant the same *OCR* may result from a different combination of K_D and D_r. Hence a given K_D may be due either to a low D_r and a high *OCR*, or to a high D_r and a low *OCR*. In order to separate the D_r effect from the *OCR* effect, i.e., to pinpoint the right *OCR*, D_r pair and then to estimate

OCR, the normalized q_c (Figure 3a) is also necessary to provide an indication of D_r on the horizontal axis. Hence both q_c and K_D would be needed to estimate OCR in sand, i.e., CPT alone or DMT alone are insufficient. The OCR-K_D correlation by Monaco et al. (2014) works well at the Treporti test site where it was calibrated because in these sands D_r is almost uniform, but it may not work at sites where D_r is variable. Based on CC tests on Busan sand samples having different D_r and OCR, Choo et al. (2015) proposed a correlation to estimate OCR in sand based on K_D and D_r, with D_r also estimated from DMT, hence using only DMT data. This OCR-K_D correlation needs to be calibrated for each specific sand.

The OCR-M_{DMT}/q_t correlation (Eq. 19) by Monaco et al. (2014), based on both DMT and CPTu data, appears to have more general validity and may provide broad OCR estimates in different sands. Additional research is encouraged to investigate the dependency of the correlation OCR-M_{DMT}/q_t on D_r, stress level and possibly sand type.

4.2 Estimating K_0 in sand from DMT & CPT

Similar considerations may be extended to the estimation of K_0 in sand. The $K_0 - q_c - K_D$ chart in Figure 8, elaborated by Marchetti (1985), is probably the first example of combined use of CPT & DMT. The chart permits to estimate K_0 once q_c and K_D are known. Figure 8 shows, besides the continuous curves obtained from CC tests, an additional scale for q_c/σ'_v based on 25 data points in Po river sand, where an average value $K_0 = 0.55$ was estimated.

Baldi et al. (1986) enriched such $K_0 - q_c - K_D$ chart with additional CC work and converted it into the following equations:

$$K_0 = 0.376 + 0.095K_D - 0.0017q_c/\sigma'_{v0} \quad (20a)$$

$$K_0 = 0.376 + 0.095K_D - 0.0046q_c/\sigma'_{v0} \quad (20b)$$

Eq. 20a was determined as the best fit of CC data, obtained on pluviated artificial sand, while Eq. 20b was obtained by modifying the last coefficient to predict "correctly" K_0 for the natural Po river sand.

Marchetti et al. (2001) recommended using Eqs 20a and 20b (Baldi et al. 1986) with the following values of the last coefficient: -0.002 in "freshly deposited" sand, -0.005 in "seasoned" sand. In this way, the influence of OCR on K_0 is incorporated by the choice of the last coefficient, which involves appreciable subjectivity (e.g., a sand could be assumed as "fresh" if $K_D = 1-2$, "seasoned" if $K_D = 5-6$).

Choo et al. (2015), based on CC testing on Busan sand, proposed a correlation to estimate K_0 in sand from DMT only, but similarly to OCR this correlation requires specific calibration for different sands.

Based on the CC data set by Baldi et al. (1986), Hossain & Andrus (2016) proposed to estimate K_0 in sand by use of the following correlation:

$$\begin{aligned} K_0 = {} & 0.72 + 0.456 \log OCR + 0.035K_D \\ & - 0.194 \log(q_c/\sigma'_v) \end{aligned} \quad (21)$$

in which the influence of OCR on K_0 is explicitly taken into account. Eq. 21 could be used in combination with OCR estimated by Eq. 19.

All the above considerations imply that the challenging task of estimating OCR and K_0 in sands requires a multi-parameter/multi-test approach, based on the combined use of DMT and CPT.

5 APPLICATIONS BASED ON COMBINED USE OF CPT & DMT DATA

5.1 Use of DMT & CPT in monitoring ground improvement

Several comparisons of pre-post CPT & DMT executed for monitoring ground improvement are available. Various studies have found the increase in M_{DMT} after soil treatment approximately twice the increase in q_c. For instance, Jendeby (1992) found an increase of the ratio M_{DMT}/q_c from ≈ 5-12 pre-compaction to ≈ 12-24 post-compaction of a loose sand fill (Figure 9a). Bałachowski & Kurek (2015) found the mean increase in M_{DMT} after vibroflotation of sand about 2.3 times higher than the corresponding increase in q_c and an increase of M_{DMT}/q_c from ≈ 2-10 pre-compaction to ≈ 10-24 post-compaction (Figure 9b). Amoroso et al. (2022a, b), using paired DMT and CPTu data before/after ground improvement with Rammed Aggregate Piers (RAP) at the Bondeno test site, found a similar trend of the ratio M_{DMT}/q_t (Figure 10), consistent with the observed increase in M_{DMT} higher than M from CPTu in treated soils (Figure 4). This evidence suggests that the DMT is more sensitive to stiffness variations as a consequence of the increase in horizontal stress produced by soil treatment, as reflected by the increase in K_0 (and OCR), also shown in Figure 10. Similar pre-post comparisons were reported by Amoroso et al. (2018). The finding that compaction (a sort of "imparted overconsolidation") increases both M_{DMT} and q_c, but M_{DMT} at a faster rate, inspired the use of the ratio M_{DMT}/q_c as a "proxy" of OCR, as previously discussed.

5.2 Liquefaction assessment based on DMT & CPT

The use of the DMT for liquefaction assessment is receiving increasing attention. Much of the interest on the development of simplified methods based on the DMT K_D derives from its high sensitivity to stress history, besides to other factors (e.g., D_r, K_0, aging) that

influence liquefaction resistance. Numerous researchers (e.g., Pyke 2003, Leon et al. 2006 and many others) have pointed out that past stress-strain history (overconsolidation, aging) is likely to have a much greater effect on increasing liquefaction resistance than penetration resistance.

Simplified methods for estimating the cyclic resistance ratio (*CRR*) based on DMT K_D have been proposed over the years, including the most recent by Monaco et al. (2005), Tsai et al. (2009), Robertson (2012), Marchetti (2016), Chiaradonna & Monaco (2022) shown in Figure 11 (valid for magnitude $M = 7.5$ and clean uncemented sand).

All these methods have in common a strong link with CPT-based methods in their origin, in an effort to relate in some way to the field performance database that provides a vast experimental validation for current methods based on CPT, but is currently limited for DMT-based methods.
Figure 9. Ratio M_{DMT}/q_c before-after compaction of sand fills/deposits: data from (a) Jendeby (1992), (b) Bałachowski & Kurek (2015).

The *CRR-K_D* curve by Monaco et al. (2005) was obtained by translating "consensus" CPT (and SPT) curves, namely the CPT curve by Robertson & Wride (1998), using the relative density D_r as intermediate parameter. This approach is inevitably affected by some uncertainty in estimating D_r from the in-situ tests. Differently, Tsai et al. (2009) obtained a *CRR-K_D* curve by translating "consensus" CPT (and SPT) curves, again Robertson & Wride (1998) for CPT, by using direct correlations between the CPT normalized clean sand equivalent cone resistance and the DMT K_D, established using data from paired CPT-DMT soundings at five saturated loose sand sites in Taiwan that experienced liquefaction.

Using a similar approach, independently, Robertson (2012) re-elaborated the CPT-DMT data set collected by Tsai et al. (2009) and proposed, for young uncemented sands ($I_D > 1.2$ and $2 < K_D < 6$), an average relationship between the normalized clean sand equivalent cone resistance $Q_{tn,cs}$, defined as:
Figure 10. Profiles of M_{DMT}/q_t, *OCR* and K_0 obtained from combined DMT-CPTu data in natural and treated soils at the Bondeno test site (modified from Amoroso et al. 2022b).
Figure 11. Recent *CRR-K_D* correlations for clean sand.

$$Q_{tn,cs} = K_c \cdot Q_{tn} \qquad (22)$$

where K_c = correction factor for fines content estimated using I_c, and the DMT K_D:

$$Q_{tn,cs} = 25K_D \qquad (23)$$

Based on Eq. 23, Robertson (2012) converted the Robertson & Wride (1998) CRR-$Q_{tn,cs}$ curve into a CRR-K_D curve. Later Marchetti (2016) obtained a new CRR-K_D curve by combining the same Eq. 23 with the CPT curve by Idriss & Boulanger (2006).

Chiaradonna & Monaco (2022) proposed an update of the CRR-K_D curve adopting the CPT-based framework by Boulanger & Idriss (2014). Using the CPT-DMT data set by Tsai et al. (2009), considering only CPT data having I_c between 1.5 and 2.6, a direct correlation was established between K_D and the clean sand equivalent cone resistance q_{c1Ncs} defined according to Boulanger & Idriss (2014):

$$q_{c1Ncs} = q_{c1N} + \Delta q_{c1N} \qquad (24)$$

where q_{c1N} is the normalized cone resistance and Δq_{c1N} accounts for the effect of fines content.

Despite the dispersion, the data set (Figure 12) is well described by a linear trend with a slope of 20. Figure 12 also shows a second data set from the Scortichino site, Italy, where both CPT and SDMT data were available (Tonni et al. 2015), which is better interpreted by a linear trend with a slope of about 30. Based on this limited data, Chiaradonna & Monaco (2022) adopted an average coefficient of 25:

$$q_{c1Ncs} = 25K_D \qquad (25)$$

which is compatible with Eq. 23 by Robertson (2012), also used by Marchetti (2016). By substituting Eq. 25 into the CRR-q_{c1Ncs} curve by Boulanger & Idriss (2014), a new CRR-K_D curve was obtained.

Average CPT-DMT correlations such as Eq. 23 (Robertson 2012) and Eq. 25 (Chiaradonna & Monaco 2022) may be useful to convert CPT- into DMT-based liquefaction triggering curves. On the other hand, the example in Figure 12 suggests that the $q_{c1Ncs} - K_D$ relationship varies from one site to another, presumably as a consequence of the higher sensitivity of K_D to stress history. Two sites may have similar q_{c1Ncs}, but different K_D depending on different stress history (Marchetti 2016). This implies that q_{c1Ncs} and K_D do not contain equivalent information, and may also explain in part the high dispersion of the CPT-DMT correlations (Marchetti 2015). Robertson (2015), recognizing the higher sensitivity of K_D to factors that cause soil microstructure (stress and strain history, age, cementation/bonding), suggested using the $Q_{tn,cs} - K_D$ relationship to assess microstructure, noting that in young uncemented sands generally $Q_{tn,cs} > 16\,K_D$, while soils with significant microstructure tend to have $Q_{tn,cs} < 16\,K_D$.

In perspective, the DMT could offer a valuable integration to current methods for liquefaction assessment based on CPT, SPT or V_S, also given the

general recommendation towards the use of "redundant" correlations based on different insitu techniques/parameters. The main drawbacks of current DMT-based methods are: (1) lack of any correction factor for the fines content, and (2) limited experimental validation based on field performance data from real earthquakes. Ongoing research is attempting to fill these gaps. The implementation of an adequate case-history database for validation of the DMT-based approach could support the introduction of more consistent liquefaction triggering curves, considering also the fines content influence.
Figure 12. Relationship $q_{c1Ncs} - K_D$ from published CPT-DMT data records at two test sites (Chiaradonna & Monaco 2022).
Figure 13. Correlation for estimating CRR based on both DMT & CPT for clean sand (modified from Marchetti 2016).

Besides the CRR-K_D curve, Marchetti (2016) also proposed a method to estimate CRR based on the combined use of DMT & CPT (Figure 13), aiming to complement the higher sensitivity of K_D to stress history with the much larger field performance support of CPT-based methods. The conceptual framework is the

following: (1) estimate *CRR* using a "consensus" CPT liquefaction curve; (2) increase (shift upwards) the *CRR* predicted by CPT if K_D is high, reduce it (shift downwards) if K_D is low. As an example, Figure 13 for a normalized cone resistance $Q_{cn} = 100$ and $K_D = 3$ provides *CRR* = 0.125 (i.e., lower than predicted by the dashed CPT curve), while for the same $Q_{cn} = 100$ and $K_D = 5$ the chart provides *CRR* = 0.17 (i.e., higher than predicted by CPT). The method proposed by Marchetti (2016) for estimating *CRR* from both DMT & CPT is another example of multi-parameter/multi-test approach. It is expectable that an estimate based on two measured independent parameters could be more accurate than an estimate based on just one parameter.

6 PROPER MATCHING OF CPT & DMT DATA

One specific issue that arises when using any interpretation or design approach that requires the combination of CPT & DMT results is the proper matching of corresponding data. In fact, the CPT measurements are taken every 10-20 to 50 mm, whereas the DMT pressure readings are taken every 200 mm. Data from paired CPT & DMT soundings shall be matched at respective elevations. Care must be adopted even when nearby soundings are carried out at the same ground elevation, particularly in non uniform, highly stratified deposits.

Comparisons between individual same-depth values from nearby CPT & DMT profiles often show considerable scatter due to variations in soil stratigraphy and consistency, hence adjacent data at the same depth may not always represent the same soil. Sand deposits are often characterized by high variability in grain size distribution and D_r, then plots of individual data points from nearby CPT & DMT may show large scatter. The profiles of q_t may also differ slightly from those of adjacent DMT since the CPT senses soil slightly ahead and behind the cone tip (up to 15 cone diameters, depending on soil strength/stiffness and in-situ effective stresses, Ahmadi & Robertson 2005). The DMT appears to be less influenced by soil layers ahead and behind since the probe is stopped and the membrane expanded in horizontal direction. Hence, in interbedded soils the CPT may be influenced by adjacent soil layers somewhat more than the DMT (Robertson 2009a).

Any comparison between adjacent CPT & DMT should be done in terms of the near continuous profiles with depth, so that any variation in soil stratigraphy can be identified from the profiles. It is also common to compare values obtained at the same depth within relatively uniform sections of a deposit. As an example, at the highly stratified Treporti test site (Monaco et al. 2014) the paired CPTu-DMT data, including the data pairs $M_{DMT} - q_t$ shown in Figure 7, were carefully selected by retaining only pairs from uniform soil layers of significant thickness to avoid any possible mismatching of data.

In general, the following matching criteria may be adopted: (1) match paired CPT & DMT profiles accounting for respective ground elevations, if not coincident; (2) correct both CPT & DMT test depths for inclination; (3) select soil type (e.g., sand-like, $I_c \leq 2.60$ and $I_D > 1$, or clay-like, $I_c > 2.60$ and $I_D < 1$) and possibly depth range of interest; (4) identify "visually" or by cross-correlation of representative parameters (e.g., q_t and M_{DMT}) corresponding soil layers in CPT & DMT profiles, to detect any depth misalignment offset; (5) identify soil layers having a reasonable thickness (e.g., in which at least two DMT readings are present) and relatively uniform CPT & DMT parameters; (6) use average values of CPT & DMT parameters in each layer. It would be desirable that the matching algorithm is implemented in software tools, although some visual inspection and judgment may be still needed.

7 CONCLUDING REMARKS

Direct-push in-situ tests such as the CPT and the DMT, particularly in their powerful seismic configurations, have proven to be remarkably expedient in geotechnical site investigations. Recent experience highlights an increasing awareness of researchers and practitioners that an adequate site investigation for a given project cannot rely solely on one isolated testing technique, delineating the trend of expanding diffusion of a multi-parameter/multi-test approach in site investigation practice.

The CPT and the DMT can be effectively combined to obtain more accurate information on stratigraphy and stress history of soil deposits, more reliable estimates of soil parameters (e.g., *OCR* and K_0 in sand) and for various design applications (e.g., monitoring ground improvement, liquefaction assessment). Moving towards an in-situ multi-parameter/multi-test approach appears a logical trend. In this respect, the availability of the DMT stress history parameter K_D is important not only "per se", but also in combination with parameters obtained from CPT.

Each test has advantages and limitations. The CPT is often used more than the DMT, especially for smaller projects, being faster and less expensive (no pauses of penetration are required for obtaining the measurements, as for the DMT). However, the DMT has been shown to be more sensitive to stress history, which has a dominant influence on soil behavior. Hence, their mutual integration could helpfully merge the respective advantages and counterbalance their limitations. For instance, the CPT could be used for a "screening" of the site on a large scale, the DMT at locations of particular relevance for the project. Adjacent CPT & DMT at selected locations should be planned. The increase in time and cost of a site investigation program including paired CPT & DMT soundings can be efficiently optimized considering that both tests can share the same insertion rig and rods, and even the same cable when using the Medusa DMT (i.e., only the probe connected to the

bottom rod needs to be changed). Such "redundancy" would be largely compensated by substantial increase in soil information.

Interrelationships between CPT & DMT can be used to expand and improve correlations and applications by using experience and databases from one test and extrapolating to the other test. The accumulation and sharing of paired data sets from companion series of CPT & DMT soundings at well-documented and benchmark test sites is a desirable address for future research and practice.

Incorporation of SH source wave parameter "SH Polarization" within DST seismic trace characterization

Erick Baziw & Gerald Verbeek

Baziw Consulting Engineers Ltd., Vancouver, Canada

ABSTRACT: Downhole Seismic Testing (DST) is an important geotechnical testing technique for site characterization that provides low strain in-situ interval shear wave velocity estimates, which are fundamental design parameters for static and dynamic soil analysis. A challenging problem in DST is to obtain an accurate assessment or characterization of the quality of the acquired seismic data, which is then used to guide the analysis process to obtain the most accurate interval velocity values. The characterization process is referred to as Seismic Trace Characterization (STC). STC derives various independent parameters of the acquired seismic data at a particular depth, which are then fused together into a single classification. To date Baziw Consulting Engineers has identified five STC independent parameters. These five parameters are the linearity estimates from the polarization analysis, the cross correlation coefficient of the full waveforms at the particular depth and the preceding depth, a uniquely developed parameter referred to as the signal shape parameter, the signal-noise-ratio and the peak symmetry differential, which provides insight into the skewing or time shifting of the peak source wave response. This paper outlines a newly identified seismic trace feature that is independent of the parameters listed above. This new parameter is SH Polarization (SHP), which quantifies the desired polarization of the generated source on the horizontal plane compared with particle motion generated on the vertical plane.

1 INTRODUCTION

The fundamental goal of Downhole Seismic Testing (DST) is to obtain accurate estimates of low strain ($<10^{-5}$) shear (Vs) and compression (Vp) velocities. These velocities are directly related to the various soil elastic constants, such as the Poisson's ratio, shear modulus, bulk modulus and Young's modulus. These parameters form the core of mathematical theorems to describe the elasticity/plasticity of soils and they are used to predict the soil response (settlement, liquefaction or failure) to imposed loads. Accuracy in the estimation of these two in-situ velocities is of paramount importance because their values are squared during the calculation of the soil elastic constants. In DST a seismic source wave is generated at the ground surface, and one or more downhole seismic receivers are used to record this wave at predefined depths. From these recorded seismic traces arrival times are estimated and corresponding interval velocities calculated.

Baziw Consulting Engineers (BCE) has invested considerable resources into the characterization of DST traces (Baziw and Verbeek 2016, 2017, and 2018) to address three fundamental concerns. 1) What is the quality of the acquired seismic data sets? 2) What signal processing techniques can be applied to improve the signal-to-noise ratio (SNR) of

the seismic data? And 3) What is the appropriate confidence level in the calculated interval velocities estimates? Over time work in addressing these three concerns has resulted in the standardization of a DST post data processing methodology, which has proven highly accurate and reliable. Currently quality assessment through Seismic Trace Characterization (STC) relies upon five independent parameters (Baziw and Verbeek 2016, 2017 and 2018):

- Parameter 1: the linearity estimates (LIN) the linearity or rectilinearity from polarization analysis. The LIN trace metric quantifies the correlation between X, Y and Z axis responses. The linearity approaches unity when the rectilinearity is high and approaches zero when the rectilinearity is low. Linearity values nearing 1.0 identify seismic recordings that have highly correlated responses and strong directionality, the quality of the data set with a high linearity value can be considered good. Lower linearity values on the other hand indicate lower quality traces.
- Parameter 2: the Cross Correlation Coefficient (CCC) of the full waveforms at the particular depth and the preceding depth. The CCC trace metric gives an indication of the similarity between the two waves being correlated when

deriving relative arrival times. CCC values approaching 1.0 indicate that the two waveforms are highly correlated. CCC values approaching 0 indicate very poor correlation.

- Parameter 3: the Signal Shape Parameter (SSP). The SSP trace metric quantifies the deviation of the shape of the frequency spectrum from an ideal bell shape. SHP values approaching 1.0 indicate that the frequency has a desirable bells shape. SHP values approaching 0 indicates that the frequency spectrum deviates significantly from the desired bell shape.
- Parameter 4: the Peak Symmetry Differential (PSD) trace metric facilitates the identification of traces whose peak source wave responses have been significantly skewed due to measurement noise or source wave reflection interference. The "peak symmetry" error assessment is also carried out on the adjacent peaks and/or troughs if the amplitude exceeds 70 % of that for the peak response. Traces with low PSD value are of a lesser quality and require more attention during analysis.
- Parameter 5: Signal to Noise Ratio (SNR). The SNR trace metric is solely provided to quantify what portion of the spectral content of the recorded seismogram resides within the desired source frequency spectrum irrespective of source wave distortions such as near-field effects, reflections, refractions, and "dirty sources".

As part of the post analysis of the seismic traces these parameters are then converted into a STC grade ranging from A to F where A is highly desirable and F is unacceptable without corrective action. Next they are used as a guide for the data analysis and seismic signal processing (Baziw and Verbeek, 2018). A central part of this processing is the source wave Signature Feature Isolation (SFI) to clearly identify the source wave in the seismic trace by applying an exponential decay function to the remainder of the trace. This can be performed in three different ways:

- ASD or Automatic Signal Decay, where the program identifies the absolute maximum amplitude on all trace under analysis and then applies the decay function on either side of that feature.
- GSD or Guided Signal Decay, where the user identifies a specific feature for the traces under analysis and then applies the decay function on either side of that feature.
- ISD or Individual Signal Decay, where the user identifies a specific feature for each trace under analysis and then applies the decay function on either side of that feature on that particular trace.

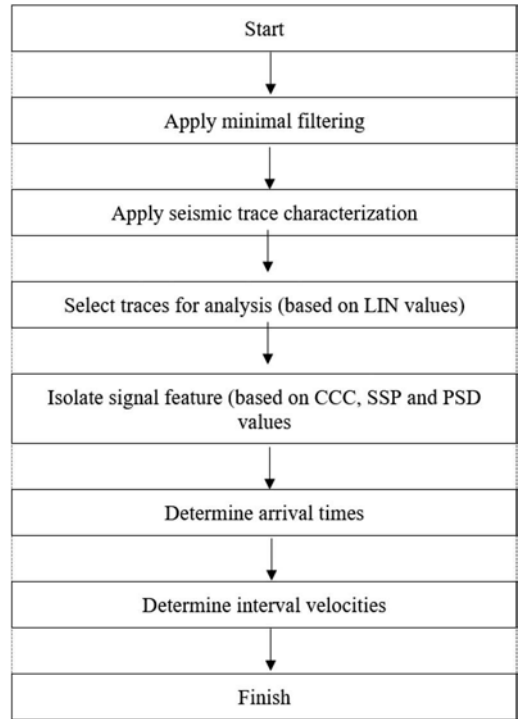
The analysis process can then be visualized as outlined in Figure 1.


Figure 1. DST data processing flow chart incorporating STC parameters.

In this paper, the preliminary implementation and mathematical details of a new STC parameter is outlined. This new parameter, the so called SH Polarization (SHP), quantifies the desired polarization of the generated source on the horizontal plane compared with particle motion generated on the vertical plane.

2 STC PARAMETER SH POLARIZATION (SHP)

Seismic sources are designed to generate either compression (P),vertically polarized shear (SV) waves or horizontally polarized(SH) shear waves. Figure 2 illustrates the compression and shear source waves impacting upon a triaxial seismic sensor package. As it is shown in Figure 2, the P-wave's particle motion is in the same direction as the raypath, the SH waves particle motion is perpendicular to the raypath and is parallel to the horizontal ground surface, while the SV wave's particle motion is also perpendicular to the raypath, but along the vertical normal to the raypath.

P or SV waves generate four outgoing waves when impacting an interface (reflected SV and P waves and transmitted SV and P waves). In contrast, SH waves have the desirable property of only generating one reflected and one transmitted SH at an interface. This results in considerably simplified seismic data sets. A popular SH source is the well-known

hammer beam (ASTM, 2017). The hammer-beam consists of applying a hammer blow laterally to the sides of special designed plates fixed at the surface.
Figure 2. Source P, SV, and SH body waves impacting upon a triaxial sensor package.

The new STC parameter SHP quantifies and applies a grade [A to F] to how closely the measured SH wave seismic traces adhere to the desired polarization of the shear wave on the horizontal plane. The SHP algorithm can be summarized as follows, assuming that a triaxial (x, y and z axes) seismic trace has been recorded.

1. Apply a minimal filter (200 Hz low pass) to the acquired SH source wave.
2. Determine time index, t^*, where the maximum absolute amplitude of the full waveform $(\rho(t) = \sqrt{x^2(t) + y^2(t) + z^2(t)})$ occurs.
3. Establish a time window T which is defined as $t^*-\Delta t$ to $t^*+\Delta t$ where $\Delta t = 30$ms.
4. Over the established time T calculate the energy of the full waveform, E_ρ, and the energy of the particle motion on the X-Y plane E_{xy} $(xy(t) = \sqrt{x^2(t) + y^2(t)})$.
5. Calculate energy ratio $ER = E_{xy}/E_\rho$.
6. Assign a SHP rank based upon calculated ER value as outlined in Table 1.

Table 1. SHP rank and description.

ER Numeric Value [0-1]	SHP Rank [A-F]	STC Description
0.8 to 1.0	A	very good to good
0.65 to 0.8	B	good to acceptable
0.5 to 0.65	C	acceptable to questionable
0.3 to 0.5	D	questionable to unacceptable
< 0.3	F	unacceptable

The SHP rankings outlined in Table 1 are preliminary values. These values will be adjusted and refined as a greater number DST seismic traces are processed.

3   IMPLEMENTATION OF SHP STC PARAMETER ON REAL DATA SETS

The first and second real data sets outlined in this section were acquired by Perry Geotech Limited located in Tauranga, New Zealand. Figure 3 illustrates a SH source wave DST vertical seismic profile (x, y and z axis responses) of SH DST seismic data acquired on the Left Side (LS) of the seismic probe, while Figure 4 shows the VSP of data acquired on the Right Side (RS) of the seismic probe. The STC parameters for the LS and RS are outlined in Tables 2 and 3, respectively.
Figure 3. Data Set 1 – real data set. VSP of data acquired on LS of seismic probe (200Hz low pass filter applied).
Figure 4. Data Set 1 – real data set. VSP of data acquired on right side of seismic probe (200Hz low pass filter applied).

As is evident from Tables 2 and 3 the data sets from the LS and RS have low STC values of 'D's and 'F's (predominantly due to low LIN values), but with high SHP rankings. This suggests that the acquired seismic traces have the desirable polarization on the horizontal plane, but will require preferable axis

Table 2. STC parameters for LS for Data Set 1.

Depth [m]	LIN [0-1]	SSP [0-1]	CCC [0-1]	PSD [0-1]	SNR [0-1]	STC [A-F]	SHP [A-F]
3	0.68	0.54	0	0.86	0.71	N/A	A
4	0.71	0.77	0.69	0.81	0.86	D	A
5	0.59	0.71	0.96	0.73	0.88	D	A
6	0.44	0.70	0.99	0.74	0.91	D	A
7	0.60	0.75	0.96	0.57	0.97	D	A
8	0.88	0.80	0.96	0.59	0.92	D	B

Table 3. STC parameters for RS for Data Set 1.

Depth [m]	LIN [0-1]	SSP [0-1]	CCC [0-1]	PSD [0-1]	SNR [0-1]	STC [A-F]	SHP [A-F]
3	0.77	0.76	0	0.89	0.54	N/A	A
4	0.30	0.77	0.77	0.94	0.88	D	A
5	0.21	0.63	0.80	0.82	0.84	F	A
6	0.46	0.65	0.87	0.77	0.88	D	A
7	0.53	0.69	0.93	0.93	0.98	D	A
8	0.34	0.73	0.85	0.97	0.96	D	B

selection (in this case the X axis) given the LIN values. The SHP rankings give added confidence in the ability to isolate SH responses and derive accurate interval velocities after SFI implementation.

Table 4 outlines the estimated LS and RS interval velocities and corresponding spread. As is shown in Table 4 there is overall high correlation between the LS and RS results (desired values should be ≤ 10% spread), with only the estimated values for the depth interval 3.0m to 4.0m showing a spread slightly above 10%.

The second data set is another example where the LS and RS have again low STC values of 'D's and 'F's (but now due to low PSD values) and high SHP rankings.

Table 4. Estimated LS and RS interval velocities.

Depth [m]	Depth Interval Velocity LS [m/s]	RS [m/s]	Avg. [m/s]	Spread[1] [%]
0.0-3.0	182.4	204.1	193.3	5.6
3.0-4.0	150.4	122.2	136.3	10.3
4.0-5.0	129.4	141.5	135.5	4.5
5.0-6.0	171.3	164.6	168	2.0
6.0-7.0	151.4	141.4	146.4	3.4
7.0-8.0	214.5	239.5	227	5.5

1 The spread is defined as ½ x (LS Interval Velocity – RS Interval Velocity)/Avg. Interval Velocity

For this data set Figure 5 illustrates a vertical seismic profile (x, y and z axis responses) of SH DST seismic data acquired on the Left Side (LS) of the seismic probe, while Figure 6 shows the VSP of data acquired on the Right Side (RS) of the seismic

probe. The STC parameters for the LS and RS are outlined in Tables 5 and 6, respectively.

The SHP rankings suggest that the acquired seismic traces have desirable polarization on the horizontal plane, but will require signal feature isolations based upon the LIN and SSP (LS) and PSD (RS) values.
Figure 5. Data Set 2 – real data set. VSP of data acquired on LS of seismic probe (200Hz low pass filter applied).
Figure 6. Data Set 2 – real data set. VSP of data acquired on RS of seismic probe (200Hz low pass filter applied).

The third data set demonstrates that for a data set with poor STC and SHP values it is (generally) not possible to obtain accurate SH interval velocity estimates. Figures 7 and 8 illustrate the LS and RS traces for a real data set acquired during an offshore DST investigation. The STC parameters are outlined in Tables 8 and 9, respectively.

The combination of very poor STC and SHP values strongly suggests that it is not possible to isolate source wave response by implementing SFI. And therefore this data set was indeed dropped and not analyzed. This shows the importance of having these parameters available in real-time during data acquisition to ensure that the collected data is useful and can be used to derive interval velocities.

4 CONCLUSIONS

Downhole Seismic Testing (DST) is an important geotechnical testing technique which provides estimates of low strain ($<10^{-5}$) shear and compression wave velocities, but there is a need for a widely accepted seismic trace characterization (STC) methodology of the acquired data.

In the past BCE had identified five independent STC parameters (linearity estimates from the polarization analysis, the cross correlation coefficient of the full waveforms at the particular depth and the preceding depth, the signal shape parameter, the signal-noise-ratio and the peak symmetry differential). In this paper, the mathematical and implementation details of a new STC parameter have been outlined. This new parameter, denoted as SHP, quantifies the desired polarization of a horizontally generated shear wave on the horizontal plane compared with particle motion generated on the vertical plane. SH source waves should have negligible particle motion along the vertical axis.

As illustrated in this paper, the initial assessment of the SHP STC parameter when processing real data sets is very promising, although it is fully expected that the SHP ranking will be refined once the parameter has been applied to additional data sets.

In addition the authors intend to develop an approach to incorporate the SHP ranking into the post-processing methodology for seismic data

Methodology for obtaining true cone bearing estimates from blurred and noisy measurements

Erick Baziw & Gerald Verbeek

Baziw Consulting Engineers Ltd., Vancouver, Canada

ABSTRACT: Cone penetration testing (CPT) is an important and widely used geotechnical *in-situ* test for assessing soil properties and mapping soil profiles. CPT consists of pushing at a constant rate an electronic cone into penetrable soils and recording the resistance to the cone tip or cone bearing (q_m). These values (after correction for the pore water pressure to get q_t) are utilized to characterize the soil profile along with measured sleeve friction and pore pressure. The q_m measurements can have significant fluctuations when penetrating sandy, silty gravelly soils, resulting in "high" peaks due to interbedded gravels and stones and "low" peaks due to softer materials or local pore pressure build-up. Furthermore, the q_m values are blurred and/or averaged which results in the inability to identify thin layers and the distortion of the soil profile characterization. Baziw Consulting Engineers has invested considerable resources in addressing these two q_m measurement challenges. The q_mKF algorithm was developed to address the additive measurement noise. In this case the dynamics of q_m are modeled within a state-space mathematical formulation and a Kalman filter is then utilized to obtain optimal estimates of q_m. The q_mHMM algorithm implements a hidden Markov model smoother so that true cone bearing are obtained from the averaged/blurred q_m values. This paper outlines the integration of the q_mKF and q_mHMM algorithms and demonstrates the performance first with test bed simulations (to show the functionality of the algorithm) and then through the analysis of various actual q_m data sets.

1 INTRODUCTION

1.1 Cone bearing measurements

The Cone Penetration Test (CPT) is a geotechnical in-situ tool which is utilized to identify and characterize sub-surface soils (Lunne et al., 1997; Robertson, 1990; ASTM D6067, 2017). In CPT a cone penetration rig pushes the steel cone vertically into the ground at a standard rate and data are recorded at regular intervals during penetration. The cone has electronic sensors to measure penetration resistance at the tip (q_m) and friction in the shaft (friction sleeve) during penetration. A CPT probe equipped with a pore-water pressure sensor is called a piezo-cone (CPTU cones). For piezo-cones with the filter element right behind the cone tip (the so-called u$_2$ position) it is standard practice to correct the recorded tip resistance for the impact of the pore pressure on the back of the cone tip. This corrected cone tip resistance is normally referred to as q_t. The distortions which effect the cone tip measurements are two-fold: 1) the cone tip resistance are smoothed/averaged (Boulanger and DeJong, 2018; Baziw and Verbeek, 2021a) where cone tip values measured at a particular depth are affected by values above and below the depth of interest, and 2) the cone bearing measurements are susceptible to anomalous peaks and troughs due to the

relatively small diameter cone tip penetrating sandy, silty and gravelly soils (Baziw and Verbeek, 2021b).

1.2 Cone bearing smoothing/averaging

The measured cone resistance at a particular depth is an averaged/smoothed measurement of the true values q_v above and below the depth of interest (Boulanger and DeJong, 2018; Robertson, 1990; Baziw and Verbeek, 2021a, 2021b). Mathematically the measured cone tip resistance q_m is described as (Baziw and Verbeek, 2021a)

$$q_m(d) = \sum_{j=1}^{60 \times \left(\frac{d_c}{\Delta}\right)} w_c(j) \times q_v(\Delta_{qm} + j) + v(d) \tag{1}$$

$$\Delta_{qm} = (d - \Delta_{wm}), \Delta_{wm} = 30 \times \left(\frac{d_c}{\Delta}\right)$$

where
  d the cone depth
  d_c the cone tip diameter
  Δ_{qm} the q_m sampling rate
  $q_m(d)$ the measured cone tip resistance
  $q_v(d)$ the true cone tip resistance (prior to pore water pressure correction)

$w_c(d)$ the $q_v(d)$ averaging function
$v(d)$ additive noise, generally taken to be white with a Gaussian pdf

In equation (1) it assumed that w_c averages q_v over 60 cone diameters centered at the cone tip. Boulanger and DeJong (Boulanger and DeJong, 2018) outline how to calculate w_c below (after correcting the equation for w_1 (Baziw and Verbeek, 2021a)):

$$w_c = \frac{w_1 w_2}{\sum w_1 w_2} \tag{2a}$$

$$w_1 = \frac{C_1}{1 + \left| \left(\frac{z'}{z'_{50}} \right)^{m_z} \right|} \tag{2b}$$

$$w_2 = \sqrt{\frac{2}{1 + \left(\frac{q_{t,z'}}{q_{t,z'=0}} \right)^{m_q}}} \tag{2c}$$

where:
   z' the depth relative to the cone tip normalized by the cone diameter
   z'_{50} the normalized depth relative to the cone tip where $w_1 = 0.5 \, C_1$

The cone penetration averaging function w_c for varying $q_{t,z'}/q_{t,z'=0}$ ratios is illustrated in Figure 1.
Figure 1. Schematic of thin layer effect for a sand layer embedded in a clay layer (Boulanger and DeJong, 2018).

1.3 *Cone bearing measurement noise*

The smoothed/averaged cone bearing measurement q_m given by eq. (1) can also contain sharp anomalous and spurious peaks and troughs (Lunne, Robertson and Powell, 1997)

These anomalous and spurious cone bearing measurements are due to the relatively small diameter cone tip penetrating sandy, silty and gravelly soils. As illustrated in Figure 2, the "high" peaks

result from the penetration of interbedded gravels and stones and the "low" peaks results from the penetration of softer materials or local pore pressure build-up. Figure 3 illustrates an example of a cone bearing profile which contains significant anomalous/spurious q_m data from approximate depths 10m to 18m and 22m to 30m. There is also significant pore pressure variability at these depths.
Figure 2. Schematic of anomalous/spurious cone bearing data (after Mortensen and Sorensen, 1991).
Figure 3. Combined results of piezocone test and nuclear density test at Gullfaks C in the North Sea (Tjelta et al. 1985).

2 FILTER FORMULATION

2.1 *qmHMM algorithm formulation*

The initial algorithm developed by Baziw and Verbeek (2021a) (the so called q$_m$*HMM-IFM*) to address the smoothing/averaging of cone bearing measurements (eq. (1)) combined a Bayesian recursive estimation (BRE) Hidden Markov Model (HMM) filter with Iterative Forward Modelling (IFM) parameter estimation in a smoother formulation. The q$_m$*HMM-IFM* provided estimates of the true q_v values from the measured blurred values. In recent modifications and enhancements of the q$_m$*HMM-IFM* it was possible to drop the IFM portion of the algorithm. This was predominantly accomplished by refining the HMM filter parameters.

The HMM filter (also termed a grid-based filter) has a discrete state-space representation and has a finite number of states (Arulampalam et al., 2002). In the HMM filter the posterior PDF is represented by the delta function approximation as follows:

$$p(x_{k-1}|z_{1:k-1}) = \sum_{i=1}^{N_s} w_{k-1\setminus k-1}^i \delta(x_{k-1} - x_{k-1}^i) \quad (3)$$

where x_{k-1}^i and $w_{k-1|k-1}^i$, $i = 1,...,N_s$, represent the fixed discrete states and associated conditional probabilities, respectively, at time index *k-1*, and N_s the number of particles utilized. In the case of the q_m*HMM* algorithm the HMM discrete states represent possible q_v values where

Table 1. HMM filtering algorithm.

Step	Description	Mathematical Representation
1	Initialization (k=0) – initialize particle weights.	e.g., $w_k^i \sim 1/N_s$, $i = 1,\ldots,N_s$ (4)
2	Prediction - predict the weights.	$w_{k\setminus k-1}^i = \sum_{j=1}^{N_s} w_{k-1\setminus k-1}^j p(x_k^i|x_{k-1}^j)$ (5)
3	Update - update the weights.	$w_{k\setminus k}^i = \frac{w_{k\setminus k-1}^i p(z_k|x_k^i)}{\sum_{j=1}^{N_s} w_{k\setminus k-1}^j p(z_k|x_k^j)}$ (6)
4	Obtain optimal minimum variance estimate of the state vector and corresponding error covariance.	$\hat{x}_k \approx \sum_{i=1}^{N_s} w_{k|k}^i x_k^i$ & (7)
5	Let k = k+1 & iterate to step 2.	$P_{\hat{x}_k} \approx \sum_{i=1}^{N_s} w_{k|k}^i (x_k^i - \hat{x}_k)(x_k^i - \hat{x}_k)^T$

In the above equations it is required that the likelihood pdf $p(z_k|x_k^i)$ and the transitional probabilities $p(x_k^i|x_{k-1}^j)$ be known and specified.

maximum, minimum and resolution values are specified. The HMM governing equations are outlined in Table 1.

The q_m*HMM* algorithm implements a BRE smoother. BRE smoothing uses all measurements available to estimate the state of a system at a certain time or depth in the q_v estimation case (Arulampalam et al., 2002; Baziw and Verbeek, 2021a; Gelb, 1974). This requires both a forward and backward filter formulation. The forward HMM filter ($\hat{q}_k^F$) processes measurement data (q_m) above the cone tip ($j = 1$ to $30 \times (\frac{d_c}{\Delta})$) in (1)). Next the backward HMM filter ($\hat{q}_k^B$) is implemented, where the filter recurses through the data below the cone tip ($j = 30 \times (\frac{d_c}{\Delta})$ to $60 \times (\frac{d_c}{\Delta})$ in (1)) starting at the final q_m value. The optimal estimate for q_v is then defined as

$$\hat{q}_k^v = (\hat{q}_k^F + \hat{q}_k^B)/2 \quad (8)$$

where the index k represents each q_m measurement.

In both the forward and backward HMM filter formulation a bank of discrete q_v values ($i = 1$ to N) varying from low (q_{tL}) to high (q_{tH}) and a corresponding q_t resolution q_{tR} is specified. The required number of fixed grid HMM states is given as $N_S = (q_{tH} - q_{tL})/q_{tR}$. In Table 1 the notation of the states x^i is mapped to q^i to reflect the bank of q_t values.

In the q_m*HMM* forward and backward filter formulation the transitional probabilities (i.e., $p(x_k^i|x_{k-1}^j)$ or $p(q_k^i|q_{k-1}^j)$ for each HMM state (i.e., discrete cone tip, q^i) is set equal due to the fact that there is equal probability of moving from a current cone tip value to any other value between the range q_{tL} to q_{tH}. The likelihood PDF $p(z_k|q_k^i)$ in the HMM filter outlined in Table 1 is calculated based upon an assumed Gaussian measurement error as follows:

$$p(z_k|q_k^i) = \frac{1}{\sqrt{2\pi}\sigma} e^{\left[-\frac{(q_c(d)-z_k^i)}{2\sigma^2}\right]} \quad (9)$$

where σ^2 is the variance of the measurement noise. Baziw and Verbeek (2021a) outline the details of the q_m*HMM* algorithm forward and backward filter formulation.

2.2 *qmKF algorithm formulation*

The Kalman Filter (Gelb, 1974) is an optimal (least squares) recursive filter which is based on state-space formulations of physical problems. Application of this filter requires that the physical problem be modified by a set of first order differential equations which, with initial conditions, uniquely define the system behaviour. The filter utilizes knowledge

Table 2. KF governing equations.

Description	Mathematical Representation	
System equation	$x_k = F_{k-1}x_{k-1} + G_{k-1}u_{k-1}$	(10)
Measurement equation	$z_k = H_kx_k + v_k$	(11)
State estimate extrapolation	$\hat{x}_{k|k-1} = F_{k-1}\hat{x}_{k-1|k-1}$	(12)
Error cov. extrapolation	$P_{k|k-1} = F_{k-1}P_{k-1|k-1}F_{k-1}^T$	(13)
Measurement extrapolation	$G_{k-1}Q_{k-1|k-1}G_{k-1}^T$ $\hat{z}_k = H_{k-1}\hat{x}_{k|k-1}$	(14)
Innovation	$\Delta_k = z_k - \hat{z}_k$	(15)
Variance of innovation	$S_k = H_kP_{k|k-1}H_k^T + R_k$	(16)
Kalman gain matrix	$K_k = P_{k|k-1}H_k(S_k)^{-1}$	(17)
State estimate update	$\hat{x}_{k|k} = \hat{x}_{k|k-1} + K_k\Delta_k$	(18)
Error covariance update	$P_{k\backslash k} = [I - K_kH_k]P_{k|k-1}$	(19)

In (10) and (11) v_k and u_k are *i.i.d* Gaussian zero mean white noise processes with variances of Q_k and R_k, respectively (i.e., $v_k \sim N(0, R_k)$ and $u_k \sim N(0, Q_k)$).

of system and measurement dynamics, assumed statistics of system noises and measurement errors and statistical information about the initial conditions.

Table 2 outlines the KF governing equations. In Table 2 x_k denotes the state to be estimated, F_{k-1} denotes the state transition matrix which describes the system dynamics, u_{k-1} the process or system noise (model uncertainty), G_{k-1} describes the relationship between x_k and u_{k-1}, and H_k the relationship between the state and the available measurement (measured cone resistance q_m). The KF can be applied to problems with linear time-varying systems and with non-stationary system and measurement statistics. The KF can be implemented for estimation, smoothing and prediction.

The motivation of implementing the KF for the optimal removal of spurious cone bearing measurements is that it can use any number, combination and sequence of external measurements. For example, it is envisioned measurements from the vane shear test undrained strength could be incorporated within q$_m$KF algorithm based upon empirical correlations. Furthermore, it also fits into our goal of implementation of data fusion techniques into CPTU and SCPT.

Baziw and Verbeek (2021B) present a thorough outline of the q$_m$KF algorithm. For completeness, the KF state and measurement equations are described below.

2.3 System model

To specify the q$_m$KF systems equations in the standard KF state-space form, the following states need to be defined

$$\begin{bmatrix} x_1 \\ x_2 \\ x_3 \end{bmatrix} \equiv \begin{bmatrix} q_m\ conebearingposition \\ q_m\ conebearingvelocity \\ q_m\ conebearingacceleration \end{bmatrix} \quad (20)$$

The discrete system equation (eq. (10)) is given as

$$\begin{bmatrix} x_{1k+1} \\ x_{2k+1} \\ x_{3k+1} \end{bmatrix} = \begin{bmatrix} 1 & \Delta & \Delta^2/2 \\ 0 & 1 & \Delta \\ 0 & 0 & a_w \end{bmatrix} \begin{bmatrix} x_{1k} \\ x_{2k} \\ x_{3k} \end{bmatrix} + \begin{bmatrix} 0 \\ 0 \\ b_w \end{bmatrix} u_k \quad (21)$$

where Δ is the q_m sampling rate and a_w, and b_w are the defining parameters of a first order Gauss-Markov (GM) process, The GM process describes the cone bearing acceleration and w_k is white Gaussian noise with zero mean and unit variance.

2.4 Measurement model

Currently two synthesized measurements are incorporated into the q_mKF algorithm: 1) The best fit seventh degree polynomial to the q_m profile and 2) Output after applying a fourth order low pass frequency filter to the q_m profile. At a later date it is envisioned that additional measurements could be incorporated into the q_mKF algorithm as previously described.

$$\begin{bmatrix} z_1 \\ z_2 \end{bmatrix} \equiv \begin{bmatrix} seventh\ order\ polynial\ best\ fit \\ output\ after\ applying\ low\ pass\ filter \end{bmatrix} \quad (22)$$

A best fit 7thdegree polynomial is made to the q_m measurements every 1m to 1.4 m depth increment (allowed to be refined by investigator based upon data under analysis) so that the anomalous and spurious peaks and troughs are minimized. This polynomial is then fed into the q_mKF algorithm as a measurement. The order of the polynomial and depth increment were selected due to the averaging/blurring of the q_m measurements where it would be highly unlikely that there would be greater than 6 turnings[1] in a 1m to 1.4m depth increment. This assumption was tested with extensive test bed simulation.

A 4th order 250Hz to 300 Hz (allowed to be refined by investigator based upon data under analysis) Butterworth low pass frequency filter is applied to the q_m measurements measurement so that the anomalous and spurious peaks and troughs are minimized even further. This 250Hz low passed frequency filtered trace is then fed into the q$_m$KF algorithm as a measurement.

---

1 The maximum number of turnings of a polynomial function is always one less than the degree

3 IMPLEMENTATION OF Q_MHMM AND Q_MKF ALGORITHMS

3.1 Test bed simulation

The performance of the q_mHMM and q_mKF algorithms were evaluated by carrying out challenging test bed simulations. This section outlines one of those simulations.

Figure 4 illustrates a simulation of thin bed layering (0.2m) where there is alternating true q_v values of 30MPa and 90MPa (light grey trace) interbedded within a 50 MPa background layer. As is shown in Figure 3 there is a resulting oscillation averaged/ smooth q_m trace (black trace) with no sharp peaks or troughs. The output (black dotted trace) of the q_mHMM algorithm is also illustrated in Figure 4. It shall be obvious that the q_mHMM algorithm performed well as the derived $q_v^/$ values closely matched the originally specified q_v values.

Figure 5. Simulated cone bearing averaged/blurred q_m (black trace) of Figure 3, spurious q_m trace (red trace) feed into the q_mKF algorithm, and the q_mKF algorithm output (blue trace).

Figure 4. Simulated true cone bearing measurements q_v (light grey trace) and corresponding averaged/blurred q_m (black trace) measurements. The q_mHMM estimated $q_v^/$ trace (black dotted trace) is superimposed upon the true cone bearing values.
Figure 6. Simulated true cone bearing measurements q_v (light grey trace) and corresponding averaged/blurred q_m (black trace) measurements. The q_mHMM estimated $q_v^/$ trace (black dotted trace) is superimposed upon the true cone bearing values.

Figure 5 illustrates the simulated q_m data of Figure 4 (black) with additive noise to represent anomalous/ spurious q_m data (red trace). The spurious data was simulated with Gauss-Markov process noise (Baziw and Verbeek, 2021b) with a variance of 60 and time constant of 0.1. The simulated Gauss-Markov noise then had a 250Hz high pass filter applied.

Figure 6 illustrates the estimated q_v (black dotted) trace from the q_mHMM algorithm after processing the output of the q_mKF algorithm (blue trace) of Figure 5. Superimposed on these traces is the true q_v (light grey) trace of Figure 4. As is evident from Figure 6, the combination of the $qmKF$ and $qtHMM$

algorithms results in obtaining impressive estimates of true q_v values from challenging q_m data sets.

3.2 Real data examples

After extensive test best analysis, the q_mKF and q_mHMM algorithms were evaluated implemented on real data sets. Figures 7a, 7b and 7c show q_m profiles acquired by Perry Geotech Limited located at Tauranga New Zealand. It is clear from the results presented in these figures that the effect of averaging/

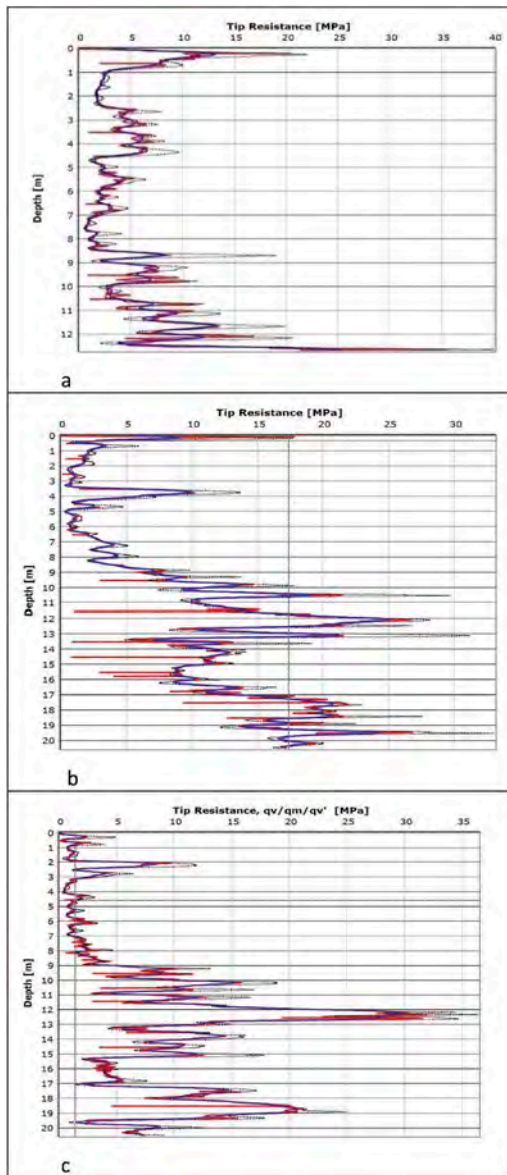
smoothing of the true q_v values (eq. (1)) can results in a significant reduction in the recorded peaks of q_v values, which may very well impact the design based on the CPT data. The q_mKF and q_mHMM algorithms significantly minimize or undo this effect.


Figure 7. Real data sets. q_m (red trace), output from q_mKF (blue trace) and q_mHMM estimated q_v' trace (black dotted trace).

4 CONCLUSIONS

The q_mKF and q_mHMM algorithms outlined in this paper can effectively minimize the anomalous and spurious peaks and troughs to provide a more accurate depth profile of the cone tip resistance.

By applying these algorithms CPT will provide a more realistic soil behavior profile and also allow for more accurate identification of thin layers. In turn it will provide more accurate input data for any design process that uses the CPT results as direct input.

Evaluation of parameters inducing desaturation of a piezocone: Saturation liquid viscosity and exposure to dry sand

G. De Backer, R.D. Verastegui-Flores, W. Vervaele, L. Vincke & K. Haelterman
Department of Mobility and Public Works, Flemish Government, Ghent, Belgium

ABSTRACT: Several CPTU tests were performed in both ideal and adverse conditions at a test site in Zwijnaarde. The influence of exposure to unsaturated soils was examined by holding well-saturated piezocones in dry sand for several minutes without a protective rubber membrane. After the exposure to dry sand, penetration was performed from the ground level through the unsaturated and saturated subsoil. These tests show suboptimal pore pressure measurements, compared to the tests under ideal circumstances, regardless of the duration of the exposure to dry sand. Results reveal that, in adverse conditions, the densely packed sandy top layer, rather than the exposure to dry sand, has contributed to the desaturation of the piezocones. The impact of the viscosity of the saturation liquid on pore pressure quality was studied by performing tests with a 50 and 100 cSt silicone oil. Under ideal circumstances, the viscosity does not play a role in terms of quality of the pore pressure measurements. However, in adverse conditions, results showed a better performance for a silicone oil with 100 cSt viscosity.

1 INTRODUCTION

The repeatability of CPTU parameters has been evaluated in many research studies. Generally a reasonably good repeatability is found for pore water pressure measurements, provided good saturation is achieved and maintained, even when performed with equipment from different manufacturers, as described by e.g. Paniagua et al. (2021), Lunne et al. (2018), Powell et al. (2005). Although dynamic pore water pressure measurements might be a reliable parameter, it is known that many aspects can influence these measurements, such as the element location, design and volume of ports, the type and degree of saturation of the fluids, cavitation of the element fluid system, resaturation lag time, depth and saturation of soil during testing (ASTM 2012). The importance of properly saturating a piezocone sensor has been elaborately documented in literature (e.g. Lunne et al. 1997, ISO 22476-1:2012, ASTM 2012). The need for de-airing the saturation liquid in a vacuum chamber has often been emphasized.

In our daily practice, we experience that even well-saturated piezocones may produce poor pore water pressure measurements, if penetration is started above the groundwater level. This is generally avoided by executing a pre-drilling. However, the problem still occurs in cases where the groundwater level is not exactly known or where the groundwater is to be found at considerable depth. In these situations in presence of unsaturated soils we noticed that the penetrometers seem to be quite prone to desaturation.

In this paper, the influence of the viscosity of the silicone oil on the quality of the pore water pressure measurements is evaluated. Also the influence of exposure to unsaturated soils is evaluated by holding the penetrometer several minutes in dry sand.

2 TEST SITE IN ZWIJNAARDE

The test site in Zwijnaarde is located in the south of Ghent, Belgium. The subsoil consists of Quaternary sand layers, with small sublayers of sandy silt to silt, as can be seen in Figure 1. The Quaternary layers have a thickness of approximately 17 m. With a depth of 15 m, all CPTUs in this testing campaign were performed in the Quaternary layers.
Figure 1. CPTU-data and soil classification.

In the sandy layers, the measured pore water pressures equal the hydrostatic pressure, since the sand is permeable. When passing through the silty layers a drop in the pore water pressure can be noticed in Figure 1. This reduction in pore water pressure is noticed for all pore pressure measurements and is caused by dilative behavior of the dense silt layers, when being sheared during penetration. Although the tests are performed in a small area, there are some spatial variations, both in terms of level and magnitude of the peak cone resistance in the sand layers as well as in the occurrence of the small silt layers, causing pressure drops in the pore pressure measurements.

3 TEST CAMPAIGN AND CONE PENETROMETER DATA

The test campaign took place from March to April 2020. All tests were carried out within an area of 10 by 25 m with a distance of approx. 1 m between two neighboring test points. Four identical piezocones from the same manufacturer were used. The piezocones are of the compression type.

The pore pressure is measured at the u_2 location, which is just above the conical part. A silicone oil, with varying viscosity, was used as saturation fluid.

An overview of the piezometer characteristics is given in Table 1.

Table 1. Cone penetrometer data.

Cone type		Compression
Ac		10 cm²
Filter type		HDPE - 10 micron
Capacity*	q_c	75 MPa
	f_s	1 MPa
	u_2	2 MPa
Saturation fluid		Silicone oil

* Nominal values – penetrometers calibrated according to EN ISO 22476-1 2012 class 2

The same saturation procedure has been used for all tests, according to EN ISO 22476-1 (2012). The silicone oil was de-aired in a vacuum chamber together with the filters for a duration of at least 24 hours. In a next step, the cone tip was filled with de-aired silicone oil using a syringe. Thereafter, the cone was assembled with a pre-saturated filter and placed back in the vacuum chamber for at least 2 hours at vacuum followed by 20 minutes at atmospheric pressure before removing and covering it with a protective rubber membrane.

4 TEST PROGRAM

4.1 *Exposure to dry sand*

To examine the impact on desaturation, well-saturated piezocones were kept in a bucket with dry sand for a certain time interval before executing a CPTU test. The piezocones were protected with a rubber membrane which was removed right before entering a bucket of dry sand. The dry sand is known as 'Mol Sand', characterized by a median particle diameter D_{50} of 0.2 mm and a uniformity coefficient $UC = D_{60}/D_{10}$ of 1.6. Four different time intervals were considered: 5 min, 15 min, 30 min and 60 min.

Immediately after exposure to dry sand, CPTU tests were performed over a depth of 15 m. The results of these pore pressure measurements in adverse conditions are evaluated and compared with CPTU tests performed in the same test field, however, this time starting from the saturated subsoil (ideal conditions). To achieve this, these CPTUs were initiated from a pre-drilled borehole of a depth of 1.5 m. PVC tubes along the shaft prevented collapse of the borehole. The piezocone filters were covered with a rubber membrane directly after saturation. Water was added to the drilling hole, while descending the piezocone in the borehole. The additional water dissipated entirely in the sandy top layers before penetration through the saturated subsoil started. The CPTUs performed according to best practices are referred to as tests under ideal circumstances. Adverse conditions in the present research refers to exposure to dry sand, absence of the protective rubber membrane and no pre-drilling.

4.2 *Viscosity*

The standard saturation liquid, as recommended by the piezocone manufacturer, is a silicone oil with a viscosity of 50 cSt, combined with a filter with a 10 μm pore diameter. In order to decrease desaturation, a more viscous silicone oil of 100 cSt was also used to saturate the piezocone. Similar CPTU tests were carried out as with the 50 cSt liquid.

Table 2 gives an overview of the parameters that were varied in relation to the number of tests performed.

Table 2. Test program.

Parameter	Tested values	Number of tests
Viscosity	50 cSt	12
	100 cSt	12
Duration in dry sand	0 min*	9
	5 min**	4
	15 min	4
	30 min	3
	60 min	4

* Zero minutes in dry sand corresponds to 'ideal circumstances'.
** For one test the duration was 7 min instead of 5 min.

4.3 Evaluation criteria

All pore pressure measurements were evaluated and divided into 4 quality categories: good, fair, mediocre and poor. Evaluation criteria were: similarity to the hydrostatic pressure line and speed of response of the sensor.

Based on a borehole measurement, the water table is at about 7.3 m above sea level, which corresponds to 1.5 to 1.7 m depth. At a depth of 15 m a short dissipation test was conducted for all soundings, resulting in a slightly lower water table. Pore pressure measurements show this slight shift in hydrostatic line too at approximately 0 to 1 m reference level, where a small silty layer occurs. For this reason, an upper and lower hydrostatic line is drawn in all pore water pressure figures, indicated by u_{0-u} and u_{0-l} respectively.

Figure 2 shows an example of pore pressure measurements for each category. The blue dashed line represents a good measurement as it coincides well with the hydrostatic pressure lines and shows a quick response after a pressure drop, as can be seen at e.g. a level of 6.5 m. Some small peaks above the hydrostatic pressure can be noticed between level -3 and -5 m. Unfortunately, there are no cohesive soils at the test site that would generate large and sustained positive pore pressures which would facilitate the evaluation of the sensor response. The pore pressure drops in Figure 2 are not the result of a drop in penetration speed. A constant speed of 2 cm/s was achieved, using a continuous sounding technique. However, the drops agree well with the occurrence of small silty layers in the corresponding CPT-profile.

The green dotted line represents a 'fair' pore pressure measurement. Slightly slow response is noticed after a pressure drop, for instance at around 5 m and -0.5 m. However, it still rejoins the good measurement line. The red dotted line shows the 'mediocre' results, for which the sensor shows even slower response and a larger deviation from the hydrostatic line.
Figure 2. Examples of 4 quality categories of pore pressure measurements versus reference level.

For the 'poor' measurements, in Figure 2 indicated with a light blue solid line, a clear sluggish res-ponse is noticed and it is impossible to determine the hydrostatic line from the pore pressure measurements.

5 TEST RESULTS

5.1 Comparison of measured data

Figure 3 shows the measured cone resistance q_c, sleeve friction f_s and pore water pressure u_2 for all tests, grouped according to their pore pressure quality category. The reference level is based on the depth measurements corrected for inclination and elevation.

As expected, all tests performed under ideal circumstances show good pore pressure measurements. Remarkably in this group, one outlier has been 60 minutes in dry sand and still shows no clear signs of desaturation. This is not the case for the other tests that have been a certain time in dry sand without the protection of a rubber membrane.

Although not the purpose of this study, it is worthwhile to have a look at the q_c and f_s measurements as well. For the top layers the repeatability of q_c is generally quite good. The values of f_s show more scattering. Larger variations for f_s compared to q_c are also found in literature (Paniagua et al. 2021, Lunne et al. 2018). Some anomalies also drew our attention: S112 (cone 2) and T59 (cone 3) show lower q_c and f_s values, whereas T31 and S94 (both cone 4) give higher f_s values. It is unclear what might have caused these anomalies. Since the pore water pressure measurements don't seem to be affected, they were not excluded from the analysis.

Note that the less reliable pore pressure measurements cannot be attributed to a single underperforming piezocone, since all 4 piezocones showed very similar pore pressure measurements in ideal circumstances and because no correlation was observed between any pore pressure quality category and a particular piezocone.

5.2 Viscosity

Since all tests with zero exposure to dry sand produced good pore pressure measurements, regardless of the viscosity of the silicone oil, it can be stated that the viscosity has no influence on the results, if they are performed under ideal circumstances.

However, when the piezocone is exposed to dry sand and subjected to relatively high suction pressures during shearing, it seems that the viscosity does play a role. Based on the results depicted in Figure 4, it is likely that a 100 cSt viscosity might withstand better to desaturation than a 50 cSt viscosity. However, the results should be interpreted with caution given the relatively small number of tests. Further research is to

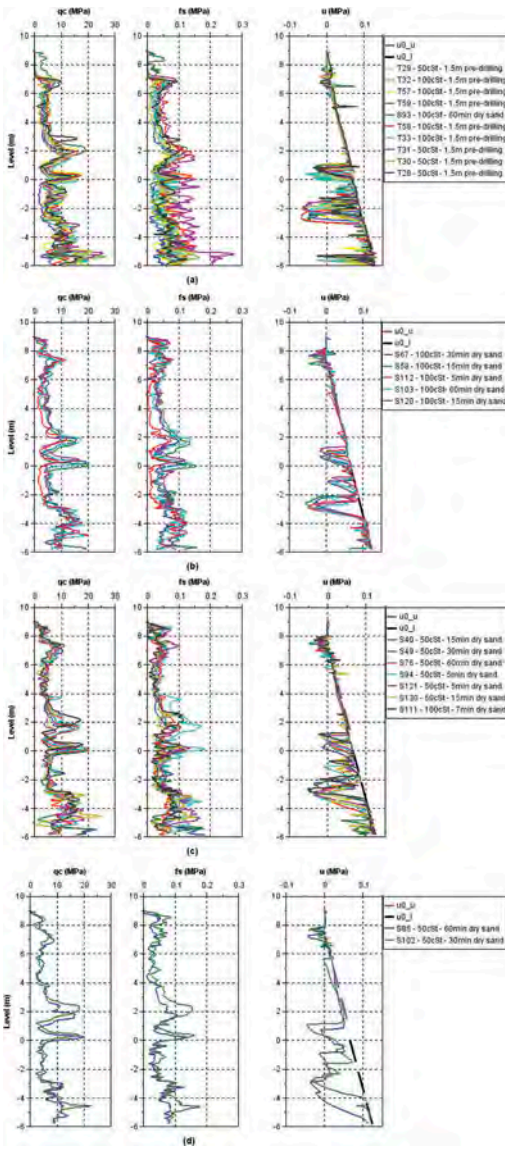
123


Figure 3. Measured qc, fs and u grouped by quality category based on the pore pressure measurements (a) good, (b) fair, (c) mediocre and (d) poor.

Figure 4. Percentage of tests under adverse conditions as a function of pore pressure quality categories for 100 cSt and 50 cSt viscosity of silicone oil.

be carried out to better understand the advantages and possible drawbacks of using a more viscous silicone oil.

5.3 Exposure to dry sand

The impact on the quality of the pore pressure measurements as a function of the time of contact with dry sand is presented in the bubble plots of Figure 5 for both silicone oil viscosities, 50 cSt and 100 cSt.

Each bubble shows the number of tests for a certain combination of pore pressure quality category and number of minutes in dry sand. One would expect a descending trendline showing decreasing quality in the pore pressure measurements for increasing minutes in dry sand. However, this is not the case, especially not for the plot with 100cSt. There is no clear relation between pore pressure quality and contact duration in dry sand. Only zero minutes in dry sand results in an obvious link with good quality measurements.

During pore water pressure observation tests in dry sand, no or very small suction pressures - smaller than the measurement accuracy- were measured. On the other hand, significant negative pore water pressures were observed going from -30 to -50 kPa during penetration for the tests in adverse conditions. For this reason, it seems likely that the negative pressures, occurring shortly after penetration, have been more detrimental to the saturation of the piezocone than the static contact with dry sand. At small depth fairly high q_c values are registered (up to approx. 10 MPa), indicating a high relative density of the sand layer. This sand dilates during penetration and it mobilizes negative pore pressures. This might explain why the contact time in dry sand seems not to be decisive on the quality of the pore pressure measurement and moreover, it might explain why the outlier (CPTU S93), which remained 60 minutes in contact with dry sand, still produced good pore pressure measurements. During penetration this test experienced rather small q_c values (max. 6.5 MPa) just above the water table and consequently small suction pressures were measured (up to -15 kPa), which is in the same order of magnitude as for the other tests producing good results.

Number of tests - 50 cSt

Number of tests - 100 cSt
Figure 5. Pore pressure quality category in relation to the exposure to dry sand for 50 cSt and 100 cSt silicone oil.

6 CONCLUSIONS

Twenty-four CPTUs were performed at the test site in Zwijnaarde in both 'ideal' and 'adverse' circumstances in order to compare pore pressure measurements.

The tests have been performed for two different values of viscosity of the saturation liquid, i.e. 50 and 100 cSt. The results showed that, under optimal conditions, good pore pressure measurements are observed, regardless of the viscosity. However, in adverse conditions, the results suggest that cone penetrometers saturated with 100 cSt silicone oil might withstand better to desaturation compared to those saturated with 50 cSt silicone oil. Further research is to be carried out to evaluate the impact of the viscosity of the silicone oil on desaturation.

The influence of exposure to unsaturated soils was simulated by holding initially well-saturated piezocones in contact with dry sand for several minutes. During their exposure to dry sand the piezocones were not protected by a rubber membrane. All but one piezocones showed clear signs of desaturation during penetration, even when exposed briefly to dry sand. Since no or very small suction pressures were generated during the pore pressure observation tests in dry sand, it is likely that mainly the negative pressures, associated with dilation during penetration of the sandy top layer, have adversely impacted the saturation rather than the exposure to dry sand. In a subsequent study it would be interesting to separate the effect of exposure to dry sand and initial penetration through the unsaturated dense sandy layer, by also performing a pre-drilling for the penetrometers exposed to dry sand.

Large diameter cone penetrometers: What is an appropriate location for the transition to the rod diameter?

D.A. de Lange, T.A. van Duinen & D.J. Peters
Deltares, Delft, The Netherlands

ABSTRACT: 15 cm^2 cone penetrometers are typically pushed to depth by means of 10 cm^2 rods. Therefore, a transition in diameter will be present at a certain distance from the cone shoulder. Although the standards give a requirement for the position of this transition, cone penetrometer configurations that don't meet this requirement are often preferred by CPT sounding companies and are being used in practice. This raises a dilemma. In order to fuel discussion, a first step was made by performing two series of 9 CPTs with different penetrometer geometries. The effects of the penetrometer designs on the measured quantities were investigated. From a preliminary analysis of the results no systematical differences between the different penetrometers were observed. When these preliminary findings are better understood and validated, the standards can be updated.

1 INTRODUCTION

From perspective of a CPT sounding company it is beneficial to have a system that has enough resistance against breakage of the pushing rods and allows deep penetration without the need of an excessive load. For Dutch practice, most commonly utilized cone penetrometers have a projected base area of 10 cm^2 (diameter, D = 3.6 cm) or 15 cm^2 (D = 4.4 cm). However, in general similar pushing rods are used for both cone types, which implies the need for a transition from the wider penetrometer to the smaller pushing rods in case of a 15 cm^2 cone penetrometer. According to NEN-EN-ISO 22476, the lowest point of the transition should be at least 11.2D (= 49 cm) above the cone shoulder. In practice, however, we notice that companies do prefer and use configurations in which the transition is much closer to the cone shoulder (±23 cm or about 5D). The main reason for this deviation from the standards is reduction in required force to reach depth, as the configuration acts like a friction reducer. Further, smaller inclination deviations are observed with a 15 cm^2 cone compared to a 10 cm^2 cone. Therefore, it is understandable that CPT sounding companies prefer such a system over systems that meet the standards.

These observations lead to the following questions:

1. What are the effects of the penetrometer configuration on cone resistance, q_c, sleeve friction, f_s, and/or pore water pressure?

2. What was the basis for the requirements in the testing standards?

Some companies refer to Powell & Lunne (2005) and claim that the measured quantities are hardly affected by the shorter distance from shoulder to transition. Powell and Lunne discuss tests in UK clays, utilizing 15 cm^2 piezocones with sleeve areas of 200 and 300 cm^2. They conclude there is little difference in results between the different sleeve areas. However, the distances from shoulder to transition are not mentioned. Heijnen (1972) presents extensive field research on the shape of the cone penetrometer (10 cm^2), as different results in q_c were observed from a "Dutch mantle cone" and a "straight electrical cone" in sands. Heijnen concluded that a reduction in diameter behind the cone might influence q_c significantly, but that such effects also rapidly decrease with distance from the cone shoulder. Interestingly, no significant differences were observed between a "straight" cone (constant diameter over full length) and a cone with a reduced diameter from 10 cm above the cone "tip" (2.8D). However, we believe that such conclusions should treated with caution due to natural variability of the subsoil and measurement uncertainty.

Most likely, the basis for the requirements in NEN-EN-ISO 22476 are the classical analytical solutions for the bearing capacity of footings, like the Prandtl-wedge. The size of the failure wedge is typically a function of the friction angle of the soil and can extend to great distances from the cone

shoulder, e.g. Figure 1. However, this seems to contradict with the pile base shape factors from NEN 9997-1+C2, see Figure 2. For instance, in case of a 15 cm^2 cone with 10 cm^2 rods (D_{eq}/d_{eq} = 1.5), only H ≥ 2D is required to become comparable with a fully straight pile concerning the tip resistance in sands.

From above findings it might be expected that the different configurations of the 15 cm^2 cone as we come across in the field will not significantly influence q_c. However, it is important to validate this with empirical evidence. Further, the potential influence on the friction readings is less clear so far, as the penetrometer geometry also might affect the horizontal soil stresses around the sleeve. Deltares proposed a series of CPTs using 15 cm^2 cone penetrometers having the transition at different distances from the shoulder. This paper discusses the test details, results, and the next steps required to solve this issue.

Figure 2. Pile base shape factor β for piles in sand (NEN 9997-1+C2).

2 MATERIALS AND METHODS

Two test series were performed in April and December 2021. In total 18 CPTs were executed at a green field, that has been empty for years, adjacent to the Deltares campus, Delft, The Netherlands. Four different 15 cm^2 penetrometer configurations have been used. Configurations A and B do meet the requirements of NEN-EN-ISO 22476 with respect to the location of the transition, while configurations C and D don't. The cone dimensions are given in Figure 3 and Table 1. As can be observed, the area and the location of the friction sleeve was near identical for all penetrometers. All penetrometers were manufactured by the same company and all tests were executed by the same company. The locations and the order of the CPTs are given in Figure 4. E.g. "A2" refers to penetrometer type A and the second CPT of the test series. The target penetration level was 25 m below surface level for all tests, passing through Holocene clay and peat deposits and Pleistocene sand. Pore water pressures were not measured.

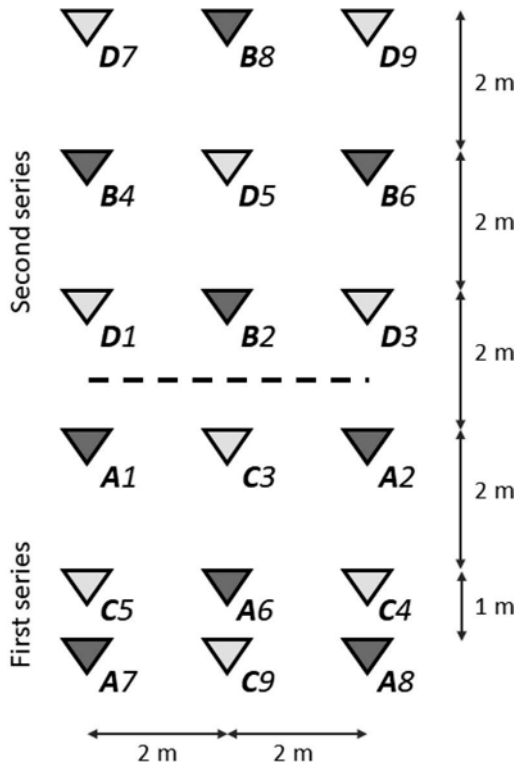

Figure 4. CPT locations and order.

3 PRELIMINARY RESULTS

The results are presented in Figures 5-14. Total cone inclinations of about 1° to 3° were measured at final depth. Therefore, interference between the tests are excluded. Figure 5 shows the q_c-profiles from all type-A tests to indicate the inherent variability. The results of the central CPT are emphasized. Figure 6 also presents the results of this central CPT, but now with respect to the results of all type-C tests. Similar plots are given for f_s, see Figures 7-8. q_c- and f_s-profiles as

Figure 14. Results from D5 with respect to type B results (zoomed in on the soft Holocene layers).

being measured during the second test series are given in Figures 9-14. From the results, no systematical differences were observed, neither for q_c nor f_s, neither in clay nor peat nor sand.

4 CONCLUDING REMARKS

In practice, different penetrometers with large cone diameter are used, several of which don't meet the requirements of the standards. A range has been tested in the presented first investigation. The location of the diameter transition ranged from 4.4 to 12 times D from the cone shoulder. From a preliminary analysis of the results no systematical differences were observed. This is an important finding. As a first next step, the results can be analyzed in more detail. Further, we foresee the need to consult archives and involved people to understand the background and motivation of the adopted standards. In order to achieve a broader basis and have a better statistical support of present results, tests should be repeated at other locations, in other soil types. For better understanding of the mechanisms, a combination of numerical (e.g. MPM) and physical modelling can be applied. Lastly, should you want to contribute, any relevant information from your side is more than welcome! Please contact the corresponding author.

Issues related to piezocone sleeve friction measurement accuracy in soft sensitive clays

B. Di Buò & M. D'Ignazio
Tampere University / Ramboll Finland Oy, Tampere, Finland

T. Länsivaara & M. Haikola
Tampere University, Tampere, Finland

ABSTRACT: Over the past decades, the piezocone testing has been increasingly adopted for field investigation as it offers a quick and cost-effective methodology for subsoil profiling and geotechnical parameters estimation. Although the piezocone testing has revealed good applicability worldwide, difficulties are encountered in complex soil conditions, such as soft sensitive clays. One of the key issues in such soils is represented by the poor quality of the sleeve friction (f_s) measurement due to inaccuracy and poor resolution of the sleeve sensor. This paper investigates the influence of f_s data quality on soil parameters determination with particular emphasis on the soil behavior type (SBT) chart classification. The field investigation was conducted in a soft sensitive clay site located in Finland using two different penetrometers: a standard piezocone and an advanced piezocone characterized by enhance accuracy sleeve friction sensor. Results show that the use of high-resolution piezocone plays a key role in soft clays to avoid misleading soil type classification.

1 INTRODUCTION

1.1 *Cone penetration testing (CPT)*

Cone Penetration Testing (CPT) is a fast and reliable means of conducting subsurface investigation for soil profiling, site characterization and geotechnical parameters evaluation. Since the first introduction of the mechanical probe in 1930s, the equipment has been significantly improved by adding porous filters and transducers, obtaining the modern electronic piezocones (CPTu). Nowadays, the traditional piezocone testing provides three independent readings with depth: the cone tip resistance (q_c), the sleeve friction (f_s), and the excess pore water pressure (u_2) measured behind the cone tip (u_2). The q_c value should be corrected (q_t) to consider the pore pressure acting behind the shoulder. This correction is significant in soft to stiff clayey soils (Jamiolkowski et al. 1985, Robertson and Campanella 1988, Lunne et al. 1997).

The data provided by piezocone test is generally characterized by high precision and accuracy. The sensor accuracy is the difference between the target and the measured value while the precision refers to the degree of reproducibility of a measurement. These aspects are summarized in Figure 1.

Another aspect that plays a key role in data quality is the sensor resolution which is the smallest detectable incremental change that can be measured.
Figure 1. Accuracy and precision definition (source Wikipedia).

This is crucial in soft sensitive clays as the value of f_s is generally very low (<1 kPa).

The equipment available on the market are characterized by different features such as dimensions, tolerances, and sensor accuracy. However, all the specifications, technical requirements, and test procedures are outlined in the European Standards (EN-ISO 22476-1) and American Standards (ASTM D5778 - 20). All these aspects are extensively discussed by (Lunne at al. 1997). Although several piezocones can be employed for CPTu testing, it is fundamental to choose the appropriate equipment to obtain high-quality and reliable data, especially in soft sensitive clays. As an example, studies conducted by

Tampere University (Di Buò et al. 2016, Di Buò 2020) have revealed that standard penetrometers are not suitable to correctly measure f_s in Finnish soft soil, which negatively affects the data interpretation and the accuracy of soil profiling as the small variability of f_s throughout the entire deposit cannot be detected. Moreover, the f_s is fundamental for the soil classification based on the Soil Behavior Type (SBT) chart proposed by Robertson (1990) or for the assessment of a number of geotechnical parameters, such as the soil sensitivity (Mayne 2014). Despite the importance of the f_s data, its correct measurement is still considered one of the main challenges in soft sensitive clays.

This paper presents the CPTu test results obtained from a soft sensitive clay test site located in Pohja, Southern Finland. The soundings have been performed using a "standard" probe and a penetrometer characterized by enhanced sensor accuracy and resolution, herein after referred to as "advanced". The results are analyzed and compared, pointing out the influence of f_s measurement on the SBT classification and the improvements that can be obtained using high accuracy sensors. The main goal of the study is to investigate the influence of the piezocone sensor accuracy on the soil interpretation, rather than a comparison between cone manufacturers.

1.2 Equipment

The two penetrometers adopted in this study were provided by two different manufacturers. Both cones are characterized by 60° apex angle, 10 cm^2 base and 150 cm^2 sleeve area. The first one, referred to as "standard", has been largely used for site investigation in Finnish soft clays as detailed by Di Buò et al. (2020): it consists of an electronic instrumented probe with a nominal range of 7.5 MPa, which is particularly suitable for soft soils investigation. The second, referred herein after as "advanced", is characterized by a nominal range of 50 MPa and higher accuracy compared to the previous cone. This cone has been used at the Pohja site as an attempt to overcome the issues related to the f_s measurement previously discussed. The technical features of both piezocones are summarized in Table 1. The enhanced accuracy of the advanced penetrometer is the result of the embedded sensors type and their configurations. In particular, the q_c and f_s load cells are characterized by four strain gauges wired into a Wheatstone bridge configuration. The bridge is compensated with four modules: two for the material elastic modulus temperature compensation, one for the zero-offset correction and the last one for zero-offset temperature compensation. The Wheatstone Bridge circuit consists of two simple series-parallel arrangements of resistances connected between a voltage supply terminal and ground producing zero voltage difference between the two parallel branches when balanced. It has two input terminals and two output terminals consisting of four resistors configured in a diamond-like arrangement. This configuration allows for high accuracy in the parameter

Table 1. Technical features of the piezocones.

Standard penetrometer

	q_c	f_s	u_2	Inclination
Maximum capacity	7.5 MPa	0.15 MPa	2 MPa	20°
Accuracy	0.2% (15 kPa)	0.7% (1 kPa)	0.25% (5 kPa)	0.5°

Advanced penetrometer

	q_c	f_s	u_2	Inclination
Maximum capacity	50 MPa	1.6 MPa	2.5 MPa	20°
Accuracy	0.01% (5 kPa)	0.0025% (0.04 kPa)	0.0015% (0.04 kPa)	0.5°

measurement. Similarly, the u_2 sensor consists of a silicon piezoresistive load cell in Wheatstone bridge configuration.

1.3 Test site

The Pohja site locates on the southern coast of Finland along the railway line connecting the cities of Helsinki and Turku. The ground elevation is around 9 m above current sea level and the overall topography is flat. However, on a wider scale, the site locates in a valley surrounded by shallow hills with bedrock outcrops. The Pohja site subsoil consists of about 1.5 m thick dry crust layer overlaying a soft slightly consolidated clay layer. Below. silty and sandy layers are encountered. The bedrock is located at depth of 14 m. The water content decreases with depth, from 130% between 2m and 4m till reach 60% at about 7.5 m depth. The natural water content exceeds the liquid limit throughout the entire deposit. Plasticity index is 30–60 and sensitivity, defined as the ratio between intact (s_u) and remoulded undrained shear strength ($s_{u,rem}$), varies between 40 and 60 below the dry crust layer. The undrained shear strength evaluated by the fall cone (FC) test is 7 kPa under the dry crust layer and increases linearly with depth reaching 12 kPa at the depth of 7.5 m. The geotechnical properties of Pohja clay are shown in Figure 2.
Figure 2. Index properties of Pohja clay.

2 CPTU DATA ANALYSIS

2.1 *CPTu soundings*

A total of three CPTu soundings are performed, two of them obtained from the advanced piezocone and one representative vertical from the standard cone. The main purpose herein is to investigate the impact of the sensor accuracy in the measurement readings. The same testing procedure has been adopted for both penetrometers. An initial pre-drilling is made to avoid pushing the cone into the dry crust layer which may cause the desaturation of the porous stone. Prior to CPTu sounding, the cone is placed into the hole filled with water for temperature balancing. Then, the apparatus is pushed into the soil at a standard rate of penetration of 20 mm/s till reaching the coarse layer ($\approx$ 7 m). The measured q_c has been further corrected to account for the pore water pressure acting behind the cone as follows:

$$q_t = q_c + u_2(1 - a) \qquad (1)$$

where *a* is the net cone area ratio provided by the manufacturer after the calibration process. The soundings are conducted using a ceramic filter element replaced after each test. The saturation is ensured by submerging the cone tip into a silicon oil bath in a vacuum device.

Results illustrated in Figure 3 indicate the presence of a homogeneous clay layer from 1 m to 7 m depth followed by interlayers of silts and sands. It is worth observing that both piezocones provide nearly identical response in terms of q_t and u_2 while f_s measurements made using the standard cone are characterized by poor accuracy and low resolution. In particular, higher f_s values are measured by the standard cone (>4 kPa) while the advanced cone indicates f_s values lower than 1 kPa. Even though this difference may seem neglectable, the total error is significant, and it has a great impact in the SBT classification as soil parameter estimation as discussed later.
Figure 3. CPTu soundings at Pohja site.

2.2 *Soil Behavior Type (SBT) chart*

Since its first introduction, the CPT has been widely used for soil profiling and classification. Several authors have proposed classification charts that link the CPT parameters (q_t and f_s) to the soil type (Begemann 1965, Robertson et al. 1986, Robertson 1990). Among them, the soil behavior type (SBT) chart proposed by Robertson et al. 1986 has become quite popular. It identifies 12 types of soil based on the qt and fs values. This approach is mainly based on classifying the soil based on the in-situ behavior which depends on the strength, stiffness and compressibility. In contrast, the unified soil classification system (USCS) does not provide any information on the mechanical behavior as it is based on the grain-size distribution and plasticity. However, in most cases, both approaches agree fairly well as detailed by Molle (2005). The SBT chart has been further improved introducing the normalized parameters:

$$Q_t = \frac{q_t - \sigma_{v0}}{\sigma'_{v0}} \qquad (2)$$

$$F_r = \frac{f_s}{q_t - \sigma_{v0}} \times 100 \qquad (3)$$

$$B_q = \frac{u_2 - u_0}{q_t - \sigma_{v0}} \qquad (4)$$

where Q_t is the normalized cone tip resistance, F_r is the normalized friction ratio, σ_{v0} is the total overburden vertical stress, σ'_{v0} is the vertical effective stress, u_0 is the hydrostatic pore water pressure. The normalized SBT (SBTn) chart is more reliable as it takes into account the influence of the in-situ stress in the soil classification which is particularly important when the sounding is performed at great depths. The charts are illustrated in Figure 4.
Figure 4. Normalized SBT chart proposed by Robertson 1990.

More recently, Robertson et al. (1998) introduced a normalized cone parameter with a variable stress exponent (n), defined as:

$$Q_{tn} = \left[\frac{q_t - \sigma_{v0}}{p_a} \right] \left(\frac{p_a}{\sigma'_{v0}} \right)^n \qquad (5)$$

$$n = 0.38(I_c) + 0.05 \left(\frac{\sigma'_{v0}}{p_a} \right) - 0.15 \qquad (6)$$

where p_a is the atmospheric pressure ($\approx$100 kPa) and I_c is the SBT index first introduced by Jeffries and Davies (1993) and further modified by Robertson (1990) as:

$$I_c = \sqrt{(3.47 - logQ_t)^2 + (logF_r + 1.22)^2} \qquad (7)$$

The normalized SBT chart is shown in Figure 5 with the indication of the I_c values for the different soil type regions.
Figure 5. Contours of I_c on a normalized soil behavior type (SBTn) chart (Robertson 1990).

Recently, Robertson (2016) proposed an updated version of the SBT chart to capture the contractive-dilative soil behavior (Figure 6).

In this study, the original SBT chart proposed by Robertson (1990) is taken into account as the main purpose is to evaluate the soil sensitivity instead of the contractive-dilative soil behavior. It is worth observing that soft sensitive clay region is located at the bottom left of the Q_{tn} and F_r chart, or in the bottom right of the $Q_t - B_q$ chart (Figures 7, 8, and 9). Clearly, the correct evaluation of the f_s is fundamental for a correct evaluation of the SBT. To investigate this aspect, the CPTu soundings performed with the two penetrometers have been assessed separately for soil classification by using
Figure 6. Proposed updated SBTn chart based on Q_{tn}–F_r (Robertson 2016).
Figure 7. Soil behavior type (SBTn) chart based on standard CPTu cone data.
Figure 8. Soil behavior type (SBTn) chart based on the S-1 sounding (advanced cone).
Figure 9. Soil behavior type (SBTn) chart based on the S-2 sounding (advanced cone).

the SBTn charts. Results are presented in Figures 7,8, and 9. As expected, in the Q_{tn}- F_r chart, the data obtained using the advanced cone fall almost entirely in the sensitive clay region while the data points provided by the standard cone fall between the clay and organic clay regions. The reason for this lies obviously in the overestimation of f_s from the standard cone which negatively affected the SBT evaluation. In contrast, the $Q_{tn} - B_q$ chart provides more reliable SBT classification in both cases, even though most of the standard cone data points appear to fall in the clay region.

3 SENSITIVITY EVALUATION BASED ON CPTU DATA

In addition to the SBT classification, the f_s is used in a number of correlations for soil parameters estimation. Several authors (Schmertmann 1978, Robertson and Campanella 1988, Lunne et al. 1997, Robertson 2006) tried to obtain the soil sensitivity based on f_s or the normalized friction ratio (FR). From a theoretical point of view, it is reasonable to correlate the f_s data with the remoulded shear strength ($s_{u,rem}$) obtained from the fall cone test. As shown in Figure 10, the f_s measurement provided by the advanced cone fits fairly well with the $s_{u,rem}$ data (Figure 10) while the standard cone does not catch the trend.

4 DISCUSSION AND CONCLUSIONS

The presented study investigated the influence of the sleeve friction f_s measurement accuracy and resolution on the interpretation of piezocone data in soft sensitive clays. The study is limited to a single test site located in Pohja, Southern Finland. It has been shown that in these soils f_s values are significantly low (<1 kPa) and, therefore, the sleeve sensor should have sufficient resolution to perform accurate measurements. As shown for the Pohja site, traditional piezocones with f_s resolution >1 kPa may provide misleading results, thus inducing to an incorrect classification of the soil type based on the SBT charts. Moreover, the f_s appears to be a key parameter for a reliable estimation of the soil remoulded strength and sensitivity. Therefore, when performing CPTu soundings in soft sensitive clays, it is highly suggested to adopt suitable piezocone equipment with accurate and precise sleeve friction sensor for a reliable and robust data interpretation

The use of high-accuracy site investigation equipment is a key aspect for geotechnical risk assessment in soft sensitive clay areas. This aspect is relevant in relation to detection of sensitive clay layers that may trigger progressive failure during e.g. excavation works, or, as often observed in Norway or Canada, may induce large landslides because of human activity in the area or by other natural phenomena.

Flow cone – new CPTU add-on module trialled in Halden silt

A.S. Gundersen, T. Lunne, R. Stelzer & Ø. Blaker
Norwegian Geotechnical Institute

G.W. Tucker & L. Krogh
Ørsted

ABSTRACT: Hydraulic conductivity is an important soil parameter for design of shallow foundation concepts for offshore wind, and there is a need for a new tool that can measure this parameter in a reliable way. A new module has been developed that can be mounted behind a standard piezocone test (CPTU) probe. Water can be injected in a controlled manner into the CPTU equipment and flow out into the surrounding soil through a filter an offset behind the friction sleeve, while water pressure (u_f) is measured by a transducer mounted in the filter itself. During penetration of the CPTU probe, water flows out at a constant rate, while u_f is measured in addition to CPTU parameters q_c, f_s and u_2. At desired depth intervals penetration can be stopped and either a dissipation test or constant flow rate test can be carried out to determine hydraulic conductivity.

Hydraulic fracture tests can be performed in low permeability soils, where water flow is used to induce a vertical crack in the soil. The vertical crack is then allowed to close while pore pressure is monitored, from which the closing pressure can be determined and subsequently used to determine the in-situ K_0-condition.

This paper describes a series of hydraulic conductivity tests and a hydraulic fracture test carried out at one of Norway's recently established geotechnical test sites, a silt dominated site in Halden. Several tests were successfully carried out and the results were benchmarked against hydraulic conductivity as measured by falling head tests in standpipes and laboratory tests. In general, the results compared well to credible benchmarking tests, showing a promising potential for this tool.

1 INTRODUCTION

Hydraulic conductivity (k) and coefficient of earth pressure at rest (K_0) are required parameters for a wide range of geotechnical engineering problems, including design of shallow foundation solutions for offshore wind. However, these parameters are challenging to measure accurately, both in-situ and in the laboratory. The purpose of the flow cone add-on module is to measure hydraulic conductivity in sands but trial testing at the Halden silt site suggests a wider range of application for the tool. This paper presents results from cone penetration testing, dissipation testing and hydraulic fracture testing in Halden silt, including current interpretation methodology for flow cone dissipation data in low permeability soils.

2 HALDEN SITE

The site is located close to the city Halden in a recreational park, Rødsparken. A silty, clayey sand constitutes the topsoil and extends down to about 4.5-5.0 m below ground level (Unit I), being generally loose to medium dense, with some organic material.

The normally consolidated clayey silt layers below (Units II and III) extend down to about 15-16 m below ground level (bgl) in the southwest corner of the site. The silt is uniform and structureless to mottled, with primary bedding and laminations almost absent due to bioturbation. Units II and III contain similar amounts of quartz (40%), plagioclase (30%), feldspar (12%), clay minerals and mafic minerals (amphibole). Classification and in-situ tests suggest that the silt becomes sandier closer to the deeper soil unit, which consists of a low to medium strength clay (Unit IV). The clay unit has a slightly laminated structure, with occasional shell fragments and drop stones (Blaker et al., 2019).

3 OVERVIEW OF TESTS

This paper presents a range of laboratory and in-situ tests as part of the assessment of flow cone results. To facilitate easy reading, Table 1 is included providing a general overview of benchmark tests and flow cone tests, number of tests carried out, nomenclature and depth ranges.

Table 1. Overview of benchmark tests and flow cone tests.

Equipment	Test type	Number of tests	Test abbreviation	Location IDs	Test IDs	Depth range	Comments
Oedometer	Constant head*	22	Oedometer	-	-	4.5-18.7 m bgl	Benchmark tests
Triaxial	Constant head	13	Triaxial	-	-	5.3-14.6 m bgl	Benchmark tests
Standpipe	Falling head	10	HA-SLT	1 to 5	1 to 2	6-15 m bgl	Benchmark tests
CPTU	Cone penetration	1	HA-CPTU	-	-	2-18 m bgl	Benchmark test
Flow cone	Cone penetration	4	HA-FCPTU	1 to 4	-	2-18 m bgl	
Flow cone	Dissipation	13	HA-FCPTU	1 to 4	1 to 4	6-15 m bgl	
Flow cone	Hydraulic fracture	1	HA-FCPTU	4	5	16.41 m bgl	

*Hydraulic conductivities at zero axial strain (back-extrapolated along the linear e-log(k) line)

4 BENCHMARK TESTS

4.1 Oedometer and triaxial tests

Constant-head hydraulic conductivity tests were conducted at different stress levels during a selected number of oedometer tests and during the consolidation stage of several triaxial tests (Sandbækken et al., 1986, Berre, 1982). Hydraulic conductivity was determined by flowing de-aired water through the specimens. Values from oedometer tests represent hydraulic conductivity at zero axial strain (i.e., at a void ratio comparable to in-situ conditions). Values from triaxial test specimens represent the hydraulic conductivity at the in-situ effective stress state (i.e., after consolidation and some subsequent change in void ratio).

4.2 In-situ falling head tests

Ten in-situ falling head tests (slug tests) were conducted in parallel with flow cone testing at five corresponding depths. The excess pore pressure from standpipe installation could dissipate for 24 hours before falling head tests were initiated by pouring clean tap water into the standpipes. Figure 1 illustrates pressure heads with velocity and best fit linear regression lines, showing good repeatability for all tests except the tests 15 m bgl, which may be explained by a small gap between the standpipe and surrounding soil for test HA-SLT-5-1.

For interpretation of hydraulic conductivity, the velocity method was preferred over time lag method due to its simplicity and independence of piezometric level (Chapuis, 2012). From the slope, m_v, of the linear regression lines in Figure 1, the hydraulic conductivity, k, was determined using Equation (1), refer to Daniel (1989) for further details, where A is the internal cross-sectional area of the standpipe and L and D are the length and diameter of the well screen, respectively.

$$k = \frac{A * \ln\left(\frac{L}{D} + \sqrt{1 + \left(\frac{L}{D}\right)^2}\right)}{m_v\left(2\pi L - 2.8D * \ln\left(\frac{L}{D} + \sqrt{1 + \left(\frac{L}{D}\right)^2}\right)\right)} \quad (1)$$
Figure 1. Pressure head with velocity from in-situ falling head tests. Measured results and best fit linear regression lines.

5 EQUIPMENT AND PROCEDURES

The flow cone is a standard cone penetrometer paired with a custom-built hydraulic module, see Figure 2 (Gundersen et al., 2019). The hydraulic module consists of a bronze filter offset behind the cone sleeve and a control system at ground surface. The control system handles data acquisition and provides flow rate control by means of a linear step motor driving a piston. Parameters such as ambient pressure, system pressure, water pressure inside filter (u_f) and flow rates are recorded. During cone
Figure 2. Equipment and setup of the flow cone (Gundersen et al., 2019). The offset between u_2 and u_f measurements is 123 cm.

penetration, water flows into the surrounding soil through the filter at a constant rate while u_f is measured in addition to cone resistance (q_c), sleeve friction (f_s) and pore pressure (u_2). The purpose of water flow during cone penetration in low permeability soils is to maintain filter saturation and prevent filter clogging. At desired depths penetration can be stopped and either a dissipation test, constant flow rate test or hydraulic fracture test can be conducted.

A hydraulic fracture test is performed by inducing a crack in the soil by water flow for subsequent monitoring of pore pressure decay. The test is intended for low permeability soils with $K_0 < 1$, meaning that the in-situ horizontal stress is lower than the vertical, and thus a vertical crack is expected to initiate first. To split the soil, a sufficiently high flow rate must be applied. At Halden, 30 ml/min was selected based on previous experience from testing in soft clays. The vertical crack closes when the pore pressure equals the soil pressure normal to the crack, and the basis for K_0 derivation is that this soil pressure is equal to the in-situ total horizontal stress, σ_{h0} (Bjerrum and Andersen, 1972).

All tests at Halden were carried out using a standard 10 cm² Geotech Nova cone with acoustic data transmission from probe to user interface, with standard penetration rate of 20 mm/s ± 5 mm/s. In total, 13 dissipation tests were carried out to a target 75 % dissipation of initial excess pore pressure where all CPTU parameters were logged including u_f.

6 MEASURED AND DERIVED PARAMETERS

6.1 Cone penetration tests

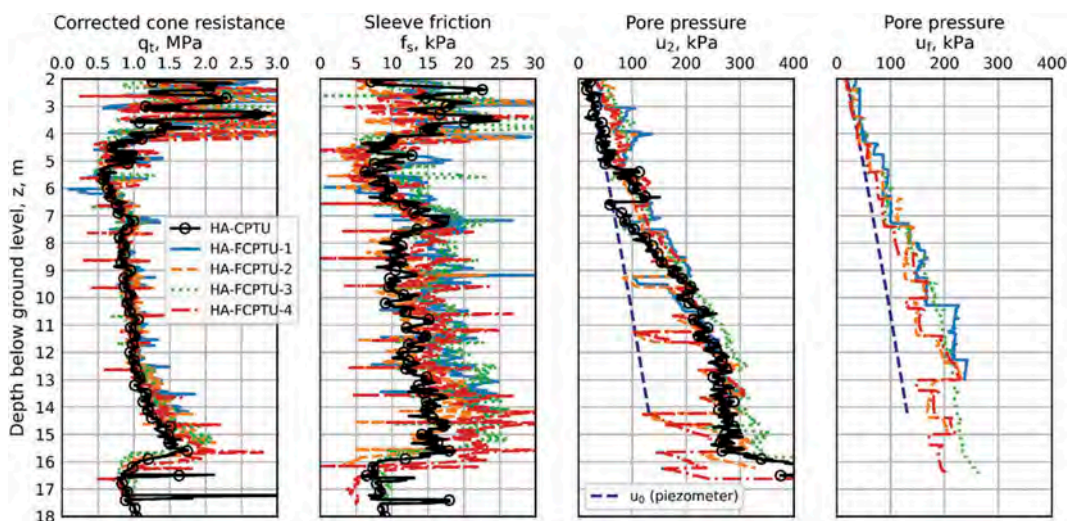
Figure 3 illustrates the corrected cone resistance (q_t), sleeve friction (f_s) and pore pressures (u_2 & u_f) with depth below ground level corrected for inclination. The figure includes results from a standard CPTU (HA-CPTU), suggesting that a constant flow rate of 5 ml/min during cone penetration, which was selected based on previous experience, has negligible effect on the standard cone penetration measurements (i.e., q_c, f_s, and u_2).


Figure 3. Corrected cone resistance, q_t, sleeve friction, f_s, pore pressure behind cone shoulder, u_2, and pore pressure, u_f, with depth.

6.2 Pore pressure dissipation tests

Figures 4 and 5 illustrate the measured pore pressures u_2 and u_f with square root of time. Most of the tests in Figure 4 exhibit dilative behavior (non-monotonic), which is consistent with previous dissipation tests conducted at the Halden site (Carroll and Paniagua, 2018). The pore pressure, u_f, generally exhibits a monotonic decrease with time but a small delay in pore pressure decay is evident in Figure 5.

The square root method proposed by Sully et al. (1999) was used to determine hydraulic conductivity from u_2-dissipation data, back-calculating the initial pore pressure, assuming an initial linear relationship between pore pressure and square root of time.

Rigidity index ($I_r = G/s_u$) and constrained modulus (M) are required for estimating hydraulic conductivity from flow cone dissipation tests. Teh and Houlsby (1991) showed that I_r influences the plastic failure zone around the cone tip during penetration and hence the associated stresses and pore pressures. Carroll and Paniagua (2018) interpreted u_2-dissipation results from Halden using I_r based on advanced laboratory testing and conservative undrained shear strength. In addition, two methods proposed by Krage et al. (2014) were examined, Method-A and Method-B. The latter compared the best with advanced laboratory data and has thus been applied. Method-B rigidity index is calculated using Equation (2), where G_{max} is the small strain shear modulus and σ_{v0} and σ'_{v0} are the in-situ total and effective vertical stress, respectively.

$$I_r = 0.26 \left(\frac{G_{max}}{\sigma'_{v0}} \right) \left(\frac{1}{0.33 \left[0.33 \left(\frac{q_t - \sigma_{v0}}{\sigma'_{v0}} \right) \right]^{0.75}} \right) \quad (2)$$

Best estimate values of G_{max}, σ_{v0}, σ'_{v0} and M found in Blaker et al. (2019) were used as basis for interpretation of hydraulic conductivity. Input of corrected cone resistance in Equation 2 was derived from linear interpolation of the results presented in Figure 4.

As part of proposing an interpretation methodology for u_f-dissipation, triple element CPTU results from Halden were reviewed. This review suggested that the initial excess pore pressure, $u_{f,i}$, is primarily caused by the cone penetration itself, not the input water flow of 5 ml/min. On this basis, it was concluded that the Teh and Houlsby (1991) framework for location 10 radii behind the cone shoulder could be used to estimate the hydraulic conductivity. Figures 6 and 7 show the head ratio with dimensionless time factor for u_2-dissipation and u_f-dissipation using the framework by Teh and Houlsby (1991). The figures show a good fit to the shape of the theoretical solutions, which is discussed further in Section 7.

6.3 Hydraulic fracture test

One hydraulic fracture test was conducted 16.41 m below ground level, the result of which is illustrated in Figure 8. The figure shows measured pore pressure with velocity (i.e., how quickly the pore pressure decays). The pressure at which the crack closes was estimated to 2240 cm. Based on piezometric level from standpipe falling head tests and an average soil unit weight of 19.2 kN/m³, this yields a K_0 value of 0.44, which falls within the expected K_0-range (0.4 to 0.65) for the Halden site.

7 DISCUSSION AND COMPARISON

Figure 9 illustrates the hydraulic conductivities from benchmark tests (oedometer, triaxial and in-situ falling head tests) and flow cone u_2-dissipation and u_f-dissipation tests with depth. Oedometer and in-situ falling head tests generally present the highest and lowest hydraulic conductivities, respectively. The difference may be explained by the oedometer values being picked at zero axial strain with presumably higher void ratio than in-situ conditions. For the in-situ falling head tests, a concern is filter clogging during installation, causing reduced water injection area and lower calculated hydraulic conductivities. Other aspects of the in-situ falling head tests involve soil disturbance, stress changes, transient consolidation, variations in piezometric level, shape factor, etc.

Hydraulic conductivities from u_2-dissipation and u_f-dissipation show good agreement with triaxial test results, especially from 10 m to 15 m bgl. It is evident from Figure 9 that u_2-dissipation and u_f-dissipation tests can identify the main soil layering i.e., the clay below 16 m bgl and the sand 4 m bgl presenting significantly lower and higher hydraulic conductivities, respectively, as expected.

Except for falling head and u_2-dissipation results below 14.5 m bgl, in-situ tests show good repeatability. In contrast, oedometer results show some scatter which may be due to disturbance during sampling and sample handling having significant influence on the results due to small sample size.

Distribution of excess pore pressures around the cone tip and shoulder are generally more complex than alongside friction sleeve and CPTU rods. Based on Teh and Houlsby (1991) it is expected that flow patterns for u_f are predominantly radial and more repeatable compared to u_2. With pure radial flow, the influence of filter size is expected to be negligible, however this should be investigated for confirmation.

The laboratory and in-situ tests differ in that for laboratory tests, de-aired water was used for hydraulic conductivity testing, while clean tap water was used for in-situ tests. For future in-situ testing water with properties as in the field should be used. In addition, the laboratory tests gave vertical hydraulic conductivity while horizontal consolidation properties dominate in-situ dissipation, suggesting hydraulic conductivity anisotropy ratio close to one at Halden.

The proposed interpretation methodology for flow cone hydraulic conductivity requires input of rigidity index and constrained modulus, which may be unknown or difficult to determine. The impact of these parameters on the estimated hydraulic conductivity should be further investigated.

From the testing at Halden it is evident that the effect of water flow during cone penetration is pore pressure build-up. However, the influence of 5 ml/min of water flow on the excess pore pressure was negligible compared to that from cone penetration itself. It is suggested that flow rate be determined based on experience and equations from Gundersen et al. (2019) to produce project specific hydraulic heads. It is considered most important to avoid flow rates yielding excessive hydraulic heads and thereby zero effective stresses in the soil surrounding the u_f-filter also leading to significant soil disturbance and/or erosion.

The determined K_0-value from hydraulic fracture test compares well with the general trend presented in Blaker et al. (2019). However, more tests should be carried out before conclusions can be drawn on the appropriateness of K_0-determination using flow cone module.

8 SUMMARY AND CONCLUSIONS

The flow cone is a standard cone penetrometer paired with a custom-built hydraulic module including a pressure transducer inside a porous cylindrical filter located an offset behind the friction sleeve and was trialled at the Halden silt site. Pore pressure development with time was measured at two locations, behind cone shoulder, u_2, and 1.23 m behind cone shoulder, u_f. The majority of u_2 dissipation plots suggest dilative behavior and a square root of time method was used to correct the initial pore pressure.

Hydraulic conductivity from flow cone dissipation (u_2, u_f), in-situ falling head and constant head oedometer and triaxial tests were compared. u_f dissipation presents best repeatability, whereas in-situ falling head tests and constant head oedometer tests yielded the lowest and highest values of hydraulic conductivity respectively. Due to the larger volume of soil and greater height of the triaxial test specimen, the hydraulic conductivity measurements made on these specimens are generally expected to be more reliable. Results from flow cone dissipation and constant head triaxial tests compare well. These observations present a confident potential of the proposed methodology for u_f dissipation, which is based on classical uncoupled solution for undrained cone penetration and subsequent pore pressure dissipation. However, further studies should be carried out to fully verify the proposed interpretation methodology, also considering the influence of rigidity index, compressibility, filter size, soil disturbance and general soil behavior.

One hydraulic fracture test was conducted in the clay unit at Halden resulting in a coefficient of earth pressure at rest that compares well with the general trend from literature.

Estimating in-situ frozen loamy soil viscosity from CPT

O.N. Isaev
Gersevanov Research Institute of Bases and Underground Structures (NIIOSP), "Research Center of Construction" JSC, Moscow, Russia

ABSTRACT: Viscosity is used for calculation of settlements and deformations of frozen loamy soils and ice caused by viscous flow at constant speed under action of long-term loads. A method for determining the viscosity coefficient of frozen loamy soil by CPT was developed. Experimental studies by CPT were carried out in a quasi-static mode (a series of short tests at low well-controlled speeds) and in a step-increasing relaxation-creeping mode (a series of penetrometer stabilizations in which the penetrometer and the speed of its penetration gradually decreased). Comparative data «unit cone resistance q_c – velocity of penetration v_c» were analyzed using mathematical statistics methods. For frozen loamy soil, a generalized regression equation $q_c = M(v_c)^m$ was established. Parameters M and m are calculated based on empiric equations, depending on the soil temperature. Viscosity values obtained by uniaxial compression CPT were compared. As a result of statistical analysis, an empirical transition coefficient between them was established.

1 INTRODUCTION

Permafrost soils (Roman 2002, Khrustalev 2005) occupy 25% of the world dry land: 65% in Russia, 50% in Canada, 60% in Alaska, 65% in Mongolia and 22% in China. They possess special physical and mechanical properties due to ice. If permafrost soils are frozen during construction and operation, settlements of foundations must be determined taking into account the developing plastic deformations (flow) of ice.

The flow rate is calculated based on the viscosity coefficient. It is determined by the laboratory test for uniaxial compression with an increasing stepwise load in accordance with the Standard (GOST 12248.9-2020). There exist other laboratory methods for the viscosity coefficient to be determined: in-plane shear method (Pekarskaya 1963), "ball" method (Maslov 1984), multi-plane shear device (Recommendations 1989), ball stamp (Roman & Kotov 2013, Roman & Kotov 2016) and viscometer (Ter-Martirosyan & Ermoshina 2019). They have not been widely used yet. In-situ methods have not been used until recently.

Laboratory methods have some disadvantages: soil under natural stress cannot be tested; soil samples are often damaged when drilling out. As a result, reconsolidation is required before testing; extra work is also required (drilling to select samples; transportation, storage and preparation of samples for testing). When drilling out samples of frozen soils, their original temperature can be disturbed and soils may thaw.

The paper proposes a method for determining the viscosity coefficient of frozen loamy soils by CPT.

2 EXPERIMENTAL AND THEORETICAL PREREQUISITES FOR DETERMINING THE VISCOSITY COEFFICIENT OF FROZEN SOILS BY CPT

When testing plastic-frozen loamy soils with a temperature of -0.3 … -0.1 °C, Ladanyi (1976) revealed that cone resistance q_c versus the velocity of penetration v_c is perfectly described by the power law

$$q_c = q_c^0 \left(v_c / v_c^0 \right)^m = M(v_c)^m \qquad (2.1)$$

where q_c^0 and v_c^0 = coordinates of a point on the cross-plot $q_c(v)$; $M = q_c^0 / \left(v_c^0 \right)^m$ = empirical parameter; $m < 1$ – nonlinearity parameter. If $v_c^0 = 1$ ($M = q_c^0$) and $q_c^0 = 1$ ($M = 1/\left(v_c^0 \right)^m$) the formula (2.1) takes a simpler form $q_c = q_c^0 \left(v_c \right)^m$.

Let us assume that the thickness of the frozen soil compression zone under the cone is approximately (generally, compression zone has more complex dependence on penetrometer diameter) equal to one

tenth of its diameter. Then the relative velocity of penetration $\dot{\varepsilon}_c$ is equal to

$$\dot{\varepsilon}_c = v_c/(0.1d_c), \qquad (2.2)$$

where d_c = cone diameter.

The relationships $\tau(\dot{\gamma})$ and $\sigma(\dot{\varepsilon})$ are mostly non-linear in frozen soils and ice. Viscosity coefficients η_τ and η_σ depend on the applied load during creeping. The rheological equations for shear and compression stresses are $\tau = \eta_\tau(\tau)\dot{\gamma}$ and $\sigma = \eta_\sigma(\sigma)\dot{\varepsilon}$. Such viscosity is characteristic for bodies possessing structural strength. This viscosity is sometimes referred to as structural viscosity. Such bodies include frozen soil and ice.

Let us consider cone penetration into a nonlinear viscous body with a variable viscosity coefficient η. The rheological equation is as follows

$$q_c = \eta_c(q_c)\dot{\varepsilon}_c, \qquad (2.3)$$

where η_c = conditional viscosity coefficient of soil in CPT. Using (2.1) and (2.2) $- \dot{\varepsilon}_c/\dot{\varepsilon}_c^0 = \left(q_c/q_c^0\right)^{1/m}$. Let us change this equation to (2.3)

$$q_c = \left[\frac{\dot{\varepsilon}_c^0}{q_c^0}\left(\frac{q_c}{q_c^0}\right)^{\frac{1-m}{m}}\right]^{-1}\dot{\varepsilon}_c \qquad (2.4)$$

Thus, the conditional viscosity coefficient in CPT will be

$$\eta_c = \left[\frac{\dot{\varepsilon}_c^0}{q_c^0}\left(\frac{q_c}{q_c^0}\right)^{\frac{1-m}{m}}\right]^{-1}. \qquad (2.5)$$

Taking into account that $\dot{\varepsilon}_c^0 = v_c^0/(0.1d_c)$ and $M = q_c^0/\left(v_c^0\right)^m$, the equation (2.5) is as follows:

$$\eta_c = \left[\frac{v_c^0}{0.1d_cq_c^0}\left(\frac{q_c}{q_c^0}\right)^{\frac{1-m}{m}}\right]^{-1} = 0.1d_c(M)^1(q_c)^{m-1} \qquad (2.6)$$

Using (1.1) and (2.2) - (2.5) can be $\eta_c(v_c)$ or $\eta_c(\dot{\varepsilon}_c)$

$$\eta_c(v_c) = \left[\frac{v_c^0}{0.1d_cq_c^0}\left(\frac{M(v_c)^m}{q_c^0}\right)^{\frac{1-m}{m}}\right]^{-1} = 0.1d_cM(v_c)^{m-1}, \qquad (2.7)$$

$$\eta_c(\dot{\varepsilon}_c) = 0.1d_cM(v_c)^{m-1} = (0.1d_c)^mM(\dot{\varepsilon}_c)^{m-1}. \qquad (2.8)$$

Let us take the uniaxial viscosity coefficient η_{uc} as a reference value. The condition of equality of the viscosity coefficients for uniaxial compression η_{uc} and CPT η_{CPT} is

$$\eta_{uc} = \eta_{CPT} = \psi\eta_c, \qquad (2.9)$$

where ψ - empirical transition coefficient (further - transition coefficient).

Thus, in order to determine the viscosity coefficient from CPT η_{CPT}, it is enough to determine the transition coefficient ψ. The following problem is discussed further.

3 GENERAL DESCRIPTION OF SOILS. EQUIPMENT AND METHODS FOR EXPERIMENTAL STUDIES

CPT was performed in-situ and in the laboratory (refrigeration chamber). Permafrost soils were tested in-situ: loams, sandy loams and clays – less frequently; soil temperature T = -0.2 …- 2.1 °C; moisture content w = 12 … 38 %; massive and thin-layered cryogenic texture; ice inclusions up to 1-4 mm. Artificially frozen loams were tested in the laboratory, T = -1.1 and -2.2 °C, w = 21%.

A penetrometer with a friction sleeve, Ø35.6 mm (Ryzhkov & Isaev 2016) and a temperature sensor in a cone (to measure soil temperature T) was used. In-situ tests were carried out in a quasi-static mode and a stepwise stabilization mode.

The quasi-static mode involved the procedure of penetrometer stopping and holding until it froze into soil. The penetrometer is then tested by performing a series of short pushes of the penetrometer was performed at different velocities v_c = $3 \cdot 10^{-4}$ … 2 m/min. To prevent the effect of soil heterogeneity on the test results, high and low velocities were alternated.

Stepwise stabilization (relaxation-creep) mode – the test is also performed after stopping and holding until it froze into soil. However, it differs from the quasi-static in that the penetrometer is tested by performing a series of stepwise increasing stabilizations. The stabilization of the penetrometer at the step was carried out by supplying oil to the hydraulic jacks which push the penetrometer. The given value q_c having been obtained, the supply of oil was stopped and the stabilization mode started. The load acting on the penetrometer and its velocity (as a result of relaxation-creep of the surrounding soil) gradually decreased and the intensity decreased as well, v_c = $2 \cdot 10^{-5}$ … 0.6 m/min.

The quasi-static mode was used in the refrigeration chamber. The velocity of penetration was set by regulating the speed of the screw press on which the lever was dropped, $v_c = 10^{-6} \ldots 0.08$ m/min.

The study procedure was as follows.

Stage 1: The test results were divided into statistical samples of data pairs «$q_c–v_c$» depending on their mode and soil temperature.

Stage 2: An approximation (1.1) was used for each statistical sample; M and m were determined; sampled values of the correlation coefficient ρ, determination coefficient R^2 and theoretical correlation ratio R were determined as well; the degree of linearization of the experimental data in the coordinates «$\ln q_c \sim \ln v_c$» was visually evaluated.

Stage 3: The effect of the test mode and soil temperature on M and m was assessed. Statistical analysis was performed; the regression equations applicable for M and m to be determined by temperature T were specified; M and m, ρ, R^2 and R were also determined.

Stage 4: The conditional viscosity coefficient in CPT η_c and the viscosity coefficient obtained during uniaxial compression tests η_{uc} were compared; the transition coefficient $\psi = \eta_{uc}/\eta_c$ was determined. The values of η_{uc} were taken from the books on laboratory data for uniaxial compression tests. The values of η_c were taken based on the generalized results of CPT under the quasi-static mode – in accordance with the empirical equations (see stage 3). The compared pairs of values η_{uc} and η_c had the same values of T and $\dot{\varepsilon}_c$.

Stage 5: The effect of various factors on the transition coefficient ψ was studied (cone resistance q_c, velocity of penetration v_c, relative speed of soil deformation $\dot{\varepsilon}_c$, soil temperature modulus |T|, compressive stresses under uniaxial compression σ, soil type). Regression equations were calculated.

Stage 6: Two-stage verification of the proposed method for determining η_{uc} from CPT data was carried out. The first stage was based on the data used in the previous stages. The second stage was based on the new comparative data used on the experimental site.

4 RESULTS AND ANALYSIS OF EXPERIMENTAL STUDIES

The total number of data pairs «$q_c–v_c$» – over 400. Typical cross-plots are shown in Figure 4.1.

Statistical analysis has shown that q_c versus (v_c) is described by the power equation (2.1); a high degree of data linearization in the coordinates «$\ln q_c \sim \ln v_c$» is revealed (Figure 4.1). The values of R have been as follows: 0.76 … 0.98 for in-situ tests under the quasi-static mode, 0.89 … 0.98 under stepwise stabilization, 0.92 … 0.94 under laboratory conditions. The cross-plot of q_c versus (v_c) is described by a single curve

(2.1) without an inflection point on the plot «$\ln q_c \sim \ln v_c$» if $T = -0.2 \ldots -2.2\,°C$ and $v_c = 10^{-6} \ldots 4 \cdot 10^{-2}$ m/min.

Figure 3.2 makes it possible to conclude that M possesses great variability and depends on the test mode and soil temperature. Its value is slightly higher under stepwise stabilization than when tested under the quasi-static mode. The difference in M values during in-situ and laboratory tests is due to the fact that the soil is permafrost in the first case, and it is artificially frozen in the second case. This obviously led to its decompaction and decrease in strength. In addition, the difference in soil moisture and dispersion also affected. A linear relationship has been established

$$M = a_M T + b_M, \qquad (4.1)$$

where a_M and b_M = empirical coefficients, for in-situ tests under the quasi-static mode $a_M = -10.07$ and $b_M = 5.060$.

Due to soil strength increase, M increases when temperature decreases. Extrapolation of the straight lines $M\,(T)$ for all test modes illustrates that the straight lines intersect approximately in one point which shows the initial temperature of soil freezing. When loamy soils are in a thawed state - $M = 6.57 \ldots 7.58$ for the temperature range of the onset of freezing (-0.15 … -0.25 °C).

The nonlinearity coefficient m is less variable, $m<1$. With the temperature decrease m decreases, i.e. the nonlinearity of the equation (1.1) increases since ice-cement content and rheology of soil increase. The value of m hardly depends on the test mode and soil type. Temperature T has the greatest effect on it. Figure 4.2.b illustrates that the experimental values of $m\,(T)$ obtained for various modes and test conditions can be described by the general linear relationship

$$m = a_m T + b_m \qquad (4.2)$$

where a_m and b_m = empirical coefficients, for the general linear relationship $a_m = 0.0235$ and $b_m = 0.1280$, for in-situ tests in the quasi-static mode $a_m = 0.0184$ and $b_m = 0.1217$.

The correlation coefficient ρ between m and T is 0.59 for the total statistical sample. This can be considered acceptable, since it takes into account the large heterogeneity of the data included in it. Substituting (4.1) and (4.2) in (2.7) and (2.8), the conditional viscosity coefficient η_c can be as follows:

$$\eta_c(v_c) = 0.1 d_c (a_M T + b_M)(v_c)^{a_m T + b_m - 1}, \qquad (4.3)$$

a)

b)

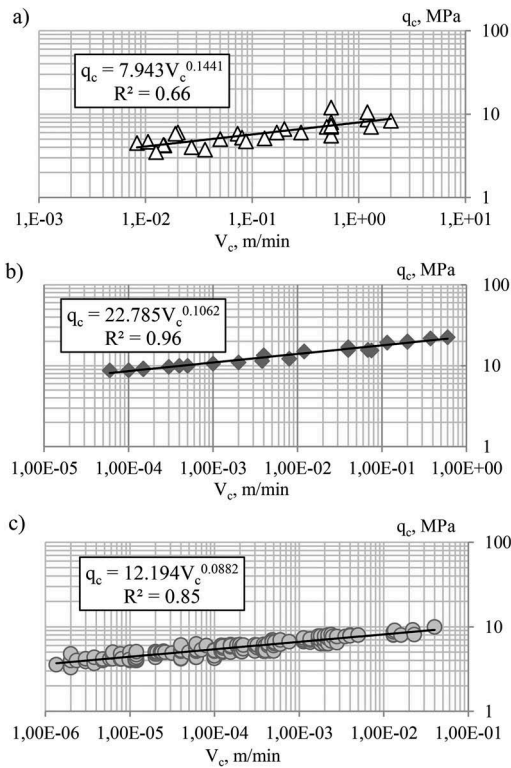
c)


Figure 4.1. "$v_c - q_c$" diagrams: in-situ tests under a quasi-static mode, $T = -0.2\ °C$ (a); in-situ tests under stepwise stabilization, $T = -1.0°C$ (b); laboratory tests in a refrigeration chamber under the quasi-static mode, $T = -1.1°C$ (c).

$$\eta_c(\dot{\varepsilon}_c) = (0.1d_c)^{a_m T + b_m}(a_M T + b_M)(\dot{\varepsilon}_c)^{a_m T + b_m - 1}. \tag{4.4}$$

For in-situ tests in the quasi-static mode (4.3) and (4.4) are as follows:

$$\eta_c(v_c) = 0.1d_c(-10.07T + 5.060)(v_c)^{0.0235T - 0.8720} \tag{4.3.a}$$

$$\eta_c(\dot{\varepsilon}_c) = (0.1d_c)^{0.235T + 0.1280}(-10.07T + 5.060)(\dot{\varepsilon}_c)^{0.0235T - 0.8720} \tag{4.4.a}$$

According to (2.7), the conditional viscosity coefficient of thawed loamy soils η_c is as follows for the temperature range of the onset of freezing (thawed state):

$$\eta_c(v_c) \approx 0.7d_c(v_c)^{-0.87}. \tag{4.4.b}$$

The viscosity coefficients of frozen loamy soils obtained after uniaxial compression tests η_{uc} (data taken from the books, Table 4.1) and η_c evaluated by the formula (4.4.a) depending on $\dot{\varepsilon}_c$ and T have been compared.

The transition coefficient $\psi = \eta_{uc}/\eta_c$ was used for correlation. The influence of various factors on ψ was studied: cone resistance q_c, velocity of penetration v_c, relative speed of soil deformation $\dot{\varepsilon}_c$, soil temperature modulus $|T|$, stresses under uniaxial compression σ, loamy soil type. The values of $|T|$, $\dot{\varepsilon}_c$ and σ were taken after uniaxial compression tests; v_c was evaluated by the formula (1.2); q_c – by the formula (1.1); M and m – by the formulas (3.1) and (3.2).

Analysis of the results presented in Table 4.2 and in Figure 4.3 makes it possible to conclude the following.

The greatest influence on ψ is exerted by q_c and T, the relationship is nonlinear. The linkage is strong or very strong. The influence of v_c, $\dot{\varepsilon}_c$ and σ on the coefficient ψ is very weak. The influence of the soil type (loam, clay loam, sandy loam) is insignificant – the points referring to experimental data for different soils do not meet any definite patterns.

Empirical equations for the viscosity coefficient of frozen loamy soil under uniaxial compression based on CPT data were proposed

Table 4.1. Comparison of viscosity coefficients (η_{uc}) and (η_c) obtained after uniaxial compression tests (data taken from the books) and calculated by the formula (4.4.a).

Soil type	T, °C	σ, MPa	$\dot{\varepsilon}$, min^{-1}	$\psi = \eta_{uc}/\eta_c$	n	Uniaxial compression tests after
Loam W=31…38 %	-7.9…-1.7	0.25…0.50	$2.5 \cdot 10^{-5} \ldots 2.4 \cdot 10^{-4}$	0.002…0.129	4	Tsytovich 1973

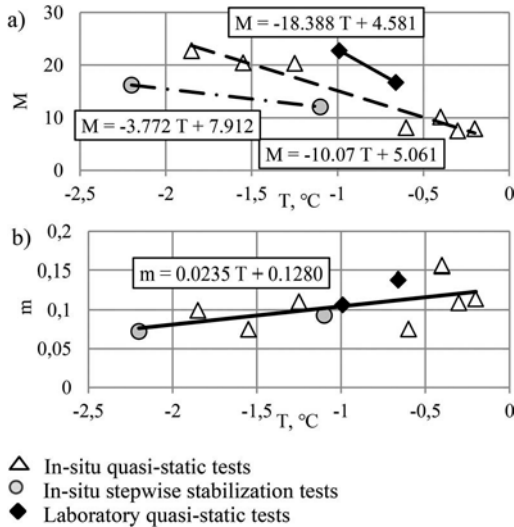
Notes: ρ – sample correlation coefficient; R^2 – sample determination coefficient; R – theoretical correlation ratio


Figure 4.2. Diagrams of $M(T)$ and $m(T)$ after in-situ and laboratory CPT data.

$$\eta_{CPT(q)} = \psi_q \eta_c, \qquad (4.5)$$

$$\eta_{CPT(T)} = \psi_T \eta_c \qquad (4.6)$$

where ψ_q and ψ_T = empirical coefficients; $\psi_q = 0.330q_c^{-0.860}$, $\psi_T = 0.195e^{-0.531|T|}$.

Experimental verification of (4.5) and (4.6) was carried out in two stages by calculations and statistical analysis of the ratios $\eta_{CPT(q)}/\eta_{uc}$ and $\eta_{CPT(T)}/\eta_{uc}$.

The data from Table 4.1 were used at the first stage. The value of η_c in (4.5) and (4.6) was evaluated by (4.3.a). Figure 4.4 shows the histograms of these ratios. The analysis showed that the statistical data were close for $\eta_{CPT(q)}$ and $\eta_{CPT(T)}$. Taking into account the influence of a large number of factors, they can be considered quite acceptable.

At the second stage, verification was carried out by direct comparative tests on the experimental site. The viscosity coefficients of plastic-frozen clay loam calculated from CPT data were compared with the coefficients ψ_q and ψ_T obtained after direct tests for uniaxial compression η_{cu}. The CPT procedure was done next to a deep pit where uniaxial compression tests were carried out. $T = -0.6 \ldots - 0.7$ °C, $w = 17.9 \ldots 18.2$ %, ice content $0.1.v_c = 3.1 \cdot 10^{-4}\ldots 2$ m/min, $q_c = 4.1\ldots 8.5$ MPa. Figure 4.5 shows that the coefficient ψ_T is more accurate $- \eta_{CPT(T)}/\eta_{uc} = 0.75$ and ψ_q- less accurate $- \eta_{CPT(q)}/\eta_{uc} = 0.44$. The medians Me of the ratios $\eta_{CPT(q)}/\eta_{uc}$ and $\eta_{CPT(T)}/\eta_{uc}$ actually coincide with their mean values, i.e. the values are significant. Experimental verification has shown that the transition coefficient ψ_T evaluated by (4.6) makes it possible to determine the viscosity coefficient of frozen loamy soil under uniaxial compression by CPT data with sufficient accuracy for practical use.

5   CONCLUSIONS

At present, laboratory methods are the only ones used to determine the viscosity coefficient of frozen soil. The uniaxial compression test is the one which is preferred. Proposed is the method to determine the viscosity coefficient of frozen loamy soils from CPT data. CPT can be performed in the quasi-static or relaxation-creeping modes. The method is based on the power equation of cone resistance versus velocity of penetration. The studies have resulted in power-law regression equations to be obtained. The effects of the CPT mode and soil temperature on soil parameters have been studied. Empirical relationships have been established to determine the transition coefficient from the conditional viscosity coefficient under CPT to the viscosity coefficient under uniaxial compression. Thus, soil resistance to CPT and soil temperatures exert the greatest influence on the transition coefficient. Experimental verification of the method has shown its applicability in practice.

Determination of natural stress state parameters for clay soils by using 3LSU-CPTU penetrometer

O.N. Isaev, R.F. Sharafutdinov & D.S. Zakatov
Gersevanov Research Institute of Bases and Underground Structures (NIIOSP), "Research Center of Construction" JSC, Moscow, Russia

ABSTRACT: The article presents the results of experimental studies on the use of lateral stress measurements by using the LS-module (includes full and pore pressure sensors) of 3LSU-CPTU penetrometer to determine the parameters of the natural stress state (NSS) of clay soils (the coefficient of lateral pressure at rest K_o, the effective pre-compaction stress POP, the over-compaction stress σ_c', the overconsolidation ratio OCR, the natural total σ_{ho} and effective σ_{ho}' horizontal stress in the soil). In experiments, the LS-module with three pairs of sensors located in areas with different diameters (Ø37 mm, Ø41 mm and Ø45 mm) was used. The results of a statistical analysis of the relationships between LS-module (twenty-six direct and derived types were considered) and NSS parameters of clay soils are presented. It is shown that K_o, OCR, σ_{ho}' in the soil is determined with the greatest accuracy.

1 INTRODUCTION

The efficiency of using CPT is higher when using penetrometers with additional sensors and devices (Burns & Mayne 1998, Lunne et al. 2004, Ryzhkov I. B. & Isaev 2016). For example, a penetrometer with a lateral stress module (LS-module), includes full and pore pressure sensors. These penetrometers have been developed and investigated since the 1980s (Campanella et al. 1990, Howie et al. 2014, Huntsman et al. 1986, Bayne & Tjelta 1987, Sully & Campanella 1990, Sully & Campanella 1991, Takesue & Isano 2001). However, according to the Lunne et al. (2004), «the lateral stress cone is still not a tool that has found practical use». In the USSR and Russia, until recently, they have not been developed or investigated.

Modern powerful software geotechnical platforms (PLAXIS, MIDAS GTS, Z-Soil, etc.) are using numerical methods. Knowledge of natural stress state parameters of soils is required as initial data of numerical calculations.

The paper presents the results of experimental studies on the use of lateral stress measurements by using the LS-module of 3LSU-CPTU penetrometer to determine the parameters of the natural stress state (NSS) of clay soils (the coefficient of lateral pressure at rest K_o, the effective pre-compaction stress POP, the over-compaction stress σ_c', the over-consolidation ratio OCR, the natural total σ_{ho} and effective σ_{ho}' horizontal stress in the soil). Studies to determine the natural pore pressure in soil u_0 are described in detail in Isaev et al. (2020a) paper.

2 INVESTIGATED SOILS, EQUIPMENT AND TEST PROCEDURE

The main physical and mechanical properties of clay soils are given in Table 1. Stiff clay and firm-stiff loam were studied. Soils lay at a depth of 3.5-41.7 m. Tests were carried out at experimental sites in Moscow.

Table 1. Properties of clay soils.

Soil	ρ, g/cm³	e, d.q.	I_p, d. q.	I_l, d.q.	C, kPa	φ, °	E, MPa
Stiff clay	1.77	1.17	0.45	0.18	57	20	25
Firm-stiff loam	2.00	0.65	0.14	0.36	10	22	10

The following parameters were calculated and defined: natural (hydrostatical) pore pressure in the soil u_0, over-compaction stress σ_c', effective pre-compaction stress $POP = \sigma_c' - \sigma_{vo}'$, overconsolidation ratio $OCR = \sigma_c'/\sigma_{vo}'$, coefficient of lateral pressure at rest $K_o = \sigma_{ho}'/\sigma_{vo}'$, natural total σ_{vo} and effective $\sigma_{vo}' = \sigma_{vo} - u_0$ vertical stress in the soil, natural total σ_{ho} and effective σ_{ho}' horizontal stress in the soil.

The σ_c', POP, OCR parameters were determined by the methods of Casagrande (1936) and Becker et al. (1987) by laboratory tests in compression
Figure 1. General schematic of LS-module.
Figure 2. 3LSU-CPTU penetrometer general assembly.
Figure 3. Example of σ_{LS}, u_{LS}, σ'_{LS} profiles with a layer of stiff clay at Moscow (Isaev et al. 2020b)

instruments. The results of both methods were averaged. Coefficient K_o was calculated by Meyerhof (1976) formula, coefficient – by Jaky (1944):

$$K_o = K_o^{nc} OCR^\alpha = (1 - \sin\varphi)\, OCR^\alpha \qquad (1)$$

where φ – angle of internal friction; $\alpha = 0.5$ - degree index.

The σ'_{ho} value was calculated using the formula

$$\sigma'_{ho} = K_o \sigma'_{vo} \qquad (2)$$

Tests were carried out using 3LSU-CPTU probe. It was developed and manufactured jointly by NIIOSP and USM-Engineering (Isaev et al. 2020b). It included two modules (Figure 1, 2) – the CPTU main (lower) module with a cone and friction sleeve and 3LSU additional (upper) module with lateral sensors of soil pressure and pore pressure. Above the modules was a unit with electronics, above it there was a push rod. The main module had Ø35.7 mm. The 3LSU-module included three pairs of sensors located in cylindrical sections of Ø37 mm, Ø41 mm and Ø45 mm. When the probe was pushed, total (σ_{LS1}, σ_{LS2}, σ_{LS3}), pore (u_{LS1}, u_{LS2}, u_{LS3}) and effective ($\sigma'_{LS1} = \sigma_{LS1} - u_{LS1}$, $\sigma'_{LS2} = \sigma_{LS2} - u_{LS2}$, $\sigma'_{LS3} = \sigma_{LS3} - u_{LS3}$) pressures were measured by pairs of sensors (pore pressure and lateral stress) №1, №2, №3 on the lateral module surface.

Studies were carried out in several stages.

First stage. Listing and NSS parameterization. Six parameters were selected: K_o, POP, σ'_c, OCR, σ_{ho}, σ'_{ho}. Listing and LS-module parameterization. Nine direct parameters (σ_{LS1}, σ_{LS2}, σ_{LS3}; u_{LS1}, u_{LS2}, u_{LS3}; σ'_{LS1}, σ'_{LS2}, σ'_{LS3}) and seventeen combined parameters ($\sigma_{LS3}/\sigma_{LS1}$, $\sigma_{LS2}/\sigma_{LS1}$, $\sigma_{LS3}/\sigma_{LS2}$; u_{LS3}/u_{LS1}, u_{LS2}/u_{LS1}; $I_{D13} = \Delta\sigma_{LS13}/\Delta\sigma_{LS1U}$, $I_{D12} = \Delta\sigma_{LS12}/\Delta\sigma_{LS1U}$; $K_{D1} = \Delta\sigma_{LS1U}/\sigma'_{vo}$, $K_{D2} = \Delta\sigma_{LS2U}/\sigma'_{vo}$, $K_{LS1} = \sigma_{LS1}/\sigma_{vo}$, $K_{LS2} = \sigma_{LS2}/\sigma_{vo}$, $K_{LS3} = \sigma_{LS3}/\sigma_{vo}$, $K'_{LS1} = \sigma_{LS1}/\sigma'_{vo}$, $K'_{LS2} = \sigma_{LS2}/\sigma'_{vo}$, $K'_{LS3} = \sigma_{LS3}/\sigma'_{vo}$; $E_{D13} = R_1\Delta\sigma_{LS13}/\Delta R_{13}$, $E_{D12} = R_1\Delta\sigma_{LS12}/\Delta R_{12}$) were investigated.

Where $\Delta\sigma_{LS12} = \sigma_{LS2} - \sigma_{LS1}$, $\Delta\sigma_{LS13} = \sigma_{LS3} - \sigma_{LS1}$, $\Delta\sigma_{LS1U} = \sigma_{LS1} - u_0$; $\Delta\sigma_{LS2U} = \sigma_{LS2} - u_0$; $\Delta R_{12} = R_2 - R_1$, $\Delta R_{13} = R_3 - R_1$; R_1, R_2, R_3 = radius of LS-module in the areas where the sensors are located 1, 2, 3.

The NSS and LS-module parameters for each comparative test were combined into one data group. 19 comparative data groups were compiled.

Second stage. Correlation data mining, determination of the strength of statistical linkage between NSS and LS-module parameters of the clay soils. The value and statistical significance of the sample correlation index ρ was determined. Assessment of the presence of nonlinear significant statistical relationships.

Third stage. Regression data analysis for strength correlations. Approximation of data by linear and

nonlinear (exponential, logarithmic, polynomial, power-law) function. Selection of dependencies with maximum correlation coefficient ρ, theoretical correlation relation R, coefficient of determination R^2. The strength of the statistical relationship (for ρ and R) was estimated in accordance with Chaddock-Snedecor scale.

Fourth stage. Comparison of NSS parameters obtained by standard (direct) methods and calculated using LS-module parameters (based on regression equations). Estimation of the accuracy of determining the parameters of the NSS by empirical dependencies.

Statistical analysis was performed using IBM SPSS Statistics and MS Excel software.

3 RESULTS AND ANALYSIS OF EXPERIMENTAL STUDIES

Tables 2 and 3 summarize the experimental data for LS-module and NSS parameters of clay soils. Table 4 give the correlation matrix of ρ for statistical relationship between LS-module and NSS parameters of clay soils.

Table 2. Generalized LS-module measurement results of clay soils.

$\sigma_{LS1}/\sigma'_{LS1}/u_{LS1}$, kPa	$\sigma_{LS2}/\sigma'_{LS2}/u_{LS2}$, kPa	$\sigma_{LS3}/\sigma'_{LS3}/u_{LS3}$, kPa
254 … 1657	84 … 1879	67 … 2090
42 … 1576	88 … 1409	42 … 1706
-17 … +215	-20 … +670	-15 … +383

Table 3. Generalized NSS parameters of clay soils.

σ'_c, kPa	OCR, d.q.	POP, kPa	K_o, d.q.	σ'_{ho}, MPa
140 … 2400	2.9 … 12.7	77 … 1938	0.93 … 2.23	0.06 … 0.72

Regression data analysis showed that the empirical data can be approximated with approximately equal accuracy by linear and nonlinear regression equations (the difference between ρ and R in almost all cases is less than 5%).

Analysis of Table 4 allows to note the following.

1. For σ'_c the highest degree of correlation ($\rho = 0.61\ldots0.68$) was revealed with σ_{LS1}, σ'_{LS1}, σ_{LS2}, σ'_{LS2}, σ_{LS3}, σ'_{LS3} (Figure 4). In other cases, it is less. For factors of the combined type, it is mainly statistically insignificant. With an increase in σ'_c, the values of σ_{LS} and σ'_{LS} also increase, but with little change in intensity ($\Delta\sigma'_c/\Delta\sigma_{LS} = 0.5\ldots0.8$ and $\Delta\sigma'_c/\Delta\sigma'_{LS} = 0.7\ldots0.8$), which weakly depends on the diameter of the module.

2. For OCR the highest degree of correlation strength ($\rho = -0.56\ldots-0.60$) was revealed with the parameters of the combined type $\sigma_{LS2}/\sigma_{LS1}$, I_{D13}, K_{D2}, E_{D12} (Figure 5). As the OCR increases, the parameter values decrease. The relationship with most of the other parameters is statistically insignificant.

3. For K_o the highest degree of correlation strength ($\rho = -0.58\ldots-0.64$) was revealed with the parameters of the combined type K_{D2}, $\sigma_{LS2}/\sigma_{LS1}$ and K'_{LS2} (Figure 6). With their increase, the value of K_o decreases. In other cases, the relationship is insignificant.

4. The correlation between σ_{ho} and LS-module parameters is the strongest. The maximum correlation ($\rho=0.91\ldots0.95$) was found for σ_{LS1}, σ'_{LS1}, σ_{LS2}, σ'_{LS2}, σ_{LS3}, σ'_{LS3} (Figure 7).

Table 4. Correlation matrix of ρ for statistical relationship between LS-module and NSS parameters.

LS-module parameters	Natural stress state (NSS) parameters					
	σ'_c	OCR	POP	K_o	σ'_{ho}	σ_{ho}
σ_{LS1}	0..66	-0.39	0.48	-0.34	0.92	0.95
u_{LS1}	0..03	-0.47	-0.10	-0.47	0.29	0.35
σ'_{LS1}	0.68	-0.35	0.51	-0.30	0.93	0.95

$\sigma_{LS2}/\sigma_{LS1}$	0.17	-0.60	0.01	-0.59	0.49	0.56
u_{LS2}/u_{LS1}	0.51	-0.43	0.36	-0.38	0.75	0.80
$\sigma_{LS3}/\sigma_{LS2}$	0.01	0.14	0.04	0.16	-0.06	-0.09
I_{D13}	0.23	-0.51	0.09	-0.49	0.01	0.11
K_{D1}	-0.50	-0.04	-0.43	-0.10	-0.55	-0.53
E_{D13}	0.38	-0.48	0.21	-0.46	0.66	0.70
I_{D12}	-0.37	-0.16	-0.43	-0.20	-0.22	-0.18
K_{D2}	-0.23	-0.60	-0.32	-0.64	0.02	0.11
E_{D12}	0.19	-0.56	0.03	-0.54	0.50	0.59
K'_{LS1}	-0.07	0.04	-0.04	-0.01	-0.11	-0.10
K'_{LS2}	-0.33	-0.54	-0.38	-0.58	-0.14	-0.07
K'_{LS3}	-0.06	-0.48	-0.15	-0.50	0.14	0.20
K_{LS1}	-0.39	-0.43	-0.42	-0.49	-0.23	-0.16
K_{LS2}	-0.40	-0.48	-0.45	-0.54	-0.23	-0.16
K_{LS3}	-0.29	-0.35	-0.32	-0.39	-0.17	-0.12

The degree of strength of the statistical relationship (Chaddock-Snedecor scale):

- the relationship is statistically insignificant
- $\rho = 0.3$-0.5
- $\rho = 0.5$-0.7
- $\rho = 0.7$-0.9
- $\rho = 0.9$-0.99

The relationship can be approximated by linear equations of the form $y = kx$ or $y = kx + b$. For σ_{LS1}, their plots actually overlap and pass through the origin of coordinates. For other lateral pressures, the line plots are also quite close to each other. With an increase in σ_{ho}, the values of these LS-module parameters increase with little change in intensity ($\Delta\sigma_{h0}/\Delta\sigma_{LS} = 0.4\ldots0.5$ and $\Delta\sigma_{h0}/\Delta\sigma'_{LS} = 0.5\ldots0.6$).

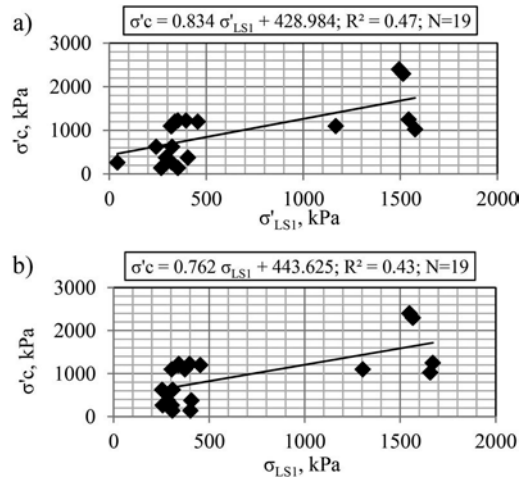
A weaker relationship with the results of measurements by pore pressure sensors and the combined parameters obtained on their basis. The exception is u_{LS1}, for which it is not statistically significant. This is probably due to the fact that, in comparison with the soil adjacent to the probe, the change in pore pressure with time has less inertia – as the friction sleeve passes along the soil layer, before the u_{LS1} sensor approaches it, the pore pressure has time to change significantly. Additional effects on u_{LS1} do not occur, because the cone with the friction clutch and the u_{LS1} section have approximately the same diameter.


Figure 4. Regression analysis of relationship between over-compaction stress σ'_c, and LS-module parameters σ'_{LS1} (a) and σ_{LS1} (b).

With other LS-module parameters of the combined type, the relationship is much weaker. For most of them it is statistically insignificant.

5. The nature and strength of the statistical relationship σ'_{ho} with LS-module parameters are generally similar to that for σ_{ho}.

6. The correlation between POP and LS-module parameters is not statistically significant, except for σ_{LS1} ($\rho=0,48$).

For strong correlations, regression equations were calculated. The verification of their applicability was

Table 5.   Verification the accuracy of regression relationships.

Ratio	Regression equation	$\bar{B}$	Me	σ	V_σ
$\frac{\sigma'_{ce}}{\sigma'_c}$	$\sigma'_{ce} = 0.834\sigma'_{LS1} + 428.984$	1.56	1.12	1.32	0.85
	$\sigma'_{ce} = 0.762\sigma_{LS1} + 443.625$	1.60	1.09	1.39	0.86
$\frac{OCR_e}{OCR}$	$OCR_e = 15.403e^{-0.394*K_{D2}}$	1.11	1.04	0.50	0.45
	$OCR_e = -8.341\frac{\sigma_{LS2}}{\sigma_{LS1}} + 13.033$	1.29	0.98	0.68	0.53
$\frac{K_{oe}}{K_o}$	$K_{oe} = -0.276K_{D2} + 2.280$	1.05	1.06	0.24	0.23
	$K_{oe} = -0.967\frac{\sigma_{LS2}}{\sigma_{LS1}} + 2.293$	1.07	0.99	0.28	0.26
$\frac{\sigma_{hoe}}{\sigma_{ho}}$	$\sigma_{hoe} = 0.000556\sigma_{LS1} - 0.0269$	1.18	0.99	0.63	0.54
	$\sigma_{hoe} = 0.000439\sigma_{LS2} + 0.0723$	1.23	0.98	0.74	0.60
$\frac{\sigma'_{hoe}}{\sigma'_{ho}}$	$\sigma'_{hoe} = 0.000334\sigma_{LS1} + 0.0472$	1.18	0.92	0.61	0.51
	$\sigma'_{hoe} = 0.000354\sigma_{LS1} + 0.0480$	1.16	0.92	0.58	0.50

carried out by analyzing the ratios of the calculated (according to the regression equations) to the reference values of NSS parameters (Table 5): σ'_{ce}/σ'_c, OCR_e/OCR, K_{oe}/K_o, σ_{hoe}/σ_{ho}, $\sigma'_{hoe}/\sigma'_{ho}$.

$\bar{B}$ = mean; Me = median; σ = standard deviation; $V_\sigma = \sigma/\bar{B}$ = variability index; e = subscript, means that parameter is calculated according to the regression equation

Regression equations for determining: σ'_c – give unsatisfactory mean ($\bar{B}$=1.56…1.60) and variability ($V_\sigma = 0.85\ldots0.86$); OCR, σ_{ho} and σ'_{ho} – give relatively satisfactory mean ($\bar{B}$=1.11…1.29) and great variability ($V_\sigma = 0.45\ldots0.60$); K_o – give good mean ($\bar{B}$=1.05…1.07) and satisfactory variability ($V_\sigma = 0.23\ldots0.26$).

In order to improve the accuracy of determining OCR and σ'_{ho}, the possibility of their estimation based on the regression equations obtained for K_o (Table 5) was investigated.

Formula (1) can be transformed to the form $OCR = [K_o/(1 - \sin\varphi)]^{1/\propto}$. Substituting into it from the Table 5 regression equation $K_o(K_{D2})$, you can obtain semiempirical equation in form $OCR(K_{D2}, \varphi)$. If we substitute the regression equation for K_o from the Table 5 into the expression $\sigma'_{ho} = K_o\sigma'_{vo}$, we obtain a semiempirical equation $\sigma'_{ho}(K_{D2}, \sigma'_{vo})$. Both semiempirical equations are shown in the Table 6.

Verification and assessment of the applicability of semiempirical equations were performed (Table 6). For this purpose, the statistics of the ratios OCR_e/OCR and $\sigma'_{hoe}/\sigma'_{ho}$ were calculated for the new equations and compared with the previous statistics given in Table 5.

Comparative analysis showed that semiempirical equations, compared to regression ones, have less variability (coefficient of variation V_σ is 2 times less). Therefore, they allow more precise definition of OCR and σ'_{ho}.

Table 6. Verification the accuracy of semiempirical relationships.

Ratio	Regression equation	Ratio statistics			
		$\bar{B}$	Me	σ	V_σ
$\frac{OCR_e}{OCR}$	$OCR_e = \left[\frac{-0.967\frac{\sigma_{LS2}}{\sigma_{LS1}}+2.293}{1-\sin\varphi}\right]^2$	1.12	0.88	0.57	0.21
$\frac{\sigma'_{hoe}}{\sigma'_{ho}}$	$\sigma'_{hoe} = (-0.276K_{D2} + 2.280)\sigma'_{vo}$	1.05	1.07	0.25	0.23

$\bar{B}$ = mean; Me = median; σ = standard deviation; $V_\sigma = \sigma/\bar{B}$ = variability index; e = subscript, means that parameter is calculated according to the semiempirical equation

Thus, for preliminary geotechnical calculations, parameters of the natural stress state of stiff clay and firm-stiff loam according to the LS-module measurements are recommended to be determined using the following equations:

$$K_o = -0.276K_{D2} + 2.280 \qquad (3)$$

$$OCR = \left[\left(-0.967\frac{\sigma_{LS2}}{\sigma_{LS1}} + 2.293\right)/(1 - \sin\varphi)\right]^2, \qquad (4)$$

$$\sigma'_{ho} = (-0.276K_{D2} + 2.280)\sigma'_{vo}, \qquad (5)$$

where $K_{D2} = (\sigma_{LS2} - u_0)/\sigma'_{vo}$ = normalized total soil pressure on lateral surface of LS-module second section; σ_{LS1} and σ_{LS2} = total soil pressures on lateral surface of LS-module first and second sections; $\sigma'_{vo} = \sigma_{vo} - u_0$ = effective vertical stress in the soil, u_0 = natural pore pressure in soil; φ = angle of internal friction.

Equations (3) - (5) have features.

a. They are valid only if the coefficient of lateral pressure at rest K_o is determined by formula (1).
b. Calculations by equations require knowledge of the soil pressure on the lateral surface, both of the first and second sections of the LS-module (σ_{LS1} and σ_{LS2}). In this case, the diameters of the first and second sections should be Ø37 mm and Ø41 mm.
c. All equations contain not direct measurements of pressures σ_{LS1} and σ_{LS2}, but their normalized (combined) values (K_{D2}, $\sigma_{LS2}/\sigma_{LS1}$).

4 CONCLUSIONS

The paper shows that the parameters of the natural stress state of clay soils can be determined through the use of tests by penetrometer with cylindrical lateral stress module (LS-module).

It is recommended to use LS-module with two sections with different diameters. For section diameters Ø37 mm and Ø41 mm, empirical dependences are proposed to determine coefficient of lateral pressure at rest K_o, overconsolidation ratio OCR and effective horizontal stress in the soil σ'_{ho}.

Towards correlating seabed penetrometer and chirp sonar measurements

R. Jaber & N. Stark
Virginia Tech, Blacksburg, VA, USA

ABSTRACT: Cone Penetration Testing (CPT) and seabed coring represent key methods to determine geotechnical properties offshore. Physical testing is typically combined with geophysical surveying, i.e., chirp sonar sub-bottom profilers, and results are qualitatively related to extrapolate geotechnical properties between physical test locations. Literature suggests that more quantitative relationships can be established between geotechnical properties and geoacoustic responses. However, specific correlations are still rare, and correlating frameworks are often complex and in need of additional parameters. This study attempts to explore correlations between geotechnical properties measured using a portable free fall penetrometer (PFFP) and determined from soil samples and chirp sonar at a frequency of 8-12 kHz. Preliminary results focusing on fine-grained sediments using data collected in the York River, Virginia, USA suggest relations between sediment properties using PFFP measurements and geoacoustic properties using chirp measurements and laboratory testing.

1 INTRODUCTION

The development of coastal infrastructure and offshore renewable energy, scour and erosion prediction and assessment, as well as naval applications require a thorough understanding of seabed sediment properties (Harris et al. 2008). In-situ geotechnical testing such as Cone Penetration Testing (CPT), soil sampling, and core extraction are typically relied on to determine geotechnical seabed properties (Saleh & Rabah 2016). Geophysical methods provide high-resolution bathymetry, sub-surface soil strata mapping, seabed morphology, and even estimates of sediment properties (Ballard 2017). The ability of geophysical methods to survey large areas of the seabed efficiently have contributed significantly to the knowledge and understanding of the seabed (Saleh & Rabah 2016, Jackson & Richardson 2007). The development of more robust frameworks that utilize penetrometer testing for the calibration of geophysical tools to derive geotechnical properties with high accuracy and reliability from geophysical surveying while reducing the need for physical testing and coring has the potential to increase efficiency and decrease costs in offshore site investigation, as well as provide more geotechnical data during scour and erosion monitoring.

Several studies examined the integration of acoustic and geotechnical testing, towards better soil characterization, scour assessment, and direct correlations between geotechnical properties and acoustic measurements (Wang & Stewart 2015, Pecknold & Osler 2011, Harris et al. 2008, Osler et al. 2006, Bull et al. 1998). Most correlations between geotechnical properties and acoustics evolved from empirical approaches

(Harris et al. 2008) to geoacoustic models that investigate the theory of sound propagation using direct or indirect methods (Ballard 2017, Hamilton 1980). Geoacoustic parameters such as acoustic impedance, reflection coefficient, backscatter intensity, index of impedance, and others have been related to geotechnical soil properties such as porosity, particle size and bulk density. However, specific geoacoustic frameworks readily available and including geotechnical soil properties particularly from in-situ testing are still rare, and often hampered by the need for and sensitivity to multiple input parameters which may be difficult to obtain (Pecknold & Osler 2011). Challenges also include the spatial variability of seabed stratification on the order of centimeters which obscures field calibration and validation (Jackson & Richardson 2007).

This study makes an attempt to relate portable free fall penetrometer measurements (PFFP) and chirp sonar sub-bottom profiling at 8-12 kHz towards a direct correlation between penetrometer tests and geoacoustic response for seabed site investigation. With regards to geoacoustic properties, this study focuses on acoustic impedance and the reflection coefficient.

2 METHODS & SURVEY LOCATIONS

Data was collected in the York River estuary, Virginia, USA, with water depths ranging from ~ 2 m to ~ 7.5 m. For this article, a cross-transect was chosen that started at 37°20′23.15″N 76°37′52.35″W and ends at 37°20′44.75″N 76°37′0.16″W (Figure 1), featuring predominately fine-grained sediments.
Figure 1. The investigated cross-shore transect in the York River estuary indicated by the red arrow with the five stationary stations (S1-S5) along the station indicated by the different colors (Map data: Google, SIO, NOAA, U.S Navy, NGA, GEBCO).

The chirp sonar was installed at the side of the boat with its head approximately 30 cm under water. The entire transect was measured with the chirp sonar with longer stationary recordings at five specific locations (S1-S5) along the transect (Figure 1). The PFFP was deployed from the same vessel simultaneously to chirp sonar surveying at locations S1-S5. Five PFFP deployments were conducted per location. Box core samples of ~ 30 cm length below seabed surface were recovered at the same locations.

Chirp sonar data was collected using a firmware data acquisition software. The chirp sonar was operated at an 8-12 kHz sweep in low energy mode to focus on sediments in the upper < 10 m of the estuary bed (Stratabox HD manual 2016). The chirp sonar sends sound signals into the water column, which then penetrate the seabed. The intensity of the signal reflected at different soil layers varies based on the different soil layer properties and interfaces with different geoacoustic properties. It should be noted that chirp sonars are typically deployed for deeper soil stratigraphy investigations, while the work presented here explores the deployment of chirp sonar to investigate top-surface sediments at a sediment depth < 1 m in line with the depth of interest for sediment dynamics as well as with the PFFP penetration depth.

Portable free fall penetrometers (PFFP) are a rapid in-situ investigation tool of the uppermost seabed layers (Randolph 2016). PFFP results have evolved from rapid seabed characterization to detection of soil layering, characterization of geotechnical sediments, mapping of sediment type, and more quantitative site characterization (Stark & Wever 2009, Stoll & Akal 1999). The PFFP was used in this study to estimate quasi-static bearing capacity (qsbc) and undrained shear strength (su) of seabed surface sediments. The specific lightweight instrument enabled multiple tests per location in a rapid manner and simultaneously to

the chirp sonar surveying. The data processing from the measured PFFP deceleration to estimate qsbc and su followed the concept presented by, e.g., Aubeny and Shi (2006) and Albatal and Stark (2017) and as discussed by Stark and Ziotopoulou (2017) for the PFFP used. A detailed description can be found in those publications, amongst others. In this paper, the qsbc calculations utilizes logarithmic and power law expressions for strain rate correction factors (Steiner et al. 2014; Stark and Ziotopoulou 2017).

Box core samples were tested in the geotechnical laboratory for grain size analysis, laboratory miniature vane shear, water content, and bulk density using ASTM D1140, D4648, D2216, and D7263 respectively. Porosity was measured from the core samples and deduced from phase relationships using water content.

2.1 Acoustic impedance from sediment samples

The results of porosity and bulk density were used to calculate the expected acoustic impedance $Z=\rho_b c_b$, and reflection coefficient RF based on LeBlanc et al.'s (1992) approach summarized in the equations below:

$$c_b = \left(\frac{\frac{1}{\beta_b} + \frac{4\mu}{3}}{\rho_b} \right)^{0.5} \tag{1}$$

$$\beta_b = \beta_w n + \beta_g (1 - n) \tag{2}$$

where c_b is the compressional wave velocity, β_b is the bulk compressibility of water, ρ_b is the bulk density of sediment, μ is the bulk modulus of rigidity, β_g is the grain compressibility, $\beta_g = \beta_R \beta_w$ taken as 4.85E-11 m^2, n is the soil porosity, β_w is the compressibility of bottom water, and β_R is the grain compressibility relative to bottom water. The bulk modulus of rigidity can be estimated using:

$$\mu = \mu_o \left(\frac{\rho_b}{\rho_w - 1} \right)^{\eta} \tag{3}$$

where μ_o is the rigidity constant taken as 5E-7 N/m^2, ρ_w is the density of water, and η is an arbitrary exponential power constant, taken as 1.

The reflection coefficient can then be calculated:

$$RF = \frac{Z - Z_w}{Z + Z_w} \tag{4}$$

where Z_w is the impedance of water $(\rho_w/\beta_w)^{1/2}$, taken as 1.53E06 kg/m^{2}s and Z is the acoustic impedance of seabed sediments.

At each of the stationary sites, the chirp sonar recorded the same location for a few minutes.

The recordings were saved in segy format files and were read and processed in a MATLAB code that displays the variation in the signal amplitude envelope (without phase information) with seabed depth. The multiple reflection approach suggested by Bull et al. (1998) was then tested to calculate the reflection coefficient of the seafloor using the amplitude and the two-way travel time of the primary seabed reflector and the first multiple of the seabed reflector as shown in the formula below:

$$RF = \frac{TWT_m A_m}{TWT_P A_P} \quad (5)$$

where TWT_m is the two-way travel time of the first multiple of the seabed reflector, A_m is the amplitude of the first multiple seabed reflector, TWT_p is the two-way travel time of the primary seabed reflector, A_p is the amplitude of the primary seabed reflector. The acoustic impedance of the sediments can then be calculated from the reflection coefficient results using Eq. 4. The reflection coefficient was calculated after applying a moving average of the trace range amplitudes to account for local noise variations.

3 RESULTS

The chirp sonar measurements along the measured transect as derived from the manufacturer software is shown in Figure 2 with S1-S5 highlighted. In the following sections, results from the stationary chirp recordings, PFFP deployments, and soil testing of core samples collected at sites S1 through S5 are presented.
Figure 2. Depiction of chirp sonar backscatter intensity (as relative digital number) along the cross-transect at York River, VA. The five different locations surveyed are marked by the arrows with annotations S1-S5.

3.1 Chirp sonar

The porosity varied slightly with a minimum and a maximum of 0.74 and 0.83 at sites S2 and S4, respectively (Table 1). The bulk density ranged between a minimum of 1.21 g/cm^3 and a maximum

of 1.69 g/cm^3 at sites S3 and S5, respectively. Hence, following LeBlanc et al. (1992) (Eqs. 1-4), the lowest acoustic impedance Z and reflection coefficient RF based on sediment properties predicted from the core samples are 1.9E+06 kg/m^{2}s and 0.11 at S3 respectively, and the highest are 2.3E+06 kg/m^{2}s and 0.2 at S5, respectively (Table 1).

Table 1. Sediment geotechnical and acoustic properties for sites S1-S5.

Site	n	ρ_b (g/cm^3)	Z (kg/m^{2}s)	RF
S1	0.78	1.28	2.0E+06	0.13
S2	0.74	1.54	2.2E+06	0.18
S3	0.81	1.21	1.9E+06	0.11
S4	0.83	1.46	2.0E+06	0.15
S5	0.75	1.69	2.3E+06	0.20

Table 2 shows the Z and RF derived from the chirp sonar following the approach by Bull et al. (1998) (Eq. 5) for sites S1-S5. The presented ranges account for variability observed during the stationary measurements. It should be noted that "stationary" still included some boat motion within the range of a single anchor line.

Table 2. Acoustic impedance and reflection coefficient results from the chirp sonar.

Site	Z (kg/m^2.s)	RF
S1	3.6-4.6E+06	0.40-0.50
S2	3.7-8.5E+06	0.42-0.70
S3	3.2-4.6E+06	0.35-0.50
S4	1.9-6.0E+07	0.85-0.95
S5	4.6-9.8E+06	0.50-0.73

The reflection coefficients estimated ranged from 0.35 up to 0.73 for all sites, except for S4, where the results seem to be drastically higher than the rest of the sites. The acoustic impedance varied between 3.2E+06 kg/m^{2}s and 9.8E+06 kg/m^{2}s, except for S4 also where the results reached up to 6.0E+07 kg/m^{2}s. No clear reason for the observations at S4 was found. It may be hypothesized that gas was present in the sediment from biogenic processes, but due to a lack of data to confirm or reject the hypothesis, chirp results at S4 will be rejected from further analysis.

3.2 PFFP results

A representative deceleration profile for each of the five sites (S1-S5) along the transect is shown in

Figure 3. A maximum deceleration (*dec*) of ~ 3.5 *g* was recorded for sites S1, S4 and S5 and a higher maximum deceleration of ~ 5.7 and 7.5 *g* was recorded for sites S2, and S3, respectively. The increase in deceleration with depth at sites S1, S4, and S5 seems gradually linear compared to a steeper increase at S2 with some irregularities observed in the profile between 20-30 cm. The deceleration profile at S3 can be divided into two layers, an upper softer layer (above ~ 40 cm), and a stiffer lower layer (below ~ 40 cm).

The maximum deceleration was then used to calculate the maximum *qsbc* and s_u using strain rate parameters *k* and *β* ranging from 0.1 to 0.15, and 0.035 to 0.085, respectively (Chow et al. 2017, Steiner et al. 2014). Cone factor (N_{kt}) values typically reported for CPT in fine-grained sediments range between 4 and 20 (Robertson & Cabal 2015). Mayne & Peuchen (2018) reported N_{kt} ranging from 8 to 25 based on a database composed of 62 clays. Therefore, cone factors of 12.3 and 10 were chosen for this study based on the values reported by Mayne & Peuchen (2018) for offshore normally consolidated clay and sensitive clays, respectively.
Figure 3. Deceleration and qsbc-depth profiles for sites S1-S5. Different colors represent the different sites.

4 DISCUSSION

Based on LeBlanc et al. (1992) and others, these values suggest sediments coarser than sand, and thus, represents not only a mismatch to the estimates obtained from sediment samples, but also with expectations based on literature. The difference between both reflection coefficients varied between a factor of 2 and 4. However, no consistent factor was obvious, likely indicating that

the multiple approach adopted by Bull et al. (1998) might not be applicable. A reason for this may be the local water depth. Warner (1990) initially introduced this approach for deep water investigations, and Bull et al. (1998) applied it to water depths of ~ 9 m. The water depth along the tested transect reached only ≤ 7.5 m. Also, multiples are only clearly visible at some of the target locations when revisiting the initial output (Figure 2). This necessitates the need to explore different processing methods to calculate the reflection coefficient, likely utilizing phase information that were not collected here for simplification, or to investigate the application of an inverse model as suggested by Wang & Stewart (2015). However, it should be noted that despite the mismatch in *Z* and *RF* between the geoacoustic properties estimated using the chirp measurements and those estimated from sample testing, both seem to follow a similar trend with respect to the different locations. For instance, sites S2 and S5 record the highest reflection coefficients while sites S1 and S3 record the lowest, as reported by both measurement methods. This supports further evidence for the expected response of the chirp sonar backscatter intensity based on differences in sediment properties; however, also highlights limitations of the Bull et al. (1998) approach to accurately derive *Z* and *RF* for the shallow water – shallow penetration conditions encountered here.

Table 3 summarizes the main results of the PFFP, represented by the maximum *dec*, *qsbc*, and s_u along with the chirp and laboratory testing results represented by one of the geoacoustic properties, *RF*. The multiple *qsbc* and s_u results reported per site correspond to the different strain rate correction methods, parameters, and cone factors used.

The variation in the *qsbc* values at each site based on the different *k* and *β* reaches up to ~ 10 kPa, with the variations becoming more significant at large deceleration values (e.g. S2 and S3). The power-law equation for the strain rate correction with *β* of 0.085 always seem to give the lowest *qsbc* result. Similarly, the undrained shear strength values seem to vary between 0.3 up to 0.9 kPa with the largest variations reported at sites S2 and S3. Sediment strength was relatively consistent towards the estuary banks (S1, S4, and S5) and higher and more variable in the center of the estuary (S2 and S3). The significant difference of S4 observed in the chirp sonar was not reflected in the PFFP. Acoustic methods are highly sensitive to gas, while gas content would be expected to decrease sediment strength, the threshold for detection may be higher.

Table 3. PFFP results (dec, qsbc, su), chirp and sample testing results (RF) at the five sites (S1-S5) for different strain rate parameters and cone factors.

Site	k/β	dec (g)	$qsbc$ (kPa)	s_u N_{kt}-12.3	s_u N_{kt}-10	RF-chirp	RF-sample
S1	0.1	3.4	24.1	2.0	2.4	0.45	0.13
	0.15		22.1	1.8	2.2		
	0.035		24.6	2.0	2.5		
	0.085		19.5	1.6	2.2		
S2	0.1	5.7	40.2	3.3	4.0	0.56	0.18
	0.15		36.9	3.0	3.7		
	0.035		41.1	3.3	4.1		
	0.085		32.1	2.6	3.2		
S3	0.1	7.5	53.3	4.4	5.3	0.43	0.11
	0.15		49.3	4.0	4.9		
	0.035		54.5	4.4	5.5		
	0.085		43.7	3.6	4.4		
S4	0.1	3.4	24.2	2.0	2.4	-	0.15
	0.15		22.3	1.8	2.2		
	0.035		24.7	2.0	2.5		
	0.085		19.5	1.6	2.0		
S5	0.1	3.4	24.3	2.0	2.4	0.62	0.20
	0.15		22.4	1.8	2.2		
	0.035		24.8	2.0	2.5		
	0.085		19.6	1.6	2.0		

Focusing on S1 and S5 showing similar PFFP profiles with soft sediments (Figure 3 and Table 3), significant differences were noted in the chirp sonar (Figure 1 and Table 2), and similarly, differences were noted in the sediment cores' bulk density and porosity (Table 1). This may suggest that those slight variations in porosity ($n = 0.75$ and $n = 0.78$) affect the geoacoustic response noticeably, particularly when considering the possibility of abundant gas content), but may not affect the sediment strength, and thus, the PFFP to the same degree.

Location S3 suggested an overall higher sediment strength based on the maximum values throughout the penetration; however, matched the observations at S1 and S5 up to a penetration depth of 40 cm. As sediment cores were only obtained to a penetration depth of 30 cm and the method applied to estimate Z and RF from the chirp sonar bases on surface layer reflection, a discussion of PFFP vs. chirp sonar for S3 may be included in the discussion of S1 and S5. Then, S3 matches well with S1, and S5 strikes as an outlier (Table 3). Revisiting Figure 3 reveals that S5 shows stronger reflections and variability with multiple stronger reflectors within the top meters of the seabed. Similar to S4, the presence of gas may be hypothesized. Additionally, the shallower water depth approaches the systems minimum, possibly also affecting the chirp response.

Finally, location S2 suggested an increased sediment strength for the entire PFFP penetration depth over all other deployment locations, and indeed, a higher reflection coefficient RF was suggested from the sediment samples and confirmed by the chirp sonar (Table 3).

Despite the limited variability in the seabed sediments, results seem to suggest certain trends between sediment strength and reflection coefficient, as measured by the PFFP and the chirp sonar. This encourages further work that would follow-up on current findings and address limitations and shortcomings mentioned here. This mainly includes considering different soil types, layered systems, and comparisons at different sediment depths. Additionally, it includes exploring reasons behind the mismatches observed between the RF results based on the chirp and sample testing and exploring different processing methods that are better suited for shallow water depths.

5 CONCLUDING REMARKS

This paper investigates the relations between reflection coefficients and acoustic impedance predicted from sediment samples and observed from chirp sonar measurements with portable free fall penetrometer (PFFP) testing along a transect crossing the York River estuary characterized by fine sediments. The presented data set is a small excerpt of a larger data set that includes many different seabed sediment characteristics. A limitation of the presented data set is the limited variability of the seabed sediments. Nevertheless, the data suggests that locations of increased sediment strength (S2 with an undrained shear strength estimated of up to 4.1 kPa within the uppermost meters of the seabed surface) also featured lower porosity suggesting a higher reflection coefficient which was confirmed by the chirp sonar measurements. It should be noted that this trend was visible even with the limited sediment variability of lower undrained shear strength sites reaching up to 2.5 kPa within the upper meter of the seabed surface. However, the data also revealed the need for further considerations such as: i) Which sediment depths or sediment depth ranges should results be compared at? ii) Related to i), how should layering be addressed then? iii) The effects of gas content on geotechnical properties versus geoacoustic properties. iv) Possible limitations regarding water depth in which chirp sonar is deployed in. v) What is the sensitivity of the PFFP and the chirp sonar to different sediment properties? These questions will be addressed further in follow-on work.

Development of free fall cone penetration testing system

Hyoun Kang, Osoon Kwon, Changjoo Shin, Jungmin Seo, Insung Jang & Man Dong-Woo
Korea Institute of Ocean Science & Technology, Busan, Korea

ABSTRACT: For the rigorous design of offshore structures, the geotechnical characteristics of the seabed ground should be rigorously investigated, in the deep water, seabed ground surveys are complex equipment and costly. Free fall type ground survey equipment that can acquire a simple and comparatively accurate ground is developed when only the characteristic investigation of the shallow depth ground such as the submarine pipeline, the submarine cable burial is the main concern. In this study, FFCPT was developed. Based on behavior results of numerical model simulation for FFCPT, it was manufactured. Water depth was obtained using pressure sensor and penetrated depth was estimated by the double integration of acceleration signal. In addition, we can verify vertical penetration at real field test of FFCPT using 2axis of inclinometer. So, the results of the seabed type offshore CPTu experiment and the developed model were compared and the performance was evaluated.

1 INTRODUCTION

Recently, various types of equipment that are operated underwater have been developed. Among them, it is very important to characterize the seabed ground for the movement of equipment. However, there is not much technology of the equipment to understand the characteristics of the seabed ground, size of the equipment is large, and It takes a very complicated process to identify the characteristics of the seabed ground. The Free-Fall cone penetration testing system (FFCPT) has been developed as a tool for the rapid environmental assessment of seabed and water column properties for anti-submarine warfare and mine counter measure operations

The FFCPT makes direct measurements of geotechnical properties of the seabed. It has the same scaling factors as a conventional pushed cone penetrometer, but with a larger diameter to house the instrumentation and power supply. It is designed to free-fall into the seabed and to survive impacts with rock, if and when that happens. It consists of a nose cone instrumented with geotechnical sensors, power supply, electronics, and tail pressure sensor. It measures acceleration and dynamic sediment pore pressure as a function of depth of penetration into the seafloor. The FFCPT also records hydrostatic pressure, to monitor its descent velocity during free-fall, and optical backscatter for the detection of the water-sediment interface which is particularly helpful on high porosity fluid-mud seabed.

CPT(Cone Penetration Test) is the most accurate field survey method to measure the strength and characteristics of the ground in the field. In the ocean, CPT(Cone Penetration Test) are conducted in a variety of ways.

In this study, compared to the equipment used on land, it is relatively easy to carry in the marine field, A Free Fall Cone Penetration Testing System(FFCPT) was developed to obtain accurate ground data(tip resistance, friction resistance). and the characteristics of the seabed ground were identified by the sea trials.

In addition, the depth of subsea ground and ground data were finally compared with the results of the seabed type offshore cone penetration test and Free Fall Cone Penetration Testing System in the same area to assess performance.

2 SITE CONDITIONS AND INVESTIGATION

In this study, experiments were conducted in Gunsan, located on the west coast of South Korea, as shown in Figure 1.

As shown in Figure 2, the feasibility of the experimental location was evaluated by the seabed type offshore cone penetration test subsea survey results, and the subsea ground survey results were shown.

Figure 1. Test site location map.

Figure 2. Result of test site location.

The water depth is about 1.0 meter at low tide and about 8.0 m at high tide. The prevailing current velocity is 1.59 m/sec at maximum and 0.80 m/sec at minimum. The seafloor at the test site consists of roughly 8.0 meter of clayey silt or sandy clay underlain by medium silty sand. As shown in Figure 2, the characteristics of the ground as a distribution map.

3 DEVELOPMENT OF FFCPT

FFCPT should not be disturbed by power or communication line, in order to increase penetration force during freely falling. Therefore, all parts such as power source, electronic board, sensors, etc. must be installed in body of the FFCPT except recovery wire.

Figure 3 is the canister for electronic part is made of aluminum alloy to have a light weight and buoyancy compared to the rod and cone probe which are made of iron. Since the center of buoyancy is set to be 0.6m upper than the center of mass, the flip-over motion of FFCPT can be prevented during free fall.

Figure 3. Configuration of FFCPT.

Several sensors and electronic parts such as DAQ, battery, etc. are embedded as shown in Figure 4(a). To obtain these signals, NI crio for DAQ was applied. Estimation of the penetration depth of FFCPT using acceleration is the fundamental data for ground characteristics analysis, so dedicated

equipment that can accurately measure it is required. In addition, the acceleration signal and other sensor signals require time synchronization. For this purpose, a dedicated module for vibration measurement and a DC-type acceleration were used, and when other sensor signals were input, time synchronized measurements were performed based on the acceleration signal. A 2-axis inclinometer is installed for tracking the underwater free fall motion. The pressure sensor was applied to check the water depth at the test point. It is manufactured so that it can operate continuously for more than 8 hours after power on using large-capacity battery. According to Newton's Law, the underwater terminal speed just before impact is calculated by integration of the obtained acceleration.

4 TESTING METHODS AND RESULTS

4.1 Testing methods

Figure 5 is the an experiment was conducted to obtain subsea ground data (cone tip resistance, friction resistance) using the developed FFCPT
Figure 5. FFCPT.

Figures 6 and 7 are the FFCPT with a length of 4m and weight of 38kg was placed on a moving crane and dropped freely in sea 20m deep. In order to verify the performance of the developed FFCPT, free fall experiments were repeated five times and data were obtained.

Figure 6. Drop test of FFCPT_1.

Figure 7. Drop test of FFCPT_2.

4.2 Result of test

In this study, subsea ground characteristics data(cone tip resistance, friction resistance) were obtained using the developed FFCPT(Free Fall Cone Penetration Testing System).

As shown in Table 1, the final penetration depth was 0.21 m, 0.24 m, 0.26 m, 0.22 m and 0.49 m, and the average was 0.28 m.

Table 1. Result of test.

	Final penetration depth(m)	Cone resistance(MPa)	friction resistance(MPa)
FFCPT-1	0.21	0.0048~5.2755	0.0~0.0153
FFCPT-2	0.24	0.0006~4.8709	0.0~0.0118
FFCPT-3	0.26	0.0141~5.3009	0.0~0.0114
FFCPT-4	0.22	0.0131~4.2026	0.0~0.0116
FFCPT-5	0.49	0.0006~2.5260	0.0~0.0115

4.2.1 *Result of FFCPT-1*

Figure 8 is the final penetration depth of FFCPT-1 was 0.21m and ground data (cone tip resistance, friction resistance) values were measured. The results of the experiment were shown as follows
Figure 8. Result of FFCPT-1.

Figure 8 is the distribution range of cone tip resistance was measured in the range of 0.0048 to 5.2755MPa, and the distribution range of the friction resistance was measured in the range of 0.0000 to 0.0153MPa. As a result of the experiment, from 0m to 0.1m, it is judged as Clay silt to silty clay, and up to 0.2m, it is judged as Silty sand to sandy silt.

4.2.2 *Result of FFCPT-2*

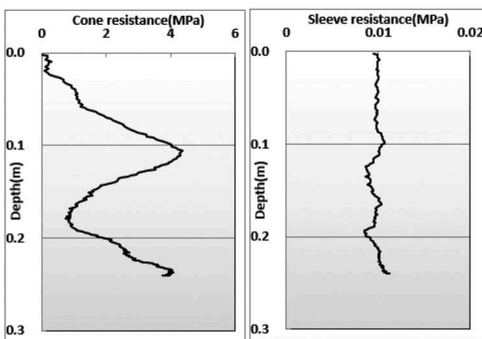
Figure 9 is the final penetration depth of FFCPT-1 was 0.24m and ground data (cone tip resistance, friction resistance) values were measured. The results of the experiment were shown as follows.


Figure 9. Result of FFCPT-2.

Figure 9 is the distribution range of cone tip resistance was measured in the range of 0.0006 to 4.8709MPa, and the distribution range of the friction resistance was measured in the range of 0.0000 to 0.0118MPa. As a result of the experiment, from 0m to 0.1m, it is judged as Silty sand to sandy silt, from

0.1m to 0.18m, it is judged as Clay silt to silty clay, and up to 0.25m, it is judged as Silty sand to sandy silt.

4.2.3 *Result of FFCPT-3*

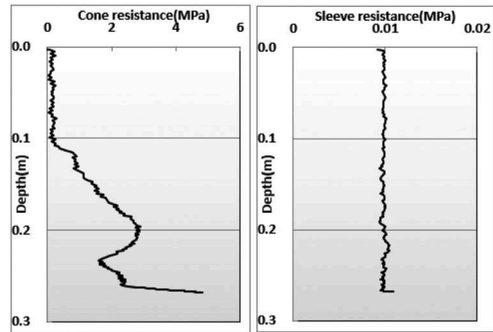
Figure 10 is the final penetration depth of FFCPT-1 was 0.26m and ground data (cone tip resistance, friction resistance) values were measured. The results of the experiment were shown as follows.


Figure 10. Result of FFCPT-3.

Figure 10 is the distribution range of cone tip resistance was measured in the range of 0.0141 to 5.3009MPa, and the distribution range of the friction resistance was measured in the range of 0.0000 to 0.0114MPa. As a result of the experiment, from 0m to 0.2m, it is judged as Silty sand to sandy silt, and up to 0.27m, it is judged as Clay silt to silty clay.

4.2.4 *Result of FFCPT-4*

Figure 11 is the final penetration depth of FFCPT-1 was 0.22m and ground data (cone tip resistance, friction resistance) values were measured. The results of the experiment were shown as follows
Figure 11. Result of FFCPT-4.

Figure 11 is the distribution range of cone tip resistance was measured in the range of 0.0131 to 4.2026MPa, and the distribution range of the friction resistance was measured in the range of 0.0000 to

0.0116MPa. As a result of the experiment, from 0m to 0.17m, it is judged as Clays-clay to silty clay, and up to 0.22m, it is judged as Silty sand to sandy silt.

4.2.5 *Result of FFCPT-5*

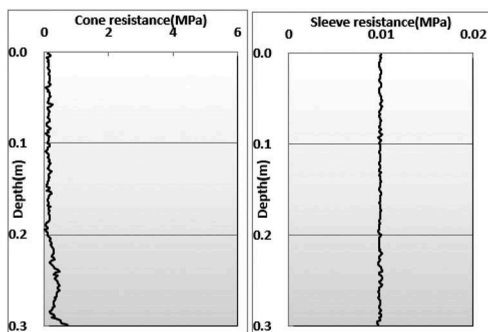
Figure 12 is the final penetration depth of FFCPT-1 was 0.49m and ground data (cone tip resistance, friction resistance) values were measured. The results of the experiment were shown as follows.


Figure 12. Result of FFCPT-5.

Figure 12 is the distribution range of cone tip resistance was measured in the range of 0.0006 to 2.5260MPa, and the distribution range of the friction resistance was measured in the range of 0.0000 to 0.0115MPa. As a result of the experiment, from 0m to 0.3m, it is judged as Clays-clay to silty clay.

5 CONCLUSIONS

FFCPT was developed to obtain seabed geotechnical properties conveniently. After the FFCPT falls under water and impacts on seabed ground, the device acquires the geotechnical properties during penetration. It is very important to secure the penetration depth because the equipment measures the properties according to the penetration depth. Sea-trial free-fall test was performed.

Analysis of this study, subsea ground characteristics data were obtained using the developed FFCPT. The analysis results are as follows.

The final penetration depth was 0.21 m, 0.24 m, 0.26 m, 0.22 m and 0.49 m, and the average was 0.28 m. This is judged not to penetrate more than 0.49m because it is not deep water and it is light weight of ffcpt.

FFCPT1-5 are the distribution range of cone tip resistance was measured in the range of 0.0006 to 5.3009MPa, and the distribution range of the friction resistance was measured in the range of 0.0000 to 0.0153MPa.

According to the comparative analysis of the seabed type offshore cone penetration test and FFCPT, it was difficult to accurately compare the locations of the test sites because it was judged that there was a gap of up to 5 to 10 meters due to the movement of the ship.

Due to the following conclusions, it is deemed necessary to estimate the appropriate depth of water in future field experiments. In addition, it is deemed necessary to increase the weight of the FFCPT even if the depth of the water is not deep enough to improve the final penetration depth.

Through this study, the basis of underwater behavior analysis of the FFCPT for seabed penetration was secured. If this equipment is improved and apply to obtain the ground characteristics in deep seabed, it is expected to be used very conveniently at low cost.

Evaluation of statistical fluctuation of measured data from nuclear density cone penetrometer

Muthusamy Karthikeyan
Surbana Jurong Consultants Pte Ltd, Singapore

ABSTRACT: This paper describes research conducted to investigate the statistical fluctuation and interpret the density profiles obtained by a nuclear-density cone penetrometer (ND-CP). The laboratory results show that the amount of fluctuations present in the ND-CP measurements can be approximated by Normal or Gaussian distribution. The coefficient of variation for RI count and BG count data's is 2.4% and 15.1% respectively. The moving-average technique has been employed for the measured raw data at different time intervals in order to reduce the statistical fluctuation. It was found that the error due to the statistical fluctuation in ND-CP measurement is less than 1% if an averaging span of 10 cm is used. The raw data obtained from the field results when averaged over 10cm depth shows that the cone profile count distribution trend is not distorted or deformed compared to the original raw data, which means the loss of information about the density through the filtering is negligible. This averaging is necessary to smooth the measured wet density profile. Therefore, the ND-CP measurements are averaged over a span of 10cm depth to minimize the statistical fluctuations.

1 INTRODUCTION

The in-situ wet density of soil can be measured reliably using Nuclear-Density Cone Penetrometer (ND-CP) (Shibata et al., 1993; Karthikeyan et al., 2001; 2004; Tan et al., 2004; Dasari et al., 2006 and Karthikeyan et al., 2007; Karthikeyan and Tan, 2008; Rui et al. 2013). Most of the earlier researchers mentioned above have focused on the effectiveness of the ND-CP in determining the soil properties for settlement analysis, evaluation of liquefaction potential of sandy deposits and determination of the strength of sub-soil after ground improvement. Recently, the ND-CP was used to characterize a reclaimed land (Karthikeyan et al., 2004, Dasari et al., 2006 and Karthikeyan et al., 2007).

Natural deposits laid down under water are often layered. Sometimes, these layers can be identified by changes in the density of soil. The ND-CP measurement is affected by the measuring volume and if this volume is occupied by layers of different densities, then the relationship between the observed count rate and true wet densities become correspondingly more complex (Karthikeyan and Tan, 2008). As the measuring volume of the ND-CP traverses through this soil with changing density, the count rate measured corresponds to a measurement of some composite material. If the ND-CP is used to characterize soil with greater heterogeneity, for example, a fill made of lumps, the interpretation of the exact nature of such lumpy fill is more complex. As the density and

thickness of each layer change, the ND-CP measurements will produce a pattern that changes correspondingly. An ability to interpret this signature is essential to the profiling of such soil, which is a major challenge. Any measurement based on observing the radiation emitted in nuclear decay is subject to some degree of statistical fluctuation. These inherent fluctuations represent an unavoidable source of uncertainty in all nuclear measurements and often can be the predominant source of imprecision or error. To account for uncertainty in cone measurement, knowledge of the uncertainties should be understood. In this paper, results from an experimental investigation will be presented to investigate the statistical fluctuation and interpret the density profiles obtained by a nuclear-density cone penetrometer (ND-CP) so as to improve the interpretation of the actual soil profile.

2 DESCRIPTON OF NUCLEAR-DENSITY CONE PENETROMETER (ND-CP)

Figure 1 shows major components of a ND-CP. The lower part of the cone houses various sensors to measure the usual cone parameters, namely, cone resistance (qc), sleeve friction (fs) and pore pressure (u2). The size of the lower part conforms to the standards recommended by the International Society for Soil Mechanics and Foundation Engineering (ISSMFE, 1989) for cone penetration testing and ASTM Standard D 5778. The diameter of the cone is

35.6 mm and the apex angle is 60°. The base area of the cone is 10 cm^2 and the area ratio, a, is equal to 0.75 which is determined from calibration measurement at the laboratory (the effort to eliminate the adverse effects of friction sleeve and unequal cone tip). A porous ceramic filter is located just behind the cone tip. The total length of the shaft housing the sensors is 258 mm. After this, the shaft tapers outwardly at an angle of 15°. The tapered portion of the shaft is 49 mm long, above which the shaft has a constant diameter of 48.6 mm and extends for a total length of 896 mm. This upper part houses the radioisotope source, the detector, and a preamplifier

The ND-CP uses gamma-ray as the source. Gamma rays interact with soil predominantly depending on the level of the energy. The Compton scattering is predominant within an energy range of 600 keV and 1.2 MeV, and is a function of the material density. If the detector is designed to measures only the incoming photons within the range described, then the incoming photons are a function of the density of the material only. The gamma ray source used in the construction of the ND-CP is a Cesium (Cs137) isotope with a half-life of 37.6 years, and the detector is sodium iodide activated with thallium (NaI (TI)) scintillator mounted on a photomultiplier tube. The length of the NaI scintillation detector is 10.2 mm. The separation distance between the source and center of gamma detector is 255 mm. The ND-CP is pushed into the soil layer at a rate of approximately 1 - 2 cm/sec and cone resistance (qc), sleeve friction (fs), pore pressure (u2), radioisotope (RI) count are recorded continuously.

The intensity of the radioisotope sources used in these cones is very low compared to the radioisotopes used in medical equipment that pose problems to human health. However, it is still necessary to take precautionary measures to avoid radiation exposure in humans by wearing a lead apron and also by frequent monitoring of radiation exposure using a radiation meter (Dasari et al., 2006).

In using the ND-CP, it is the net above the background (BG) radioisotope count that is used. Thus, a separate reading of this BG count has to be taken either immediately prior or after the test. The

Figure 1. Diagram of Nuclear-Density Cone Penetrometer (ND-CP). (after Shibata et al., 1993 and Dasari et al., 2006).

detailed description and working procedure of ND-CP have been discussed by Karthikeyan (2005), Dasari et al. (2006), Karthikeyan et al. (2007) and Karthikeyan & Cisy (2019).

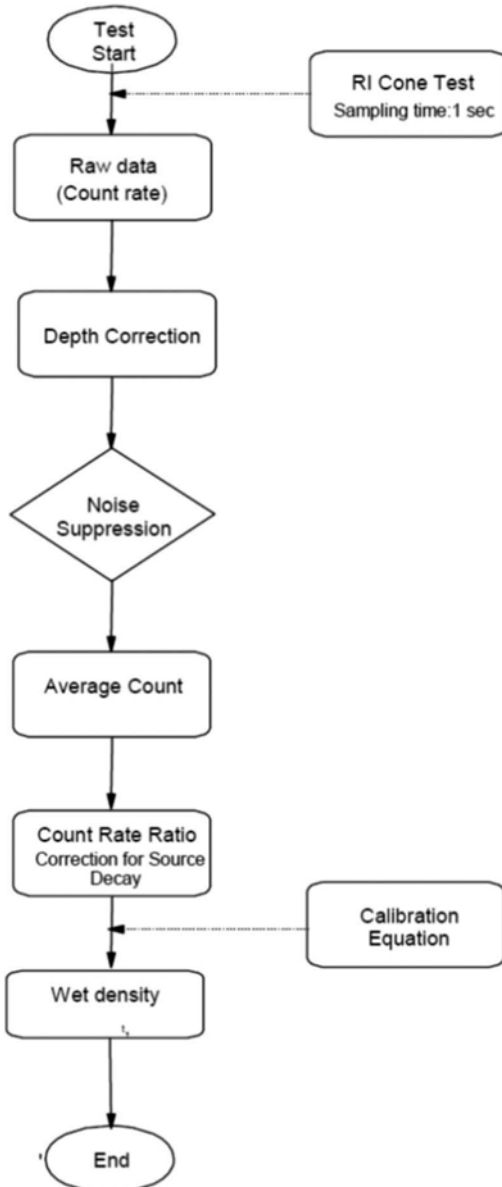
2.1 *Procedure for processing the ND-CP results*

Current design of the ND-CP requires two probings for every single measuring point, one probing to obtain the background (BG) count of naturally occurring gamma photons and another probing to measure the actual nuclear density (RI) count. The background count is measured using a dummy cone, in which only the detector is placed to measure the naturally occurring gamma photons. This natural radioactive (background) count is a type of noise which must be subtracted from the count measured to give the actual nuclear density measurement. To determine the wet density and water content of soil, the measured raw data needs to be processed for the final profiles through the following steps: (i) depth corrections (ii) noise suppression or elimination (iii) statistical fluctuations and averaging of measured RI cone data. Figure 2 also shows the flow chart for processing of measured RI cone data. The detailed procedures for processing of measured RI cone data will be discussed subsequently in the following section.

2.1.1 *Depth corrections*

As stated earlier, the upper part of the RI cone houses the radioisotope source, the detector and a preamplifier. The lower part of the cone houses various sensors to measure the usual cone parameters, namely cone resistance, pore pressure and the sleeve friction. Therefore, it is important to correct the measurement of the different sensors reading into the same depth level as the other parameters to ensure proper characterization of soil layers. Therefore, the following depth correction needs to be carried out for raw data for further interpretations. If the measurement center for a RI cone is considered at the cone resistance sensor (load cell), then the other sensors readings are corrected accordingly, for example, the depth of sleeve friction, pore pressure, RI count, BG count are raised about 0.11 m, 0.04 m, 0.60 m and 0.36 m, respectively. The distances are based on the function of the cone design.

2.1.2 *Noise suppression or elimination*

In several practical cases, it is possible that the depth-meter reading could be affected by either delayed response or disturbing inertial effects, caused, for example, by velocity fluctuations (acceleration, vibrations, and so forth). Hence, it will affect the accuracy of RI cone measurement. To avoid this discrepancy in the RI cone results, it is important to measure the RI Count and BG Count in both penetration and uplift stage so that the retardation error can be pointed easily. The "analog recording" of the density–depth profile
then will show "retardation hysteresis" loops, which enclose the representative density profile. Figure 3 shows the typical BG count profile measured for both penetration stage and uplift stage profile. From the figure, it can be seen that there is an abnormal behavior observed in the penetration stage measurement due to undesirable shock. These undesirable shocks can be removed by comparing with the uplift stage measurement. Figure 3 illustrates the typical BG count profile after elimination of the undesirable noise.


2.1.3 *Averaging of measured RI cone data*

Radioactive decay is a random process. Consequently, any measurement based on observing the radiation emitted in nuclear decay is subject to some degree of statistical fluctuation. These inherent fluctuations represent an unavoidable source of uncertainty in all nuclear measurements and often can be the predominant source of imprecision or error (Knoll, 2000). The source-originated fluctuations affect the precision of the RI cone. The error in density/water content due to these fluctuations can be minimized by designing equipment such that the radioactive count is high. Many sources of uncertainties can be reduced with increased sampling and good practices, but due to the nature of geomaterials, inherent uncertainties cannot be eliminated. Inherent uncertainties can be quantified by a statistical analysis. The error can also be minimized by decreasing the statistical fluctuation through filtering data over a short depth. Nobuyama (2000) reported that the RI cone measurement needs to be averaged over a depth in order to reduce the statistical fluctuation. To re-evaluate the statistical fluctuation of RI cone measurement, a laboratory counting experiments is carried out and discussed in the following paragraphs. The understanding of these statistical fluctuations is also important in the interpretation of the ND-CP results for highly heterogeneous soils.
Figure 3. An example of Noise Suppression or Elimination (after Nobuyama, 2000).

3 EXPERIMENTAL SETUP

An experimental setup was designed for studying the statistical fluctuation of wet profile measured by ND-CP. A series of laboratory counting experiment was carried out using the ND-CP under identical conditions. One of the controlling factors is the size of the

Figure 2. Flow chart for processing the RI cone results.

laboratory calibration chamber. The density is measured using a source and detector. The signals from the source interact with soil and the modified signals are captured by the detector. The degree of modification of the signals is a function of material property. RI cone measurements (density) are evaluated in an extended volume around the central point of the radioactive source and detector configuration, which is called the "measuring volume".

Based on the theory of gamma scattering and neutron methods, the "measuring volume" around the source was found to be about 30 cm radius. Karthikeyan and Tan (2008) reported that the maximum radius of the influence zone for ND-CP is 23.6 cm when used in water and it decreases with increasing wet density of the material. It was also established that the ND-CP measurement provides the average wet density of the composite soil within the measuring volume.

Therefore, a stainless-steel chamber with diameter of 700 mm and height of 1000 mm was used for the experiments. This calibration chamber was filled with water and the ND-CP was kept inside at the centre of the calibration chamber to measure the statistical fluctuations of RI Count and BG Count under identical condition.

4   STATISTICAL FLUCTUATION OF ND-CP

Figure 4 shows the typical variations of RI count and BG count data measured in water under ideal condition. There are 121 separate measurements, each taken at a 1 sec interval. When the measurements were being made during the 121 secs, the source of the radiation was 'steady'. The source of the radiation did not change in its nature. Nevertheless, the number of counts recorded per sec is clearly not constant. This is the statistical nature of ND-CP measurement.

The frequency of occurrence of an error of any given magnitude can be calculated for a given determination by the application of the laws of probability. Various distribution laws are used to relate the magnitude of a deviation from true average and the number of events which experiences that particular deviation. The normal distribution is useful for describing the spread in data occurring in various aspects of nuclear-radiation detection (Price, 1964; and Tsoulfanidis, 1995). The extent of the statistical fluctuations about the true mean may be expressed in terms σ, the standard deviation and is approximated by normal distribution (Nobuyama, 2000). The standard deviation is defined as the square root of the scatter data about the mean value. The standard deviation is used commonly to indicate the accuracy with which a sample of a given size can estimate the mean value of test results. The coefficient of variation, COV, is another measure of variability of a sample and is defined as the ratio between the standard deviation and mean value. The COV expresses the magnitude of variability as a fraction or as a percentage of the mean value. This facilitates comparison of data from different samples

because the mean and standard deviation tend to change together, so typically the coefficient of variation remains fairly stable (Snedecor and Cochran, 1989).
Figure 4. Typical variations of RI Count and BG Count data measured in water under ideal condition.

Figure 5 illustrates the form of normal distribution along with its mean and standard deviation of measured RI count and BG count data. This figure show that the amount of fluctuations present in the ND-CP measurements can be approximated by Normal or Gaussian distribution. It is also noted that the ND-CP measurements fluctuate within the range of $\pm$ (twice of the standard deviation, σ) from its mean value. The coefficient of variation for RI count and BG count data's is 2.4% and 15.1% respectively. Nobuyama (2000) reported that the error could be minimized through filtering the data over a short depth. For this, the moving-average technique has been employed for the measured raw data at different time intervals.

Figure 6 shows the changes in COV for different moving-averaging interval for RI Count and BG count data. From the figures, it can be seen that the COV decreases with increasing moving-average time interval. It is also inferred from Figure 6 that the COV is fairly constant after a moving-average interval of 6 secs to 7 secs. This further confirms that the averaging or filtering of wet density profiles measured by ND-CP is necessary to reduce the statistical fluctuations.

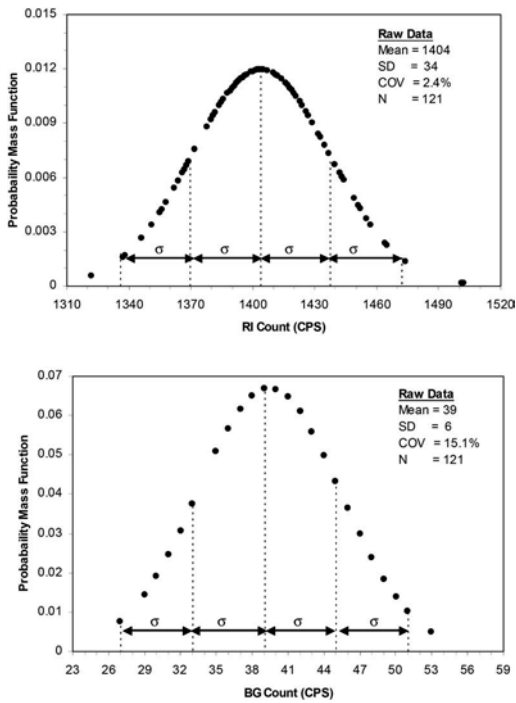
In field test, the ND-CP was pushed into the ground at a rate of approximately 1.5 cm/sec, and thus it will cover a distance of 10 cm within 6 – 7


Figure 5. Illustrating the statistical fluctuations of RI Count and BG Count data in the form of normal distribution along with its mean and standard deviation (σ) (a) RI Count (b) BG Count.
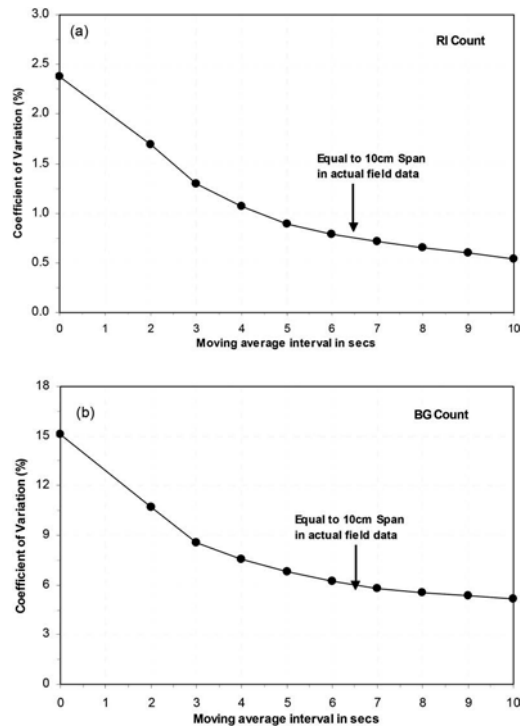

Figure 6. Changes in COV with different moving averaging intervals (a) RI Count (b) BG Count.

secs. While comparing the BG count with RI count in water, the BG count is too small, and it is almost equal to the minimum detectable count of ND-CP. Therefore, if the effect of the BG count is neglected, as can be seen in Figure 6 (a) the error due to the statistical fluctuation in ND-CP measurement is less than 1% if an averaging span of 10 cm is used. This can be also demonstrated using the field results shown in Figure 7 (a) and (b) which were obtained by averaging over 5 cm and 10 cm depths respectively. The raw data are also shown for comparison purpose. As can be seen, when averaged over 10 cm depth, the RI cone profile count distribution trend is not distorted or deformed compared to the original raw data, which means the loss of information about the density and moisture through the filtering is negligible. This filtering is necessary to smooth the density profile. Therefore, the RI cone measurements that are reported subsequently are averaged over a span of 10 cm depth to minimize the statistical fluctuations.

5 CONCLUSIONS

This paper describes research conducted to investigate the statistical fluctuation and interpret the density profiles obtained by a nuclear-density cone penetrometer (ND-CP) so as to improve the
Figure 7. Comparison of measured ND-CP raw data and averaged data (a) 5 cm average span (b) 10 cm average span.

interpretation of the actual soil profile. The laboratory results show that the amount of fluctuations present in the ND-CP measurements can be approximated by Normal or Gaussian distribution. It was also found that the averaging or filtering of wet density profiles measured by ND-CP is necessary to reduce the statistical fluctuations. It was found that the error due to the statistical fluctuation in ND-CP measurement is less than 1% if an averaging span of

10 cm is used. The raw data obtained from the field results when averaged over 10 cm depth shows that the cone profile count distribution trend is not distorted or deformed compared to the original raw data, which means the loss of information about the density through the filtering is negligible. This averaging is necessary to smooth the measured wet density profile. Therefore, the ND-CP measurements are averaged over a span of 10 cm depth to minimize the statistical fluctuations.

On the accuracy and precision of the seismic cone penetration test – a field test study on the seismic source

O. Koreta, A.H. Augustesen & L. Krogh
Ørsted

K. Lundvig & S. Bøtker-Rasmussen
Geo

ABSTRACT: The seismic cone penetration test (SCPT) is one of the most frequently used *in situ* testing methods for deriving the small strain shear modulus. Offshore SCPT results often present large scatter, in particular when data are obtained with different operational setups. No standard or industry consensus exist in terms of requirements to system key characteristics, operational testing procedures, interpretation and the numerical quality control of the traces obtained. Seismic sources currently deployed as part of the offshore industry practice have been developed individually by the various suppliers. This paper presents the findings of an onshore experimental study with the objective to increase the understanding of the influence of the offshore seismic source setup on SCPT results under controlled operational procedures. Accuracy and precision of the SCPT are investigated as part of the study.

1 INTRODUCTION

With the expansion and development of the offshore wind industry, the small strain stiffness (G_{max}) has become a key parameter for offshore wind facility designs, especially for the design of monopile foundations. G_{max} can be derived from laboratory and *in situ* tests.

The seismic cone penetration test (SCPT) is a cost-effective *in situ* technique used to derive G_{max}, through the measurement of the velocity (V_s) of propagating shear waves. The SCPT was initially developed for onshore use with simple beam sources equipped with sledge hammers. In contrast, the offshore seismic sources are complex electro-mechanical systems and the SCPT offshore is associated with additional challenges compared to the onshore source; less control of the source orientation and contact with the seabed (detached sources) and difficulties in isolating the background noise originating from the vessel, umbilical or drill string (source attached to the frame).

The offshore seismic sources are designed and built individually by the suppliers. The main differences between the various offshore applications involve a) method of deployment, b) source characteristics (frequency, energy, geometry, horizontal distance between source and SCPT, orientation, method of contact), c) type of triggers (contact, sensor), d) type and distance between receivers (geophone, accelerometers) e) acquisition system and f) method of interpretation.

Most of the details concerning the listed system parameters are not standardized in ISO (2014).

This implies that the acquisition of SCPT data offshore suffers from a) a significant degree of scatter (Gibbs et al. 2018, Masters et al. 2019), b) challenges to acquire reliable data at large scale c) challenges to replicate results in a consistent manner, d) lack of numerical control and acceptance criteria, e) inefficient operational procedures. Furthermore, a key concern remains the quantification of the measurement uncertainty, i.e. accuracy and precision of the measurements.

An onshore field test study was performed with the key objective to increase the understanding of the influence of the offshore seismic source setup on SCPT results under controlled operational procedures. Furthermore, accuracy and precision were investigated as part of the study. The high-level scope of work compares performance of adjacent SCPTs using an offshore and an onshore seismic source, each with a different frequency content, recorded with the same receivers at the same SCPT location.

As no standard reference test exists for the SCPT, the accuracy cannot be known exactly. However, a series of laboratory (bender element and resonant column testing) and alternative *in situ* (seismic dilatometer, SDMT and multichannel analysis of surface waves, MASW) stiffness measurements were performed to validate and benchmark the SCPT results. This paper presents the background, the test program, and relevant results from the field test study.

2 BACKGROUND

Campanella et al. (1986) presented the SCPT for offshore applications. However, there are no comprehensive studies on the evaluation of accuracy and precision of modern offshore seismic sources. In contrast, extensive studies have been performed in relation to the repeatability of the onshore source (beam) setup (e.g. Rice, 1984, Campanella & Robertson, 1984, Robertson et al.,1986).

Rice (1984) developed a beam source (sledge hammer), with a length between 2-3 m, loaded using a weighted plank such as a CPT rig vehicle. High quality and polarized signals could be achieved to a depth of 30 m without stacking the signals.

Laing (1985) confirmed the results using the source proposed by Rice (1984) and concluded that the beam source produced strong, directional, and repeatable shear waves. The beam source is used nowadays as a common form to generate shear waves (ASTM 2019). As a consequence of preceding literature studies, the beam source is used as benchmark for the results from the offshore source.

Gillespie et al. (1985) and Gillespie (1990) investigated the repeatability of V_s from SCPT through a series of onshore testing at three Norwegian research sites, Onsøy and Drammen (clay sites) and Holmen (sand site). The tests were performed using a beam source, with the same characteristics as described by Rice (1984).

Three adjacent SCPT tests at the clay sites showed agreement within ±5% of the measured V_s. In sand, the V_s was more scattered, visually exceeding a variation of ±10%, which was attributed to the variation of cone resistances between adjacent tests.

Gillespie (1990) concluded that ensuring a close contact between source and ground will significantly improve the quality of the signal and subsequently the identification of the arrival times. The error on the V_s was found to be as low as ±2% for a V_s of 200 m/s. The depth control of the test was shown to induce an additional error of up to ±5%.

3 TESTING PROGRAM

3.1 Site conditions

The test site is located in a sand pit near Kongensbro west of Aarhus, Denmark. The soil conditions were initially confirmed by a CPT (CPT2) and an adjacent borehole (BH1) to depths of 20 m and 17 m, respectively (Figure 3). The ground water table (GWT) was constantly monitored at a depth of 0.6 m during the test period. The soil comprises of a 0.3 m thick layer of sand fill overlying a medium to coarse medium dense sand to a depth of 11.5 m. The sand is uniformly graded. A layer of marine clay continues to the end of the BH/CPTUs. The CPTUs show uniform soil conditions with some local variations in the cone resistances

Table 1. Summary of soil parameters.

Soil type	Depth	Fines content	Plasticity index	Undrained shear strength	Peak Friction angle
	m	%	%	kPa	°
Sand	0.0-11.5	1-5	-	-	33-39
Clay	11.5-20.0	-	18-28	200-270	-

(Figures 8-9). A summary of classification and strength parameters is provided in Table 1.

3.2 Equipment and test setup

The SCPTs were conducted using Geo's CPT crawler rig with a maximum thrust capacity of 20 tonnes (Figure 1). The 10 cm^2 seismic module consists of a dual receiver array spaced at 0.5 m distance and equipped with triaxial accelerometers. The SDMT consists of a dual accelerometer dilatometer.

The onshore source is a timber beam with a length of 3.5 m equipped with steel plates at both ends. The two steel hammers (left and right) have each a length of 1 m and a weight of 12.8 kg. The offshore seismic source is a dual-hammer source designed and built by Geo. The total weight is 1300 kg and the sampling frequency is 5000 Hz.
Figure 1. Photo from the field test setup (main configuration).

To obtain comparable testing conditions, both seismic sources were placed with their centers at a distance of 2.6 m from the SCPT (Figure 2). The respective orientations of both sources and hammer directions (left and right) were kept consistent for all tests.

3.3 Test program

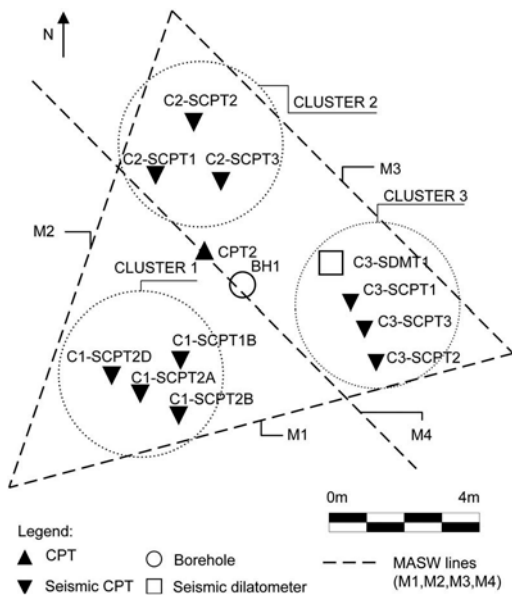
The test program comprised three clusters of tests, equally distributed in a 3 m radius around the center (Figure 3). Three SCPT tests were performed for
Figure 2. Seismic test setup (main configuration).


Figure 3. Detailed field test program.

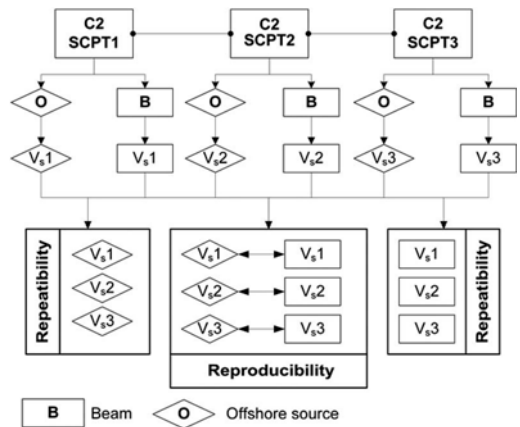
each cluster and the signals were recorded in sequence from both seismic sources. One SDMT test was performed in Cluster 3 and four MASW lines (M1 to M4) were run in a triangular setup within the same area. The target penetration depth for SCPT tests was 15 m. The SCPTs at Clusters 1 and 2 were scheduled for assessing repeatability and reproducibility of the measured Vs. With reference to the tests performed in cluster 2, Figure 4 shows the approaches used for clusters 1 and 2.


Figure 4. Test program for Cluster 2 illustrating the approach for assessing repeatability and reproducibility.

The repeatability was investigated by comparing results from multiple adjacent SCPT tests from the same source (being either the offshore or onshore beam source). The reproducibility was investigated through variations in the results as a consequence of using two different sources for generating the shear waves (each with a different frequency content) recorded with the same receivers at the same SCPT location.

Two SCPTs in Cluster 3 aimed to investigate the effect of source distance by changing the horizontal distance between the offshore source and the SCPT. Distances of 5 m (C3-SCPT1) and 10 m (C3-SCPT2) were adopted. The remaining test (C3-SCPT3) aimed to investigate the effect of cone size on the SCPT results by using a $15cm^2$ cone. This test was unfortunately aborted after cone refusal on a stone.

Laboratory and other *in situ* (SDMT and MASW) tests were performed for benchmarking the SCPT results. The SDMT was performed using a different set of receivers. A total of 15 bender element (BE) tests (vertically propagating, horizontally polarized waves) were performed in conjuction with isotropically consolidated triaxial tests (CID). The shear wave velocity (V_s) was measured at five different frequencies at the target consolidation stress to estimate the optimal frequency and the peak-to-peak and zero crossing methods were adopted to interpret the traces. In addition, two resonant column (RC) tests were performed.

4 RESULTS

4.1 *Quality assessment*

The interval V_s has been calculated from left and right shots using traces that met certain quality requirements only. Figure 5 shows an example of a representable signal of acceptable quality. The Seismic Trace Characterization (STC), as proposed by

Baziw & Verbeek (2017), has been performed on all traces to evaluate the quality of the signals. The data quality varies from acceptable (Class C) to very good (Class A). The quality of traces at shallow depth (less than 2 m) has been problematic to unacceptable (Class D, F) for both sources. However, in general a higher signal quality is observed from the beam source compared to the offshore source.
Figure 5. Seismic signals for C2-SCPT3 from both sources.

4.2 Uncertainties

The key input to the determination of V_s includes travel time and travel distance. They are susceptible to uncertainty originating from the specific system characteristics, including sampling frequency, trigger repeatability, data filtering, depth uncertainty, etc.

For a given sampling frequency, the error induced on V_s can theoretically be expressed as a function of V_s and the distance between receivers as presented and demonstrated by Rice (1984). Adopting Rice's approach to the SCPT data in this study, Figure 6a shows that for a sampling frequency of 5 kHz and a distance between receivers of 0.5 m, the error on V_s varies from 4% to 12 %. Figure 6b shows that in order to reduce the V_s error to 10% (accuracy requirements according ISO 2014), the sampling frequency must be increased to 6 kHz. Alternatively, the accuracy can be increased by increasing the distance between receivers for the same sampling frequency.

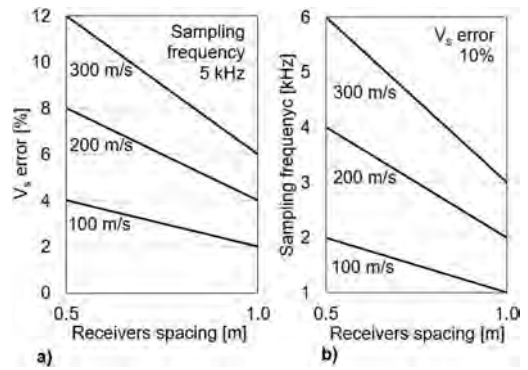
The error induced on V_s due to trigger repeatability has been assessed by comparing the arrival times between stacked and multiple unstacked signals at the same depth. The offset between relative arrival time should be less than 1%, as recommended by ASTM (2019). For the range of measured V_s at the site, the error due to trigger repeatability is assessed to a maximum of ± 2%. This error is reduced to zero when V_s is calculated from traces generated by the same shot in a dual array setup.


Figure 6. Induced error on Vs as function of sampling frequency, distance between receivers and soil V_s (maximum measured V_s is 300 meter per second, m/s).

Bandpass filters have not been applied on the acquired data. However, the application of filters close to the dominant frequency (60 Hz to 80 Hz for the offshore source) can cause a phase shift and induce an additional error to V_s. The time shift caused by the application of a low pass filter can be estimated based on Rice (1984). For the project presented in this paper, an application of a low pass filter with a cut-off frequency of 60 Hz is expected to induce an error larger than 10% for a V_s equal to 200 m/s.

The depth accuracy of the CPT rig is estimated to be better than 1%. In general, the uncertainty in the depth penetration for push systems is determined with high accuracy.

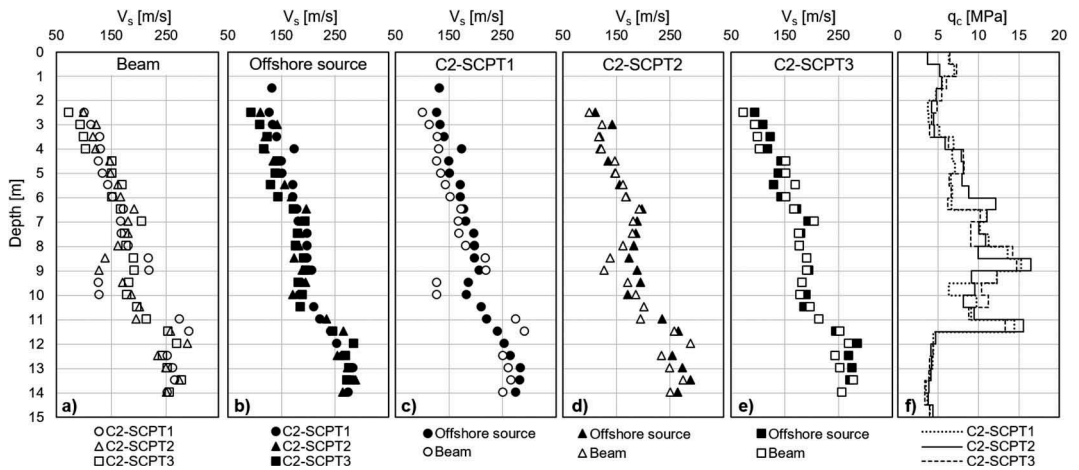
The uncertainties on V_s related to the interpretation method depend primarily on the data quality and on the assumed travel path. As described by Lunne et.al (1997), correction of the travel path due to refraction can have a considerable impact on V_s. According to Laing (1985), the straight-line approximation is satisfactory for calculation of V_s when the angle of travel path is higher than 45°. Hence, for depth shallower than the horizontal source distance, refraction of shear waves along the soil boundaries is likely to occur.
Figure 7. Illustration of seismic traces at Cluster 3, for three considered offshore source distances.


Figure 8. Comparison of the SCPT measured V_s at Cluster 2 between Beam (onshore source) and Offshore source.
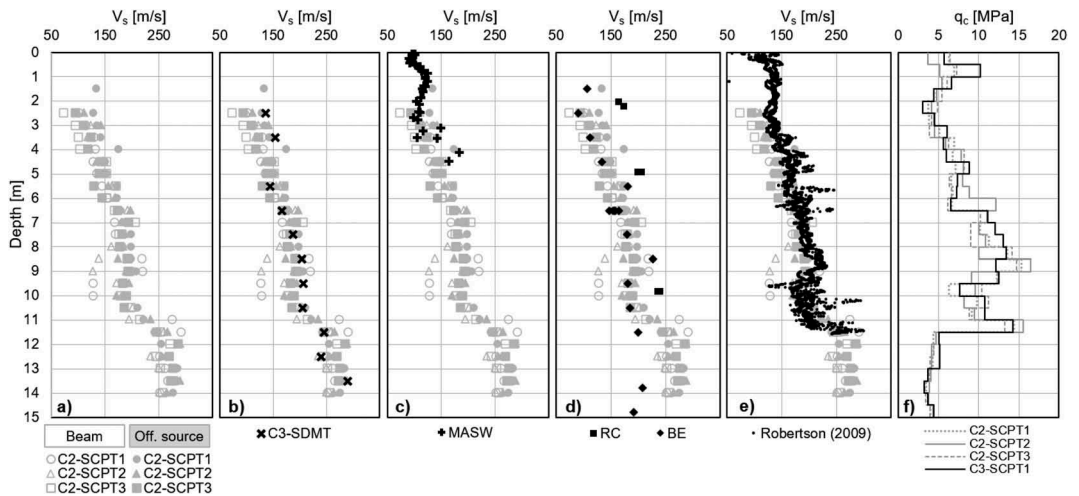

Figure 9. Comparison of the measured V_s at Cluster 2 between SCPT, seismic dilatometer (SDMT), multichannel analyses of surface waves (MASW), bender elements (BE), resonant column (RC), correlation from CPT data using Robertson (2009) correlation.

The impact of the horizontal distance between the seismic source and the SCPT was investigated by placing the offshore source at different distances of 2.6 m, 5.0 m and 10.0 m to the SCPT. Figure 7 shows the signal quality (signal-to-noise-ratio) decreasing with increasing distance. The results are in line with the findings by Rice (1984).

4.3 Repeatability and reproducibility

Figures 8a-f present the comparison of the derived V_s from the different sources for Cluster 2. Figures 8a and b indicates a good repeatability for both sources, with an average coefficient of variation

in V_s of up to ±10 %. Locally, the variation of certain V_s measurements exceeds ±20 % (8–10 m depth). This difference cannot immediately be explained by the data. However, the larger variation in V_s is reflected by correspondingly larger variations in cone resistances (q_c), indicating that differences in V_s from the two sources are likely also reflecting local changes in geology. No obvious differences were observed in the variation in V_s between the sand and the clay. The repeatability of V_s for both clusters is similar and is summarised in Table 2.

The reproducibility of V_s is found reasonable for Cluster 2, with a variation from ±6 % to ±11 % (Figures 8c-e). The differences observed for the two

sources cannot be attributed to the geology as the tests were performed at the same position. However, the individual travel paths of the shear waves may be subject to local soil variations. Another factor contributing to the reproducibility is the trigger timing. It appeared challenging in the field to run the trigger signal from both sources simultaneously, using the same software. Table 3 presents similar reasonable reproducibility of V_s for both clusters. In general, both repeatability and reproducibility of the sources show an average variation of about ±10 %.

Figures 9a-f compares SCPT results for Cluster 2 with SDMT, MASW, BE and RC test results as well as V_s based on Robertson (2009).

Table 2. Source repeatability.

Cluster	Beam %	Offshore source %
Cluster 1 (SCPT1 vs SCPT2)	±9	±8
Cluster 2 (SCPT1 vs SCPT2 vs SCPT3)	±10	±7
Average all tests	±10	±8

Table 3. Source reproducibility.

	Cluster 1 SCPT		Cluster 2 SCPT			Average
	1	2	1	2	3	All tests
Sources	%	%	%	%	%	%
Beam vs Off. source	±11	±9	±11	±6	±6	±10

Figure 9b illustrates the results of using a set of different receivers on the SDMT and confirms the assumption that V_s is independent of the recording equipment (receivers), which is in accordance with similar findings from McGillivray & Mayne (2004).

MASW data is uniform and overlaps the SCPTs in the depth range of 1.5 m to 4.5 m. V_s measured from BE test is comparable with SCPT measurements for the sand, whereas the RC tests return higher values. The range of V_s from all measurement are similar and representative of the soil conditions.

5 CONCLUSIONS

The small strain stiffness (G_{max}) has become a key parameter for offshore wind facility designs, especially for the design of monopile foundations. Hence, accurate and precise measurements of G_{max} is important. For position-specific wind turbine foundation designs, G_{max} is traditionally determined from SCPTs. However, the performance of SCPTs are affected by a number of factors associated with the seismic source and with the operational setup in general. Therefore, the repeatability and reproducibility of offshore SCPTs have been observed to relatively low compared to an onshore setup. The main objective of this study was to obtain an understanding of the impact of the offshore seismic source setup on SCPT results and to understand the challenges with the existing setups and hence shed light on the scatter observed offshore. Therefore, two different sources were used in a sand pit in Denmark. The SCPT results using an offshore source were benchmarked against the SCPT results using an onshore source. The results show that under reasonably controlled operational conditions and when potential sources of errors are taken into account, the SCPTs can be satisfactorily repeated and reproduced with a variation of ±10%, using both onshore and offshore sources. Careful preparation and execution of the SCPTs are essential. Especially it is deemed necessary to a) obtain a good contact between the ground and the source, b) orientate the source towards the receivers to maximise the signal amplitude in one direction, and c) position the source horizontally. Furthermore, key system characteristics (sampling frequency, trigger repeatability) play an important role in the accuracy of the measured shear wave velocity.

ABSTRACT: In common practice the most usual positioning of the filter location for the piezocone (CPTU) is at the cone shoulder (u_2) which is recommended by ISO 19901-8:2014 and ISO 22476-1:2012. However, these ISO standards allow additionally for pore pressure measurements to be taken at the cone face (u_1) or behind the friction sleeve (u_3). The triple element piezocone (CPTU3) offers a solution whereby measurements of pore pressure can be taken simultaneously at all three locations. By taking these three pore pressure measurements the soil behaviour classification may be enhanced by interpretation in terms of c_h from u_1, u_2 and u_3 and by correlations to overconsolidation ratio (OCR) and lateral stress ratio (K_0). In this paper the correlations to OCR are explored by establishing a database from historical data as presented in international geotechnical literature.

1 INTRODUCTION

The pore pressure measurement taken using the piezocone (CPTU) can be recorded with depth or as dissipation over time when penetration is paused. The most common pore pressure measurement is behind the cone shoulder (u_2), as preferred by ISO 19901-8:2014 and ISO 22476-1:2012. However, these ISO standards allow additionally for penetration pore pressure measurements to be taken on the cone face (u_1) or behind the cone sleeve (u_3) as shown in Figure 1. The so-called triple element piezocone (CPTU3) was used by several researchers in the 1980s and 1990s but has seen very little use in the last 25 years. The available literature indicates that CPTU3 has considerable potential relative to the standard CPTU including:

- Correction of sleeve friction (f_s) for pore pressure effects
- Increased reliability of assessment of horizontal coefficient of consolidation (c_h) from three sets of dissipation tests
- Evaluation of drainage conditions around the cone – especially for intermediate soils where partial drainage occurs
- Improved layering detection using u_1 compared to u_2

- Enhanced correlations to stress history and in situ horizontal stress

This paper explores the last aspect of correlations to stress history by developing a database from available CPTU3 tests published mainly in the 1980s and 1990s. First a review of the earlier reported use of pore pressures in connection with CPT is made.

2 HISTORY OF PORE PRESSURE MEASUREMENT IN THE CPT/CPTU

Pore pressure measurement during penetration of a probe was introduced in the 1970s (Janbu & Senneset, 1974, Torstensson, 1975, Wissa et al., 1975). The pore pressure probe used by Janbu & Senneset (1974) resembled an electrical cone, with the same area at the base of the cone. The other probes had different geometries and dimensions, but all had cylindrical porous elements. From the beginning, the large potential of such probes was recognised. At that time, CPTs and pore pressure probe tests were performed in adjacent deployments, for instance Janbu & Senneset (1974) used a CPT and in parallel a standard NGI piezometer.

Although Parez et al. (1976) had already developed and used equipment able to measure cone resistance (q_c) and pore pressure simultaneously, it was only in the early 1980s that many researchers

around the world started to use a pore pressure measurement element incorporated in the electrical cone (e.g. Roy et al.,1980, Campanella & Robertson, 1981). Battaglio et al., (1986) presented results from CPTU3 tests carried out in a medium to stiff clay at the Pontida site (Italy). Fugro and McClelland both developed CPTU3 probes in the mid1980s, see Bayne & Tjelta (1987) and Zuidberg et al. (1988).

Based on CPTU data from several clays with a range of overconsolidation ratio (OCR) values, Robertson et al. (1986) presented a conceptual pore pressure distribution along the length of a penetrating

Figure 1. Pore pressure measurement positions.

cone penetrometer for clays, ranging from normally consolidated to heavily overconsolidated clays (Figure 2). The pore pressure distribution is normalised by in-situ hydrostatic pore pressure (u_0).
Figure 2. Pore pressure distribution in saturated clays around a penetrating cone based on field measurements (Robertson et al., 1986).

Figure 2 indicates that the pore pressure measured at the tip or face of the cone (u_{1t} or u_{1f}, designated u_{uc} and u_1 respectively on inset of Figure 2) is higher than that measured at u_2, which again is higher than that measured at u_3. Figure 2 also illustrates the potential to use relative values of u_{1t} or u_{1f}, u_2 and u_3 to estimate OCR and possibly lateral stress ratio (K_0).

Early studies based on limited data, reported by Sully et al. (1988), Sully & Campanella (1991) and others showed the potential of correlations among Pore Pressure Difference (PPD) = $(u_1-u_2)/u_0$ vs OCR and

suggested that they will vary with soil type as shown in Figure 3, this was later confirmed by Powell and Lunne (2005).

3 LEARNINGS FROM DATABASE

Based on the potential use of the CPTU3 seen from the literature review, it was decided to collect available data from previously published field test results to
Figure 3. PPD vs OCR for OCR > 10 (Sully et al., 1988).

create a database of pore pressure measurements, index properties and stress history values. The objective of the database was to evaluate reported correlations between the measured pore pressures and reported correlations between geotechnical engineering parameters and parameters derived from pore pressure measurements, referred to hereafter as pore pressure parameters.

The data used to create the database represent a range of clays from Europe and the USA, taken mainly from Chen & Mayne (1994), Larsson & Mulabdic (1991), Sandven (1991), Powell & Lunne (2005), and from unpublished data from offshore soil investigations in the North Sea where NGI was the consultant and some recent NGI projects. When possible, datasets were checked by studying the original source. Uncertain or poor-quality data were removed from the originally prepared database where appropriate.

Altogether, the final database contained 546 datasets from 63 sites (both offshore and onshore). OCR values, based on oedometer tests, are available for

all 63 sites, whereas K_0 values are available from 5 UK and 2 Norwegian clays, mainly based on results of self-boring pressuremeter tests.

Table 1. Details of relevant datasets in final database.

Parameter	u_{1t}	u_{1f}	u_{1f}*	u_2	u_3
Data points	56	381	36	512	413
Parameter	OCR	K_0			
Data points	313	112			

* Calculated from u_{1t} (as explained later in the paper)

In addition to PPD (defined above) other derived pore pressure parameters utilising u_1 and u_2, are found in literature:

1. Pore pressure ratio (PPR) = u_1/u_2 (Sully et al., 1988)
2. Excess pore pressure ratio (PPR1) = $(u_1-u_0)/(u_2-u_0)$ (Sully et al., 1988)
3. Normalized Pore Pressure Difference (PPSV) = $(u_1-u_2)/\sigma'_{v0}$

Since the present database contained a reasonably good number of datasets for u_3 also, similar parameters involving u_1 and u_3, and u_2 and u_3 were also derived. Parameters derived using u_1 and u_2 were designated with suffix 'a', using u_1 and u_3 with suffix 'b' and using u_2 and u_3 with suffix 'c'.

Excellent correlation was found between u_{1t} and u_{1f} (Figure 4). Using this relationship u_{1f} was calculated for 36 datasets where only u_{1t} values were measured. For subsequent analyses

Figure 5. PPDa vs OCR for global data base.
Figure 6. PPSVb vs OCR for global data base.

Figure 4. Relationship between u_{1t} and u_{1f} for global data base.

only u_{1f} was used and for simplicity called u_1. However, ratios involving u_1 and u_2, u_1 and u_3 or u_2 and u_3 did not show good correlations when all data were plotted. With reference to Figure 2 this is as expected.

The database contains OCR ranging from 1 to 80, evaluated mainly from oedometer test results. OCR data plotted against PPRa, PPRb and PPRc, and against PPR1a, PPR1b and PPR1c did not show any clear trends. PPDa, PPDb, PPDc, PPSVa, PPSVb and PPSVc showed only a weak trend of increasing with increasing OCR but no clear relationship could be established due to
Figure 7. Relationship between Q_t vs OCR for global data base.

Figure 8. Correlation of PPDb vs OCR for Cowden glacial till.

very large scatter, as shown by the examples in Figure 5 and 6. Figure 7 shows that the most frequently used correlation between OCR and Q_t (= $(q_c - \sigma_{v0})/ \sigma_{v0'}$), also shows a very large scatter where it was not meaningful to fit a trendline.

The findings from the database indicate that it may not be possible to establish a strong correlation between pore pressure parameters and OCR that are valid for all cohesive soils. This status is similar to the correlation factor N_{kt}, the ratio of net cone resistance to undrained shear strength, where after decades of attempts by researchers and industry reported N_{kt} values are still wide ranging. With this example in mind, it will therefore be necessary to establish local correlations between pore pressure parameters and OCR as is commonly the practice for N_{kt}.

4 ATTEMPTS AT LOCAL CORRELATIONS

4.1 *General*

Two data sets that are believed to be of good and reliable quality have been selected for an illustration of local correlations.

– The glacial till at Cowden, UK, thoroughly tested in the 1990s as documented by Powell and Butcher (2003).
– Two Norwegian moderately overconsolidated stiff marine clays tested by Sandven (1991).

4.2 *Glacial till at Cowden*

Part of the programme was to carry out new CPTU3 tests at Cowden. However, the pore

Figure 9. Correlation of PPSVa vs OCR for Cowden glacial till.

pressures measured suffered from unsatisfactory saturation and historic measurements given by Powell and Lunne (2005) were used, since these were considered to be of good quality. Correlations to PPD parameters showed equally good results when based on $u_1 - u_2$ (PPDa) and $u_1 - u_3$ (PPDb). An example of the latter is shown in Figure 8. The same conclusion can be drawn regarding OCR to PPSV where, as an example, PPSVa is shown in Figure 9. All four PPD and PPVS correlations had R^2 values in the range 0.83 -to 0.87.
Figure 10. Correlation of Q_t vs OCR for Cowden glacial till.
Figure 12. Correlation of PPDb to OCR for Bakklandet and Glava clays.
Figure 11. Correlation of PPDa vs OCR for Bakklandet and Glava clays.
Figure 13. PPSVa vs OCR for Bakklandet and Glava clays.

Figure 10 shows that the most frequently used correlation between OCR and Q_t is actually showing less scatter, with an R^2 value of 0.92, compared to the PPD and PPSV correlations.

4.3 Trondheim area clays

Sandven reported results of CPTU3 tests from two sites in the Trondheim area of Norway: Glava and Bakklandet. Both sites are described

as moderately overconsolidated stiff marine clays. Figure 11 show that for PPDa a reasonably good correlation can be found with the Bakklandet data generally plot somewhat lower compared to Glava data. However, when plotting OCR vs PPDb as shown in Figure 12 the Bakklandet data plot significantly lower compared to Glava data, but both the sites show local and reasonably good linear trends.

In Figure 13 PPSVa show a reasonably good correlation to OCR, whereas Figure 14 shows that for
Figure 14. PPSVb vs OCR for Bakklandet and Glava clays.
Figure 15. Q_t vs OCR for Bakklandet and Glava clays.

PPSVb Bakklandet data plot somewhat lower than the Glava data.

Figures 12 and 14 really show that the difference between u_2 and u_3 is much lower for the tests at Bakklandet compared to Glava. Sandven (1991) does not make any comments about this difference.

Figure 15 shows that the correlation that is mostly used for standard CPTUs based on Q_t (e.g. by Lunne et al., 1997) actually gives a better correlation than PPD or PPSV illustrating with this example that there may not be any additional benefit using

CPTU3 OCR correlations compared to correlations with a standard CPTU.

5 DISCUSSION ON CORRELATIONS

The correlation attempts described in this paper are relatively simple.

Since the data base includes soil classification parameters like water content liquid and plastic limits, future work could explore multiparameter regression analyses to see if this can result in any better correlations. Since K_0 estimates are also available at 7 (out of 63) sites, correlations to this parameter could also be explored.

6 SUMMARY AND CONCLUSIONS

Based on geotechnical literature and unpublished material a data base has been established with CPTU3 parameters (q_c, f_s, u_2, u_1 and u_3) as well as laboratory data giving index parameters and stress history values in terms of overconsolidation parameters. After removing some uncertain data in quality assessment process, the data contain data sets from 63 sites representing a range of clays from Europe and the USA.

The simple correlation study reported in this paper indicates that using all the data available it is not really possible to show any reliable correlation between pore pressure parameters and OCR.

When choosing two sets of local data from the data base (Cowden glacial till and Trondeim area moderately over consolidated marine clays) reasonably good correlations have been found with pore pressure parameters PPD and PPSV. However, for the two sub-data sets even better correlations are obtained when using correlations to Q_t which can be obtained from standards CPTU tests. This indicates that regarding correlations to OCR the inclusion of u_1 and/or u_3 in the CPTU may not improve the accuracy/reliability of the OCR values over the values obtained from standard CPTU.

Other advantages of the CPTU3 relative to the standard CPTU, including results of dissipation tests, are not evaluated in this paper.

ABSTRACT: This paper presents the comparison of results obtained from CPT/CPTU tests carried out in past investigations and from recent DMT tests carried out using the automated Medusa DMT, adopting different test procedures (standard, repeated A-readings, A-reading while penetrating), at the benchmark soft clay test site of Fucino-Telespazio, Italy. In particular, the depth profiles of the undrained shear strength s_u of the Fucino clay obtained from CPT/CPTU interpretation are compared with the s_u profiles obtained from standard DMT and from Medusa DMT using different test procedures, as well as with the s_u values obtained from field vane test (FVT), self boring pressuremeter test (SBPT) and laboratory tests available from past investigations, resulting generally in good agreement.

1 INTRODUCTION

Benchmarking is of significant importance in geotechnical engineering for testing and validating both innovative soil investigation methods and foundation solutions. The growing interest in this topic is documented by the 1st International GeoTest Site Symposium ISGTS, Oslo, 2019, aiming to promote an increasing use of benchmark test sites, selected to ensure simplicity of geotechnical conditions (i.e., relatively homogenous soil deposit) and ease of interpretation (i.e., pre-existing laboratory and field data).

Fucino-Telespazio is a well known benchmark 'GeoTest site' in Italy, constituted by a thick deposit of cemented, homogeneous soft lacustrine clay of high plasticity. The site was extensively investigated at the end of the 1980s by means of several in situ and laboratory tests carried out by various international research groups (Burghignoli et al. 1991). Earlier experimentation with the flat dilatometer (DMT) at this site was carried out in the 1970s, as reported by Marchetti (1980). Subsequently, in 2004-2005 the site was selected for validation of the seismic dilatometer (SDMT, Foti et al. 2006, Marchetti et al. 2008). More recently,

in 2020 the same site was selected for experimentation with the automated Medusa DMT, ideally linking past experience and recent technological developments.

This paper presents the comparison of results obtained at Fucino-Telespazio from cone/piezocone penetration tests (CPT/CPTU) carried out in past investigations and from recent DMT tests carried out using the Medusa DMT equipment (briefly described in the next section) by adopting different test procedures. In particular, the focus in this paper is on the evaluation of the undrained shear strength s_u of the Fucino clay by different test methods.

2 MEDUSA DILATOMETER TEST

The Medusa DMT (Figure 1) is the last-generation, fully-automated version of the DMT. It is a self-contained probe able to autonomously perform dilatometer tests using a blade of standard dimensions without the pneumatic cable, the control unit and the gas tank required in the traditional pneumatic DMT configuration. A motorized syringe, driven by an electronic board powered with

rechargeable batteries, hydraulically expands the membrane to obtain the DMT *A*, *B*, *C* pressure readings, which are acquired and stored automatically at each test depth (typically every 0.20 m). The automatic (volume controlled) hydraulic pressurization of the membrane is highly repeatable and permits to impose a programmable timing (i.e., the recommended standard timing, or different timing corresponding to variable pressurization rates) to obtain the pressure readings. The probe may operate in cableless mode, which is a significant practical advantage in the offshore industry and for deep investigations. An optional electric cable may be used to obtain real-time data during test execution.
Figure 1. Main components of the Medusa DMT.

The Medusa DMT has several advantages over the traditional DMT equipment in terms of test automation, field productivity and increased accuracy (Marchetti 2018, Marchetti et al. 2019). It also provides the possibility of performing additional measurements, not feasible with the traditional DMT, including continuous measurement of the total horizontal pressure against the membrane with time at a stationary test depth, to obtain information on soil response in terms of fully drained/partially drained/undrained behavior, or during probe penetration, to obtain information on the in-situ stress state. Due to the increased accuracy of pressure measurements and controlled pressurization rate, the Medusa DMT is particularly useful for testing soils which are usually difficult to characterize using common in-situ techniques, such as very soft or even nearly liquid soils (Marchetti et al. 2021), mine tailings and intermediate soils (Monaco et al. 2021).

3 THE FUCINO-TELESPAZIO BENCHMARK TEST SITE

The Fucino-Telespazio test site is located in the Fucino basin, central Italy, about 80 km east of Rome. In 1986 the site was selected as a national benchmark test site and investigated by means of a joint effort of a number of Italian and international research groups. The primary aim of the investigation was to carry out comparative in situ and laboratory tests in a suitable soft clay deposit. The choice fell on the Fucino-Telespazio site due to its marked spatial homogeneity and apparently simple geological history. The site is constituted by a thick deposit of soft, homogeneous, highly structured $CaCO_3$ cemented clay of lacustrine origin (Fucino clay). The experimental activity, which lasted more than two years (1986-88), was documented in several research reports and papers. In particular, the data shown in this paper are taken from Burghignoli et al. (1991), who presented a comprehensive description of the in situ and laboratory testing program and a detailed geotechnical characterization of the Fucino clay.

The in situ testing program included boreholes with undisturbed sampling, cone/piezocone penetration tests (CPT/CPTU), self boring pressuremeter tests (SBPT), flat dilatometer tests (DMT), field vane tests (FVT), seismic cone tests (SCPT), cross-hole tests (CH), down-hole tests (DH), surface wave tests (SASW) and piezometer measurements.

Laboratory tests were carried out on a large number of undisturbed samples, including determination of index properties, incremental loading (IL) and constant rate of strain (CRS) oedometer tests, unconsolidated undrained (UU), isotropically consolidated drained (CID) and undrained (CIU) triaxial compression tests, direct simple shear tests (DSS-CK_0U), laboratory vane tests (VT), resonant column tests (RC) and cyclic torsional shear tests (CTS).

To minimize the influence of spatial variability of the clay properties, the field investigations were concentrated in an area of 10×40 m^2, to a depth of about 40 m. The superimposed profiles of the cone resistance q_c measured from four CPTs performed at the corners of the area (Figure 2) show a fair homogeneity of the site, both in vertical and horizontal directions: the soil stratigraphy is virtually identical at all test locations, with thin sandy layers identified at the same depths by all tests. Similar results were found in three CPTUs carried out in the same area.

The Fucino clay is characterized by high plasticity (plasticity index *PI* mostly between 40 and 70%, natural water content *w* between 60 and 120%). Despite its relatively recent deposition, the clay is highly structured and cemented. The calcium carbonate

CONE RESISTANCE
q_c (MPa)
Figure 2. CPT results from past investigations at Fucino-Telespazio (Burghignoli et al. 1991).

CaCO₃ content was found to range between 10 and 30% in the upper 25 m, increasing to an average value of about 60% below this depth. The clay deposit is geologically normally consolidated. However both laboratory and in situ tests indicated a light overconsolidation, which was attributed mostly to diagenetic interparticle bonding due to $CaCO_3$ cementation. Burghignoli et al. (1991) pointed out that structure and cementation have a dominant influence on stress history, compressibility, consolidation and shear strength properties of the Fucino clay.

4 MEDUSA DMT TESTS AT THE FUCINO-TELESPAZIO BENCHMARK TEST SITE

An experimental program at the Fucino-Telespazio test site, including three Medusa DMT soundings and one traditional pneumatic DMT sounding carried out using the SDMT equipment, was completed in September 2020. All soundings were performed at close mutual distance, to a depth of 30 m.

The Medusa DMT soundings were carried out using three different test procedures (see Monaco et al. 2022 for details), which differ essentially for the technique adopted for measuring the A-pressure.

4.1 Standard DMT procedure (STD)

The STD procedure is the same procedure of the traditional pneumatic DMT test. As soon as the

test depth is reached, the penetration is stopped and the DMT test cycle starts. The activated motorized syringe gradually increases the hydraulic pressure to the membrane. When the internal oil pressure equals the external soil pressure, the membrane lifts-off from its seat and starts to expand laterally. When the membrane has expanded of 0.05 mm at its centre, the A-pressure is recorded. After the A-reading, the motorized syringe continues to increase the pressure until the membrane displacement at the centre equals 1.10 mm. At this instant the second pressure reading B is recorded. As soon as the B-reading is obtained, the motorized syringe starts decreasing the oil pressure. If the C-pressure reading is requested, the motorized syringe applies a gradual and controlled depressurization after the B-reading and the membrane slowly returns to its initial position against the sensing disc. At the instant in which the contact reactivates, the corresponding pressure is recorded as the C-pressure reading. In the STD procedure the pressurization rate is regulated by the motorized syringe so that the A-pressure reading is obtained 15 s after start of pressurization and the B-pressure reading 15 s after the A-pressure reading, in accordance with existing standards of the pneumatic DMT (ASTM D6635-15, ISO 22476-11:2017(E)). The C-reading is typically obtained 30 s after start of depressurization following the B-reading.

4.2 DMT repeated A-readings procedure (DMT-RA)

The DMT-RA procedure differs from the STD procedure only in the first part of the measurement sequence, before membrane expansion, while the B- and C-pressure readings are taken exactly in the same way. As previously described, in the STD procedure the A-reading is taken when the membrane centre has expanded horizontally 0.05 mm against the soil, replicating exactly the same procedure implemented in the traditional pneumatic DMT test. The motorized syringe of the Medusa DMT, driven by the electronic board, is also able to maintain the membrane in equilibrium with negligible horizontal displacement of the membrane. The DMT-RA procedure makes use of this capability. The initial stage of the DMT test cycle with the DMT-RA procedure, before penetrating to the next test depth, consists in maintaining the membrane in equilibrium with the soil pressure. This state is obtained with very rapid pressure corrections operated by the motorized syringe, with negligible membrane displacement. In this situation the membrane is in equilibrium at 0.05 mm distance from the sensing disc. When the new test depth is reached, the test cycle starts ($t = 0$) and repeated sequential A-readings are taken with time during the rapid pressure corrections of the motorized syringe, monitoring the total horizontal soil pressure against the membrane with time. All the

sequential *A*-readings are obtained without any displacement of the soil, because the blade is advanced to the test depth with the membrane already at 0.05 mm displacement from the sensing disc. Such DMT-RA procedure is characterized by the duration (T_{diss}) of the sequential *A*-readings taken with time (dissipation), before concluding the DMT test cycle with the standard *B* and *C* readings. The parameter T_{diss} is selected and pre-programmed before starting the test cycle, so that the membrane expansion will be activated after the time T_{diss} has elapsed. At Fucino-Telespazio T_{diss} was set equal to 15 s, to comply with the standard timing adopted in the STD procedure. The procedure and timing for taking the *B* and *C* readings are the same as in the STD procedure.

4.3 *DMT A-reading while penetrating procedure (DMTA-WP)*

The capability of the Medusa DMT to maintain the membrane in equilibrium with negligible horizontal displacement enables to obtain continuous measurements of the total horizontal pressure of the soil against the membrane during penetration of the probe. The DMTA-WP procedure consists in performing repeated *A*-pressure measurements (equivalent to *A*-pressure reading at $t = 0$ instead of the standard time of $t = 15$ s) recorded during penetration of the Medusa DMT at a constant rate. The sequence of *A*-readings is generally taken over depth intervals of 1 m, corresponding to the typical length of push rods. Almost all penetrometers require to stop penetration every meter to add a push rod, during which *B* and *C* pressure readings may be taken without employing additional time. A constant penetration rate of 20 mm/s, as in the standard test procedure, is generally adopted. The current Medusa DMT equipment does not include instrumentation to measure the penetration depth during the readings. Most penetrometers include an encoder (for CPT measurements) and may output a time versus depth file, helpful for accurately associating the *A*-readings to the corresponding depth at which they were taken. When such information is missing, the time-depth relation may be estimated assuming an average speed of penetration, estimated by measuring the time for penetrating a 1-meter rod. The average speed and the time from the start of penetration enables to estimate the depth of each *A*-reading. Although not as accurate as with an encoder, the error is reasonably limited in terms of % error, since each measuring interval is maximum 1 m long.

4.4 *Comparison of results obtained by different test procedures*

Figure 3 shows the comparison of the results obtained by Medusa DMT using the three different test procedures (STD, DMT-RA, DMTA-WP) and the results obtained by traditional DMT. The test results obtained from Medusa DMT were processed using the same data reduction and interpretation formulae used for the traditional DMT test (ISSMGE TC16 Report, Marchetti et al. 2001). In particular, Figure 3 shows the depth profiles of the corrected pressure readings p_0, p_1, p_2 (*A*, *B*, *C* corrected with the calibration offsets ΔA, ΔB to account for membrane stiffness), as well as of the derived parameters material index I_{D} and horizontal stress index K_{D}. For the DMT-RA sounding, the *A*-pressure reading used in data processing is the last value obtained from the *A*-dissipation series, i.e. the *A*-pressure recorded 15 s after start of pressurization. In the processing of data from all soundings the groundwater table was assumed at a depth of 0.60 m below the ground surface, as indicated by the p_2 values observed in the very few thin sand layers.

The profiles of p_0 obtained by Medusa DMT using the three different test procedures are very similar, despite the different techniques adopted for measuring the *A*-pressure, and in good agreement with the profile of p_0 obtained by traditional DMT.

The profiles of p_1 and p_2 obtained by Medusa DMT (all test procedures) and traditional DMT are nearly coincident. The values of p_1 and p_2 obtained by the DMTA-WP procedure are discontinuous, because in this case the *B* and *C* pressure readings are performed at depth intervals of 1 m, instead of 0.20 m as in the STD and DMT-RA procedures.

The profile of the material index I_{D}, which depends on the difference ($p_1 - p_0$), shows some inconsistency between the values obtained by different test procedures. In particular, the values of I_{D} calculated from p_0 and p_1 data acquired by the DMTA-WP procedure appear significantly lower than the I_{D} values provided by the STD and the DMT-RA procedures. This discrepancy could be due to the fact that in the DMTA-WP procedure the *A*-pressure is measured at $t = 0$ instead of $t = 15$ s, resulting in lower values of the difference ($p_1 - p_0$), and for low I_{D} values such incongruity is amplified by the logarithmic scale. The values of the horizontal stress index K_{D}, which depends only on p_0, do not seem influenced by the adopted test procedure.

5 EVALUATION OF THE UNDRAINED SHEAR STRENGTH FROM CPT/CPTU AND DMT

As described by Burghignoli et al. (1991) and Soccodato (2003), the shear strength characteristics of the Fucino clay were determined by means of a variety of in situ and laboratory tests carried out in the 1987 investigation. In particular, the undrained shear strength s_{u} was obtained from CPT and CPTU interpretation with the usual relationships, respectively:

$$s_u = \frac{q_c - \sigma_{v0}}{N_k} \qquad (1)$$
Figure 3. Results obtained by Medusa DMT using different test procedures and by traditional DMT at Fucino-Telespazio.

$$s_u = \frac{q_t - \sigma_{v0}}{N_{kt}} \qquad (2)$$

where q_c = cone resistance (CPT), q_t = corrected cone resistance (CPTU), σ_{v0} = total overburden stress, N_k and N_{kt} = cone bearing capacity factors for CPT and CPTU respectively, which were assumed to range between 14 and 22.

The undrained shear strength s_u was estimated from DMT results, both obtained by traditional pneumatic DMT and by Medusa DMT in the 2020 investigation, using the original correlation proposed by Marchetti (1980):

$$s_u = 0.22\sigma'_{v0}(0.5K_D)^{1.25} \qquad (3)$$

Figure 4 shows the comparison of the depth profiles of the undrained shear strength s_u obtained at Fucino-Telespazio from different in situ and laboratory tests in past investigations and in the 2020 Medusa DMT campaign. In particular, the s_u profiles from the 1987 investigation shown in Figure 4 (data from Burghignoli et al. 1991) were obtained in situ from several CPT and CPTU tests, field vane tests (FVT), self boring pressuremeter tests (SBPT), DMT tests, and in the laboratory from direct simple shear tests (DSS-CK$_0$U), unconsolidated undrained triaxial compression tests (UU) and laboratory vane tests. For CPT and CPTU only the lower- and upper-bound trend lines, corresponding to the average s_u estimated from Eqs. 1 and 2 by assuming N_k and N_{kt} equal to 22 and 14 respectively, are plotted in Figure 4. The values of s_u from FVT in Figure 4 are not corrected for strain rate and anisotropy effects.

Figure 4 shows an overall agreement between the s_u values obtained from different in situ and laboratory tests. With reference to the various field tests results obtained in 1987, Burghignoli et al. (1991)

observed that, below an upper desiccated crust, there is a fair agreement between the s_u values resulting from FVT and DMT. The SBPT provided values of s_u significantly higher than those resulting from other in situ and laboratory tests. Soccodato (2003) suggested that low values of N_k for CPT are needed in order to match the data, while $N_{kt} = 15$ seems to
Figure 4. Undrained shear strength s_u at Fucino-Telespazio from recent DMT tests vs. s_u from CPT/CPTU and other in situ and laboratory tests obtained in the 1987 investigation (modified from Burghignoli et al. 1991).

be appropriate for CPTU. As to laboratory tests, the values of s_u resulting from UU and from DSS-CK$_0$U tests show a marked increase below a depth of about 25 m, reflecting the increase of $CaCO_3$ content with depth. This feature is not reflected by the results of the in situ tests with the exception of the SBPT, which provided a different trend of s_u below 24-25 m of depth. Burghignoli et al. (1991) commented that in highly structured soft clays, like the Fucino clay, the results of push-in situ testing techniques, such as CPT/CPTU and DMT, can be hampered by the destructuration of the tested soil induced by the insertion of the probe, which may partially obliterate the effect of diagenetic bonds on the inferred s_u.

In Figure 4 the profiles of s_u estimated by Eq. 3 from the results of the three Medusa DMT tests carried out adopting different test procedures (STD, DMT-RA and DMTA-WP) and from the traditional DMT carried out in the 2020 campaign are superimposed to the profiles obtained by all test methods in past investigations. As already noted with reference to the K_D profiles (Figure 3), which are used to estimate s_u by Eq. 3, the s_u values are not practically influenced by the adopted test procedure. The s_u values obtained from Medusa DMT and the traditional pneumatic DMT are almost coincident, and also in very good agreement with the s_u obtained from DMT tests carried out in 1987. In general, the profiles of s_u obtained from all DMTs plot in between the s_u profiles determined by other in situ and laboratory tests. This finding is in line with previous experience. In fact, as described in the TC16 DMT Report (Marchetti et al. 2001), the s_u estimated from DMT by Eq. 3 has generally been found to be in an intermediate position between the s_u estimated from other tests, as presented by various researchers in different clays (e.g., Nash et al. 1992 at the National Research Site of Bothkennar, UK).

6 CONCLUSIONS

Benchmark GeoTest sites, such as the Fucino-Telespazio soft clay test site, prove to be of paramount importance for testing and validating innovative soil investigation methods. In this respect, the recent experimental program at Fucino-Telespazio with Medusa DMT (the last-generation, fully-automated version of the DMT) could uniquely benefit of the availability of an existing large and consistent data set obtained in past investigations from a variety of high-quality in situ and laboratory tests.

Due to the increased accuracy of pressure measurements and controlled pressurization rate, the Medusa DMT is particularly useful for testing very soft soils, in which the measured pressures are typically very small. Moreover, its technical features permit to implement alternative test procedures (repeated A-readings, A-reading while penetrating), besides the 'standard' DMT procedure. The

comparison of the results obtained at Fucino-Telespazio indicate a substantial consistency of measurements provided by Medusa DMT adopting different test procedures and by traditional pneumatic DMT.

The interpretation of Medusa DMT test results in terms of soil parameters takes advantage of the wide experience available for the traditional pneumatic DMT test, and essentially shares the same set of established soil property correlations available in literature. The profiles of s_u obtained from both Medusa DMT and traditional DMT in Fucino clay are found in an intermediate position between the s_u profiles determined by other in situ and laboratory tests, in particular by CPT/CPTU tests. This finding is in agreement with other comparisons of s_u estimated from DMT and from other tests, available from several soft clay test sites.

ABSTRACT: CPT testing of extremely soft soils and tailings materials requires the ability to detect and measure very low q_c values and extremely low f_s values. The former of these can and has been solved by use of low capacity cones with high quality well-calibrated load cells. The latter, detection and measurement of extremely low f_s values is an industry-wide problem, often treated as an "elephant in the room". This paper describes development of an innovative new CPT cone that the authors believe has largely solved this problem.

1 INTRODUCTION

Insitu Geotech Services (IGS) undertakes much CPT testing in soils and sediments that can be described in everyday terms as "extremely soft", or even as "ooze"; for clients who are seeking data that permits them to make confident designs.

As a consequence they are almost every day working in an arena where one would aspire to better than Application Class 1 testing quality, if being described according to ISO 22476-1-2012.

To achieve the highest quality that they can in testing these conditions and in satisfying clients they:

– Use known good quality CPT cones. In soft soils these have been previously usually of 25MPa or 10MPa tip capacity.
– Maintain/manage all CPTs meticulously.
– Undertake in-house calibration-checking-recalibration under a very stringent program, as described below.

The IGS calibration program is run in-house because, as you can see from the explanation below, it would be unworkable to contract it out:

a) Every cone is calibrated before every job, then recalibrated after the job, each time using the cone's actual dimensions, not nominal values. If the job runs more than one week, then the cones are changed over with freshly calibrated cones on an approximate 7-day service cycle. All of this is carefully recorded and a calibration-drift-performance type of history is developed for each cone.
b) Recalibration data is then always compared to the data from the previous calibration, to cross-check for any significant change.

c) And, they take before-vs-after zero-load-drift comparisons, as part of each test's management.

It's rigorous, it works, and it's business as usual, built into the company culture and cost structures.

Following the above approach IGS has been successful in regard to the ability to defensibly and repeatably measure very low q_c values, and to be as good as reasonably achievable at measuring f_s values.

2 LIMITATION RE MEASURING VERY SMALL SLEEVE FRICTIONS

In regard to f_s though, they have run up against the "industry normal" limitation in measuring very small sleeve frictions; a limitation that is associated with the design of normal Compression Cones.

To help discussion of this, refer to Figure 1 below.
Figure 1. Design of Cone Penetrometers (Lunne et al 1997).

In this paper type (a) is designated as a Compression Cone and type (c) as a Subtraction Cone.

For this discussion, the relevant difference between a Compression Cone and a Subtraction Cone is that:

- A Compression Cone has separate load cells for the tip and the sleeve. Hence these load cells can be sized for the purpose; typically a larger cell for the tip and a smaller load cell for the sleeve.
- A Subtraction Cone has two load cells that must both be of the larger variety. Typically they would be identical or nearly identical. One of these, that just behind the tip, measures the tip load only and the other, above the screwed on connection to the sleeve, measures the combined tip-plus-sleeve load.
- Software subtracts one value from the other to determine the sleeve friction load. Hence a relatively big number is subtracted from another relatively big number to get a smaller number. If calibration of either or both load cells is not precise, or they drift differently during a test or after calibration, one can reasonably expect significant errors in the sleeve values determined this way.

Compression Cones (these authors perceive) were developed in the first instance ostensibly to improve a CPT's ability to measure sleeve friction.

3 THE CURRENT PARADIGM

So this is the current industry-wide paradigm:

- If you want to most accurately measure sleeve friction, you must use a Compression Cone.

In support of this statement that this is the current paradigm, refer (Robertson et al 2015), as follows:
For accurate sleeve resistance measurements in soft sediments, it is recommended that cones have separate (compression) load cells.
And in support of something that follows in this paper, quoting from the same document as above, the following paragraph, referring now to Compression Cones:
f_s measurements, in general, will be less accurate than tip resistance, q_c, in most soft fine-grained soils.
The problem is that, in extremely soft or ooze-like soils, this "in general expected lower accuracy" in f_s typically ends up meaning no f_s measurement at all, or something too low to be credible.

4 EXPLANATION – WHY VERY SMALL SLEEVE FRICTIONS ARE ELUSIVE

4.1 *A simple explanation – referring to Figure 1*

- In a Compression Cone, the sleeve has to move slightly to permit it to apply load to the friction sleeve load cell.
- Dirt seals behind the friction sleeve resist this slight movement and use up some of the force applied by soil friction to the friction sleeve.
- Hence a noticeable error occurs if this applied force is very low (as it will be in extremely soft materials).

If one is testing stronger materials then it's not a significant issue at all, but if one is testing extremely soft material it becomes a problem.

Until recently this limitation was typically handled as an "elephant in the room", not talked about much, but rather agonisingly hanging around in the shadows in the background of CPT testing.

But it's become a pretty big deal for organisations like IGS that nowadays do much testing in extremely soft or ooze-like soils; and for their clients.

4.2 *References to this problem by others*

This issue was discussed at CPT'14 in a paper (Santos et al 2014) where the authors ascribed the problem to the friction in sleeve seals and presented an example sleeve calibration showing the difference in load cell readings compared to applied load (Figure 2a) without friction sleeve seals, and (Figure 2b) with seals.
Figure 2(a). Sleeve calibration with no seals (Santos et al 2014).
Figure 2(b). Sleeve calibration with seals (Santos et al 2014).

Those authors discussed an innovative spring-loaded (preloaded) sleeve seal design to attempt to solve the problem. This has/had been taken up by A.P. van den Berg for their cone design.

The issue was again mentioned in a paper at the 2021 Mine Waste and Tailings Conference, (Entezari et al 2021). In that paper, the authors were discussing limitations in the use of CPT data to determine the fines content of extremely soft oil sands tailings.

In that paper, for the analysis they were undertaking, many data points were "*screened out in order to remove data where the soil-sleeve friction was less than internal o-ring (sic) friction*".

This meant discarding a good deal of their data.

5 IGS WANTED A SOLUTION – NOT AN EXCUSE OR ANOTHER COMPROMISE

IGS wanted a solution, so talked at length to their supplier/partner Geomil as to what this might entail. They then jointly conceived and funded an atypical design as a trial.

The conversation and thinking went as follows:

a) As described in Section 4, Compression Cones have friction sleeves that must move a small amount to be able to register an f_s reading.
b) The sleeves of Subtraction Cones do not have to move more than a miniscule amount to register friction load. But they have the historically-deemed problem of having to subtract one big number from another big number to get a small one, as discussed in Section 3.
c) As one solution, would it be possible to develop a Subtraction Cone with unusually high quality and sensitive load cells, and to calibrate these very rigorously to help overcome the problem in subtracting a big number from a big number?
d) And would it be possible to design for much lower cone capacity overall, hence making the two big numbers smaller, further reducing the problem?
e) And would it be possible to make the load cells more responsive than normal, by adopting different construction materials for the elastic bases on which the cells' strain gauges would be fixed?

Of course this would all comprise a significant paradigm shift, compared to the existing one. Reiterating here: *If you want to most accurately measure sleeve friction, you must use a Compression Cone.*

Some heart was taking in the knowledge that Fugro's very sensitive Fibre Optic Cone, announced at the prototype stage via a paper (Looijen et al 2018) at CPT'18 in Delft, also designed for testing soft materials, is a Subtraction Cone with unusually sensitive load cells; in principle the same idea.

So IGS and Geomil talked more and eventually Geomil made a first small run of special cones to the agreed design. In accord with (c) and (d) above, they opted for a cone size of $15cm^2$ and tip capacity of only 3MPa; this being adequate for the testing of extremely soft materials that were/are the target.

And, in accordance with (e) above they opted for a special alloy base for the load cells, giving a physical strain gauge response approximately 300% greater than it would be for a conventional steel base.

Of course, also in accordance with (c) above, IGS has adopted the same calibration regime discussed in Section 1, with the enhancement of using dead weights for the application of load to the tip and sleeve for (at the moment) the bottom approximate 6% of loading; ie up to ~0.17MPa on the tip and ~11.5kPa on the sleeve. Planning is that in the future IGS will go full-range with the dead weights. At present they are using a very sensitive calibrated load cell of just 5kN capacity for the remainder of the range.

6 HIGH HOPES AND EXPECTATIONS

Because of high hopes for these cones, IGS has set a policy in place that, to the extent possible, they will calibrate these cones to achieve the accuracy outcomes proposed by the new draft international standard ISO/DIS 22476-1 criteria for Class 1+ cones.

To date that objective is looking good. A full IGS calibration for one of these cones is shown on the last page of this paper.

In other words, these cones, under these rigorous calibration processes, are pretty remarkable by current measures.

Of course calibration is just one aspect of a CPT. How have these cones behaved in the field?

7 FIELD TRIALS

IGS has had several 3MPa cones in operation now for a few months, in one place testing very soft natural soils and in other places testing ooze-like tailings sediments. The results are satisfying, demonstrating:

a) Ability to repeatably detect, measure and record very low q_c values – say 10kPa and even below.
b) Ability to repeatably detect, measure and record very low f_s values that make sense when compared to the q_c values being measured – say 1kPa and even below.

Figure 3 below, shows the improved response to sleeve friction compared to what was previously possible.

Laboratory tests on samples taken from this coal tailings dam site showed the materials tested (in the test plot "troughs") to have:

– 37% fine sand, 51% silt size, 12% clay size.
– Liquid Limit 34%, Plasticity Index 9%, Moisture Content 40.5% (ie in liquid phase).
– Soil Particle Density ("SG") $1.52t/m^3$.
Figure 3. Q_c and f_s plots – new 3MPa cone vs 10MPa Compression Cone – tests by IGS – plotted to 4.0m depth for relevance.

All the tests undertaken with these new cones show the ability to measure very low q_c and a much improved response in regard to sleeve friction.

8 CPT-BASED SOIL BEHAVIOUR TYPE (SBT)

Data from the tests shown in Section 7 have been processed using the computer software CPeT-IT v.3.0 – CPT Interpretation Software (Ioannides 2007) to plot CPT-based Soil Behaviour Type using the classification system proposed by Robertson (2016). Plots are shown below as Figures 4(a) and (4b).
Figure 4(a). SBT to 3.2m from 10MPa Compression Cone.
Figure 4(b). SBT to 3.2m from the new 3MPa Cone.

CCS: Clay-like – Contractive – Sensitive
CC: Clay-like – Contractive
CD: Clay-like – Dilative
TC: Transitional – Contractive
TD: Transitional – Dilative
SC: Sand-like – Contractive
SD: Sand-like - Dilative

The data from the new 3MPa cones interpret SBT that is significantly different to that from the 10MPa Compression Cone.

9 FIELD TRIALS - ZERO-LOAD-OFFSETS

The CPT industry/profession is passionate on the issue of comparing "before-vs-after" zero-load-offset values as a method of determining/monitoring:

– the quality and actual condition of a cone itself, and
– the quality of a test that has been undertaken.

IGS's cone history recording system will one day allow a report on the reliability of this dependence on zero-load-offsets; a quantified study to support the passion (or otherwise).

In the meantime however it is acknowledged that this is an accepted field indicator of the quality of a test undertaken, so monitoring and recording these zero-load-offsets is part of IGS's every-test practice.

The new draft ISO/DIS 22476-1 relies heavily on this parameter in determining test quality, called "Test Category", with different Categories/qualities numbered A to D in the draft; A being the highest quality.

Under the draft standard, one decides the Test Category by:

a) the Class of cone used and
b) the drift/difference in the before-vs-after zero-load-offset values.

In the draft standard, a before-vs-after drift/difference of less than 15kPa for the tip, combined with less than 2kPa drift/difference for the sleeve, categorises the test as Class A, the highest test quality classification.

This typically involves measuring the after-test-offsets once the cone has been cleaned and reassembled after testing. It cannot be a value extracted from the completed test's data file, as this immediately-after value is likely to be influenced by dirt in seals and gaps after cone extraction.

Figures 5(a) and 5(b) below show sets of before-vs-after drift/difference data from the first three IGS jobs, using two of these new 3MPa cones.
Figure 5(a). Before-vs-After Tip Zero-Load-Offsets -23 tests by IGS (grey shaded band is +/- 15kPa).
Figure 5(b). Before-vs-After Sleeve Zero-Load-Offsets -23 tests by IGS (grey shaded band is +/- 2kPa).

The data shows that, except for one test, all of these tests undertaken using the 3MPa cones have experienced drift/difference of less than the designated 15kPa for the tip, and all achieved better than 2kPa for the sleeve.

The single test that fell outside 15kPa for the tip was the second test ever made using one of these cones and the before-vs-after monitoring process in

that instance had not been undertaken cautiously – transient temperature shift was a possible cause of that aberration – remember that these are all very small numbers.

By the time of the CPT'22 Conference IGS's database will be more comprehensive.

10 TRANSIENT TEMPERATURE EFFECTS

Transient temperature effect is a matter that IGS takes seriously in all of their testing. Their default testing procedures do what is reasonably possible to minimise these effects during all stages of a test.

The new 3MPa cones are each fitted with a temperature sensor and IGS is currently developing a plot format for these cones that will include temperature along with the usual parameters of q_c, f_s and u.

The work has not yet been done; however we anticipate that these new cones may stabilise more quickly than conventional cones due to the use of the special alloy instead of steel in the load cell bases.

By the time of the CPT'22 Conference we authors expect to be able to report on this aspect of these new 3MPa cones.

11 SUMMARY AND CONCLUSIONS

Measurement of extremely low sleeve friction (f_s) values during CPT testing is an industry-wide problem, often treated as an "elephant in the room".

This paper describes the development of an innovative new CPT cone that the authors believe has largely solved this problem.

The solution has involved shifting of the paradigm, that "*if you want to most accurately measure sleeve friction, you must use a Compression Cone*". This solution involved the use of a Subtraction Cone design.

The solution also involved development of more-responsive-than-conventional load cells using a special alloy for the load cell base, rather than steel.

So far the new CPT, calibrated and managed as described in this paper, is meeting or exceeding the authors' expectations.

Assessment of seismic cone penetration testing for small strain shear modulus

N. Parasie, T. Franken & J. Peuchen
Fugro, Nootdorp, The Netherlands

ABSTRACT: Reliable values of in situ shear modulus at small strain (G_{max}) are important for foundation design, particularly for large investments in offshore wind energy. The seismic cone penetration test (SCPT) method is commonly considered as primary reference for providing G_{max} of soil. The SCPT data acquisition process covers a combination of cone penetration testing and seismic downhole testing. Values of shear wave velocity are correlated with G_{max}. This paper presents a complete inventory of SCPT standard uncertainty components for G_{max}. These components are ranked as Low, Medium or High, indicating relative impact on a combined standard uncertainty budget for derived values of G_{max}. Supplementary discussion is provided based on theory and practice, with suggestions on uncertainty reduction. The focus of the assessment is on conventional SCPT systems, with a hammer impact source at ground surface and a dual-receiver seismic cone penetrometer.

1 INTRODUCTION

The in situ shear modulus at small strain (G_{max}) is one of the important soil parameters for geotechnical design situations for which relatively small displacements are critical to structure performance, for example monopile response to horizontal load is governed by soil stiffness and monopile stiffness. By reducing the uncertainty in soil stiffness, the monopile foundation design can be further optimized.

At this low strain level, the soil response is too small for direct measurement of G_{max}. Therefore, G_{max} is typically derived indirectly from shear wave velocity (v_s) and bulk (mass) soil density (ρ), using $G_{max} = \rho \cdot v_s^2$.

Due to good cost-quality ratio, the seismic cone penetration test (SCPT) is one of the most commonly applied acoustic methods for providing G_{max} of soil. SCPT data acquisition covers a combination of cone penetration testing and seismic downhole testing. SCPT methodology is well documented; examples are ISO 19901-8 (2014), ASTM D7400 (2019) and Campanella & Davies (1994). Styler et al. (2016) provide an excellent overview of 35 years of SCPT experience, including equipment, procedures and interpretation of seismic signals.

SCPT data acquisition provides derived values of '$v_{s;vh}$', where v and h refer to (approximately) vertically downward propagating (v), horizontally polarized (h) shear waves. Hence, G_{max} discussed in this paper is '$G_{max;SCPT}$'.

Various publications cover individual uncertainty components for G_{max} derived from SCPT data.

Examples include Gillespie (1990), Howie & Amini (2005), Stolte & Cox (2020), and Styler et al. (2016). This paper provides a complete overview of standard uncertainty (u_i) components for G_{max} (Sections 3 and 4) as basis for a combined standard uncertainty (u_c) budget (Section 5). Supplementary quantification and discussion are provided based on theory and practice, with suggestions on uncertainty reduction.

A clear and complete insight in G_{max} uncertainties is a first step into improving SCPT measurements and consequently providing more accurate G_{max} values for foundation design.

2 PREMISES

This paper uses a Type B evaluation of standard uncertainty (u_i) as defined by ISO (2008). Where a Type A evaluation is obtained from repeated observations, a Type B evaluation is obtained by scientific judgement based on all of the available information on the possible variability of input quantities.

The presented uncertainty assessments consider a conventional SCPT system and two settings for soil conditions (Table 1). Procedure, operator and system design errors are not considered.

The selected SCPT system and procedures comply with ISO 22476-1 (2012), ISO 19901-8 (2014) and ASTM D7400 (2019). It has a polarized hammer impact source at ground surface, with the centre point of the source at

a fixed horizontal offset of 1 m from the initial vertical axis of the push rods of a CPT thrust machine (refer to Section 4.2 for discussion on other source offset distances). A dual-receiver seismic piezocone penetrometer applies, with two sets of 3-component geophones with a centre-to-centre spacing of 1 m (refer to Section 4.3 for discussion on other receiver spacings). The cone penetrometer is stationary for the selected test depth interval and the uncertainty assessments only consider data for the dual-receiver interval. The selected signal sample rate is 3 kHz, with incorporation of pre-trigger data recording. Stacking of 5 to 10 seismic traces is assumed to be applied as standard practice.

Table 1. Soil conditions – two cases.

Case	Depth	G_{max}	q_c	v_s	ρ
	m	MPa	MPa	m/s	kg/m^3
C1 OC clay	4-5	17	~0.65	100	1700
C2 Dense sand	25-26	180	~36	300	2000

OC = overconsolidated q_c = CPT cone resistance

3 INVENTORY OF UNCERTAINTIES

Tables 2 to 4 show u_i components for G_{max}, derived for Cases C1 and C2. The uncertainties are grouped by time/timing components, spatial/ distance components and equipment/setting components. Quantification of the uncertainties is based on values published in literature when available, calculated estimates and/or best-estimate expert assessments (Type B evaluation of u_i).

The 1st column 'Uncertainty ID' in the table lists the G_{max} uncertainty components.

The 2nd column 'Impact' refers to the influence of the u_i component on G_{max}, expressed as percentage of standard uncertainty (u_i) normalised to the corresponding derived value for G_{max} given in Table 1, i.e. u_i/G_{max}. Tables 2 to 4 use the following categories: L = Low impact with u_i/G_{max} in the range of 0 to 1 %, M = Medium impact with u_i/G_{max} in the range of 1 % to 5 %, and H = High impact with $u_i/G_{max} > 5$ %. Indicators with a '?' are for a best guess uncertainty impact, i.e. more research may be required. The selected ranges for u_i/G_{max} allow focus on understanding and reducing those uncertainties that have M or H impact. About 2/3 of the uncertainly components fall in the L range, 1/6 in the M range and 1/6 in the H range.

The 3rd column 'Comp.' stands for 'Complexity' and refers to challenges in quantification of an u_i component, rated from Low (L), Medium (M) to High (H) complexity. High complexity items often depend on specific situations or on other u_i

components, which makes them more difficult to quantify and mitigate.

The 4th column 'Dep.' Refers to dependencies of u_i components, i.e. primary and secondary uncertainties shown by the IDs in the left column of each table.

The 5th column 'Notes' includes items such as brief clarifications of the u_i components, references to literature and/or references to Section 4 for more detailed discussion.

4 SUPPLEMENTARY NOTES

4.1 *Ray path between source and receivers*

This section provides notes on Uncertainty ID 5 of Table 3. The uncertainties assessed for cases C1 and C2 assume straight-line ray paths between source and receivers. The uncertainties are ranked as High impact.

A straight-line assumption is according to common practice, e.g. ASTM D7400 (2019). This practice should be adequate for relatively homogeneous soil conditions within the immediate zone of the depth interval selected for deriving G_{max}. Soil homogeneity (or otherwise) can be readily interpreted from the location-specific CPT profile acquired as part of the SCPT activities.

Actual ray paths between source and receivers are largely controlled by (1) source offset and depth of receivers discussed in Section 4.2 and (2) soil heterogeneity, particularly layer boundaries with high contrast of acoustic impedance. Travel time errors from interval methods generally diminish with depth, as the angle of incidence of ray paths between source and receivers becomes increasingly vertical and the assumption of a straight line becomes more applicable (Butcher & Powell 1996).

Kim et al. (2004) and Hallal & Cox (2019) illustrated high impact on v_s (and thus G_{max}) with a linear ray path assumption where soil layer boundaries with high impedance contrast are in-between the two sets of receivers. For this situation ASTM D7400 (2019) suggests accounting for refracted ray paths by applying Snell's law using ray tracing methods (RT), or estimation of shear wave velocities from linear trends per layer with support from CPT profiles using slope-based methods (SM). Kim et al. (2004) provide details for these methods.

4.2 *Source offset*

This section provides notes on Uncertainty ID 7 of Table 3. Cases C1 and C2 consider a lateral source offset of 1 m. The uncertainties are ranked as Medium impact and Low impact.

ASTM D7400 (2019) suggests a lateral source offset in the range of 1 m to 6 m. In practice, both small and large source offsets have advantages and disadvantages.

Table 2. Uncertainties related to time/timing components.

| Uncertainty ID | Impact | | | | Notes |
	C1	C2	Comp.	Dep.	
1. Trigger timing	L	M	L	4, 21	ISO 19901-8 (2014) and ASTM D7400 (2019) consider trigger timing. Accurate trigger timing can be obtained in several ways, such as trigger-receiver clock synchronization, or by using a very high signal sample rate. Calculations indicate that trigger timing variability accounts for approximately $u_1/G_{max} = 1$ % for C1 and $u_1/G_{max} = 3$ % for C2.
2. Signal latency	L	L	L	-	Signal latency has no influence on interval velocity, as it is a constant within a particular data acquisition system.
3. Arrival time selection	L	L	L	1, 6, 14	Stolte and Cox (2020) indicated that arrival time selection methods (first cross-over, maximum peak, cross-correlation) vary by approximately 0.1 ms if any influence from ground conditions is removed. A measurement error of 0.1 ms implies $u_3/G_{max} = 0.4$ % for C1 and C2. Presentation of a velocity range for several methods can be useful for insight in sensitivity of arrival time selection.
4. Signal sampling rate	L	L	L	10	ISO 19901-8 (2014) and ASTM D7400 (2019) consider signal sampling rate. For recording of traces the Nyquist sampling theorem must be met, i.e. a sampling rate that is at least twice the maximum source signal frequency. Calculations indicate $u_4/G_{max} = 0.1$ % for C1 and $u_4/G_{max} = 0.2$ % for C2. For accurate arrival time selection, the signal should be up-sampled to at least 40 kHz.

Table 3. Uncertainties related to spatial/distance components.

| Uncertainty ID | Impact | | | | Notes |
	C1	C2	Comp.	Dep.	
5. Ray path between source and receivers	H	H	H	4, 7, 8, 9, 11, 20	Refer to Section 4.1.
6. Signal damping and signal distortion along ray path	M	M	M	3, 4, 10, 11, 14, 15, 21	Howie and Amini (2005) indicated effects of waveform shape, near-field influence, attenuation, frequency content, peak frequency shift and signal widening on arrival time selection methods (first cross-over, maximum peak and cross correlation). For a depth range of 4 m to 10 m, the (collective) uncertainties were estimated to be within 0.2% to 2% of theoretical v_s. This implies $u_6/G_{max} = 0.4$ % to 4% for C1 and C2.
7. Source offset	M	L	M	5, 8, 11, 20	Refer to Section 4.2.
8. Spacing of receivers	M	M	H	4,5,9, 11,16	Refer to Section 4.3.
9. Spatial position of cone penetrometer relative to source	L	L	H	3,5,7	ISO 22476-1 (2012), ISO 19901-8 (2014) and ASTM D7400 (2019) require determination of vertical position of a cone penetrometer by measurement of penetration length and inclination. Calculations indicate $u_9/G_{max} = 0.7$ % for C1 and $u_9/G_{max} = 0.1$ % for C2, based on considerations given by Peuchenand Wemmenhove (2020). Polarization analysis can be applied to estimate relative orientation of the receivers.

For a linear ray path assumption, a source offset in the range 1 m to 4 m will give a relatively small angle of incidence between source and horizontal soil layering. For heterogenous conditions, a source offset closer to the axis of the SCPT push rods is preferred, because the effects of refraction decrease with diminishing source offset (Kim et al. 2004). For penetration depths of less than 5 m, Butcher & Powell (1996) indicate u_7 ranging from approximately 1 % of v_s for a 1 m source offset to 20 % of v_s for source offsets of > 4 m. These values correspond to $u_7/G_{max} = 2$ % and $u_7/G_{max} = 44$ %.

For source offsets > 4 m the assumption of linear ray paths should not be applied and refracted ray paths should be accounted for (refer to Section 4.1). The use of larger source offsets can limit near-field effects of refracted waves and improve estimation of interval velocities (Baziw & Verbeek 2014).

Table 4. Uncertainties related to equipment/ setting components.

Uncertainty ID	Impact C1	Impact C2	Comp.	Dep.	Notes
10. Frequency spectra of source and receivers	L	L	M	-	Low impact for C1 and C2 considers that the receivers are capable of recording the source frequency spectrum. Records of the source signature (signal) can be useful for evaluation of frequency spectra.
11. Soil stratigraphy and soil anisotropy	M	M	H	-	Refer to Section 4.4.
12. Imperfect source	L	L	H	15	A hammer source is theoretically seen as a point source creating a perfect pulse signal. In practice, the source has inertia and has a specific geometry; the pulse signal will be imperfect. Gillespie (1990) concludes that source-soil coupling and stacking significantly reduce impact of variations in the source impulse. Isolation of the first arrival peak may be considered during data processing to remove, for example, ringing in the recorded signal.
13. Inertia of push rod and seismic cone penetrometer	L?	L?	H	-	The receivers are fixed in a stiff metal rod instead of fully decoupled points in soil. Resulting uncertainties appear unknown.
14. External noise	H	H	H	-	Cases C1 and C2 consider common levels of external noise. External noise is typically expressed as signal to noise ratio (SNR). Examples for SNR improvement are (1) a more powerful source, (2) SCPT system engines switched-off and (3) selection of day/ time of data acquisition with low external noise conditions related to traffic and/or weather. SNR can be determined by evaluating the magnitude spectrum of external noise recorded from e.g. pre-trigger of the receivers. Filtering for external noise can be applied outside the frequency range of the seismic source signal.
15. Source-soil coupling and decoupling from hold-down mass	L	L	M	11, 12	Depending on source characteristics and source-soil interface, soil degradation can progressively develop with number of hammer strikes. The use of dampers between hold dawn mass and source is common. Examples for potential improvement are (1) increase of the hold down mass (or vertical force), (2) implement geometry/ material for high shear coefficients at source-soil interface and (3) locally increase ground resistance by surface levelling and/or ground improvement.
16. Receiver characteristics	L	L	L	10	Detrending and demeaning of recorded data can be applied to remove system drift. A systematic error of system drift between receivers is sometimes observed. The cause of this error is unclear, although Styler et.al. (2013) rule out a systematic orientation bias and time-bias between receiver pairs.
17. Receiver-soil coupling	L	L	M	8, 9, 11	SCPTs generally provide good receiver-soil coupling. Soil containing e.g. gravel, cobbles or cemented zones may be unfavourable. ISO 19901-8 (2014) and ASTM D7400 (2019) allow a seismic receiver module with a slightly larger diameter compared to the push rod section below and above the seismic receiver module.
18. A/D conversion of receiver data	L	L	L	4, 10	Cases C1 and C2 assume appropriate design for instrument response, analogue to digital (A/D) conversion, jitter, etc.
19. Near field effects	H	L	H	3,7, 8,9, 10, 12,14	Especially at shallow depths (<5 m), seismic signals can be affected by interference with surfaces waves, acoustic reflections from ground surface at shallow depth and limited recordable source frequency spectrum.
20. Wave propagation through push rods	L	L	H	5	Acoustic waves through steel push rod are much faster than v_s for soil and therefore pose no problem in interpretation of S-wave arrivals. Decoupling of push rods from the thrust machine (unclamping) may reduce unwanted wave propagation through the push rods.
21. Source signal repeatability	L	L	L	1, 12, 15	Gillespie (1990) mentions time measurement repeatability within 0.05 ms due to varying frequency content of the source. For C1 and C2, this would imply $u_{21}/G_{max} = 0.2\,\%$. Monitoring of non-normalized traces acquired during SCPT data acquisition can allow removal of any 'bad' traces from the dataset.
22. CPT thrust machine imposes stresses and strains to soil	L?	L	M	-	Uncertainty for G_{max} for C1 depends on soil stratigraphy for depth zone of 0 to 5 m. In general, uncertainty is assessed as Low impact below about 5 m below ground surface.
23. Push rods and cone penetrometer impose stresses and strains to soil	L?	L?	H	-	The soil influence zone is in the order of 0.15 m around the push rod, potentially creating a higher velocity zone. The geometry of this zone typically shows minor dependence on soil conditions. Therefore, uncertainty is assessed as Low impact. Actual uncertainties appear unknown.
24. Velocity to shear modulus conversion	H	H	M	11	Contributing uncertainties include (1) applicability of theoretical model $G_{max} = \rho.v_s^2$, (2) input of soil density ρ and (3) error for v_s (squared). Soil density derived from measurements of (nearby) high quality soil samples can reduce uncertainty compared to CPT/ SCPT based correlations for soil density.

4.3 Spacing of receivers

This section provides notes on Uncertainty ID 8 of Table 3. The uncertainties for Cases C1 and C2 are ranked as Medium impact for a dual-receiver interval of 1 m.

A choice for spacing of receivers typically represents a trade-off for considerations such as practicability, depth resolution and accuracy of G_{max} values (e.g. Gibbs et al. 2018).

Variation in v_s of approximately 2% has been demonstrated by Styler et. al (2013) between receiver pairs spaced 0.5 m and 1 m at a depth of 5 m, corresponding to $u_8/G_{max} = 4$ % for Case C1.

Ghose (2012) presented results of two field experiments conducted with a seismic cone penetrometer with 7 tri-component accelerometers at 0.25 m spacing. An advantage of multi arrays is that it allows for evaluation of measurements over more multiple spacings within a single CPT push. No evidence for reduction of data quality was observed with 0.25 m receiver spacing compared to larger spacings within the same CPT push. These findings suggest that high accuracy G_{max} data can be obtained with relatively small receiver spacing. For heterogeneous soil, a small depth interval improves G_{max} resolution with depth. On the other hand Gibbs et. al. (2018) mention that an improved resolution with 0.5 m receiver spacing may not compensate for the difficulties in accurately determining the shorter time delay between the traces compared to a system with 1 m spacing of receivers.

Selection of a large depth interval allows 'averaged' results for G_{max}, with due consideration of ray paths affected by soil layer boundaries with high impedance contrast (see Section 4.1). SCPT results for a combination of small depth intervals and overlapping large depth intervals within one soil unit can provide insight in G_{max} sensitivity for receiver spacing.

4.4 Soil stratigraphy and soil anisotropy

This section provides notes on Uncertainty ID 11 of Table 4. The uncertainties for Cases C1 and C2 are ranked as Medium impact.

Comments on soil stratigraphy are included in Section 4.1.

Soil anisotropy effects on G_{max} are usually not considered or well understood.

Soil can be represented by an elastic stiffness matrix with three shear components G_{vh}, G_{hv} and G_{hh}, where the subscript h denotes horizontal direction and the subscript v denotes vertical direction. Soil is anisotropic, i.e. the isotropic condition where $G_{vh} = G_{hv} = G_{hh}$ is a theoretical simplification. Cross-anisotropy (axi-symmetric conditions where $G_{vh} = G_{hv} \neq G_{hh}$) is a more realistic representation of in situ soil conditions. Pennington et al. (1997) provide an example for cross-anisotropy affecting G_{max} where $G_{hh} \approx 1.5 G_{vh}$. Furthermore Pennington et al.

(1997) highlight cases for clays with azimuthal stress variations where $G_{vh} \approx 1.3 G_{hv}$, i.e. the assumption of cross-anisotropy does not apply.

The SCPT method records signals of wave propagation in approximately vertical direction with particle motion in an approximately horizontal plane. This means that G_{max} values derived for SCPTs are largely representative of the G_{vh} component for a simple cross-anisotropic case. Soil heterogeneity, stress conditions and more complex anisotropy can require further attention.

Note that cross-hole seismic testing (e.g. ASTM D4428 2014) can approach the G_{hh} component.

5 COMBINED STANDARD UNCERTAINTY

The uncertainty inventory of Tables 2 to 4 is complete, thus allowing approximate estimates to be made for a combined standard uncertainty (u_c) budget for G_{max}.

A simplified approach by assuming sensitivity coefficients c_i equal $_n$ to 1, would be to calculate u_c according to $u_c^2 = \sum (c_i u_i)^2$ (ISO 2008), where i refers to the uncertainty IDs of Tables 2 to 4. Approximately average values of the selected uncertainty intervals can be assumed for an initial estimate of u_c: $u_i/G_m = 0.2$ % for Low impact, $u_i/G_{max} = 2$ % for Medium impact and $u_i/G_{max} = 7$% for High impact. This calculation approach gives $u_c/G_{max} = 14.6$ % corresponding with $u_c = 2.5$ MPa for Case C1 ($G_{max} = 17$ MPa) and gives $u_c/G_{max} = 12.8$ % corresponding with $u_c = 23.0$ MPa for Case C2 ($G_{max} = 180$ MPa).

The estimated u_c values seem reasonable for the test method (SCPT) and cases considered.

Experimental procedure for checking the saturation degree of piezocone tips

I. Rocchi

Department DICAM, University of Bologna, Italy

ABSTRACT: A correct measurement of the water pore pressure is essential to obtain reliable CPT results. Although this has always been a major concern, it still remains a possible relevant source of error in common engineering practice. In addition to usual reasons, such as malfunctioning of the equipment, its poor calibration and/or maintenance, a lack of complete saturation of the piezocone tip can play a major role. In fact, a correct and timely pore pressure measurement relies entirely on the full saturation of the pore pressure system. The variety of saturation fluids and methods that is encountered in practice is a clear evidence of the still existing uncertainties on the most suitable procedure. Furthermore, unless the saturation process is explicitly detailed, its choice is typically left to the contractor and the measurement quality can only be established a posteriori, after the test has been completed. This paper describes a novel experimental equipment that enables quantifying the degree of saturation of the piezocone tip prior to testing. The methodology proposed is inspired to the B-value check, which is routinely used in geotechnical laboratory testing to assess the degree of saturation, e.g. prior to triaxial testing. In addition, it could also be applied after a test, so that it would be possible to assess whether saturation was retained while testing. This promising approach, when extended to different saturation procedures and validated by engineering practice, has the potential to become a relevant benchmark for reliable CPT testing.

1   INTRODUCTION

Piezocone testing in its simplest version, i.e. including independent measurements of cone resistance (q_c), sleeve friction (f_s) and pore pressure (u_2), was established in the eighties and has since gained a leading role in field classification and characterization of soils. Piezocone measurements can be affected by a number of impreciions, as accurately explained by Sandven (2010). These include, but are not limited to malfunctioning of the equipment, poor calibration and/or maintenance, which are shared with other experimental techniques. However, a lack of complete saturation plays a key role and is specific to CPTU tests. Although this has long since been acknowledged and has been a major concern since the advent of CPTU, it still remains a large source of error in common engineering practice, possibly the most important.

A correct measurement of the pore pressure is essential to obtain reliable CPTU results in terms of both soil profiling and mechanical properties evaluation. In terms of profiling, high quality measurements of pore pressure are particularly important for fine grained materials and intermediate soils, where pore pressure response is crucial to an accurate soil classification, for example using normalized pore pressure parameters as suggested by Schneider et al. (2008).

Furthermore, reliable pore pressure measurements are also important because the correct cone resistance (q_t) is determined as $q_t = q_c + (1 - a)u_2$, where a is the area ratio of the cone, typically between 0.8-0.9. In addition, thin lenses are better detected by sudden variations in the pore pressure readings, as layers ahead of the tip might influence the resistance recorded due to plugging or punch through phenomena (Lunne et al. 1997). Furthermore, high quality measurements are fundamental to provide reliable input parameters. For example, compliance in the measuring system can provide misleading results when assessing consolidation parameters by means of dissipation tests.

Variables such as the (porous) filter element location and design, the volume of the chamber connecting the filter to the pore pressure transducer, the saturation fluid and its degree of saturation, the air entry (i.e. cavitation) value of the system and lag time required for "resaturation", as well as the depth and saturation of soil during testing, all affect the pore-water pressure measurement during testing (dynamic measurement) and dissipation, upon stopping the advancement of the tip. However, the quality can only be established a posteriori, i.e. after the test has been completed.

This paper describes an innovative approach that allows quantifying the degree of saturation of the

piezocone prior to testing. The methodology proposed uses the pore-pressure parameters proposed by Skempton (1954) and is routinely used in laboratory testing to assess saturation, e.g. prior to triaxial testing. Preliminary laboratory measurements on a given piezocone, filter and saturation fluid under different saturation conditions of the filter are presented to establish whether there is a measurable correlation between the pore pressure coefficient and the saturation degree of a piezocone tip.

2   SATURATION IN LABORATORY TESTING

Saturation of soil pores is of paramount importance in laboratory testing, not simply because the strength and deformability properties may differ considerably between saturated and unsaturated states, but also because any effective stress analysis is developed based on tests results obtained in experimental set ups that rely heavily on this assumption. For example, the consolidation theory formulated by Terzaghi & Fröhlich (1936) is based on the assumption that volumetric strain is solely a result of change in the void ratio, or water content, of the soil, i.e. that the soil grains and water are incompressible and the soil is saturated. While it is possible to calculate the volumetric strain in an oedometer without relying on this assumption, by measuring the change in the height of specimen, this is not in other cases, such as triaxial tests. In this case, the volumetric strain calculated is based on the volume of water entering or leaving a closed hydraulic system connected to the soil specimen. Therefore, any element in this hydraulic system having compressibility higher than the soil specimen (i.e. air bubbles) affects the strain measured as a result of an increment in stress. On the other hand, in a triaxial undrained test the effective stress is calculated as the difference be-tween the applied total stress and the pore pressure measured in a closed system connected to the soil specimen Based on the pore-pressure coefficients (Skempton 1954)

$$\Delta u = B[\Delta\sigma_3 + A(\Delta\sigma_1 - \Delta\sigma_3)] \qquad (1)$$

Where $\Delta\sigma_1$ and $\Delta\sigma_3$ are the changes in the principal stresses, while A and B are the pore-pressure coefficients. Assuming a closed hydraulic system disconnected from the specimen, if the system is not compliant (i.e. infinite stiffness) an isotropic increment of stress, must result in an equal increment in the fluid pressure, which corresponds to the pore pressure in the soil specimen. Compliance may arise from deformability of the hydraulic system, soil grains or the fluid, but typically, it is assumed that the two increments are the same for a saturated soil. In other words, the only relevant source of compliance is assumed to arise from air in the soil pores or elsewhere in the system.

Saturation in triaxial tests is checked based on this principle, by applying an isotropic increment of total stress (i.e. cell pressure) in undrained conditions and monitoring the response in pore pressure. The ratio between the increment observed in pore pressure and the increment applied in cell pressure (B) is approximately 1 for saturated soils. Since the smaller the ratio, the larger the error in the measurement, standards require to proceed with testing only after having achieved B = 0.95-0.97 for sands and B = 0.97-0.99 for clays. Because correct pore pressure and volumetric strain measurements rely entirely on the full saturation of the pore pressure system, if the B value is not satisfactory, the pressure of the hydraulic system (i.e. back pressure) is increased maintaining a constant effective stress, so that air bubbles are dissolved and the compressibility of the fluid reduced.

3   SATURATION IN PIEZOCONE TESTING

Table 1 provides an overview of the porous materials and pore size suggested in different standards and used in practice, based on an international survey by DeJong et al. (2007). The great variety of saturation methods and media encountered in engineering practice is a symptom of the uncertainties that still exist on the subject. The most commonly used materials are relatively few. Polypropylene filters have the advantage to be inexpensive and disposable, but have comparably higher compressibility than sintered steel or ceramic filters, which are respectively subject to wear or brittleness on the other hand. The range of the filter pore size is rather wide. In fact, there is one order of magnitude difference in the ranges allowed by ASTM (D5778-12) and EN ISO 22476-1-2012 (i.e. the standard recommended by also the Eurocode7), while several sizes are encountered in practice, where the largest size used is beyond the prescribed ranges.

Table 1.   Filter characteristics in piezocones.

Setting	Material	Pore size μm
ASTM Standard D5778-12	Sintered steel or bronze Ceramic Plastic	20-200 μm
EN ISO (EC7) Standard	Sintered steel or bronze Ceramics Porous PVC and HDPE Carborundum	2-20 μm
Current practice*	Sintered steel or brass Ceramic Plastic Sintered glass beds	10, 50, 80, 120, 150, 250 μm

*Data from DeJong et al. (2007).

With regards to the saturation fluid for the filter, both ASTM and Eurocode7 suggest deaired water only if tests are carried out throughout saturated non-dilative (e.g. dense sands) soils. Otherwise, glycerin or similar high viscous fluids are suggested, such as silicon oil. However, according to DeJong et al. (2007) a much wider variety of fluids is used, including hydraulic oil, vegetable oil and water-glycerin mix. While higher viscosity diminishes the risks of cavitation, it is counterproductive with respect to the ability to deair the fluid. Similarly, risks of cavitation reduce with pore size, but saturation is more difficult to achieve due to lower permeability.

Finally, with regards to saturation of the filters, ASTM suggests either applying a 90 kPa vacuum while submerging the filters or boiling them in water, both for at least 4 h. Eurocode7 suggests either applying the filters in a vacuum for 24 h, or boiling them in water for at least 15 min. DeJong et al. (2007) investigated the minimum time requirement and vacuum needed to ensure saturation based on a qualitative assessment of 15-45 µm polypropylene filters. Their cross sections was examined after saturation using different fluids mixed with food coloring. Based on this study, saturation by vacuum requires at least 85 kPa. Glycerin takes at least 4 h to saturate the filters, while water and silicon oil take just above and below 1 h, respectively. In particular, the best performance was obtained with low to intermediate viscosity silicon oil (100-1000 cS).

While a correct functioning of the pore pressure measuring system requires saturation of the filters, this is not sufficient in itself to guarantee good results. Air bubbles may be trapped within the tip threaded hollow (1) as showed in Figure 1, or in the chamber connecting the pore pressure transducer and the filter (2). For this reason, the code of practice suggests specific methods to assemble the tip to ensure saturation. In particular, ASTM suggests assembling the filter onto the piezocone while submerged in the deaired medium used to prepare the elements, flushing all confined areas with fluid to remove air bubbles, before tightening the tip on the piezocone. Eurocode7 also suggests assembling the piezocone while submerged in the de-aired saturation fluid. However, it suggests that saturation of the disassembled piezocone can be carried out either by injection of fluid in the chamber connecting the pressure transducer and the filter or by placing the disassembled piezocone under vacuum for 15-30 min. Alternatively, filter-less piezocones can be employed, where the pressure transducer is in direct contact with the soil by means of a grease-filled slot. This so called "slot-filtered" piezocone does not require a specific saturation procedure. However, it must be ensured that no air is trapped while assembling the tip. Furthermore, because of the higher viscosity of the "saturation fluid" it might be more difficult to ensure that it is deaired.
Figure 1. Piezocone tip: (a) disassembled, (b) schematic cross section showing likely location of air bubbles and (c) assembled tip. 1 piezocone tip, 2 porous filter, 3 seals, 4 chamber connecting porous filter to pore pressure transducer and 5 pore pressure transducer.

4 PROCEDURE PROPOSED TO CHECK PIEZOCONE SATURATION

Figure 2a shows a schematic diagram of the device proposed to check the saturation of the pressure sensing system of a piezocone directly on site, whereas the photo of a prototype can be seen in Figure 2b. In essence, the device applies a pressure impulse on the assembled tip through an annular chamber that is placed around the piezocone filter (2 in Figure 2a). The invention is patented by the University of Bologna (Rocchi et al. 2017).

The ratio between the increment recorded by the pore pressure sensor placed inside the piezocone and an independent pressure transducer monitoring the impulse applied, is used to calculate the pore pressure coefficient B. The degree of saturation of the piezocone pore pressure measuring system can then be assessed as a whole, by associating the measured B ahead of testing to the quality of the CPTU test performed. Once the thresholds values for B that guarantee satisfactory results in terms of pore pressure measurements in CPTU tests are established, testing should proceed only if these values are achieved. Otherwise, the tip would be saturated and assembled again, replacing the filter if necessary, until obtaining a satisfactory result (see the flow chart in Figure 3). The test could also be performed at the end of the CPTU so as to assess whether saturation was retained during the test.

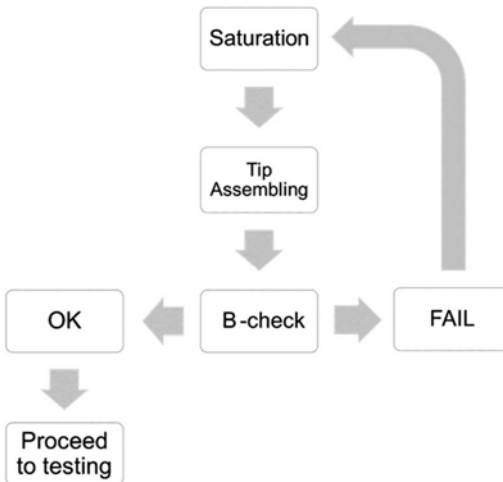

Figure 3. Flow chart of testing procedure including assessment of the pore pressure measuring system saturation.

5 METHODOLOGY

Three different saturation conditions were investigated on a given piezocone, filter type and saturation fluid. The filter position in the piezocone used was u_2. Furthermore, the filter was made of 5 µm sintered stainless steel purchased already saturated with a 20 cS silicon oil. The tests were performed at the laboratory floor, i) under ideal saturation conditions as recommended by the standards; ii) partial desaturation induced by pressurizing the filter with air at 85 kPa for 24 h; iii) desaturation by pressurizing the filter with air at 600 kPa for 1 h. Based on the weight loss recorded, which is due to the oil expelled from the filter, the saturation degree was estimated to be 100%, 91% and 3%, respectively. These conditions are therefore subsequently referred to as S, for ideal saturation conditions and LD and HD, for low and high desaturation, respectively. While they clearly do not correspond to the conditions encountered as a result of different saturation procedures they were selected to investigate the widest extent by which the measured B can vary with relevant saturation degrees.

In all cases, ahead of mounting the filter and assembling the cone, the piezocone and the seals were placed under an 85 kPa vacuum in a silicon oil chamber. After 15 min, the vacuum was released and a syringe was used to inject silicon oil in the chamber connecting the pore pressure transducer to the filter (4 in Figure 1), while the piezocone remained submersed. After an additional 15 min under vacuum, the tip was assembled while immersed in silicon oil and tightened. For the tests designated with S only, the assembled cone was subsequently placed under vacuum in the same oil chamber for further 15 min.

Afterwards, the device was positioned onto the cone while the assembled cone was still in the oil chamber so as to ensure hydraulic contact, while applying a small pressure (i.e. <5 kPa). The cone and the device were then remove from the oil chamber and a 50 kPa was applied in the device chamber. Subsequently, the device was used to apply a series of pressure impulses ranging from 50 to 300 kPa. Each impulse of nominally 50 kPa, was applied within a 1 s interval and kept for 30 s before increasing the pressure in the device further. The pore pressure measurements recorded by the piezocone and the device were datalogged continuously during the process.

6 PRELIMINARY RESULTS

Figure 4 shows a set of preliminary results obtained, where it can clearly be seen that the measured pore pressure coefficient B differs for the 3 saturation conditions employed. For each of the conditions investigated, 3 filters were tested. The subsequent results present the average values

measured under each condition, while the error bars indicate the minimum and maximum values recorded. Under each condition, there is a relatively good degree of repeatability, independently of the pressure applied for fully saturated conditions. On the contrary, B increases with the pressure applied for LD because the compliance of the system is reduced, as the pressure increases and air becomes less compressible. As expected, the B values measured for HD are almost zero because of the almost fully desaturated conditions of the filter. However, there is a considerable difference measured at 50kPa for S and LD conditions, even though the saturation degree of the filter is still above 90%. In summary, a strict correlation between the saturation degree of the filters and the pore pressure coefficient B was found.
Figure 4. Comparison of pore pressure coefficient measured on piezocone assembled with filters having different degrees of saturation.

7 CONCLUSIONS

The article discusses the still open issues related to poor saturation in piezocone testing and presents an innovative methodology and device, based on a pore-pressure coefficient, that can be used to quantitatively assess saturation before proceeding to testing. This would provide a great advantage as typically the quality of tests can only be assessed a posteriori. In addition, this measurement can also be applied after carrying out a test so that it would be possible to assess whether saturation was retained.

The preliminary results presented herein demonstrate that there is a strict correlation between the pore pressure coefficient and the saturation conditions of the filter. Based on this proof of concept, the device invented should be validated on other tips and with different saturation degrees of the entire hydraulic system and could be then subsequently employed to investigate the most suitable saturation processes and media. Furthermore, comparison of pore pressure measurements for CPTU performed on a same unit under different conditions as attested by the proposed methodology are recommended to identify threshold values suitable for testing.

ABSTRACT: Geotechnical assessment of vertical seabed stiffness during small vertical cycles of riser movement is important for riser fatigue analysis. These stiffness values change both with the amplitude of the cycles (because of non-linear stiffness) but also as the seabed consolidates under the small amplitude loading during long-term operation. To encapsulate both effects in design, a series of site-specific small displacement ball penetrometer testing was conducted both at seabed and in box-core samples on deck during a geotechnical survey for a recent deep water project. The paper describes the cyclic load and displacement controlled in situ testing, the results obtained, and how this data aided design. Of particular note were the long duration cyclic tests which were carried out for sufficiently long so as to not only capture secant stiffness reduction due to remoulding, but also subsequent stiffness increases due to consolidation. This novel test program performed on intact soil (as opposed to reconstituted samples in the laboratory or geotechnical centrifuge) confirms that consolidation hardening can occurs in naturally structured near-seabed soils.

1 INTRODUCTION

Subsea risers experience cyclic and axial strain due to environmental and operational loads. These are generally concentrated within the touchdown zone (TDZ), or the zone of the riser which first comes into contact with the seabed. Since operational riser movements are predominantly vertical in the TDZ, the riser response depends on the vertical seabed stiffness. Previous investigations of vertical seabed stiffness concentrated on steel catenary risers (SCRs) which experience large amplitude movements within both the vertical and lateral planes, resulting in seabed softening and trenching (Bridge and Howells, 2007). This has led to the development of non-linear soil models that describe the change in vertical seabed reaction (V, or P) during vertical penetration (z), extraction and re-penetration (e.g. Bridge et al. 2004; Randolph and Quiggin, 2009; Aubeny and Biscontin, 2009; Clukey et al. 2017; see Figure 1). Although there has been significant focus on large amplitude movements, some models have

investigated the hysteretic seabed resistance developed during relatively small riser movements and how the normalized stiffness ($K_{sec} = k_{sec}/N_c s_u$, where $k_{sec} = \Delta P/\Delta z$, N_c is a bearing factor, and s_u is the undrained shear strength) reduces with increasing displacement amplitude.

As compared to the SCR, TDZ movements of a lazy-wave riser (LWR) are several orders of magnitude smaller, in the range of 0.1 to 1% of the riser diameter. These movements may lead to initial seabed softening but are unlikely to lead to significant trenching. Instead, the focus is on the non-linear relationship between seabed stiffness and riser displacement amplitude, with the structural fatigue assessment using equivalent linear-elastic springs (k_{sec}).

Recent data obtained from centrifuge tests in normally consolidated clay (e.g. Hodder et al., 2009; Yuan et al., 2016) suggest that the riser-seabed stiffness could increase or 'harden' with time due to soil consolidation. For overconsolidated clay this consolidation hardening effect on riser seabed stiffness remains uncertain (Clukey et al. 2017). Long-term

consolidation hardening has only been observed in model tests conducted with reconstituted clays or kaolin clay (e.g. Clukey et al., 2005; Hodder et al., 2009, Yuan et al., 2016; Hou et al., 2018) and to the authors' knowledge there is no published model test data on intact soil samples nor is there any existing design framework to incorporate this hardening behavior in a site-specific manner.

This paper reports a series of in situ tests conducted offshore on the seabed and in box cores to support a deep water oil and gas development. The tests were able to take site-specific measurements of cyclic softening and hardening and were used to inform riser design. Recommendations for future testing are made based on the findings.
Figure 1. Schematic of cyclic vertical load-penetration response for pipelines and risers.

2 SITE AND DESIGN CONDITIONS

The soil conditions across the project site comprised a thin (5 to 15 cm) drape of very soft clay with undrained shear strength (s_u) values less than 5 kPa, below which is a soft clay layer with a slight 'crust' with s_u up to 12 kPa, extending down to 0.5 m below the seabed. The strength profile then gradually reduces to normally consolidated conditions (Figure 2).

A conventional geotechnical site investigation campaign was conducted including sampling by piston coring and box coring and in situ testing by T-bar penetrometer. The long term cyclic ball penetrometer tests described here are novel and were performed specifically to support geotechnical design advice regarding operational riser-soil interaction.

During operation, the lazy-wave risers (LWRs) were expected to cycle vertically under small amplitudes ranging from about 0.1% to 1% of the riser diameter. Since high seabed stiffness reduces fatigue life, accurate quantification of the stiffness in the 'crust' layer was key to the riser design and the variation in stiffness throughout their design life was important to quantify.

3 FIELD TESTING

3.1 Overview

The field testing comprised in situ ball penetrometer testing at seabed and on-deck ball penetrometer testing in box core samples. The ball penetrometer tests comprised 'standard' tests (such as monotonic penetration/extraction and large amplitude displacement-controlled cyclic events to measure s_u profiles and sensitivity (S_t), respectively). These were supplemented with novel small amplitude load and displacement-controlled cyclic tests designed to replicate the expected field riser movement. The advantage in the box core and in situ tests is that the 'crust' material is undisturbed, avoiding the challenge of having to recreate field conditions in a laboratory model test set-up. This allowed the in situ soil response to be measured, capturing the effect of soil structure of an overconsolidated clay on changes in stiffness. Another advantage of this approach is that test results were available during the geotechnical campaign, rather than having to wait for sample transport, testing and interpretation as would be required during conventional laboratory ex-situ testing.
Figure 2. Undrained shear strength profile at site.

3.2 In situ ball penetrometer testing

In situ testing was performed using the Fugro Sea-Calf seabed frame system deployed from the back of a geotechnical drilling vessel (Figure 3). A ball penetrometer of diameter 78 mm (hence projected

base area of 4778 mm^2) was pushed with a rod of 25 mm diameter and measurements of penetration resistance, sleeve friction and pore pressure were recorded during the tests.

The cyclic tests involved displacement-controlled cycles of fixed amplitude (typically ranges from ±0.02 m to ±0.15 m) conducted at a displacement rate of 0.02 m/s. The cyclic tests started with 30 cycles of large amplitude cyclic displacement (± 0.1 m to ±0.15 m) to remold the soil, followed by long term (up to 35 hours) small amplitude cyclic displacement (± 0.02 m) to measure the long term cyclic load response.

Figure 3. Fugro SEACALF system.

3.3 *In box core ball penetrometer testing*

A ball penetrometer of 33 mm diameter was actuated using Fugro's DeckScout system mounted on the top of 0.5 m x 0.5 m x 0.5 m box core on the deck of the drilling vessel (Figure 4).

The tests were started by penetrating the ball monotonically to a target depth at a displacement rate of 200 mm/min, measuring the plastic penetration. The ball was then unloaded until the bearing pressure reached approximately 1 kPa and ready for the start of the test.

The long term cyclic test was then conducted using load control, with load limits set at +11 kPa (maximum value) and approximately 0 kPa (minimum value) for each cycle. The ball penetration rate was about 0.06 mm/min while the extraction rate was about 0.12 mm/min. This difference in displacement rate was an artefact of the testing system, but is not expected to have affected the results. The cycling was continued until no obvious changes in secant loading stiffness were observed, which required up to 8 hours (2600 cycles) of continuous cyclic loading.
4   RESULTS: IN SITU TESTING

A typical result for the in situ cyclic ball penetrometer test is shown on Figure 5. For each cycle of the test, the secant stiffness (k_{sec}) was calculated using the change in bearing pressure (Δq) from peak to

Figure 4. Fugro DeckScout system showing (a) box core sampler and (b) close up of actuator with miniature ball penetrometer.

216

trough (and vice versa) and the associated change in penetration (Δz). Figure 6 presents the resulting trend of increasing stiffness (in the loading phase) with cycles, with an approximately 40% increase in stiffness by the end of the test compared to the initial value. The final level of consolidation in the soil for this test was only about 50% based on the normalized time factor ($T = tc_v/D^2$) calculated to be 0.16, where t is the test duration, c_v is the coefficient of consolidation, and D is the ball penetrometer diameter. Further cycling would therefore have likely increased the secant stiffness further, but was not feasible because of vessel time availability.

Figure 6. Typical result from a long-term cyclic in situ ball penetrometer test (Δz/D ≈ 80%).

Figure 5. Overall load-penetration response during a long-term cyclic in situ ball penetrometer test.

5 RESULTS: IN BOX CORE TESTING

A typical box core ball penetrometer test result is shown on Figure 7. Because the cycles were load-controlled and the soil stiffness changed during the testing, the cyclic displacement amplitude reduced during the testing as shown in Figure 8a from about 1.2% of ball diameter at the start of the test to about 0.6% of diameter at the end.

As for the in situ testing, for each cycle of the in box core testing the secant stiffness (k_{sec}) was calculated using the change of bearing pressure (Δq) from peak to trough (and vice versa) and the associated change in penetration (Δz). Results are shown in Figure 8b, demonstrating the cyclic hardening behavior resulting in an increase of stiffness of approximately 80%, slightly higher in the loading phase compared to unloading. The normalized time factor $T = 0.72$ for this test is higher than the in situ SeaCalf tests, resulting in increased hardening. However, it replicates the results of similar testing performed in centrifuge model tests (e.g. Hodder et al., 2009, Yuan et al., 2016).

(a) Deduced cycle-by-cycle displacement range

(b) Deduced cycle-by-cycle stiffness
Figure 8. Typical results from a long-term cyclic box core ball penetrometer test

5.1 *Measurement quality*

Both the in situ SeaCalf and on-deck box core testing were limited by the control mechanism used, which resulted in some variation in cyclic amplitude. For the SeaCalf testing, the displacement-controlled condition resulted in soil consolidating away from the maximum depth range of the ball penetrometer, thus likely not mobilizing the full soil resistance during later downward movements. For the box core testing, the very small amplitude ball movements per cycle, e.g. 0.2 mm at the end of the test, challenged the precision of the displacement measurement system. In both cases, there is significant 'noise' in the acquired data. Consequently, long term moving averages were used to smooth out the data to allow the assessment of the evolution of soil stiffness as the tests progressed. Improvements to the testing devices have since been made to reduce this measurement uncertainty for future projects.

6 IMPLICATIONS FOR DESIGN

There remains debate within the subsea riser design community on the appropriateness of incorporating consolidation hardening in riser design (Clukey et al., 2017). The debate currently hinges upon whether cyclic riser response at the seabed is a load-controlled or a displacement-controlled process. For SCRs, the large amplitude vertical (and often lateral) motions of a riser under operational conditions limit the potential for consolidation hardening to occur. This is for two reasons: first, the seabed is continuously being softened and displaced due to the larger riser motions; second, translation of the TDZ both longitudinally and transverse to the original TDZ results in fresh seabed soil being subject to this

cyclic process and therefore limiting the time available for soil to harden. Because of these larger motions and displacement of the seabed soils, SCRs may generally be considered to be displacement-controlled in the TDZ region most subject to fatigue concerns.

For LWRs, however, the cyclic amplitudes in the TDZ are much smaller than for SCRs due the lazy-wave configuration, and the TDZ is therefore less likely to relocate during the design life. The motions of a LWR near the front of the TDZ may be displacement-controlled since they are driven by the translation of movements in the riser initiating at the floating facility. However, further along the TDZ, the upward movements are by definition displacement-controlled, but the downward movement is gravity-controlled, i.e. load controlled, and the resulting cyclic settlement of the riser into the seabed is governed by its on-bottom weight. This is likely to be similar for SCRs towards the 'back' (stationary end) of the TDZ where the catenary-induced stress concentration is negligible.

With further understanding of these differences in load and displacement-controlled behavior between SCRs and LWRs, designers can more accurately model the real response, or at minimum consider a conservative approach to fatigue design comprising a high estimate of seabed stiffness. The long-term vertical seabed stiffness of the seabed under loading conditions representative of a LWR, as illustrated through the data presented in this paper, can increase by up to 80% through this consolidation hardening process. Additional cycles of movement and time may have resulted in further increases in secant stiffness.

7 CONCLUSIONS

A geotechnical site investigation performed at a deep water site in soft clay comprised a novel program of cyclic ball penetrometer testing at the seabed (in situ) and in box core samples on deck of the vessel. The tests were performed under displacement-controlled (in situ) and load-controlled (in box core) conditions. The objective of the tests was to assess the potential for consolidation-induced increases in soil strength and resulting vertical seabed stiffness under small amplitude movements and loads which could detrimentally affect the fatigue life of the risers. The data presented confirm that consolidation hardening can occur in undisturbed overconsolidated clay, extending the observations by others for centrifuge and single-gravity model tests in reconstituted and normally consolidated clays.

The results suggest that consolidation hardening may be relevant for lazy-wave riser fatigue analysis, given the potential for long-term small amplitude cyclic movements which occur at a common touchdown zone throughout the riser design lifetime.

ABSTRACT: Detailed requirements for calibration of piezocone penetrometers are incorporated in standards published by International Organization for Standardization (ISO). The use of these standards can provide input for comparisons of cone penetration test (CPT) systems deployed in practice by means of cone penetrometer classes. It is important that parties specifying or supplying CPT data take note of the implications of the new requirements and the opportunities and benefits of appropriate selection of cone penetrometer classes. In addition, the information available from calibration and verification of a particular cone penetrometer can provide input into estimation of uncertainties of data points in CPT profiles used for design of structures.

This paper focusses on background information about topics considered for development of the ISO requirements. These topics included (1) practical and economical test methods achievable in a calibration laboratory, (2) assessment of differences in exposure conditions applied in the calibration process and site conditions likely to be encountered during actual cone penetration testing, and (3) cone penetrometers that incorporate ancillary sensors and algorithms for reducing the influence of temperature on CPT results.

1   INTRODUCTION

Detailed requirements for calibration of cone penetrometers are incorporated in (draft) standards published by ISO, International Organization of Standardization, particularly ISO/DIS 22476-1:2021 for cone penetration tests (CPT) conducted onshore and nearshore. The same calibration requirements are incorporated in ISO/DIS 19901-8:2021 for CPTs in offshore settings. The use of these standards (hereafter abbreviated to ISO 22476 and ISO 19901) can provide input for comparisons of CPT systems deployed in practice. In addition, the information available from calibration and verification of a particular cone penetrometer can provide input in estimation of uncertainties of data points in CPT profiles used for design of structures.

Earlier versions of ISO 22476 and ISO 19901 (ISO 22476:2012 and ISO 19901-8:2014) considered performance specifications by 'application classes', whereby requirements were given for accuracy of in-situ CPT results without detailed step-by-step procedures or method specifications. Application of these performance specifications proved difficult in practice (Lunne et al. 2017, Peuchen & Parasie 2019). For this reason, ISO changed to a method specification, particularly providing detailed requirements for calibration and verification of cone penetrometers in a calibration laboratory. The calibration and verification results provide the required information for assignment of a cone penetrometer to one of multiple 'cone penetrometer classes' specified in ISO 22476 and ISO 19901. A further step in method specification is required: monitoring and logging of

acquired test data, followed by assignment of test results in 'test categories'.

This paper focusses on background information about topics considered for development of the ISO requirements for calibration and verification of cone penetrometers. These topics included (1) practical and economical test methods achievable in a calibration laboratory, (2) assessment of differences in exposure conditions applied in the calibration process and site conditions likely to be encountered during actual cone penetration testing, and (3) cone penetrometers that incorporate ancillary sensors and algorithms for reducing the influence of temperature on CPT results.

ISO 22476 is a draft international standard (DIS). It was published by ISO in June 2021. Where applicable, this paper considers country feedback received for this DIS. Final published version of ISO 22476 and ISO 19901 can differ from the information presented here.

2 CALIBRATION AND VERIFICATION REQUIREMENTS

2.1 *Overview*

Table 1 presents an overview of calibration and verification requirements for cone penetrometers. The ISO column refers to both ISO 22476 and ISO 19901; ASTM refers to ASTM D5778-20.

Note that the required presentation of results of the ISO verifications covers the influences of temperature and bending on the parameters q_c, f_s, and u. Here, temperature influence is about the internal temperature in the cone penetrometer possibly affecting sensor performance.

The ISO reporting requirements for calibration and verification include assignment of the cone penetrometer to one of the cone penetrometer classes.

Table 1. Overview of calibration and verification requirements for cone penetrometers.

Item	ISO	ASTM
Calibration laboratory*	N	I
Measuring intervals for calibration	N	N
Penetrometer geometry*	N, C, U	N, V
Cone resistance*, q_c	N, C, U	N, C
Sleeve friction*, f_s	N, C, U	N, C
Pore pressure*, u	N, C, U	N, C
Net area ratios*, a and b	N, C	I, C
Temperature, T	-	I, C
Inclination, i	N, C, U	I, C
Influence of ambient temperature*	N, V	N, V
Influence of transient temperature*	N, V	-
Influence of penetrometer bending	N, V	-

C = calibration; I = informative; N = normative; U = uncertainty calculation; V = verification; * = details in sections following; - not covered.

The primary differences between ISO and ASTM are related to (1) detailed requirements for a calibration laboratory, (2) metrological calculation of calibration uncertainties and (3) normative (mandatory) versus informative (recommended) text. It can be noted that a calibration laboratory that invested in calibration and verification apparatus according to ISO 22476 and/or ISO 19901 should be able to provide the normative calibration and verification information according to both ISO and ASTM. The reverse can require additional investment.

2.2 *Calibration laboratory*

A normative reference to ISO/IEC 17025 provides the basic requirements for the calibration laboratory. ISO/IEC 17025 covers laboratory quality management, including detailed reporting requirements for calibration certificates.

2.3 *Measuring intervals for calibration*

ISO 22476 and ISO 19901 include normative text with respect to measuring intervals for calibration. For example, a minimum range is specified for inclination. Recommendations (informative) are given for selection of measuring intervals for calibration of q_c, f_s and u.

2.4 *Cone resistance and sleeve friction*

Calibration for q_c and f_s requires application of a series of axial loading and unloading series to the cone penetrometer, similar to ISO 376:2011. A notable requirement is the logging and supplementary presentation of output values of the penetrometer other than those for q_c or f_s, for the purpose of checking for any unwanted effects of axial loading on output of sensors other than the one selected for calibration.

Estimation of calibration uncertainty is prescribed in detail. Uncertainties cover those related to: (1) reference force, (2) geometry of the cone penetrometer and (3) uncertainties related to force sensor in the cone penetrometer, particularly reproducibility, repeatability, resolution, zero drift, interpolation, reversibility and apparent load transfer from cone to friction sleeve (and vice versa). Calculation equations consider standard uncertainties, combined standard uncertainties and expanded measurement uncertainties defined according to ISO/IEC Guide 99:2007.

Table 2 presents a selection of example output according to ISO requirements.

2.5 *Pore pressure and net area ratios*

Calibration for pore pressure u takes place with the cone penetrometer in a pressure vessel. A series of increasing and decreasing pressure series are applied.

Table 2. Example summary of laboratory calibration uncertainties for q_c, according to ISO requirements.

F_r [kN]	u_1 [kN]	u_2 [kN]	u_3 [kN]	u_4 [kN]	u_5 [kN]	u_6 [kN]	u_7 [kN]	u_8 [kN]	u_c [kN]	u_c [kPa]	u_{dim} [mm²]	$u_{c,dim}$ [kPa]	U_{qc} [kPa]

F_r: reference force; u_1: standard uncertainty, reference force; u_2: standard uncertainty, reproducibility; u_3: standard uncertainty, repeatability; u_4: standard uncertainty, resolution; u_5: standard uncertainty, zero drift; u_6: standard uncertainty, interpolation; u_7: standard uncertainty, reversibility; u_8: standard uncertainty, load transfer; u_c: combined standard uncertainty, calibration;; u_{dim}: combined standard uncertainty, cross-sectional area of cone tip; $u_{c,dim}$: combined standard uncertainty, u_c and u_{dim}; U_{qc}: expanded measurement uncertainty, calibration u_c and u_{dim}; cross-sectional area of cone tip used for calculation of uncertainties: 1024.74 mm²

The procedure and presentation of results are generally similar to those for q_c and f_s. The estimation of calibration uncertainty considers a reduced number of uncertainties.

Net area ratios a and b for the cone and the friction sleeve are also determined with the cone penetrometer in the pressure vessel. Values of a and b typically show slight pressure dependence. ISO determines these values at $u = 2$ MPa.

2.6 Temperature influence

Verification of a cone penetrometer for temperature influence requires two water-filled baths, one at a temperature of 0 °C and one at 30 °C. The baths are at atmospheric conditions. A prescribed alternating sequence applies for immersion of the cone penetrometer in the two thermostat baths. The cone penetrometer is thus subjected to induced change in ambient temperature as well as transient temperature cycling, see Figure 1. The 'measured temperature' shown in Figure 1 refers to temperature measured by a sensor in the cone penetrometer.

The verification procedure specifically allows for optional, explicit correction of force (q_c and f_s) and pressure (u) data for temperature influence. Uncorrected and corrected results must be reported for this case. For example, cone penetrometer class 1+ of ISO 22476 includes requirements for incorporation of a temperature sensor in the cone of the cone penetrometer. The temperature (T) data can then be used for correction of temperature influence on q_c, f_s and u.

Reporting of results is mainly by key performance indicators that relate variation of the parameter of interest (for example q_c) to the temperatures of the water baths and to time.
Figure 1. Example of verification data for temperature influence.

3 DISCUSSION

3.1 Use of results

ISO 22476 and ISO 19901 distinguish between (1) records of calibrations and verifications and (2) test report or calibration certificate.

The records include substantial data files, particularly as they include time-based logging files for a logging frequency of ≥ 1 Hz. The logging applies to output of each of the primary sensors of the cone penetrometer, for the durations of the various calibration and verification activities. The records are retained by the calibration laboratory. Inspection of the records can provide valuable information for quality management, particularly if the records are tracked for multiple calibrations of a single cone penetrometer and if the records are compared for multiple cone penetrometers.

A test report or calibration certificate covers a summary of the records. The summary is adequate for use in practice, i.e. understanding the performance of the cone penetrometer at the time of calibration.

3.2 Exposure conditions

Simulated exposure conditions for a cone penetrometer in the calibration laboratory will, inevitably, differ from in situ exposure conditions. Particularly, laboratory calibration and verification consider particular characteristics in isolation, see Table 1.

Laboratory checks would be challenging for assessing the potential influence of in situ exposure conditions, such as (1) ambient and induced stress conditions imposed by soil and water, (2) soil displacement relative to the cone penetrometer, (3) temperature exposure varying from freezing to, say, 60 ° C, (4) combined and variable axial (compressive and tensile), torsional and moment loading imposed on the cone penetrometer. Common combinations of these influences cannot be readily quantified in a laboratory setting. Robust design and quality monitoring of cone penetrometers remains important (e.g. Peuchen & Terwindt 2014; Peuchen et al. 2020).

ISO 22476 and ISO 19901 capture quality monitoring by means of test categories, as discussed above. This is normative. Additional (informative) guidance and recommendations are also provided.

3.3 Uncertainty calculations

The calibration requirements include prescriptive uncertainty calculations, i.e. a combination of detailed calibration procedures and detailed requirements for calculation of uncertainties. This approach allows easy comparison of cone penetrometers, regardless of manufacturer/ supplier.

The uncertainty calculation approach presented in the ISO standards includes equations that (1) follow metrological principles (ISO, 2008) and premises and (2) apply to the specified laboratory setting. One of the premises is that the standard uncertainty of the reference, for example the measurement unit for force reference, has much better uncertainty characteristics than the force sensor of the cone penetrometer. If this is not the case, then the results of uncertainty calculations can be dominated by the uncertainty of the reference and will not necessarily reflect the actual laboratory performance of the cone penetrometer. This dominating influence can apply to the top end of the cone penetrometer classes, where requirements for cone penetrometers can approach performance of commonly available reference measurement units.

3.4 Temperature stability of primary sensors

Figure 1 includes an example of temperature correction of q_c by post-processing. The approach for f_s and u would be as for cone resistance.

The case of Figure 1 is for a subtraction-type cone penetrometer equipped with strain-gauge load cells with conventional temperature compensation for ambient temperature influence. This particular cone penetrometer also includes a temperature sensor within the cone penetrometer. The acquired records of temperature (T) data versus time (t) are additional to the primary CPT parameters and at the same frequency. The correction method uses a temperature model that mathematically increases (or reduces) values of q_c. This model is penetrometer-specific and parameter-specific (in this case q_c). The temperature model relies on a polynomial best-fit of q_c and T (and their derivatives in time), derived from the data recorded in the calibration laboratory.

During cone penetration testing, T and q_c are recorded versus t. The temperature model is subsequently applied by post-processing of the complete CPT dataset, such that both uncorrected (raw data) and corrected q_c data are retained.

It can be seen from Figure 1 that significant reduction of temperature influence can be achieved in the laboratory. Robust design of a cone penetrometer and tested algorithms should also achieve significant reduction of temperature influence during actual cone penetration testing under conditions differing from those in the laboratory.

4 CONCLUSION AND RECOMMENDATIONS

The International Organization of Standardization published (draft) standards ISO/DIS 22476-1:2021 and ISO/DIS 19901-8:2021. These documents include detailed requirements for calibration and verification of piezocone penetrometers. These requirements are believed to be practical and economical, nevertheless exceed the extent of calibration activities that represents current (2022) industry practice.

It is recommended that parties supplying CPT data take note of the implications of the new requirements. Furthermore, it is recommended that parties involved in specifying CPTs take note of the

opportunities and benefits, notably by means of appropriate selection of cone penetrometer classes.

Standards tend to follow, not lead, technology developments or widespread application of a particular technology. A technology example for CPTs would be the incorporation of ancillary sensors and algorithms for reducing the influence of temperature on CPT results, now covered by the ISO standards. The resulting standardisation has influenced the cone penetrometer classes introduced in the ISO standards. In turn, the cone penetrometer classes allow easy comparison of cone penetrometers for use in practice, regardless of manufacturer/ supplier.

Long-term strength determination of frozen soils by CPT

Ivan Sokolov & Nikolay Volkov
Fugro, Russian Federation

ABSTRACT: Frozen soils show rheological behavior which results in changing mechanical properties in time under applied load. It is highly complicated to determine the long-term strength of a frozen soil. Rheological behavior of frozen soils appears in creep or stress relaxation. This paper presents a new method to measure long-term strength of frozen soils using CPT equipment named Stress Relaxation Test (SRT). Conventional tests are focused on the creep behavior by creating constant loads and measuring strains. The SRT is based on stress relaxation approach by creating constant deformations and measuring stress by a cone. Cone resistance (q_c) would give compression long-term strength, as for sleeve friction (f_s) – shear long-term strength. SRT long-term strength results can be applied directly to pile bearing capacity estimation. A comparison between such estimation and results from a full scale static pile load test is provided in the paper.

1 INTRODUCTION

1.1 *Frozen soil rheological behavior*

The frozen soil shows a rheological behavior under an excess load from structures. In order to describe the degree of rheological behavior, the long-term strength is used which is the resistance of a soil to failure in response to a long-term load application (Tsytovich, 1975). In other words, long-term soil strength corresponds to a stress at and below which no failure takes place within practically observable period of load application. Long-term strength of frozen soils is 5 to 15 times less than instantaneous strength, or resistance to rapid destruction. The key long-term strength characteristics of frozen soil are long-term compressive strength and long-term shear strength over the freezing surface (Sayles, 1968).

There are two ways to evaluate long-term soil strength. The first way is to measure deformation under applied constant load which are high enough to induce non-attenuating creep which results in failure with time or, in another words "deformation vs time". When several tests are conducted with various loads, the curve "load vs time of failure" is plotted. An asymptote of the curve is interpreted as the ultimate long-term strength.

The second way is to measure the excess stress caused by applied constant deformation. The definition of stress relaxation is given by Vyalov (Vyalov, 1986). It is a process of decrease in stress over time, which is necessary to maintain constant deformation. Stress relaxation

happens due to redistribution of elastic and plastic deformations in time. The relaxation period is one of the most important rheological parameters of frozen soils. It is important to highlight that relaxation period is much shorter (by several orders) compared to after-effect period. This is the main advantage of the proposed new method.

1.2 *S. Vyalov's logarithmic equation application for frozen soil behavior*

The strength of frozen soils decreases over time as a result of the absence of a long-term strength limit for ice, which is a permanent and important component of frozen soil. An accelerated method of testing soils for long-term strength, using a "dynamometric" apparatus shortening the test period was invented by Vyalov. The design of the apparatus provides the application of the load to a soil sample through a dynamometer with fixation of its position and recording of decreasing stress value on it. The logarithmic relaxation equation is used to process the obtained data.

Logarithmic equation of long-term strength:

$$\tau = \frac{\beta}{\ln \frac{t_p+1}{T}} \qquad (1)$$

where τ — measured cone resistance or sleeve friction in MPa; t_p— measurement time, s; β, T – the parameters are temperature and strain rate dependent (Vyalov, 1986).

2 CPT APPLICATION FOR LONG-TERM STRENGTH EVALUATION

2.1 *CPT in Stress Relaxation Test (SRT) mode*

The principle scheme of the dynamometric method is implemented in the Stress Relaxation Test (SRT) of frozen soil by CPT with stabilization. When the cone is deployed on a test depth, the load is kept applied to the soil, exceeding the value of its instantaneous strength, but when the cone penetration is paused like for a dissipation test, the cone is kept loaded (the rods are clamped) and the stress relaxation is recorded. For each individual SRT, a single value of long-term strength of frozen soil is obtained. To be more specific, for data obtained using a cone resistance sensor is the long-term compressive strength of the frozen soil, and for data obtained using a sleeve friction sensor, it is the value of the long-term shear strength. A result of the measurement is the values of the long-term strength of frozen soil were obtained at each depth of the cone SRT deployment.

An example of SRT relaxation curve provided below on Figure 1.
Figure 1. Stress relaxation curve.

During the stress relaxation test, an increase in plastic deformation occurs due to a decrease in the part of elastic deformation keeping the constant value of the total deformation. The proportion change causes the stress relaxation. To evaluate the value of the long-term strength of the soil, the SRT should be performed until a certain point of stress reduction in the sensor, which presents in the stage II of the relaxation curve, Figure 1. In stage I of the relaxation curve, the cone freezes into the soil after penetration pause starts. At this stage besides relaxation some creep happens and contributes some inconsistency to the measured curve. Then the stage II starts when creep contribution is negligible and the curve starts to follow the equation (1) (Sokolov, 2020).

2.2 *SRT data processing*

To process the SRT results, measurements of stress relaxation at each cone deployment depth are taken into account and processed using the long-term strength equation (1), reduced to the form y = kx+b.

$$\frac{1}{\sigma} = \frac{1}{\beta} \cdot \ln(t_p + 1) - \frac{1}{\beta} \cdot \ln T \qquad (2)$$

where $y = \frac{1}{\sigma}; x = \cdot \ln(t_p + 1); k = \frac{1}{\beta}; b = -\frac{1}{\beta} \cdot \ln T$

Figure 2 illustrates processing linearized cone resistance data for a SRT. The value of the reliability of the linear approximation of the data in this case is 0.997.
Figure 2. Example of SRT data linearization.

Based on the obtained coefficients k = 0.0125 and b = 0.025, the coefficients β = 80, T = 0.139 and the equation of long-term compressive strength is defined:

$$\sigma_c(t) = \frac{80}{\ln \frac{t_p+1}{0.139}} \qquad (3)$$

where σ_c — interpreted as the compressive long-term strength of the soil.

Equation (3) allows to calculate a long-term strength value for any period of time. For instance, for 10 days σ_c = 5.1 MPa and for 100 years σ_c = 3.4 MPa.

Similarly, based on the sleeve friction sensor data, the obtained value is interpreted as the shear long-term strength of frozen soil.

It is important to set the frame of applicability of Equation (2). The stress relaxation measurements under the tip of the cone were obtained. Successful completion of the test is reached upon condition of the stage II of the relaxation curve is met. The same situation was observed for the sleeve friction sensor. It is assumed that, on the stage I, the cone freezes into the ground, and only after that rheological behavior can be clearly observed on the data, which represents in data curves (q_c and f_s) following the Equation (2).

The field data quality assessment is required to check the applicability of the field data, i.e. if the stage 2 was reached during the test. The field data acquisition software was developed with continuous analysis array of the obtained data using Equation (2). After the stress relaxation test starts, Equation (2) is applied for an interval of the relaxation curve. In the example on Figure 3a, an interval of 100 seconds is used for calculation. The data of 600-700 seconds interval has automatically processed to calculate β, T factors (Figure 3b).
Figure 3. Field iteration processing of the SRT data.

Next, the equation of the long-term strength is derived, as shown above for the formula (3), and the soil long-term strength (σ) is calculated for lifetime period t_p = 100 years in seconds. Figure 3c shows values for 100 years (red asterisk), also shows values for 10 days (red square) at the end part of the relaxation curve 600-700 seconds.

This algorithm can be applied to calculate the long-term strength for any part of the collected data. Six previous iterations were performed correspondingly for the sections of the curve for the 1-100 seconds (the First iteration), for the 100-200 seconds (the Second iteration), etc. and displayed in blue, respectively (Figure 3c). Figure 3c shows that, the calculated long-term soil strength values are consistent started from period 400 seconds, and they are equal to 3.4 MPa for lifetime period t_p = 100 years and 5.1 MPa for the lifetime period t_p = 10 days.

Figure 3a shows slow decreasing of the stress value in the sensor, we suggest that the stress relaxation curve had to reach the stage II starting from 400 second of the test, and follows Equation (3).

Figure 3 illustrates just 7 iterations of the field QA approach, but the data acquisition software adds a new long-term soil strength value every new record of the stress in the sensor (Sokolov, 2020).

3 FIELD DATA APPLICATION

3.1 Pile bearing capacity calculation

The pile bearing capacity (PBC) calculation is based on the long-term soil strength data. The calculation is based on a similar conventional approach, the sequential summation of the values of end bearing and side friction. The difference is that the developed calculation does not use any empirical factors. The calculation is made according to the formula:

$$F_{ui} = \sigma_c \cdot A + \sum \sigma_s \cdot A_{af,i} \qquad (4)$$

where σ_c – average compression long-term soil strength; A — pile area; σ_s — average shear long-term soil strength; $A_{af,i}$ — unit side area of the pile.

The calculation is performed for the recorded values of σ_c and σ_s for each measurement of stress relaxation test. The test-time interval t_p is set as 10 days, in the case of a full-scale pile test under a static load, and the life-time interval t_p is 100 years to evaluate the ultimate long-term pile bearing capacity.

Construction site nearby Salekhard was selected to confirm the SRT based results and PBC calculation in frozen soils. On this site, full-scale static pile load tests (SPLT) were carried out. SRT was performed near the tested pile within 2 meter distance (Volkov et al, 2019).

SPLT was conducted in accordance with GOST 5686-2012. The load was applied in 10 steps, each step lasted 1 day and was equal 5 or 10 tons. The last step lasted for 24 hours was F_H = 55 tons, the next step F_H = 60 tons caused pile failure. GOST 20522-2012 provides equation (5) to calculation the ultimate long-term pile bearing capacity:

$$F_H^H = 0.65 \cdot F_H \qquad (5)$$

where $F_H{}^H$ – ultimate long-term pile bearing capacity; F_H – step load at which the pile failure occurred.

Comparison of PBC calculation results based on SRT with the results on SPLT in frozen ground provided in the Table 1.

The bearing capacity of a driven pile with length of 10.6 m in frozen soil with a time interval of 10 days is about 66 tons (663 kN), and the pile failure occurred at load step of 60 tons. The SRT value differs by 10% from SPLT value. These are very close results. In turn, the calculated SPLT value for 100

Table 1. Comparison of PBC calculation results based on SRT and SPLT.

Time period	10 days SRT	SPLT	100 years SRT	SPLT
End bearing	446*	—	292	—
Side friction	217	—	117	—
Ultimate	663	550-600	409	357-390

* All values are in kN.

years is equal to 39 tons and the calculated SRT value is about 41 tons (409 kN). The obtained results for 100 years correlate to each other relatively good as well.

3.2 *Long-term strength for various soils*

The results of σ_c and σ_s measurements were collected from the various sites in Russia where permafrost ground was encountered (Sokolov, 2020). The results were classified with different soil types and averaged to a single value. This allowed to compare them with the recommended values which are commonly used to verify the design values, in particular, R – pile unit end bearing, R_{af} – pile unit side friction (Aksenov, 2001). The comparison of the values is presented in Table 2.

Table 2. Comparison between long-term soil strength measured by SRT (σ_c and σ_s) and recommended values for pile unit end bearing (R) and pile unit side friction (R_{af}).

Soil type	Ice content	σ_c kPa	R kPa	σ_s kPa	R_{af} kPa
Lean clay	None	2430	900-1100	69	40-100
	Low	1335	800-950	35	40-100
	Medium	707	400-550	19	40-60
	Rich	517	400-550	21	40-60
Silty clay	None	2228	750-1050	114	40-60
	Low	2179	850-1050	53	40-60
Silty sand	Low	1963	1000-1800	23	50-130
Fine sand	Low	4584	1000-1700	63	50-80
Medium sand	Low	6977	1500	171	50

The results clearly show the influence of the ice content. In lean clay and silty clay σ_c and σ_s decrease if the ice content increases, so as the recommended R and R_{af}. This tendency is confirmed by theoretical studies of the ice content influence on the mechanical properties of the frozen soils.

The influence of the grain size if other conditions being equal, can also be observed for silty, fine and medium sands. An increase of coarse particles gives more resistance to both compression and shear.

4 CONCLUSIONS

Stress Relaxation Test (SRT) of frozen soil by CPT with stabilization was developed based on an accelerated laboratory method of testing soils for long-term strength, using a principle of the "dynamometric" apparatus invented by Vyalov. The logarithmic relaxation equation is used to process the field data.

SRT provides individual values of the long-term strength for frozen ground at a certain depth. Data obtained using a cone resistance sensor is interpreted as long-term compressive strength of the frozen soil (σ_c), and data from sleeve friction sensor – the long-term shear strength (σ_s).

The results on σ_c and σ_s are applicable for calculation of pile bearing capacity in the frozen soil without empirical factors.

The results of σ_c and σ_s on the various sites showed consistency and good relation with the recommended values for pile unit end bearing and pile unit side friction.

Efficiency examined of hands-free Cone Penetration Testing using the SingleTwist™ with COSON

O. Storteboom & M. Woollard
A.P. van den Berg, Heerenveen, The Netherlands

J. Verhagen
GWR Ingenieursbureau, Rotterdam, The Netherlands

ABSTRACT: The Cone Penetration Test (CPT) cabin as working environment, built on trucks, crawlers or Track-Trucks®, will more and more develop from a workshop into an office. Before, operators were mainly dealing with manual operations to keep the production going. Nowadays and in the future, it can be increasingly expected that time "on board" will be spend on design or other office-related work next to performing CPTs. This paper describes a system that has been designed to support this market development. By integrating the patented SingleTwist™ technology in a CPT cabin with the COSON continuous pushing system, an automatic and hands-free CPT machine is created. The assembly and disassembly of the CPT string takes place fully automatically. This paper describes the efficiency of the SingleTwist™ technology. The City of Rotterdam, the first owner of a Track-Truck with COSON-ST, deployed their system in different projects. One project is chosen to further elaborate on its advantages and experience in practice.

1 INTRODUCTION

Changing requirements and regulations are spurring continuous development of CPT systems. The need for increasing operational efficiency requires systems that can start up more quickly and run without further intervention or control. These systems are expected to have a simple human-machine-interface to monitor the process and receive system alerts in the event of imminent quality loss or maintenance requirements on the equipment or data acquisition system. These expectations focus on obtaining better CPT data, performed in a shorter time and with less effort. Smart and dedicated technology is required to meet these needs. A combination of digital data processing, an accurate system feedback and a simple and robust design delivering excellent quality, safety, long service life and easy maintenance is needed to face the increasing demands.

The answer is "back-to-basics". The CPT rod, the most simple and robust part of the CPT system, has become the core of a new development. The CPT rod is the connecting link between the measuring cone and the pushing system. More than 90 percent of the time required for a cone penetration test consists of handling the CPT rods. Far reaching efficiency improvements can be found in a creative approach towards these rods. This paper presents the SingleTwist (ST)-technology as the result of such a creative design process. The introduction of this new technology is preceded by an overview of pushing systems developed over time and is concluded with a description of a practical application. This new insight will ensure a changing working environment inside the CPT cabin: a shift from operator to engineer or from manual to hands-free operations and from manual labor to data processing, assessments and design work.

2 DEVELOPMENT OF CPT PUSHING SYSTEMS

To performing a CPT soil investigation, it is necessary to push a measuring cone into the soil over time. We can see that the development of pushing systems has kept pace with that of measuring cones. The first systems used in the 1930s were suitable for testing with mechanical cones. The power source used was often the operator's muscle strength, a jack was used for power transmission and the maximum pushing force was limited to 50 kN. With the arrival of the electrical cone in the 1950s, higher demands were also placed on the pushing device. Soil investigation at larger depths required higher pushing forces. A continuous speed also became important and an electrical connection to the cone was required to show measurement data in real time. Due to increasing demands for comfort, the pushing device had to be set up in a closed and conditioned cabin.

The following subsections describe the pushing systems developed at A.P. van den Berg for onshore and offshore soil investigation. The specific A.P. van den Berg trade names are indicated in brackets.

2.1 Onshore CPT pushing systems

The range of pushing systems varies from a single lightweight pushing cylinder for hand carried CPT solutions to heavy duty pushing devices built on trucks and on large crawlers.

2.1.1 Light weight systems

Lightweight CPT systems (HYSON LW) are very suitable for installation in hand carried applications and on light vehicles such as mini crawlers. The pushing system has a single hydraulic cylinder with a maximum pushing capacity of 100 kN. Due to its low weight and small size, it can easily be applied in basements, back yards and on dikes.

Figure 1. HYSON 100 kN in Mini CPT Crawler (left) and Track-Truck with HYSON 200 kN inside the cabin (right).

2.1.2 Heavy duty systems

Heavy-duty CPT pushing systems (HYSON) are very suitable for installation on crawlers (Figure 1) or inside the CPT cabin of a truck or a truck with tracks (Track-Truck®). Stand-alone CPT systems mounted on a frame can be used as a skid system onshore or on a barge or jack-up rig for near-shore applications. The pushing system has two cooperating hydraulic cylinders, which are interconnected by an upper and a lower beam. A maximum pushing capacity of 300 kN is feasible, but it is often limited to 200 kN.
Figure 2. COSON (left) and AUTOCOSON (right) 200 kN inside cabin in CPT vehicle.

2.1.3 Heavy duty continuous systems

The continuous CPT system (COSON, Figure 2) is a further development of the above-described systems with intermittent stroke. In fact, it is a dual pushing system, built on top of each other. This pushing system is equipped with four cooperating hydraulic cylinders, provided with two independently moving hydraulic clamps. This allows a continuous movement of the CPT string when pushed into the soil. The maximum pushing capacity is often limited to 200 kN.

2.2 Heavy duty automatic systems

The continuous CPT system as described above was very suitable for a further automation of the handling of CPT rods (AUTOCOSON, Figure 2). This system consists of a continuous CPT system supplemented with a carrousel system that automatically feeds the CPT rods. The cable for data transfer was replaced by light conductors inside the CPT rods for wireless data transfer (Optocone). The automatic pushing system can run a full cone penetration test without intervention of the operator. As a result, the tasks of the operator shift to monitoring and administrative work. In fact, a part of the office work can be prepared or even performed in the CPT cabin.

2.3 Offshore CPT pushing systems

Unlike onshore pushing systems which are used on land or above the water surface, offshore pushing systems are intended to operate under the water level. This imposes special demands on the equipment towards reliability and durability and use of material that are suitable for marine conditions. In offshore CPT systems we can distinguish between wireline systems for use in drill pipes, and seabed systems for performing a CPT from the seabed. Both systems require specific facilities on board of a ship.

3 PATENTED SINGLE TWIST™ (ST) TECHNOLOGY

The fact that being involved with onshore as well as offshore developments can foster cross-fertilization is proven by the development of the SingleTwist (ST) technology. Initially, the ST-technology was developed for the ROSON seabed CPT system. By incorporating the patented folding ST-rods in the seabed system, a compact, safe and easy to handle ROSON-ST is created. Later it turned out that this technology is also suitable for onshore CPT, which has resulted in the development of the COSON-ST. By integrating the patented ST-technology in a CPT cabin with the COSON continuous pushing system, an automatic and hands-free CPT machine is created.
Figure 3. ROSON-ST seabed CPT system.

3.1 *ST-rods: The foldable CPT string*

The ST-rod is the smart element that makes up the CPT string. In the next subsections the interconnection of the ST-rods, the transfer of measurement data through the ST-rods and the storage of ST-rods on the Folder are described more in detail (Figure 4).

Figure 4. Folder (left), storage of the ST-rods, Twister (middle), to connect the ST-rods.and data transfer (right).

3.2 *ST-rod connection*

By using a multiple bayonet thread, a strong and reliable connection has been invented that can be quickly fastened and loosened. The most striking external characteristic of the ST-rod connection are three separate threaded areas. Each of these areas covers 1/6th of the circumference of the rod, so that the inner thread of the female part can be directly aligned with the outer thread of the male part. This important feature of a bayonet coupling makes it possible to fix the connection with a very short 1/6 turn. The seven thread runs in combination with the high quality hardened SS material ensure a strong connection with a maximum holding force of 420 kN. At the front end of both the male and female threads a slope is provided, so that the rods slide into each other easily. The optimal design has been obtained with computer-

aided design, strength calculations according to the finite element method and computer aided manufacturing. The theoretical specifications have been confirmed with exhaustive laboratory and field tests.

3.2.1 *ST-rod data transfer*
A CPT rod not only ensures the transfer of the pushing and pulling force, but also the transfer of data. Most common is a connection between cone and data logger by means of a cable. A cable is very reliable, has a large bandwidth for data transfer, can be applied both onshore and offshore, and requires no further supporting equipment. However, the cable is vulnerable especially at rod connections, which must be taken into account particularly when used in automated systems.

The light conductor is a proven technology in CPT and a good option for data transfer. There is no continuous cable running through the rods, which makes handling a lot easier. This is a useful feature especially in automated systems. However, data transfer with light conduction has a limited bandwidth and is not very suitable for an offshore environment.

For data transfer in the ST-system it was decided to use a 4-core flexible cable with a small diameter. Because only digital cones are used, the number of cores can be limited to four. The requirement for applying ST-technology offshore was an important consideration for choosing this cable. To protect the cable it is fully integrated into the ST-rods and the intermediate ball joints at the rod connections. This minimizes the risk of damage. Furthermore, the cable must be able to compensate for the change in length during assembly and release of the ST-rods. This has been solved by using a flexible spiral cable.

3.2.2 *ST-rod storage and maintenance*
The foldable ST-string is stored on a reel called the ST-Folder as shown in Figure 4. The Folder has a diameter of 2 m and is provided with spacers at the circumference. This allows the ST-rods to be precisely positioned in 13 rows. The total storage capacity of the Folder is an ST string of maximum 70 m length. To easily reel up the string, the ST-rods have a length of 350 mm. The Folder is powered by an electric motor. This motor is electronically coupled to the Sprocket wheel, which feeds the ST-string to the pushing system. In this way, the Folder keeps pace with the movements of the pusher. To perform mainte-nance, the foldable string can be replaced completely or par-tially. The foldable string is made up of 2.8 m sections that contain eight ST-rods. Connectors on both ends of the cable inside a section allow for the electrical connection between sections.

3.3 *Twister on continuous pushing system*

The Twister (Figure 4) realizes the transition of the foldable ST-string into a solid CPT string. The Twister is mounted on the upper beam of the continuous pusher system (COSON). Both are described in following subsections.

3.3.1 Twister

The purpose of the Twister is to connect and disconnect the ST-rods. Therefore, the Twister is arranged on top of the upper beam of the pusher. The rod to be tightened is hydraulically clamped by the Twister. The other rod that is already part of the CPT string is held by the COSON clamp of the upper beam. As soon as the rods are correctly positioned, an electrically driven rotation of the Twister follows, providing a maximum torque of 350 Nm. To ensure a good connection between two tightened rods, the Twister checks both the rotation angle and the torque. At least an angle of 50° and a torque of 250 Nm must have been reached. The angle and torque are also an indication of the thread quality. If the angle becomes larger in combination with a lower torque, this may indicate wear of the thread.
Figure 5. Continuous pushing system (left) and Sprocket, wheel for connection (right).

3.3.2 Continuous pushing system

The continuous pushing system (COSON, Figure 5) is used in the ST-concept, because by using the continuous pusher the Folder can also move continuously, which is an easier process to control adding and removing rods. Furthermore, the small installation height provides sufficient room for a Sprocket wheel on top, without special roof requirements. Finally, the rod length of 350 mm is chosen to match the stroke of the continuous pusher, so each rod is clamped and (un)tightened at the same position by the Twister. The COSON continuous pushing system is a proven technology with a track record of more than 20 years.

3.4 Sprocket wheel for connection

The Sprocket (Figure 5) is the connecting link between the Folder and the Twister. It ensures the correct position of the ST-rods in relation to the Twister. It also ensures the correct feeding speed, so that a smooth cooperation between Folder and Twister is guaranteed. Furthermore, the Sprocket ensures that the rods are pushed together in order to twist them properly. In addition, vice versa that the rods are pulled apart directly after they have been loosened.

3.4.1 Correct positioning, constant speed and smooth twisting of ST-rods

The electrically driven Sprocket is mounted on the static part of the pusher. There are six guiding blocks on the sprocket that precisely position the rods.

Because the Sprocket exerts a constant push or pull load on the string, the average Sprocket rotation speed is exactly the same as the pusher speed. During a CPT the pusher moves at a continuous speed of 15 to 25 mm/sec. During retraction, this movement is non-continuous with an average speed of 70 mm/sec.

For tightening the bayonet coupling of the ST-rods, it is necessary that the seven thread runs are exactly opposite to each other. This is achieved by the constant push load of the Sprocket. The rods to be tightened are pushed together, so a connection is established properly.

3.5 Operation and HMI

The ST-system enables a fully automatic and hands-free CPT cycle. The operator just has to bring the ST-system to the correct condition to start or continue a cycle. This is done with the clear push/pull and speed symbols on the left side of the screen (Figure 6). After positioning, the cycle is started with just one push on the start button. The effect of an action is made visible within this image of the system on the right side of the screen, by changing colours or moving component parts. All movements of the different clamps, the pusher, Twister, Sprocket and Folder can be operated separately. Important process variables are continuously displayed, such as the CPT speed, the angle and torque of tightening rods, the angular position of the sprocket wheel and the oil pressure and temperature. Furthermore, it is possible to set alarm values for the maximum reachable total push load and inclination of the cone.
Figure 6. Touch screen for operation and real time presentation CPT data.

4 PRACTICAL APPLICATION

The VLG, the Engineering Department of the City of Rotterdam procured the first COSON-ST pushing system built on a Track Truck. Since

early 2019 the company in the Netherlands has used this CPT system successfully in various projects. For example the company executed more than 300 CPTs on projects in Amsterdam and 32 CPTs and 30 magneto measurements with the Icone Magneto click-on module on a project in Rozenburg (the Netherlands). Their typical workday is filled with two to eight CPTs at multiple locations. One project was selected to share as typical example in the following sections.

Compared with more traditional CPT systems, the VLG confirms that the COSON-ST automated system has removed the causes for physical strain. The operators do not have to lift, guide and screw CPT rods anymore. Secondly, the ST-system is timesaving. Preparation takes less time, as there is no need to raise a hatch and to place an end set including inner casing. The operator just has to prepare and install the Icone. The timesaving in the CPT cycle is mainly achieved during pulling. It is proven that a complete 50 m CPT can be performed approximately ten minutes faster with the COSON-ST with two hydraulic clamps than with the HYSON with one clamp. On top of that, after one push on the button, the operators 'hands are free to prepare the next test or perform other (engineering) activities. With the application of thicker CPT rods, 40 mm instead of 36 mm, the risk of buckling and breaking is much smaller and that provides the VLG with a lot of confidence. The company has regularly pushed with a total force of more than 15 tons without any problems, whereas with previous CPT systems the VLG was already on guard with respect to breakage at lower pushing forces. Due to these rods, the time-consuming use of casing for lateral support is also required less often. This all results in an average production of 10 CPTs of 40 m in a working day at one project location. On longer days with favorable conditions, the company has even reached 17 of these CPTs. The maximum CPT depth of 70 m with VLG's CPT string size has also been realized.

The selected project concerned the geotechnical investigation required for the design of new bridges that are part of the Polder path in Schiebroekse polder in Rotterdam, The Netherlands. This is a cycle link between the city of Rotterdam and the Schie nature reserve. Eight CPTs were performed.

4.1 Purpose investigation bridges polder path

The main purpose of performing Cone Penetration Tests was to calculate the load capacity for prefab concrete piles, for the determination of the pile lengths and to indicate the preconditions required to prevent the potential bursting.

4.2 Equipment used

The VLG uses the Track-Truck with COSON-ST as a standard in order to execute CPTs, because the

Figure 7. Track-Truck with COSON-ST in the cabin.

working environment is ergonomically optimized and the production rate is increased by at least 10%. In order to build new bridges (part of the Polder path in Schiebroekse polder) in Rotterdam, the CPTs were performed with the Track-Truck with COSON-ST (20 ton CPT truck with tracks) as well. A Track-Truck can run on the highway as an ordinary truck with its tracks retracted. After lowering the tracks, the Track-Truck does not get stuck in soft and hilly terrain such as the location where the new bridges will be built. Inside the cabin of the Track-Truck the COSON-ST pushing system is integrated. This matches with the safety, physical load and efficiency requirements of the VLG, the Engineering practice of the City of Rotterdam. A digital 15 cm² piezocone (Icone) was used as the measuring instrument. The modules Seismic, Conductivity, Magneto and Vane could be used along with the Icone, but additional parameters were not requested in this project.

4.3 Test method

The bearing capacity of the piles has been determined with the help of a D-foundation computer program. The pile point level must be chosen in such a way that the requirements of the NEN EN 9997-1 +C2:2017 Geotechnical design are met. The piles are calculated for pressure load.

4.4 Test results

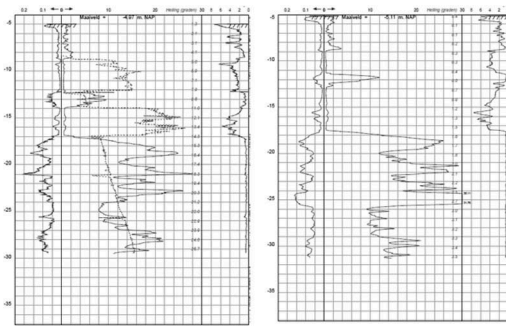
The CPTs performed with the COSON-ST and 15 cm² Icone for the design of new bridges part of the Polder path in Schiebroekse polder in Rotterdam, The Netherlands, gave a good image of the soil for the foundation advice. An aquifer was found at circa 12 m depth with the 6th and 7th Cone Penetration Test (Figure 8). In this respect, the risk for the development of wells, when digging in the (unfavorable) area at two bridges, has been checked. This check indicates that there is no bursting risk of the soil when excavating for the abutments of these two bridges. The CPTs are used to calculate the bearing capacity of precast concrete piles for a pile level at a depth of 20 m. Of these indicative calculations is the D-Foundations output included in Figure 9.


Figure 8. Left: CPT nr. 6 including pore water pressure: showing an aquifer between clay layers at 12 m depth. Right: CPT nr. 7 without pore water pressure: showing an aquifer between clay layers at 12 m depth.
Figure 9. Output D-Foundations indicative calculations piles bearing capacity.

5 CONCLUSIONS

Cone Penetration Testing (CPT) is a recognized and widespread method for efficiently performing in-situ soil surveys, for e.g. foundation advice. Over time, CPT has been improved by integrating digital electronics inside the measuring cone. In addition, the pushing system needed upgrades, because soil investigation is carried out at increasing depths, which requires higher pushing forces. In addition, developments have also focused on operational efficiency and an ergonomically optimized work environment. The CPT cabin as working environment, built on trucks, crawlers or Track-Trucks, will more and more develop from a workshop into an office. The most prominent development is the ability to perform automatic and hands-free CPTs using the patented Single-Twist™- technology with the COSON pushing system. With a single push of the button, the automatic CPT cycle is completed. The CPT string, with the measuring instrument (cone) fitted at the tip, is pushed into the soil in one continuous movement. This string is built up automatically from a reel with separate, but interconnected, ST-rods.

The so-called COSON-ST has proven to be a robust CPT pushing system providing reliable data about the soil and ensuring the operational efficiency, which is increasingly expected. The COSON-ST has more than proven itself and the VLG feels confident to let the system do its work. VLG experienced a production rate increase of at least 10%. The system works faster than standard CPT pushers, as it can start up more quickly and runs without further intervention or control. It does not require any manpower during the push/pull cycle of a CPT. The operator only has to provide the start/stop signals. Another advantage, which is proven according to VLG, is that the working environment is ergonomically optimized, because manual actions near the moving system are almost unnecessary. Indeed time "on board" is spent on design or other office-related work next to performing CPTs. An additional advantage of the COSON-ST is that the depth range is increased because of the continuous CPT push. CPTs are realized faster and in addition to the already shorter preparation time, this continuous movement results in a faster pushing and pulling process with a higher production rate as a consequence. Furthermore, the ST-rod is designed in such a way that the risk of breakage and the associated downtime and costs are limited.

Based on the input from VLG we can conclude that the COSON-ST is a welcome contribution to the expected change of the working environment inside the CPT cabin. A shift from operator to engineer and from manual operation to data processing and assessment will occur.

In addition to the onshore application described in this paper, the ST-technology can also be used offshore. The ROSON-ST is immediately operational and can perform a CPT fully automatically from the seabed in a very safe and timesaving way.

Sustainability in CPT practice: Hybrid CPT Track-Truck

O. Storteboom & M. Woollard
A.P. van den Berg, Heerenveen, The Netherlands

B. Ooms
BAM Infra Nederland, Gouda, The Netherlands

ABSTRACT: Sustainability in construction is of great importance in government projects, but also of growing concern in the market in general. In this way, earth can be passed on to future generations in a healthy way. A sustainable realization of construction projects, within strict environmental standards, is the reason for companies to invest in electrification of equipment, so without carbon and nitrogen emissions. In terms of CPT, BAM Infra Nederland has taken the world's first hybrid truck with tracks into use early 2021. The heavy 4x4 truck is, while at the project location, electrically powered without emitting harmful substances such as carbon and nitrogen emissions. Both the CPT soil investigation and driving on the tracks are executed completely electrically. On the road, the truck is powered by the usual diesel engine. BAM Infra Nederland has now used the hybrid CPT Track-Truck for various projects. In the paper, experiences from practice are further elaborated and explained.

1 INTRODUCTION

Rising prices of fossil fuels, increasing scarcity of crude oil, and government regulations and policies against diesel and gasoline powered vehicles owing to surging pollution are major factors changing the preference toward alternative fuel powered vehicles. This is a factor boosting the hybrid truck market during the coming years. Moreover, evidence suggests that road transport accounts for more than 50% of the total health impact of air pollution caused due to emissions of harmful gases from vehicles. This is prompting governments and car manufacturers to design and develop alternative solutions to curb transportation emissions. This has led to the development of hybrid technology for automotive, which unlike conventional vehicles, does not consume a large amount of fuel and emits less carbon. Furthermore, increasing automation and usage of machinery to simplify manual work in various industries such as construction, agriculture transportation, mining, and infrastructure, have fuelled the application of hybrid trucks in these sectors. However, the high initial and maintenance costs of hybrid trucks is anticipated to restrain the hybrid truck market (Automotive Team, Hybrid Truck Market, Forecast 2019 -2027). Besides this development, companies more and more want to invest in sustainability.

Towards the CPT market there is more and more a need for sustainable equipment. The hybrid truck with tracks meets this need by performing CPT soil investigation in a sustainable way. In the next paragraphs the development of onshore CPT pushing systems are described briefly. In paragraph 3 the hybrid Track-Truck is explained and in paragraph 4 experiences from practice are further elaborated.

2 DEVELOPMENT OF ONSHORE CPT PUSHING SYSTEMS

Nowadays, the range of onshore CPT pushing systems varies from a single lightweight pushing cylinder for hand carried CPT solutions to heavy duty pushing devices built on trucks and on large crawlers. With regard to the heavy duty pushing devices the importance of sustainability is increasing

2.1 *Lightweight CPT systems*

Lightweight CPT systems (Figure 1) are very suitable for installation in hand carried applications and on light vehicles such as mini crawlers. The lightweight pushing system has a compact size (165×310 mm without anchors) and low weight (only 85 kg) in combination with sufficient pushing capacity to perform a reliable CPT. The 100 kN lightweight pusher is designed to perform in-situ geotechnical soil investigations at locations inaccessible to other equipment, such as basements, back yards, swampy and overgrown land.

Figure 1. Lightweight CPT system (100 kN pusher).

Figure 2. 100 kN pusher in mini CPT crawler.

Figure 3. Truck-Truck with 200 kN pusher inside the cabin.

2.2 *Heavy duty systems*

Heavy-duty CPT pushing systems are suitable for installation on crawlers or inside the CPT cabin of a truck or a truck with tracks.

The CPT Crawlers (Figure 2) have tracks for better manoeuvrability in rough or soft terrain. The crawler is the only option at sites where the maximum allowed height is limited. Separate carriage is required for transport of the crawler. The truck with tracks (Figure 3) is suitable for soft and hilly terrain where other heavy vehicles get stuck (for more information, see paragraph 3.1).

Stand-alone CPT systems mounted on a frame can be used as a skid system onshore or on a barge or jack-up rig for near-shore applications. The pushing system has two cooperating hydraulic cylinders, which are interconnected by an upper and a lower beam. A maximum pushing capacity of 300 kN is feasible, but in many cases for reasons of maximum vehicle weights, this is limited to 200 kN.

The heavy duty pushing system is powered by the truck PTO or a separate power pack. Hybrid systems with electrical mode are available since the beginning of 2021.

2.3 *Heavy duty continuous systems*

The continuous CPT system (Figure 8) is a further development of the above-described systems with intermittent stroke. In fact, it is a dual pushing system, built on top of each other. This pushing system is equipped with four cooperating hydraulic cylinders, provided with two independently moving hydraulic clamps. This allows a continuous movement of the CPT string when pushed into the soil. The maximum pushing capacity is often limited to 200 kN.

The continuous pushing system is able to handle 1.000 mm CPT rods. Because of the continuous movement of the CPT string, the cohesion with the surrounding soil is less, so a greater penetration depth can be achieved with the same pushing force.

2.4 *Heavy duty automatic systems*

The continuous CPT system as described above was very suitable for a further automation of the handling of CPT rods. This system consists of a continuous CPT system supplemented with a carrousel system that automatically feeds the CPT rods. The cable for data transfer was replaced by light conductors inside the CPT rods for wireless data transfer.

By integrating the patented ST-technology into a CPT cabin with the continuous pushing system, a fast CPT machine for hands-free operations is created (Storteboom O. et al, 2022). On the vehicle, the workplace of the CPT operator is turning into an office environment. The assembly and disassembly of the CPT string takes place fully automatically with a continuous CPT pusher. The working environment is ergonomically optimized, because less machine work needs to be done. On average the production rate is increased by 20% compared to a standard CPT pusher.

Figure 4. Automatic CPT System.

Figure 5. Small fuel (diesel) tank in the hybrid truck.

3 HYBRID TRACK-TRUCK

3.1 CPT Truck with tracks (Track-Truck)

The Track-Truck was invented by A.P. van den Berg and has a record of accomplishment of more than 30 years. With its tracks retracted, the Track-Truck can run on the highway as an ordinary truck. After lowering the tracks, the Track-Truck is in its element in soft and hilly terrain where other heavy vehicles are stuck. The track system reduces the wheel load by 60 to 70%. Manoeuvring the Track-Truck is performed from the driver's cabin or with a remote control from a safe distance. The penetrometer is easily operated via the touch screen, the clear Human-Machine Interface (HMI). A maximum pushing capacity of 200 kN, enables any soil investigation using the cone penetration method.

3.2 Hybrid system

The hybrid truck with tracks integrates a combination of a traditional internal combustion engine system along with fuel tanks (Figure 5) and an electric propulsion system, which constitutes of an electric motor and battery pack. The 4×4 truck serves as a basis for the truck to which the hybrid part was added.

4 PRACTICAL APPLICATION

BAM Infra Nederland, part of Royal BAM Group, is a leading player in the Netherlands in the field of infrastructure. As a leading company, BAM has formulated ambitious goals in the field of sustainability. These objectives are concentrated around minimizing emissions (up to zero emissions), reducing the use of primary raw materials, the use of renewable energy and encouraging circular construction.

BAM wants to build emission-free. In the field of equipment, BAM is looking for emission-free alternatives. BAM already introduced the world's first electric roller. Beginning of 2021 the hybrid CPT truck on tracks was added to the sustainable fleet (Figure 6).

4.1 Minimizing emissions

Conducting soil investigation by a diesel-powered truck on tracks means that the diesel engine must be running to provide power to all drive systems and the CPT measuring system. Although these systems require little power, the diesel engine continuously emits combustion gasses and noise. In urban areas, this is more and more intolerable and limited by strict environmental requirements.

These restrictive conditions open up an opportunity by making soil investigation possible with targeted adjustments. To silence the diesel engine, another energy source must be available. An energy source that is clean at the point of use and produces virtually no noise emission. The most obvious choice is the use of an electro motor capable of driving the hydraulic pumps. Together with a battery pack with sufficient storage capacity for a full day of soil probing, completes this solution.

4.2 New generation CPT Track-Truck

A.P. van den Berg was approached by BAM Infra Nederland to develop a CPT Track-Truck as sustainable as possible. The solution is a hybrid variant. The heavy 4×4 truck moves over the road with a clean diesel engine that meets the highest emission requirements. On location, it is electrically powered to carry out soil investigations without emitting harmful substances such as carbon and nitrogen. In addition, the hybrid Track-Truck does its heavy work in a quiet way.

The hybrid system offers the possibility to conduct CPT soil investigations completely emission-free. The Track-Truck is equipped with a 90 kW electric motor that drives a second pump set.

Figure 6. Hybrid CPT Track-Truck.

The pump set provides hydraulic pressure to drive the tracks and to perform the CPT soil investigation. The electric motor is powered by a battery pack with a capacity of 70 kWh. This power is sufficient to perform 9 medium CPTs with a CPT depth of 25 meters and to drive the Track-Truck on the tracks for about 60 minutes. On site it is possible to change the power source for the drive from diesel to electric. With electric drive, the diesel engine can be switched off. In some cases the electric drive is stopped, then the diesel engine will start and automatically switch from electric to diesel. This transition is so smooth that the driven process is not affected by this. If no power is drawn during electric drive, the electric motor switches to an energy-saving mode, where the speed is reduced to 500 rpm. As soon as power is required, the electric motor revs up and energy is almost immediately available. If no power is drawn for a longer period of time, the electric motor switches off manually to save energy. The batteries for the hybrid system (see Figure 11) can be charged at a charging station or with a 3-phase connection with a maximum power of 22 kW. In order to fully charge the battery four to five hours is required. In addition, a small fuel tank is installed in order to drive from and to locations.

Figure 7. Digital cone.

Figure 8. 200 kN continuous pushing system inside cabin of hybrid CPT vehicle.

4.3 *Equipment used*

The digital cone (Figure 7) measures the four standard parameters: cone tip resistance (qc), sleeve friction (fs), pore water pressure (u) and inclination (Ix/y). The digital cone is mechanically 40% stronger than its analogue predecessor and is at the same time more accurate, more reliable and easier to maintain. Calibration data is stored in the cone itself, so separate data holders such as USB sticks are no longer necessary. Digital cones come with a pre-pressure and seal assembly that reduces cone maintenance.

The continuous pushing system is an advanced CPT system for performing CPTs for soil research. The continuous pushing system is able to push a CPT probe into the soil with a continuous movement and with a maximum capacity of 200 kN (Figure 8). The truck on tracks is a standard 4x4 truck with tracks between the front and rear axle. This provides the Track-Truck with a large load capacity for moving on soft subsoil. The Track-Truck is equipped with a hybrid drive. This means that all functions, except truck driving, can be powered by the diesel engine of the truck or by an electric motor. The electric motor is powered by a battery pack with a capacity of 70 kWh. The hybrid Track-Truck is capable of emission-free CPT and track driving, meeting a zero emissions requirement on site.

4.4 User experience

The hybrid CPT Track-Truck has been used for more than six months by BAM Infra Nederland (Figure 9).

Figure 9. Example of a project in which the hybrid Track-Truck is used.

4.4.1 Test results

The CPT in Figure 10 is an examples of the many CPTs which the BAM has performed in the centre of Amsterdam (The Netherlands). In this specific project 13 CPTs were performed up to a depth of 68m below ground level. The hybrid Track-Truck can enter the centre of Amsterdam without a special environmental exemption. Furthermore it was experienced as much cleaner and quieter when performing the CPTs.

4.4.2 Savings

In the first six months the hybrid Track-Truck has used 3,000 liter of diesel. The traditional Track-Truck used 9,000 liter of diesel, so in total 6.000 liter (67%) is saved. The Hybrid Track-Truck saves on average fifty liter per day, or saves approximately 32,000 kilograms of CO2 per year.

4.4.3 Sound level

In practice the engine of the Track-Truck is only used on the trips to and from the location. The fact that the engine no longer has to run during CPTs and when moving the tracks lowers the sound level considerably.

When moving on tracks and during CPTs it hardly makes any noise when you are outside the cabin. Inside the cabin a lower noise level is experienced of less than 67 dB(A). This could be lowered even more when the insulation is upgraded and special damping techniques are used.

4.4.4 CPT soil investigation

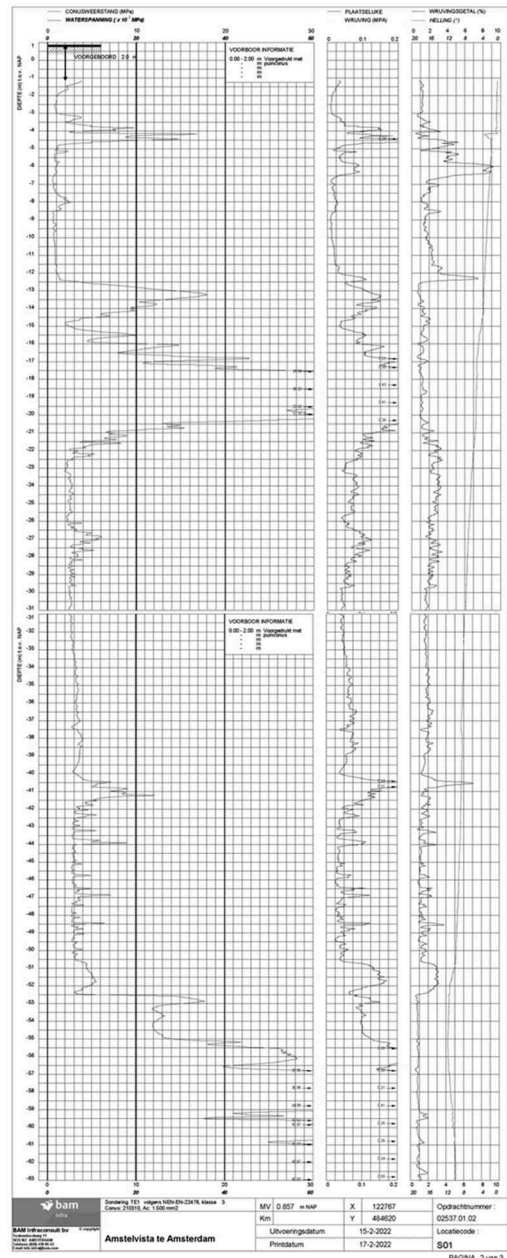
The experience regarding the CPT investigation is that the CPT soil investigation results are similar


Figure 10. CPT with the hybrid Track-Truck in the centre of Amsterdam.

to the traditional CPTs. There is no difference in pushing capacity, CPT velocity and fast pulling the probe out of the soil. In general, no quality loss is experienced when performing the CPT soil investigation fully electrical.

4.4.5 Hybrid battery

The hybrid battery (Figure 11) and drive are characterized by high operational reliability, ample drive

power and a long service life of 25 years. The safety for users is increased due to less noise and no emission of harmful gases. During times when no power is required from the system, significant savings in fuel consumption are achieved. The electrical system has a modular structure of components, which means that faults can be solved quickly and service can be provided easily. The batteries are charged with a max. capacity of 22 kW via a wall socket or a public charging stations. Experience from the practice show that you can work 1.5 day on a full battery charge.

Figure 11. Batteries for the hybrid system.

5 CONCLUSIONS

A sustainable realization of construction projects, within strict environmental standards, is the reason for companies to invest in electrification of equipment, so without carbon and nitrogen emissions.

In terms of CPT, the hybrid Track-Truck is, while at the project location, electrically powered without emitting harmful substances such as carbon and nitrogen emissions. Both the CPT soil investigation and driving on the tracks are executed completely electrically. On the road, the truck is powered by the usual diesel engine.

The hybrid Track-Truck was launched early 2021. Experiences from practice show that the fuel consumption is lowered by 67%. On daily basis fifty liter is saved and approximately 32,000 kilograms of CO_2 per yearly basis.

The tracks are electrically driven and therefore the sound level is lower compared to fuel driven Track-Trucks. With a full battery charge CPTs can be performed during 1.5 day before the battery needs to be recharged. The experience with regard to CPT soil investigations are more or less similar compared to traditional CPTs.

Elastic soil properties investigated using seismic tests to complement the CPT

O. Storteboom & M. Woollard
A.P. van den Berg, Heerenveen, The Netherlands

J.L. Rangel-Núñez
UAM-Azc and Ingeum Ingeniería, Mexico

ABSTRACT: Seismic tests are performed to investigate the elastic properties of the soil. Elastic soil properties are essential input for the prediction of soil-surface motions related to earthquake excitations and for the design of foundations for vibrating equipment, for the assessment of offshore structure behavior during wave loading and to predict deformations around excavations. To investigate these elastic properties of the soil, seismic tests can be performed. The digital Icone is easily extendable by click-on modules to measure additional CPT parameters. The Icone Seismic module is the instrument to investigate the elastic soil properties. This click-on module is automatically recognized, creating a true plug & play system. It contains three accelerometers to receive left and right shear waves as well as compression waves. The Icone Seismic system can be applied both onshore and offshore and has a 1,000 m water depth rating. In this paper the Icone Seismic system is described. Feedback from onshore fieldwork with the Icone Seismic will highlight the user experience with this approach.

1 INTRODUCTION

Elastic soil properties are essential input for the prediction of ground-surface motions related to earthquake excitation and for the design of foundations for vibrating equipment, for the assessment of offshore structure behavior during wave loading and to predict deformations around excavations. To investigate these elastic properties of the soil, seismic tests can be performed by means of the Icone Seismic system.

The seismic piezocone penetration test (SCPTu) provides multipoint simultaneous measurement of tip resistance (q_T), sleeve friction (f_s), pore pressure (u_2), and compressional and shear wave velocities (V_p and V_s, respectively) following the down-hole geophysical testing strategy, but without using pre-drilling. This type of test has been successfully applied in geotechnical exploration for more than three decades (Lunne et al., 1997; Mayne & Campanella, 2005). Improvements have now been achieved such as using dual seismic sensors to detail the stratigraphy and to perform continuous-interval seismic piezocone tests by semi-continuous wave generation using the autoseis device at the rate of 1 strike/second (Mayne & Woeller, 2015).

In the next paragraphs, the various Icone click-on modules are described with a focus on the seismic module.

2 ICONE AND CLICK-ON MODULES

Since Cone Penetration Testing (CPT) is used for soil investigation, a tremendous development has occurred in the techniques to measure soil parameters. After CPT with the mechanical cone had proven to be very useful, the development of the electrical cone brought a big step forward in ease of use and accuracy. Nowadays the advantages of digital technology are available for further improvements.

2.1 Digital cone

The digital cone or Icone measures the four standard parameters: cone tip resistance (qc), sleeve friction (fs), pore water pressure (u) and inclination (Ix/y). The Icone is mechanically 40% stronger than its analogue predecessor and is at the same time more accurate, more reliable and easier to maintain. Calibration data is stored in the cone itself, so separate data holders such as USB sticks are no longer necessary. Icones come with a pre-pressure and seal assembly that reduces cone maintenance.

2.2 Icone and click-on modules

In the past years, several click-on modules for the Icone were developed and the seismic module is part of it. In this chapter, the following three are

Figure 1. Icone data acquisition concept.

described: the conductivity module (Figure 2), the magnetometer module (Figure 3) and the vane module (Figure 4). The seismic module is described in paragraph 3. All modules except the Icone Vane can be used with a 10 cm² and a 15 cm² Icone. When CPT-data is not required, the click-on modules can also be used with a dummy tip instead.

2.3 Conductivity module

The measurement of electrical conductivity in the subsoil is a function of both the conductivity of the pore water and the soil particles, the first being the dominant factor. With the Conductivity module changes in the concentration of (dissolved) electrolytes are determined without specifying the exact nature of these electrolytes. Therefore, the module facilitates separation of zones with differentiated water content, including determining the water table depth and the thickness of the capillary zone or separation of fresh and salt water carrying soil layers. Another very important application of the conductivity module is detection of (the degree of) contamination in a soil body. Further soil investigation should provide details on the actual contaminants.

Figure 2. Conductivity module with 10 cm² Icone.

2.4 Magneto module

Unknown structures and obstacles, like unexploded ordnance (UXO), are a risk factor in the execution of earthworks. To avoid risks of damage and interruptions of work, these underground elements must be identified and mapped. Most underground structures contain metal such as sheet-piles, ground anchors and pipelines or a combination of metal and concrete, such as reinforced foundation piles. Power supply cables and above structures have in common that they affect the earth's magnetic field. Using the Magneto module, metal objects in the underground can be detected by interpreting anomalies of the earth's magnetic field.

Figure 3. Magneto module with 10 cm² Icone.

2.5 Vane module

In soft fine-grained soils, the field vane test (FVT) is a popular and effective complement to the CPT. The vane test allows in-situ measurement of the peak, residual and remolded undrained shear strength of soft fine-grained materials, such as clay, silt and mine tailings. The Icone Vane is a digital vane with a downhole motor and torque cell that is used for in-situ measurement and evaluation of shear strength that can be deployed in soft soils where a prediction of the undrained shear strength is required.

Figure 4. Icone Vane (without protection tube).

3 SEISMIC MODULE

Figure 5. Seismic module with 10 cm² Icone.

Seismic tests are performed to investigate the elastic properties of the soil. For this purpose a shear wave (S) or a compression wave (P) is guided into the soil. Elastic soil properties are essential input for prediction of ground-surface motions related to earthquake excitation and for assessment of: foundation design for vibrating equipment, offshore structure behavior during wave loading and deformations around excavations.

3.1 *Principles*

Elastic soil parameters are determined by measuring the propagation speed of an applied sound wave between two known depths. Mostly this is done by pushing the seismic module into the soil and stopping at 1-meter intervals. During the pause in penetration, a shear or compression wave is generated at surface level and the time required for the wave to reach the seismic sensors is recorded. The time difference between two consecutive seismic tests performed is a measure of the elastic properties of the soil. The following can be calculated as a function of the seismic data (shear and compressional wave velocities, V_s and V_p, respectively) and the soil density (ρ, usually already known), eqs 1 to 6: small strain shear modulus (G_{max}), constrained modulus (M), Poisson's ratio (ν), elasticity modulus (E), bulk modulus (κ) and Lame's constant (λ).

$$G_{max} = \rho V_s^2 \tag{1}$$

$$M = \rho V_p^2 \tag{2}$$

$$\nu = \frac{2 - \left(V_p/V_s\right)^2}{2\left[1 - \left(V_p/V_s\right)^2\right]} \tag{3}$$

$$E = 2G_{max}(1 + \nu) \tag{4}$$

$$\kappa = \frac{E}{3(1 - 2\nu)} \tag{5}$$

$$\lambda = \frac{E\nu}{(1 + \nu)(1 - 2\nu)} \tag{6}$$

An even faster and more accurate way is to use two seismic modules, which are mounted, at a fixed distance of exactly 0.5 or 1 meter. Since the time difference between two consecutive measurements is approximately 2 ms, a very consistent measurement of the trigger signal is required. This requirement is met by using the same high sensitive sensors for the trigger module and by placing this module in the immediate vicinity of the hammer.

3.2 *Data processing and visualizing*

Both the Icone Seismic Module as well as the Icone are part of our modular data acquisition concept that is based on digital data transfer. The system consists of a digital data logger, called Icontrol, and the Ifield software for real-time data presentation. Due to application of digital technology, multiple parameters can be retrieved by several modules. Upon connection, the Icontrol data logger and Ifield software will automatically recognize the specific cone and/or module, so it is a true plug & play system.

The output signals from the seismic sensors are being digitized inside the seismic module and from here transferred to the Icontrol data logger at surface level. After all tests have been performed, the data obtained are then analyzed offline by processing software, determining the propagation speed and corresponding elastic soil parameters for all investigated depth ranges.

4 PRACTICAL EXPERIENCES

Determination of shear wave velocity profiles has been applied to define the stratigraphic profile and to evaluate site effects, *i.e.* dynamic amplification or liquefaction, however, its field of application has now been extended. In fact, it is also applied in arability studies, for the design and control of soil treatment, and lately in the determination of the parameters of advanced constitutive equations. Therefore, it is common in an exploration campaign to determine such a profile, but this is not trivial since there are different methods and, in principle, it is necessary to define which one to use. The definition of the method depends on several factors, namely, experience and mastery of the proper execution and interpretation of the method, the alteration and deformation induced in the subsoil, the degree of heterogeneity, to mention the most important ones. For example, although the seismic refraction method is easy to perform and is a non-invasive technique, its interpretation is not easy, mainly when velocity inversion is present in the subsoil; unfortunately, in geotechnical problems this condition is frequent. Regarding the down-hole, up-hole and cross-hole techniques, it is necessary to take care not to induce an excessive alteration in the subsoil when the borehole is drilled. With respect to the techniques based on the measurement of surface waves, the problem is that the solution is not unique, so the method is very dependent on the experience and the geotechnical information available.

With respect to the seismic piezocone test (sCPTu), it has the advantage that the alteration generated in the subsurface is less than that produced with the conventional down-hole technique or with the suspension-logging test (SLT), since in the latter it is necessary to drill a borehole, where a relaxation is generated and a cake is created around the borehole.

The following are five projects where the shear wave profile was determined. Two of them were

carried out in Mexico City (CDMX) for the design of building foundations, a third for the design of the liquefiable soil deposit improvement system and the remaining two were for the study of tailings dams.

HYSON 100kN installed on a 14t Mercedes-Unimog truck was used in all projects (Figure 6). A 10 cm^2 piezocone was used with the seismic module (Figure 5). The wave generation system was by means of the lateral strike of a beam.

Figure 6. Equipment used for secondary wave profile determination.

4.1 *Building design in CDMX*

The urban area of Mexico valley can be divided in three main geotechnical zones: Foothills (Zone I), Transition (Zone II) and Lake (Zone III). In the foothills, or hills, very compact but heterogeneous volcanic soils (*i.e.* tuffs) and lava are found. These materials contrast with the highly compressible soft soils of the Lake Zone. Generally, in between, a Transition Zone is found where clayey layers of lacustrine origin alternate with sandy alluvial deposits erratically distributed. Mexico City is mainly located in the lake zone.

Very soft soil deposits of the lake area, whose average thickness is 30 m, are mainly clayey with alternating hard lenses/layers (a superficial crust and ash, silty sand lenses or thin layers), and they are characterized by an high humidity ($100<w_n<900\%$), high plasticity index, ($100<PI<500$), large one-dimensional compressibility ($C_{c,\ max}\approx10$) and low shear wave velocity ($V_s<100$m/s). Those unusual values are produced mainly by the clay microstructure and composition, and the high diatoms content (Rangel et al. 2014).

There are two important factors that affect the design of the foundation of a building in the lake and transition zones of Mexico City, where almost 80% of the buildings are located: earthquakes and regional subsidence. Regarding the first aspect, Mexico City has a high dynamic amplification coefficient, max 25 (Pérez Rocha *et al*, 2009), therefore, it is necessary to know the velocity law of the subsoil, at least in the strata that amplify the seismic wave, that is, up to 30 and 40 m depth.

4.1.1 *Building project 1*
The construction of a hotel in the lake area of Mexico City is contemplated, which consists of a 14-story tower and low-rise buildings, both with a basement. The foundation solution proposed for the tower consists of piles at a depth of 31 m.

Purpose investigation. The main purposes in using the seismic piezocone at this site, was to:

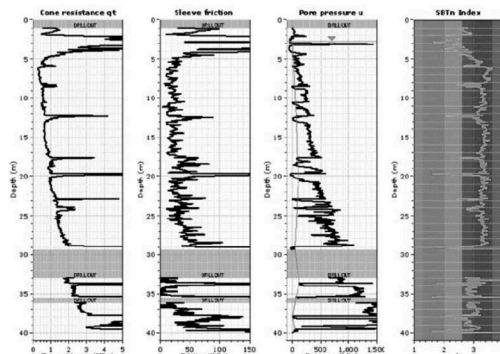
- Determine the soil stratification and dynamic properties.
- Estimate the capacity of piles.
- Determine site spectrum.


Figure 7. Primary parameters determined with the sCPTu.
Figure 8. S-wave velocity profile determined with different techniques: sCPTu, sDMT, SLT, MASW and Ovando's correlation.

Results. Because this building is located in an area with significant seismic amplification, part of the exploration campaign was directed to determine the velocity profile of the secondary wave in order to design its foundation. Figure 7 shows a detail of the stratigraphy detected with the sCPTu sounding, which is typical of the Mexico City Lake area, and

244

Figure 8 shows the secondary wave velocity profile obtained with different techniques: seismic piezocone (sCPTu), seismic dilatometer (sDMT), suspension logging Test (SLT), multi-channel analysis of surface waves (MASW) and an empirical correlation applicable to CDMX deposits (Ovando et. al., 2007). It is observed that all the techniques produce similar results, although the values determined with MASW are almost double those determined with borehole techniques. Likewise, it can be seen that the values obtained with SLT were lower, possibly attributable to the greater alteration that occurs in the soil when drilling, and in general the values determined with sCPTu, sDMT and using Ovando's correlation were very similar.

4.1.2 Building project 2

The project considers the construction of a shopping center and four towers (14, 18, 20 and 22 levels), three for residential use and one for office use, with shared parking basements on a large basement, whose maximum general excavation level is -16.00 m. The project is located in the lake area.

Purpose investigation. The main purposes in using the seismic piezocone at this site, was to:

- Determine the soil stratification and dynamic properties.
- Estimate the capacity of piles.
- Determine site spectrum.

Results. An extensive exploration campaign was carried out including the following techniques: sCPTu, sDMT, Vane Shear Test (VST), Pressuremeter (PMT), Phicometer (PHI), undisturbed sampling and laboratory tests. The geotechnical design model is presented in Figure 9. For the short-term shear strength (su), the results of the VST and TX-UU tests were used for the soft soils and the PMT and PHI for the hard soils; for the shaft strength of the piles, the fs (sCPTu test) and the residual strength determined with VST were used; the piezometric conditions were evaluated from CPTu_Δu; the compressibility moduli to determine the soil long-term behavior were obtained from piezocone correlations and oedometer tests; and finally, the dynamic response was studied from the velocity profile obtained with the sCPTu.

4.2 Subsoil improvement design

An oil refinery will be built in southern Mexico. Due to the high seismicity of the area and the existence of deposits with alluvial and fluvial soil intercalations below the groundwater level, the liquefaction potential is high, for which an improvement of the subsoil is pro-posed, so an exploration campaign has been proposed which includes the determination of S-wave velocity profiles in order to design such improvement. Figure 10 shows a sounding showing typical conditions in the project, where intercalations between soft and frictional soils are observed. Based

on the soil characterization and the design earthquake, an initial liquefaction analysis was carried out to corroborate the liquefaction potential and based on the S-wave velocity profile, the target for the design of the improvement was established, in other words, that profile where liquefaction no longer occurs.
Figure 9. Geotechnical model for design of the site 2.
Figure 10. Stratigraphic profile for the subsoil improvement zone.

4.3 Stratigraphic conditions in tailings dams

In the case of tailings dams, where there are very young and heterogeneous deposits, exploration campaigns have been carried out to determine the stratigraphic profile and mechanical parameters with *in situ* tests, since obtaining unaltered samples is difficult in most cases. It highlights the importance of shear wave profiles in conjunction with vane and CPTu_Δu tests, in order to carry out dam stability analyses and identify potentially unstable strata (determination of G_o, s_u and k). The results obtained in two mines in Mexico are presented below (Figures 11 and 12). It is observed that in all cases the values of the tip resistance q_T oscillate strongly and this gives an idea of the heterogeneity that exists in this type of deposits. This behavior is also observed in the shear velocity profiles, so it is necessary to try to decrease the distance at which the determination of velocity S-wave is made. Also, it is observed that sometimes the value of u_2 is negative, which implies the development of suction. When observing the results of the dissipation tests, it is obtained that the

245

curves differ from those obtained in natural soils, where it is difficult to obtain the initial value of the pore pressure. All these aspects make it difficult to define the stratigraphic profile and to determine the properties in the field, which is why conducting an exploration campaign in tailings dams is currently a challenge.

An alternative to determining the velocity profile is through correlations. Figure 13 shows the velocity profiles obtained from the sCPTu measurement and the one determined by means of q_T vs V_s correlations, although the correlation provides adequate values, it does not capture the peaks.
Figure 11. Results of the sCPTu_Δu tests for the case of tailings dam 1.
Figure 12. Results of sCPTu tests for the case of tailings dam 2.
Figure 13. Comparison between the s-wave velocity profiles obtained with the sCPTu and by correlations with q_T, for the sCPTu-2 borehole in tailings dam 1.

5 CONCLUSIONS

Cone Penetration Testing, as a technique for *in-situ* soil investigation, is a recognized and widespread method for efficiently performing of soil surveys. CPT is in the course of time continuously improved like developments concerning the application of digital electronics inside the cone. The most prominent of these is the ability to easily extend the digital Icone by click-on modules to measure additional parameters. Any module is automatically recognized by the Icontrol data logger, creating a true plug & play system.

To investigate elastic properties of the soil, seismic tests can be performed by means of the Icone Seismic system. Four case studies are described where the s-wave velocity profile is determined with the seismic piezocone for the following purposes: foundation design, ground improvement design and tailings dam studies. In the case of foundation design, the velocity profile is used to evaluate the amplification of clay deposits. This is determined with several techniques and it is observed that the procedure with seismic piezocone produces satisfactory results due to the low level of deformation induced during its execution. It is also shown that by combining the sCPTu_Δu techniques with VST it is possible to determine parameters of the geotechnical model for foundation design.

In the case of soil improvement design, based on the velocity profile determined with the seismic piezocone, the liquefaction potential of a soil deposit is evaluated, and then a target velocity profile is proposed for the improvement that no longer generates liquefaction. Finally, examples are presented where the velocity profile is determined for the case of tailings dams in Mexico using correlations and those determined by seismic piezocone, and it is observed that the profiles obtained with correlations are not able to capture the maximum points of the profile.

The seismic module has proven to be an accurate and reliable measuring device, which can be used for different measuring techniques for soil analysis.

ABSTRACT: CPT sounding initially passes through the vadose zone, that is the zone above the phreatic surface where pore-water pressure is negative and degree of saturation is usually lower than unity. Negative pore-water pressure (suction) significantly affects tip resistance and sleeve friction and lack of knowledge of soil suction in this zone makes CPT data difficult if not impossible to interpret. For the case of Piezocone Cone Penetration Test (CPTU), crossing the vadose zone also exposes the cone tip porous filter to desaturation jeopardising the measurement of positive pore-water pressure once the cone penetrates the saturated zone below the phreatic surface. This paper presents the concept of the Tensiocone, a cone penetrometer with the facility to measure pore-water pressure in both negative and positive range. A first prototype was tested in the laboratory and in the field to investigate one of the major challenges in Tensiocone measurement, that is whether adequate contact can be established between the ground and the tensiometer porous filter during penetration.

1 INTRODUCTION

The Cone Penetration Test (CPT) is a valuable device for characterising soil stratigraphy and estimating soil mechanical properties. The penetrometer is inserted from the ground surface and initially crosses the vadose zone, that is the zone above the phreatic surface where pore-water pressure is negative (suction) and degree of saturation is usually lower than unity. This vadose zone can extend to several meters.

Strength and stiffness of the ground in the vadose zone are significantly affected by suction variations as a result of rainfall and evapotranspiration and so do the tip resistance and sleeve friction. Empirical equations used for characterising soil properties from CPT profiles have been developed from tests conducted in the calibration chamber on soils in dry or saturated states. These equations clearly do not hold for unsaturated soils. Data acquired when crossing the vadose zone are therefore difficult if not impossible to interpret in routine practice.

In recent years, the research groups at the University of New South Wales in Australia (Pournaghiazar et al. 2012; Yang & Russell 2015, 2016) and the University of Oklahoma in the US (Miller et al. 2018; Miller & Collins 2019) have conducted extensive experimental campaigns where CPTs where performed in calibration chambers on unsaturated soils (by controlling or monitoring suction). This has led to a new generation of semi-empirical equations where soil properties can be inferred from tip resistance and sleeve friction by explicitly considering the influence of suction. However, the use of these equations in routine applications remains a challenge due to the difficulty of measuring suction in the field at depths greater than 1-2m.

The most obvious approach to measure suction during penetration is to provide the penetrometer with a High-Capacity Tensiometer to measure pore-water pressure in the negative range (Tarantino 2002; Marinho et al. 2008). A HCT can also measure pore-water pressure in the positive range and this would enable CPT measurements also in the saturated zone below the phreatic surface. The HCT could offer more accurate measurements than Piezocone Cone Penetration Test (CPTU) because it would not suffer from desaturation when passing through the unsaturated vadose zone (Mondelli et al. 2009; Sandven 2010).

This paper presents the development a new cone penetrometer named 'Tensiocone', which incorporates a high-capacity tensiometer for the measurement of pore-water tension during cone penetration. The major challenge with this design is to ensure proper contact between the high air-entry porous filter and the

ground. In laboratory measurements using standing-alone high-capacity tensiometers, a soil paste is interposed between the high-capacity tensiometer and the soil to ensure continuity between water in the soil pores and water in the tensiometer water reservoir. This paste cannot be used on the HCT installed on the penetrometer as it would be taken off as soon as the HCT touches the ground.

2 TENSIOCONE CONCEPT AND DESIGN OF FIRST PROTOTYPE

The concept of the Tensiocone is illustrated in Figure 1. An adaptor is placed between the friction sleeve and the cone tip and incorporates a High-Capacity Tensiometer (HCT) (Tarantino & Mongiovì, 2002). The first prototype presented in this paper was designed without the cone tip and friction sleeve since the aim was to test the pore-water pressure measurement. However, the same adaptor could be easily incorporated into a fully functional cone penetrometer.

The measurement of pore-water pressure is carried out laterally to minimise the stresses on the porous filter compared to the case of a porous filter located on the penetrometer tip. The major challenge with this new instrument is to ensure proper contact between the porous ceramic filter and the ground.
Figure 1. Piezocone and Tensiocone for pore-water pressure measurement below and above the phreatic surface respectively.

2.1 Tensiocone HCT

The HCT is installed horizontally into the adaptor and its size must be kept small in order to maintain the rear electrical connections near the axis of the cone and allow the electrical cables to run through the hollow push rods. Figure 2 shows the design concept for the HCT.

It consists of an integral strain-gauge diaphragm and an extension to support a perforated board with four pins to connect the thin strain-gauge wires to the thick cable wires transferring the signal through the hollow push rods. A high air-entry value porous
Figure 2. High-Capacity Tensiometer (HCT) installed in the cone penetrometer shaft.

filter (800 kPa) was cut and glued into the HCT using epoxy. The same epoxy was also initially used to fix the tensiometer to the penetrometer adaptor.

2.2 Reliability of HCT measurement

The performance of two tensiocone HCTs was initially tested via simultaneous measurement on a kaolin sample compacted to 300 kPa vertical stress at 30% water content. Measurement was carried out in the suction box described in Tarantino & Mongiovì (2003). The box lid has two holes equipped with O-rings to install the two HCTs. O-rings are also interposed between the annular cylinder hosting the sample and the base and lid respectively to prevent evaporation from inside the suction box. A small air gap was present between the top surface of the sample and the lid.

The two HCTs with an initially dry porous filter were subjected to 'one-shot' saturation directly in the saturation chamber by pressuring water to 4 MPa for 5 days. The response of the HCTs was then tested by generating water tension up to cavitation (by wiping the porous filter). Cavitation occurred at the air-entry value of the porous ceramic filter. The HCTs were then placed again in the saturation chamber at 4 MPa for 5 days.

The long-term measurement test is shown in Figure 3. The two HCTs successfully measured the same pore-water tension despite the fluctuations due to water drops condensing on the lid and falling periodically on the sample surface. Cavitation occurred as the 800 kPa air-entry value of the porous filter was approached.
Figure 3. Long term measurement using two High-Capacity Tensiometers installed simultaneously on the same clay sample.

3 TENSIOCONE MESUREMENT IN MOCK-UP LABORATORY TEST

A series of penetration tests were carried out in samples placed in a mould 100 mm diameter and 150 mm height (Figure 4). A transparent lid was used to seal the upper surface of the sample to avoid evaporation during the test. Two holes were made into the lid; the larger one was used to insert the tensiocone equipped with the HCT whereas the smaller one was used to install a HCT on the top of the sample to benchmark the measurement by the Tensiocone HCT. The aim of the test was to verify whether adequate contact could be established between the HCT porous and the soil during penetration in the absence of the clay paste typically used in HCT measurements.
Figure 4. Mock-up scale test to simulate measurement during penetration.

3.1 Lightly compacted sample

The first test was made on a lightly compacted sample, which should represent the worst case scenario (the lower the density, the lower is the radial pressure pushing the soil against the HCT porous filter). The sample was prepared using 80% of coarse fraction (sand) and 20 % of fine fraction (Speswhite kaolin clay) humidified at 30% water content calculated with respect to the dry mass of kaolinite clay only (corresponding to 6% overall water content). The two fractions were mixed dry and water was then sprayed over the mix. After mixing, the humidified soil was sealed in a plastic bag for at least 24h for water content equilibration.

In this test, the soil was placed in the mould in a single layer and compacted manually. After closing the mould with the transparent lid, the tensiocone was penetrated for about 100 mm into the sample. Another HCT was installed on the top surface of the sample. To improve the contact between the top HCT and the sample surface, a thin layer of kaolin paste (water content 100%) was interposed between the top HCT and the soil. Figure 5 shows the results of the pore-water pressure measurements of the two HCTs installed on the tensiocone and top surface respectively.

There was a lowest value of water pressure detected by the tensiocone HCT during penetration. Following penetration, pore-water pressure increased to -550 kPa and equalised to this value. The top HCT equalised to a slightly lower pressure (-560 kPa) therefore showing that adequate contact could be established between the porous ceramic filter of the tensiocone HCT and the sample.
Figure 5. Penetration test on lightly compacted sample (20% clay/ 80% sand).

3.2 Moderately compacted samples

The second part of the experimental program involved moderately compacted samples. Three samples with different coarse/fine fraction ratio and compaction water content were prepared for this purpose. The soil was first humidified and cured for at least 24h in sealed plastic bags and then compacted in three layers inside the mould using a loading frame until reaching the target dry density of 1.4 g/cm^3.

Figure 6 shows the pore-water pressure measurements during penetration in a sample composed of 80% of sand, 20% of kaolin and humidified at 40% water content calculated with respect to the mass of the fine fraction (corresponding to an overall water content equal to 8%). Similar to the lightly compacted sample, the tensiocone pore-water pressure decreased during penetration and increased once penetration was stopped until achieving equilibrium. The top HCT converged to similar values (the drop at the end of the measurement was due to the loss of contact with the sample).
Figure 6. Penetration test on moderately compacted sample (80% sand, 20% kaolin, 40% water content to kaolin dry mass).

The second compacted sample was prepared using only Speswhite kaolin humidified at 32% water content. The as-compacted suction was measured using the top HCT before starting the penetration of the tensiocone. Once the top HCT measurement reached equilibrium, the tensiocone penetration was started. Figure 7 shows the results of the measurement of the pore-water pressure of the two tensiometers during the last part of the tensiocone penetration. Again, once penetration stopped, the measurement of the tensiocone HCT attained the same value recorded by the top HCT.
Figure 7. Penetration test on moderately compacted sample (0% sand, 100% kaolin, 32% water content to kaolin dry mass).

The third sample was prepared with 60% coarse fraction and 40% fine fraction. The water content calculated with respect to the dry mass of the fine fraction was 40%, corresponding to an overall water content equal to 16%. The results of this test are shown in Figure 8. The tensiocone pore-water pressure decreased during penetration and then increased up to -145 kPa. This value was markedly different from the top HCT that equalised at about -40 kPa. This discrepancy was also observed in other tests not reported herein.

The reason for such a discrepancy was not due to poor contact between the soil and the HCT porous filter. The pore-water pressure recorded by the tensiocone HCT levelled off suggesting that adequate contact could be established. In fact, if an air gap had formed between the soil and the porous ceramic filter, water from the ceramic filter would have evaporated into the air gap and pore-water pressure would have started declining rapidly over time.
Figure 8. Penetration test on moderately compacted sample (60% sand, 40% kaolin, 40% water content pect to kaolin dry mass).

4 TENSIOCONE MESUREMENT IN THE FIELD

The tensiocone prototype (only equipped with a lateral HCT) was tested on the crest of the Adige river embankment at about 1 km downriver from the bridge that connects the local railway station to the town of Egna (BZ), Italy. The embankment made of a silty material was instrumented with two series of conventional tensiometers at depths of 1.8 m, 3.25 m, and -4.7 m and depths of -2 m, -3.45 m, and -4.5 m respectively. At the time of the CPT, these tensiometers showed a pore-water pressure profile nearly hydrostatic at depths greater than 3 m (associated with the phreatic surface located at 7m below the embankment crest). These field measurements were aimed to provide a reference to benchmark the measurements by the tensiocone HCT.

The tensiometer installed in the tensiocone was preliminarily saturated for more than 24 hours using a portable saturation chamber (at the constant pressure of 4MPa). The pressure in the saturation chamber was applied via a piston screw pump (Figure 9a). The tensiocone was then removed from the saturation chamber and placed in water for zeroing (Figure 9b). Finally, the tensiocone was removed from water and screwed onto the first push rod. Once removed from water, the porous filter was immediately covered with kaolin paste to prevent cavitation during the short period of time where the HCT remained exposed to air before penetrating the ground (Figure 9c). This kaolin paste was chipped off once the tip started penetrating the embankment.
Figure 9. Field test. (a) Tensiocone in the pre-pressuration chamber. (b) Tensiocone in free water before installation. (c) Tensiocone at the onset of penetration.

The pore-water pressure measured at different depths is shown in Figure 10. The thrust system was stopped four times at four different depths. During penetration, pore-water pressure always tended to decrease whereas equilibrium was established in a relatively short time after penetration was stopped. The pore-water pressure levelling off once penetration was stopped was taken as an indication that adequate contact could be established between the ground and the HCT porous filter.

However, the equilibrium values where not consistent qualitatively and quantitatively with a hydrostatic pore-water pressure profile controlled by the phreatic

surface at 7m depth. It was then speculated that the HCT readings were affected by spurious mechanical deformation of the HCT sensing diaphragm. Two types of stresses can influence the measurement, the radial stress due to the ground lateral compression and the axial stresses imposed by the thrust system.
Figure 10. Results of field test.

5 LOADING EFFECTS

To investigate whether the tensiocone HCT readings were affected by spurious mechanical deformation of the sensing diaphragm, the tensiocone was placed in a loading frame. The tensiocone HCT porous filter was air dried for several days so that the HCT should have measured zero-gauge pressure throughout the mechanical axial compression of the tensiocone.

Figure 11 shows the results of the axial loading test. The tensiocone was compressed in steps up to 10 kN (0kN, 2 kN, 5 kN and 10 kN) and then unloaded in steps (10kN, 5 kN, 2 kN and 0 kN). Step duration was 15 seconds. The HCT recorded significant 'false' changes in pressure up to 180 kPa. In the field test, circumferential stresses might have also generated additional spurious readings.

The first HCT prototype was designed as an integral strain gauge diaphragm and any deformation of the HCT body due to the compression of the shaft directly affected the response of the sensing diaphragm. This design is clearly not suitable for the HCT to be incorporated into the tensiocone.
Figure 11. Mechanical effect on the HCT of the first tensiocone prototype.

6 CONCLUSIONS

This paper has presented the concept of the Tensiocone, a cone penetrometer with the facility to measure pore-water pressure in both negative and positive range. A first prototype was tested in the laboratory and the field to investigate one of the major challenges in tensiocone measurement, i.e. whether adequate contact can be established between the ground and the HCT porous filter during penetration.

The clay paste usually applied to the high air-entry porous filter of standing alone HCTs to ensure adequate hydraulic continuity between the pore-water and the water in the HCT reservoir cannot be used in CPT. The measurement of the negative pore-water pressure during penetration has to rely on the contact generated by the radial compression during penetration of the CPT shaft.

Laboratory tests showed that adequate contact could be established even under unfavourable conditions, i.e. high fraction of course-grained material (this makes the contact more difficult to achieve) and lower soil density (low radial stresses develop in a lightly compacted sample). The field test also showed that equilibrium could be reached after stopping the penetration, indicating that adequate contact could be established between the penetrometer HCT and the ground in a real case scenario.

However, it was observed that the compression of the shaft induced deformations in the HCT resulting in false pressure readings. This explains the almost random values recorded during the field penetration test and the discrepancy between the suction measured by the tensiocone HCT and the HCT placed at the top of the sample in the laboratory tests. The next challenge in the design of the penetrometer shaft is therefore to isolate mechanically the HCT from the shaft and this will be the focus of future tensiocone design developments.

New portable pressiocone system for carrying out CPT+FDP tests

G. Vinco
Geotechnical Engineer, Technical Manager of URETEK SOLUTIONS Group

M. Sacchetto
Geotechnical Engineer, Freelance Consultant

ABSTRACT: Geotechnical investigations in the foundation soil of existing buildings have always been challenging due to limited space and difficult access. URETEK has developed a portable integrated system for simultaneously carrying out a CPT and a pressiometric test with Full Displacement Pressuremeter. The 30 kN thrust penetrometer to be used is very small. The reaction is given by two "microanchors". The cone is a standard 10 cm^2 digital memory cone (no cable), capable of measuring qc, fs, U every centimeter. Above the cone there is the FDP equipment with a rubber sheath covered by steel plates and connected, by a tube filled with water, to a device for creating pressure to inflate the sheath and measure pressure-volume curves as in a standard pressiometric test. The pressure-volume device and the depth transducer are connected to a microcomputer that is programmed to carry out CPT+FDP tests in an easy-to-use/user-friendly way.

1   INTRODUCTION

The recovery of existing buildings is the key to building development in Western countries where the population does not grow, and housing standards have long since reached a satisfactory level. Tax incentives and funding introduced by national governments and the European Community have strongly oriented the offer towards systems and solutions that promote the recovery and adaptation of structures to current safety and energy saving standards. Among the various sectors, geotechnics has seen the birth and development of new technologies capable of restoring the mechanical characteristics of the soil of existing foundations with a minimum impact. Injections of expanding resins represent an example of this. It is a technology that can be done in structures in operation by applying a simple and non-invasive process (Dei Svaldi et Al. 2005). The subsequent phase of verification and control of the effectiveness of the injection intervention is carried out by in situ geotechnical tests performed with small portable lightweight equipment, capable of operating in narrow and confined spaces. For the verification of the improvement of the ground following the injection of resins, the use of a small portable penetrometer, called 30-20 (Cestari, 2013) consisting of a falling weight of 0.3 kN which is dropped from a height of 20 cm onto the axis of a battery of rods with a conical tip screwed to the bottom. The vertical fall of the mass makes the cone penetrate the ground for a certain depth. The specific

energy per driving stroke is equal to 60 kJ/ m^2 and the number of strokes required for the penetration of 10 cm represents the resistance of the ground. Dynamic tests 30-20 are mainly used for a comparison between the cone resistance of the natural soil and the treated soil. Only in particular cases (clean sands), the measured values can be reliably correlated to the geotechnical parameters of resistance and deformability. The success of the consolidation technique with expanding resins, the publication of the design guide and the dissemination of dedicated software have created the increasing need for more precise information on the geotechnical parameters of the treated soils (Manassero et Al.2014). For this reason, the R&D sector of Uretek, a multinational company operating in the consolidation sector with injections of expanding resins, has been involved for some time in the construction of a light and easy-to-use instrument capable of detecting directly with the due accuracy the resistance and deformability of the treated soil.

2   GENERAL DESIGN OF THE EQUIPMENT

Dynamic tests (especially the ones with low energy, like the above mentioned 30-20) are considered reliable only in certain contexts (clean sands or granular soils); therefore, it was decided to design equipment for static tests instead than dynamic, with piezocone CPTU or electrical cone CPTE. In fact, for the CPTU/CPTE are available many correlations that

allow to reliably calculate the geotechnical parameters of the subsoil (Cestari F. 2013). However, the CPTU/CPTE are not deformative tests, but the resistance is measured breaking and displacing the soil, meaning that geotechnical parameters are obtained in an empirical/semi-empirical way and therefore do not give (if not indirectly) parameters related to the deformation and/or the stress history of the subsoil (Robertson P.K. 2009, Robertson P.K., Cabal K.L. 2012).

For this reason, it was chosen from the beginning to couple an FDP (Full Displacement Pressiometer) to the CPTU, so that the penetrometric and pressiometer data could complement each other and provide a more complete picture of the geotechnical characteristics of the subsoil (H.S. Yu et Al., 1996, J. L. Briaud, 1992, J.L. Briaud et Al. 1979, P. Cosentino 2018, Amar S. et. Al. 1991, Robertson, P.K et Al.1983).

The pressiometer is an instrument that, in the standard version with large diameter (60 mm), would require the careful execution of a pre-hole, but at this stage it was decided not to design a rotary drilling machine (albeit of small dimensions) as it would not adhere to the initial targets: portability, low or no impact, speed and ease of use even for operators who are not experienced in drilling and pressiometer testing.

There are few small diameter (36 or 44 mm) FDP systems available on the market, none of which are integrated with a CPTU/CPTE system. All the equipment used so far has been customized (P.E. Failmezger et 2005, A. Drevininkas 2017). The combination of CPT (Cone Penetration Test) and PRESSIOMETER (hence the name PRESSIOCONE) requires to be used with a static penetrometer. The penetrometers that are on the market, although some models are small, are not very suitable for working in contexts where we would like to operate.

Some commercial models are small and can be disassembled with an external power unit but require a considerable effort for setup before each test, being equipment that are not produced in large series they are also relatively expensive.

Furthermore, all the small penetrometers on the market are anchored with augers for the reaction to the thrust, which is almost never feasible in the contexts of confined spaces inside existing buildings.

For these reasons we have opted for the design of a "custom" penetrometer that meets the basic requirements of ease of use, portability, electrical operation, reduced height, anchoring without augers, with a thrust of at least 30 kN and standard driving speed. of 2 cm/s.

3 CHARACTERISTICS OF THE CONE

Although there are cones of reduced diameter (5 cm^2 with a diameter of about 2.6 cm) we chose to have a standard cone with an area of 10 cm^2 and a diameter of 3.56 cm, to have more space for digital electronics and especially for having no problems in interpreting the data (the 10 cm^2 cones are the most widely used and the correlations are very solid). Therefore, the cone is a custom model that responds to the most recent standards and allows the measurement of q_c, f_s, U; the design of the cone and electronics leaves the possibility of making a CPTE cone with only the q_c and f_s or a cone equipped with additional sensors (for instance inclinometers, seismic, resistivity, thermal, etc.).

The cone is designed for extremely easy maintenance, with the tip, filter and sleeve that can be removed on site. The filter for the U can be either in sintered metal saturated with deaerated silicone oil or slotted (slot filter) saturated with silicone grease.

Figure 1. Memory piezocone (including battery and electronics).

In order not to have problems related to the management of the cable, given that the passage through the rods would interfere with the pressiometer tube, creating many problems on site, it was decided to design a custom system with memory.

The cone electronics are structured as follows:

– high resolution A/D circuit (24 bits)
– programmable microprocessor
– Large memory capacity and expandable
– high-capacity and small in length
– rechargeable NiMh battery (60 hours of power before recharge)

A great effort was carried out to optimize the power consumption of electronics, for limiting the dimensions of the piezocone (in length), the total length of the piezocone being comparable to most cones without memory. It has been designed to be used (eventually) also with cable, transmitting digital signal.

The test procedures with the memory cone are:

a. preparation of the cone and connection with a computer or data logger, which is connected to the encoder depth transducer
b. synchronization of the cone and datalogger and definition of the time T = 0; starting from T = 0 the cone starts storing all the values of q_c, f_s, U as a function of time (scanning every second or half second) and the data logger the values of depth as a function of time (data logger is connected to the depth transducer)
c. execution of the test
d. recovery of the cone
e. downloading data from the cone and from the datalogger, at this point there are two data matrices, one coming from the cone with all the data as a function of time only, one coming from the datalogger with depth as a function of time.

f. synchronization of the matrices: the matrices are automatically synchronized allowing to have the penetrometric data vs. depth (not only vs. time, with exception of the eventual dissipation tests).

4 FEATURES OF THE FDP PRESSIOMETER

The FDP (Full Displacement) Pressiometer is made of a special rubber sheath coated with six shaped steel plates and mounted on a cylindrical body which has an attachment for the piezocone in the lower part and an attachment for the penetrometer rods in the upper part. The steel lamellae can slide up and down at both ends so to follow the expansion of the sheath.

Figure 2. Sheath and lamellae.
Figure 3. Lamellae sliding inside the tube while the sheath expands.

The length of the sheath and the lamellae is 34 cm, the diameter of the sheath (including the lamellae) is 34 mm, with an internal volume of around 200 cm^3 (not inflated), see Figures 2, 3. The pressure gauge, unlike the others on the market, has been designed to be inflated with water instead of nitrogen.

The water, in this prototype, emulsified with oil, is pressurized through a "Rilsan" plastic tube that is placed through the rods; however, we plan to use special sealed rods to avoid using the internal tubing and pressurize directly through the rods.

The sheath is pressurized by a system essentially consisting of a cylinder and a piston which will be driven (in the final version) by a worm screw connected to an electric stepping motor, digitally controlled by the programmed data logger.

Each revolution of the motor corresponds to a movement of the piston and therefore a certain volume, measured with great accuracy.

In the cylinder there is a digital pressure cell connected to the data logger (same device that manages the cone). However, the preliminary trial tests (carried out for designing the pressiometer) have been carried out with a manometer using a preliminary version of the system, not yet automatized and with a manually driven piston and a manometer for measuring the pressure
Figure 4. Setup of the FDP system.
Figure 5. Manual pressurization System and manometer.

The datalogger is programmed not only to manage the test manually, but also to automatically perform some pressiometer test "sequences".

Each sequence contains a certain number of steps which define time, volume, pressure. In this way it is possible (for instance) to set a preset for a certain automatic sequence for a certain type of soil or to memorize a manual sequence of a test in progress.

This procedure ensures maximum operational flexibility, ease of use even for Users with little or no experience in pressiometer testing and the possibility to manage tests remotely (simply by exchanging remotely the files that define a certain sequence, thus fulfilling the requirements of Industry 4.0).

5 FEATURES OF THE PENETROMETER

The most important feature of the new type of penetrometer, which distinguishes it from all models on the market, will be the anchoring, in relation to the operational context in which the tests will be performed.

In fact, the pressiocone tests will be carried out mainly under the existing foundations, mostly inside buildings, in the not treated soils first and after in treated soils with resins; therefore, it would be impossible to anchor with augers or use ballasted penetrometers.

For this reason, the penetrometer will be anchored with two Microanchors (URETEK, 2017), being small tie rods placed in the foundations after execution of a small hole (26 mm diameter) and fixed with expanding resins; numerous tests have confirmed that two anchors are more than sufficient for a thrust of 30 ÷ 50 kN (which will be the maximum thrust obtainable with the penetrometer).
Figure 6. Setup of the penetrometer.

Basically, the new penetrometer consists in a light frame with three holes, a central one for the passage of the pressiocone and two lateral ones for the installation of the two Microanchors for reaction.

The thrust devices (pistons) will be chosen according to the available space and the requested thrust. One more difference with the standard penetrometers will be that the thrust devices will not push the rods from the top of them, but will push dragging the rods laterally, with special clamps, to leave the mouth at the top of the rods free, so better managing the pressiometer tube and for reducing the height ("through spindle"). At the same time with this system any rod of any length can be pushed for any depth without constrains.

6   TRIAL TESTS

At present we have carried out some preliminary trial tests, for testing separately the piezocone, the FDP pressiometer with different types of sheaths and lamellae and the penetrometer; finally, we tested all equipment together.

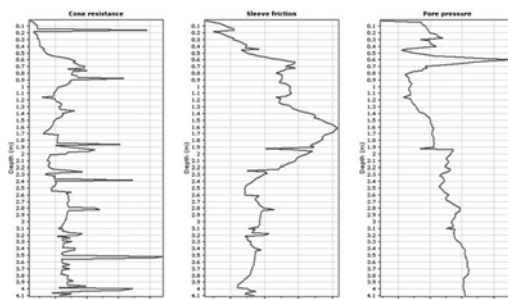
The field tests have been carried out during summer 2021 in a site (San Felice Extra, north of Verona) where the stratigraphy is gravel and small cobbles embedded in stiff silty clay, as shown in the following graph.


Figure 7. Q_c, f_s, U graph.

The groundwater table in that area is deeper than the maximum depth reached with the tests, (around -4 m) so the U seems not to be significant.

For pushing the pressiocone has been used a prototype of penetrometer, the microanchors have been installed in the natural soil instead than in the foundations.
Figure 8. Prototype of the penetrometer, anchored with microanchors.

Before starting the test, a very careful saturation of the system (pressumeter, Rilsan tube, manual pump) has been made with water (emulsified with oil), not to leave any air bubble in the circuit.

The pressiometric tests have been carried out every meter starting from -1.0 ÷ -1.5 stopping the pushing of the rods and making the sheath expand up to the double of the initial volume, sometimes with loops, measuring pressure vs. volume at times T=0 (immediately after expansion) and T=180 s (180 seconds after).

an example of a pressumeter test graph carried out at -2.5 m is shown below, the two curves show the V-P values at time T = 0 and T = 180 s
Figure 9. V-P (volume-pressure) graphs at time T = 0 and T = 180 s.

7 CONCLUSIONS

The first results were very encouraging, and all parts of the instrumentation worked properly. Thus, the guidelines for the future development of the instrumentation and for the definition of the test execution procedures were completely outlined: anchoring, preparation, and calibration of the piezo-cone and of the FDP, programming of the FDP test sequences.

This first phase will be followed in a very short time by comparative validation tests in which tests will be carried out (first in "natural" soils and then in soils treated with resins) with the pressiocone and, at a short distance, comparative tests with standard instrumentation (boreholes with sampling and laboratory tests, with execution of standard pressiometer tests, SPT, Vane Test, execution of CPTU and DMT dilatometric tests).

Characterisation of near-surface sediments using a blend of vertical and shallow rotational penetrometers

D.J. White
University of Southampton, UK

S.A. Stanier
University of Cambridge, UK

H. Mohr
University of Western Australia and MSMT Solutions, Perth, Australia

ABSTRACT: The mechanical properties of near-surface sediments – to a depth of approximately half a metre – are relevant to the design of cables, pipelines and other shallowly-embedded infrastructure, as well as benthic habitat characterisation. For this depth of interest, vertically-pushed penetrometers – such as the cone, T-bar or ball – can be supplemented by shallow rotational devices such as the toroid or hemiball. In this paper, we report vertical and shallow rotational penetrometer test procedures and show results obtained in project conditions on natural soil samples. By combining these different penetrometers, a wider and more reliable set of mechanical properties – spanning strength and consolidation behaviour – can be obtained, compared to conventional practice. The paper concludes with practical advice on testing protocols and interpretation methods to best characterise the shallow seafloor, including the use of novel shallow penetrometers.

1 INTRODUCTION

1.1 Shallow seabed properties

The properties of the shallowest half metre of the seabed are relevant to the design of cables, pipelines and other shallowly-embedded infrastructure such as rock dump and scour protection systems, as well as the study of benthic ecosystems. The importance of accurately determining the strength and consolidation properties of the seafloor is emphasized in good practice guidance (e.g. ISO 19901-4, White et al. 2017).

Typical practice to characterize the shallowest seafloor includes (i) box core or drop core sampling, (ii) penetrometer testing from a seabed frame or into a box core and (iii) index testing of samples.

In this paper, we describe how practice can be enhanced by modern vertical and shallow rotational penetrometer testing to determine more accurately the strength and consolidation properties of the seafloor.

1.2 Novel shallow penetrometer systems

Shallow penetrometers, which combine vertical movement and rotation about the vertical axis, were first trialled a decade ago, using toroid and hemiball shapes (Yan et al. 2010). Subsequent work includes laboratory studies (e.g. Boscardin & de Groot 2015,

Schneider et al. 2020a) and numerical simulations (Stanier & White 2015, Yan et al. 2017, Schneider et al. 2020b,c). Some of this work formed part of the Remote Intelligent Seabed Surveys (RIGSS) Joint Industry Project (www.rigssjip.com).

2 COMBINED PENETROMETER SYSTEM

2.1 Actuation system

A shallow penetrometer test aims to subject the seabed to a loading history that replicates the conditions around infrastructure, and provides a simple basis to interpret fundamental soil properties, including the interface shear strength at the penetrometer surface. The control requirements involve vertical and rotational motion in load-controlled contact with the seabed. These requirements exceed current systems for CPT and T-bar testing, which involve only vertical motion between specified position limits.

A system for vertical and shallow penetrometry must therefore meet the following requirements:

1. Accurate identification of the touchdown point, when the penetrometer contacts the seabed.
2. Control via feedback of the vertical load on the penetrometer, e.g. during a dissipation step.

3. Allow 'programmable motion control' so that sequences (e.g. penetration-dissipation-rotation) can be performed without intervention.
4. Allow variable speeds of movement to permit testing over a range of drainage conditions.

An actuator system that meets these requirements was developed as part of the RIGSS Joint Industry Project (Figure 1, Schneider et al. 2020a). The capabilities are summarised as follows:

1. Controlled motion at rates of 0-3 mm/s (vertical) and 0-3 deg/s (rotational), allowing drained and undrained movements in clay and silt soils (drained in sand), with positioning resolution of 0.0125 μm and 9×10^{-6} degrees.
2. Load measurement and control to an accuracy of ± 0.1 N, even on-deck under ship motion – as proven during offshore trials. This force resolution corresponds to less than 0.02 kPa of undrained strength, for the sizes of shallow penetrometer used, so the system accuracy is much better than typical sample variability.
3. A user interface and motion control system allows pre-programmed steps of consolidation (under set vertical load) and/or cyclic rotation.
4. Ruggedised packaging in plastic flight cases allows transport offshore or by plane.
Figure 2. Miniature penetrometers: Ø5 × 20 mm T-bar, Ø10 mm ball, and Ø5 mm cone (MSMT Solutions).

The shallow penetrometer actuator system is capable of operation offshore on deck, in box cores. However, it is equally suited to use in the laboratory, with recovered samples. Both modes have been used.

2.2 Miniature vertical penetrometers

To measure the shallow strength profiles of samples, miniature scaled versions of the conventional cone, ball and T-bar penetrometers are used. These attach via simple fittings to the same actuator, and provide high resolution profiles of shear strength. For the ball and T-bar, remoulded strength is also obtained through a cyclic phase. The penetrometers shown in Figure 2 have replaceable top load cells and were manufactured by MSMT Solutions (Perth, Australia).

2.3 Shallow rotational penetrometers

Three shallow rotational penetrometers are shown in Figure 3: ring and toroid penetrometers of outer diameter, D_o = 125 mm, and body width or diameter, D_b = 25 mm, and a hemiball with overall diameter, D = 100 mm. All penetrometers are roughened by a sand coating and feature embedded pore pressure transducers with porous stones flush with the curved surfaces.

2.4 Sampling and testing location

The penetrometer system mounts onto box cores, or can rest on a frame over a sample. Tests on intact samples can be performed in box cores on deck, or jumbo samples can be extracted from a box core (e.g. in a 250 mm diameter plastic tube) and transported back to the lab for penetrometer testing (Figure 4).

A typical combined testing programme for a single box or jumbo core involves (i) vertical penetrometer tests to assess the strength profile, followed by (ii) one or more shallow penetrometer tests to measure interface strength and near-surface consolidation

Figure 1. Penetrometer system: vertical and rotational actuation.

Figure 3. Shallow penetrometers: ring, toroid and hemiball.

Figure 4. Testing on deck (left) and in the lab (right).

properties. If insufficient surface area is available, extra shallow penetrometer tests can be performed after scraping away the top layer or on remoulded samples.

3 STRENGTH PROFILING

Example profiles from the miniature vertical penetrometers are shown in Figure 5, for conditions with penetration resistance from 10 to 1000 kPa.

T-bar tests in very soft clay (Figure 5a) resolve the undrained strength, s_u, to $1/10^{th}$ of a kPa, and are consistent with shallow penetrometer strength data. Miniature cone and T-bar data from undrained penetration in carbonate silt (Figure 5b) show consistent penetration resistance

across both instruments, and agreement with standard ($D = 35.7$ mm) cone data from a seabed frame system. However, for the sandy silt example (Figure 5c), the initial penetration resistance of the standard cone is lower, perhaps due to near-surface effects on the penetration mechanism, which have minimal influence on the miniature cone.

4 SHALLOW PENETROMETER TESTING

4.1 *Typical test procedure*

The usual steps of a shallow penetrometer test are illustrated in Figure 6. The steps are described in Table 1, which sets out the control applied to the vertical and rotational axes in each step, the end points of each step and the typical speed or durations
Figure 5. Vertical penetrometer tests in intact seabed samples (i) Clay (ii) Carbonate silt (iii) Carbonate sandy silt.
Figure 6. Stages of a shallow rotational penetrometer test.

relevant to testing in soft clay. On sandy soils the periods are more rapid, and the dissipation pauses may not be required. Figure 7 shows typical raw results.

4.2 Typical test results

The usual interpretation procedure for a shallow penetrometer test is set out in Table 2, and the interpreted data is shown in Figure 8. The interpretation methods for soil strength and consolidation parameters are based on bearing capacity theory and dissipation solutions. The interface strength parameters derived from the rotational stages involve a correction for 'wedging' effects for the hemiball and toroid devices. Ring penetrometer data does not need this correction.

Ideally, fully undrained and fully drained strengths can be measured, limited by the maximum actuator speed and test duration, respectively, relative to the soil coefficient of consolidation. Regard-

Table 1. Typical shallow penetrometer test procedure.

Step	Step name	Control parameters	Control values (toroid and ring)	Step procedure	Step end point
0	Prepare	Vertical rate, v Rotation rate, $\omega = 0$	$v = 0.5$ mm/s	Position penetrometer above test location in sample and drive penetrometer to test start point. Take zero readings from all transducers. Confirm response of pore pressure transducers to hydrostatic head.	Visual check: penetrometer is ~20 mm above sample surface
1	Penetrate	Vertical rate, v Rotation rate, $\omega = 0$	$v = 0.4$ mm/s	Drive penetrometer vertically to $0.5D$ embedment (or until the load cell limit, V_{limit}, is reached). Maximum measured vertical load is captured as V_{max}, and used in control of Step 2.	When $w = 0.5D$ or vertical load, $V = V_{limit}$
2	Unload	Vertical load, V Rotation rate, $\omega = 0$	$V = V_{max}/2$	Reduce vertical load on penetrometer by a factor of 2, to $V = V_{max}/2$, (to avoid excessive settlement during rotational stage of test) and hold this load. (Or unload to a specified V to match the applied stress relevant for design).	Move immediately to Step 3
3	Dissipate	Vertical load, V Rotation rate, $\omega = 0$	$V = V_{max}/2$	Hold penetrometer under load of $V = V_{max}/2$, allowing dissipation of excess pore pressure, Δu.	When $\Delta u/\Delta u_{ini} < 0.1$
3b	Set OCR, dissipate	Vertical load, V Rotation rate, $\omega = 0$	$V = (V_{max}/2)/OCR$	(Optional, _OCR test option_) Reduce vertical load by a specified ratio; repeat pore pressure dissipation. (Consider the OCR range relevant to design when planning tests. If needed, add Step 3b in some tests).	When $\Delta u/\Delta u_{ini} < 0.1$

(*Continued*)

Table 1.   (Cont.)

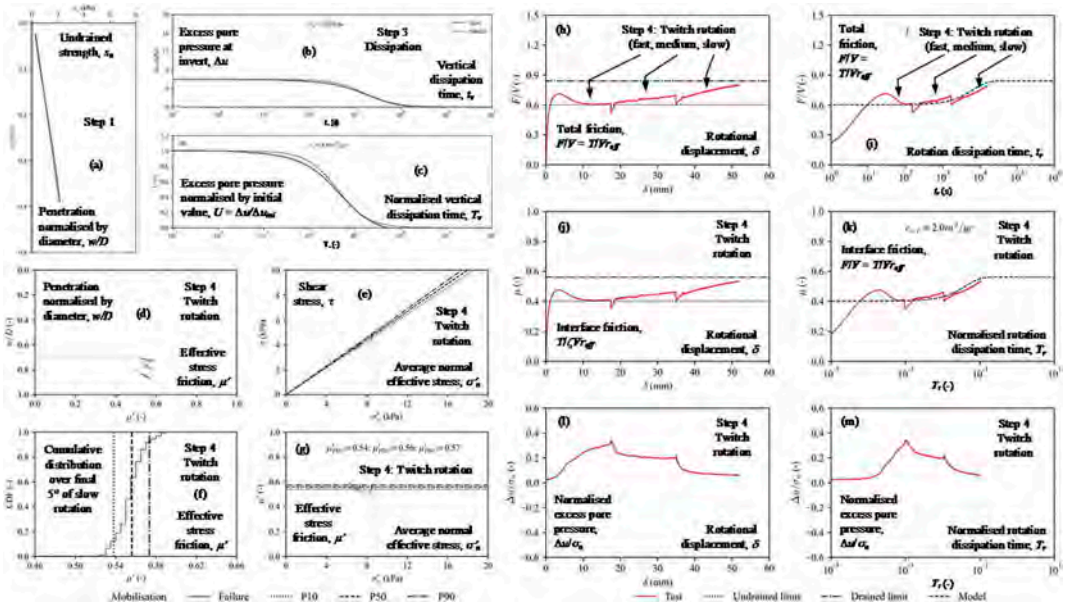
4 (4a or 4b)	4a Twitch rotation	Vertical load, V Rotation rate, ω	Fast-medium-slow, $\Delta\theta$ = 20 deg rotation at each speed, ω = 0.4, 0.04, 0.004 deg/s	*Basic monotonic test option:* Rotate device by a specified angle, at fast, medium and then slow speeds, to measure the undrained (initially) and drained (later) torsional resistance, T.	When $\theta = 60°$
	4b Episodic rotation	Vertical load, V Rotation rate, ω	ω = ±0.4 deg/s for $\Delta\theta$ = 20° t_{consol} = 30 min	*Episodic test option:* Perform episodes of rotation and consolidation. In each rotation stage turn through a fixed angle at the fast speed, alternating direction between cycles. During consolidation period, t_{consol}, between cycles, maintain vertical load. Typically the response stabilises after ~15 episodes.	When the cycles are complete
5	Drained sweep	Vertical load, V Rotation rate, ω	$dV/dt = -V_{max}/(2t_{unload})$ ω = 0.004 deg/s	Rotate penetrometer at constant slow speed while reducing the vertical load to zero over the unloading period, t_{unload}. Typically set $t_{unload} \sim 30$ minutes on clay. This step gives the change in T with V, measuring the friction across a range of normal stresses.	When $V = 0$ (i.e. when the penetrometer lifts away from the sample)
6	Retract	Vertical rate, v Rotation rate, $\omega = 0$	$v = -0.5$ mm/s	Withdraw penetrometer vertically to above the sample surface. Take additional zero readings.	Penetrometer returns to starting position above sample surface
Figure 7. Typical unprocessed results from shallow penetrometer test with a monotonic rotation step (hemiball in soft clay).


Figure 8. Typical interpreted results from a shallow penetrometer test with a monotonic rotation step (hemiball in soft clay).

less, an effective stress interpretation with a weighted average pore pressure provides effective friction parameters, even if the rotation is undrained or partially drained.

The interpreted results in Figure 8 show the following derived soil parameters: (i) profile of undrained strength, s_u (sub-figure (a)); (ii) consolidation coefficient during loading path (c); (iii) undrained interface strength (j); (iv) drained interface strength (j); (v) consolidation coefficient for shearing path (k); (vi) effective stress failure envelope (e) and (vii) effective stress friction (as distribution) (g).

5 RESEARCH STUDIES AND PROJECT USAGE

The penetrometer system has been used for >300 tests at the time of writing, for research activities and for commercial projects across three continents. Typical project test programmes have involved 10-20 shallow penetrometer tests spread over 3-4 distinct soil zones, with parallel vertical penetrometer profiling. Reliable and repeatable measurements of interface strength have been obtained for clays, silts and sands. Examples of added project value have included (i) the first ever data on consolidation coefficient at the very near-surface, (ii) better characterization of the consolidation-hardening behaviour from repeated

surface sliding on clay and (iii) more detailed and repeatable measurements of drained and undrained interface strength parameters.

The shallow penetrometers offer an alternative to the low stress interface shear box. In our experience, this test can be unreliable compared to shallow penetrometer tests due to extraneous forces polluting the shear and normal forces measured in the shear box. Further studies into shallow penetrometers, particularly focusing on the ring, are reported by Mohr et al. 2022 and Singh et al. 2022.

6 CONCLUSIONS

Vertical and shallow rotational penetrometer tests together provide a new method to obtain a wider and more reliable set of near-surface seabed mechanical properties compared to conventional practice.

The equipment, procedures and interpretation approach for the new types of shallow penetrometer are now well-established, with the key details summarized in this paper. Drained and undrained interface strength parameters, as well as consolidation properties, can be objectively derived through rapid testing in box cores or samples recovered to the laboratory.

Table 2. Typical shallow penetrometer test interpretation procedure.

Step name/ Step type	Input parameter(s)	Calculated parameter(s)	Calculation approach	Calculation coefficients	
				Ring	Toroid Hemiball
1 Penetration	Vertical load, V	Undrained shear strength, s_u	$s_{um}, k_{su} = f(V(w))$ – use iteration to fit a linear s_u profile ($s_u = s_{um} + k_{su}w$) (Stanier & White 2015) $U_I = \frac{\Delta u}{\Delta u_{ini}} = \frac{1}{1+\left(\frac{T_v}{T_{50,s}}\right)^m}$ with time $T_v = \frac{c_v t_c}{D^2}$	N/A	See S&W reference
3 Dissipation	Excess pore pressure response, $\Delta u(t_v)$	Consolidation coefficient, c_v (for stress path after vertical penetration)	Plot data and equation of $\Delta u/\Delta u_{ini}$ vs. t_v, adjust c_v. Or find $t_{v,50}$ when $\Delta u/\Delta u_{ini} = 0.5 \rightarrow c_v = T_{50,v}D^2/t_{v,50}$. t_v: time since start of dissipation (i.e. start of step 3).	$T_{50,v} = 0.0675$ $m = 1.00$ (Singh et al. 2022)	$T_{50,v}$ and m vary with w/D. See Schneider et al. (2020b)
		Undrained interface friction, μ_{ud} Drained interface friction, μ_{dr}	$\mu_{ud} = \frac{\tau_{int}}{\sigma_{v0}} = \frac{F}{V} = \left(\frac{T}{\zeta r_{eff}V}\right)$ $\mu_{dr} = \mu' = \tan\delta = \left(\frac{F}{\sigma'}\right)_n \mu d \frac{F}{V} = \left(\frac{T_r}{T_{50,r}}\right)^n$ dr	$\zeta = 1$ $r_{eff} = L + \frac{D_b^2}{12L}$, $L = \frac{1}{2}(D_o - D_b)$	
4, 5 Rotation	Vertical load, V Torque, T Total friction, $\mu = T/V$ Excess pore pressure, $\Delta u(t_r)$	Consolidation coefficient, $c_{v,r}$ (for stress path during rotation)	$\mu = \mu_{dr} - (\mu_{dr} - \mu_{ud})0.5\left(\frac{T_r}{T_{50,r}}\right)^n$ with $T_r = \frac{c_{v,r}t_r}{D^2}$ Use same method of fitting as described in Step 3. t_r: time since start of rotation (i.e. start of step 4).	$T_{50,r} = 0.25$ $n = 0.9$	ζ, r_{eff}, A_c and β vary with w/D. See Schneider et al. (2020b, c)
		Effective stress envelope, μ'	$\mu' = \left(\frac{\tau_{int}}{\sigma'_{n,ave}}\right)$ where $\tau_{int} = \frac{T}{A_c}$ and $\sigma'_{n,ave} = \sigma_{n,ave} - \Delta u_{ave} = \frac{\zeta V}{A_c} - \beta\Delta u_{pos}$	$A_c = 2\pi D_b L$ $\beta = \frac{\Delta u_{ave}}{\Delta u_{pos}} \approx 0.7$ for pore pressure at mid radius	A_c and $\beta = \frac{\Delta u_{ave}}{\Delta u_{pos}}$

These methods have been developed through >300 tests, supported by theoretical and numerical analysis, and have been applied in several commercial projects.

ABSTRACT: An enhanced seafloor CPT system has been developed to support completion of the soil investigation campaign for Dogger Bank. This enhanced system has a demonstrable and significant performance increase over standard seafloor CPT systems; capable of pushing through dense sand layers with q_c>100 MPa and through tens of meters of very stiff clays. At Dogger Bank, this enhanced system has enabled CPT penetrations of more than 40 m below seafloor, in soils where standard systems could only average in the twenties. The system enhancement has been achieved through the application and adaption of techniques well known in the geotechnical industry (water lubrication and water injection), but which have never before been combined in an offshore seafloor CPT system. The performance of the enhanced CPT system has enabled a reliance on seafloor CPTs to acquire data to beyond monopile toe depths, therefore removing absolute reliance on boreholes to acquire data at turbine locations and facilitating the fast and efficient development of a geotechnical design basis.

1 INTRODUCTION

A challenge in offshore wind farm development is designing a soil investigation campaign that efficiently and cost effectively provides the geotechnical data required for the design of pile foundations. With many years of gradually applying in situ testing as an active part of building a design basis, it is observed that seafloor CPTs are both efficient and less expensive than boreholes, yet they are often compromised by not being able to penetrate to pile toe depths.

Monopiles are the primary foundation type for the Dogger Bank wind farm development. As outlined in the companion paper (Yetginer-Tjelta et al., 2022), the design of monopiles requires soil data to 40-45 m below seafloor. Furthermore, windfarm layouts are commonly only confirmed late in project execution, necessitating a rapid turnaround from turbine location definition, to the delivery of a geotechnical design basis. Due to these factors, seafloor CPTs would be the preferred solution provided that a penetration to greater than 40m can be achieved.

Soil conditions at Dogger Bank consist mainly of dense to very dense sands and very stiff clays. For these soils, experience has shown that for "standard" seafloor CPTs, refusal frequently happens between 20-30m below seafloor. This is due to the combined effects of high rod friction in the stiff clays and high tip resistance encountered within the dense sand layers, frequently found at the base of Dogger Bank clays, at 25 to 30m below seafloor. Consequently 40+ m penetration cannot be achieved at most locations at Dogger Bank.

The seafloor CPT penetration statistics from the two preliminary soil investigation campaigns in 2010 and 2012 illustrate these factors:

Table 1. Summary of early seafloor CPT penetration depths Dogger Bank.

		Final penetration depth (m bsf)		
Year	No. CPTs 1)	Minimum	Maximum	Average
2010	97	3.8	40.2	22.5
2012	87	8.9	40.1	27.2

Whilst these CPTs provide good data for the development of a ground model, the sub 40m penetrations would not enable standard seafloor CPTs to be relied on as the primary data acquisition tool for monopile design. Therefore, for the purpose of designing the turbine location specific completion soil investigation (SI) campaign, the following options were considered:

- Revisit turbine locations with seafloor CPT refusals of less than ~40m penetration with a drillship and down hole CPTs, or
- Accept high uncertainty on soil conditions below refusal depth and build trust into a good ground model, or
- Attempt to reach deeper with an improved "deep" seafloor CPT system.

Revisiting seafloor CPT refusal locations with a drillship was deemed not acceptable for reasons of cost and time. Whilst the reliance on the ground model below refusal depth was similarly rejected due to the complex geology and reworked soils. Geophysical reflectors were frequently broken and made it difficult and often impossible to follow any layer more than a few hundred meters. Furthermore, the lower sand (base of Dogger Bank) is found between 25-35m; coincident with the seabed multiple of the UHR seismic data. This resulted in very poor confidence for the ground model below this depth since all detailed information on layer thickness and general stratigraphy disappeared in the strong multiple reflection and little details were visible below.

From the above it is clear that development of equipment and procedures for achieving larger penetration with seafloor CPTs was of critical importance to support the efficient and cost-effective delivery of the Dogger Bank completion SI campaign. This became a main objective with the various CPT campaigns in the period 2018-2021. This is further detailed in Sections 3, 4 and 5 below. It became a stepwise approach where trials, results/experience and modifications were considered on a continuous basis.

As outlined by Yetginer-Tjelta et al. (2022), 3D UHRS geophysics in 2019 (and beyond) improved the resolution and capability of the ground model but were not sufficient to replace CPT data as the basis for foundation design.

2 PREVIOUS WORK TO REACH DEEPER PENETRATION

The most common way of increasing penetration is to reduce the friction along the CPT rods. Frequently a friction reducer such as an expanding coupling is used at some distance behind the cone. Thus, the diameter of the hole is expanded and the friction between the rod and the soil is reduced. According to ISO22476-8: 2012 the friction reducer must be at least 400 mm behind a 10 cm^2 cone in order not to influence the measured CPTU parameters. Offshore soil investigations with a seafloor rig often use a 15 cm^2 cone and 10 cm^2 rods, which gives good results in many cases.

Another way of reducing the rod friction is to inject water or drilling mud at some location above the friction reducer. Jefferies and Funegard (1983) reported such a system and showed that the pushing force can be reduced by up to 50 % (Figure 1). Staveren (1995) reported that in stiff overconsolidated Belgian Boom clay, normal CPTs met refusal at 5 m penetration: using mud injection, up to 62 m penetration could be achieved.

In very dense sand, high cone resistance can be a factor limiting penetration. Bayne and Tjelta (1987) and Yagi et al. (1988) reported designs of cone penetrometers where water could be injected into the soil through channels in the penetrometer tip. The cone design reported by Bayne and Tjelta (1987) was intended to be used to investigate how much skirt penetration resistance in dense dilatant sand could be reduced by water injection. High negative pore pressures and increased effective stresses, resulting in high cone resistance, may be neutralized by adding water during penetration. This cone penetrometer was unfortunately not used in practice. Yagi et al. (1988) used their cone
Figure 1. Total cone push force with and without mud injection (adapted from Jefferies and Funegard, 1983).

penetrometer to carry out tests at various effective stresses. They controlled this by adding water or air through the tip during cone penetration.

In summary, for further work at Dogger Bank in 2018 the ideas of rod lubrication and potentially water injection at or around the cone tip were selected for further experimenting.

3 ENHANCED CPTS USING ROD LUBRICATION

A strategic cooperation contract was agreed between the Dogger Bank project and the Danish contractor Geo with the aim to improve seafloor CPT penetration below mudline from being in the low 20m's to anything towards 40m (later changed to 45 m). In 2018 the following modifications were introduced to reach this aim:

1. Increased thrust capacity, i.e. 250 kN net thrust available at seafloor.
2. A rod lubrication system which reduced or eliminated friction accumulation in the stiff clays to enable deeper penetrations in the clays and thus enable more thrust capacity in the dense sand layers at base of Dogger Bank clay units.

These first tests improved the penetration depth below seafloor significantly, from an average of 23 m to approx. 35.8 m, and with several CPTs reaching close to 40 m (target depth at that stage)
Figure 2. Thrust for Enhanced CPT with lubrication and 3 CPTs with no lubrication.

and one test meeting the target with still 5 kN thrust reserve. Figure 2 shows total thrust curves for 4 CPTs within an area of 110 x 110m with 3 standard CPTs reaching maximum thrust between 19 and 24m whilst one CPT with rod lubrication reached 35.2m including penetration through two dense sand layers.

In addition to thrust, pressure and flow rate of lubrication water are measured. There is a potential for using these parameters in the interpretation of the test results.

4 DIRECT PUSH CPT WITH WATER INJECTION AT TIP, MEASURING THRUST ONLY (DCPT)

From the testing in 2018 (above) it was clear that rod lubrication worked and enabled significantly deeper penetration. It also meant when the dense sand layers were met at about thirty meters depth, only 10-15% of the thrust capacity was spent on reaching this depth (note the relatively constant thrust with depth in mostly clay down to 30m). But some of the sand layers were very dense, with q_c values of more than 100 MPa, and for some locations significantly more than 10-15% of the thrust was required to overcome layered units. Refusal was therefore still frequently encountered in dense sand layers. To deal with locations where several sand layers made the rod lubrication less efficient, and where deeper sand layers added to frequent refusals in the 30 m range, further work took part along two parallel paths.

Firstly, further improvements were made to improve the efficiency of rod lubrication. Many options were tested, including:

– variations in water injection hole diameter and location (radially and axially)
– combination with friction reducers of various thickness and length
– high and low water pressures
– variations in water volume.

Secondly, to improve the penetration of very dense sand layers, water injection at the cone was attempted in different ways. This built on experience gained over many years from projects such as Gullfaks C (Tjelta et al.,1986), Dudgeon suction anchor trials 2013 (unpublished), and the OWA Suction Anchor Trial Installation Campaign 2015 (unpublished) where significant reduction in the penetration resistance of skirts and suction anchors was observed by injecting water at the skirt tip. The effect comes from partly reducing dilation in dense sand, removing dilation completely (and reducing effective stresses) or in some cases probably by flushing away sand particles.

Various geometries of the cone with flushing through the tip, at the face and at the neck were tried, see two examples in Figure 3. These cone types were not instrumented and were named DCPTs (Direct Cone Penetration Test), with the only

recording of penetration resistance being total thrust (a bit like the mechanical cones in the early days of cone testing). Water injection at these positions is expected to have some influence on a measured cone resistance, but nevertheless this system did result in deeper penetration and provided information of what was below the dense sand at which time the water injection can be reduced or halted.

Figure 3. Various cone tips with water flushing for DCPT cones.

Figure 4a shows an enhanced CPT to 45m depth (red curve) in parallel with a non-instrumented cone, DCPT (black curve). At this location it was possible to penetrate both cone types to 45 m (target depth). At many other locations the enhanced CPT met refusal at shallower depth and soil stratigraphy had to be inferred from thrust curves only (Figure 4b provides an example).

What this parallel test in Figure 4a shows is a very good correlation between q_c and thrust when rod friction is kept low and relatively constant. This test (black curve) uses combined rod lubrication and cone water injection.

Figure 4b shows an enhanced CPT meeting refusal due to max thrust and high tip resistance (114 MPa) whilst the DCPT reached 40m without any problem (40m was target depth at this test location), and clearly provides relevant information of soil strength and stratigraphy. For instance, the driveability of large monopiles can be considered feasible since the dense sand layers at 26 and 34m are proven to be relatively thin. When soil stratigraphy is very variable (less homogeneous and/or rod lubrication is less efficient) the thrust/q_c correlation is less accurate. Although the DCPT system worked well in 2019, some locations had to be covered by drilling and down-hole CPTs. This experience stimulated further development.

5 DCPT WITH MEASUREMENT OF TIP RESISTANCE (iDCPT)

To achieve improved penetration in the very dense sand layers at Dogger Bank (q_c in the range of 100-150 MPa), the S-cone was developed, as shown in Figure 5. This is a cone tip which combines the power of a 5 cm[2] cone in spearheading into dense sand, combined with large holes for water injection to reduce sand resistance on the face of the cone with enlargement following closely behind the cone tip. The early version of this S-cone was non-instrumented and only thrust was recorded. Later versions of the S-cone are instrumented, with q_c and inclination recorded (named the iDCPT), but due to robustness being prioritised and space limitations associated with water injection, the tool has less accuracy than a standard cone according to ISO specifications. However, as can be observed in Figure 6, where an enhanced CPT and an iDCPT were performed only meters apart; the enhanced CPT met refusal at 24 m whilst the iDCPT using the S-cone penetrated to 45 m. The correlation between q_c from the robust iDCPT and the enhanced CPT is good, and it is seen that the iDCPT provides useful information for layers below the depth of penetration attained by the enhanced CPT.
Figure 4. a) Location A (top): Comparisons between normal CPT and DCPT - enhanced CPT and DCPT both penetrate to ca. 45 m; b) Location B (bottom): Enhanced CPT refused at 26 m whilst the DCPT reached 40 m (target depth at the time, could have gone deeper).

The most efficient combination of water injection (pressure and volume), friction reducers and cone shapes may depend on the soil conditions and will invariably include some trial and error in the beginning, but the results speak for themselves (Table 2).

From pre-2018, the average CPT depth has increased from 22m to 44m in an area where dense sand layers dominate below 25-30m. These numbers do not include the iDCPT. A challenge has also been to distribute water in the most efficient way between the rod lubrication and the tip flushing.

Table 2.   Summary of Seabed CPT penetration depths Dogger Bank.

		Final penetration depth (m bsf)		
Year	No. CPTs 1)	Minimum	Maximum	Average
2010	97	3.8	40.2	22.5
2012	87	8.9	40.1	27.2
CPT equipment enhancements from 2018 onwards				
2019	100	14.3	45.6	38.8
2020	120	7.5	50.3	40.1
2021	98	23.5	58.8	44.5

Figure 6.   Enhanced CPT and iDCPT.

6   DISCUSSION

The main objective set out at the start of 2018 was to reach sufficient penetration with seafloor CPT testing without the need for drilling and down-hole CPTs.

Two main targets were identified in these early days:

1. Reduce or "eliminate" rod friction to enable deeper penetration and have more thrust capacity available when dense sand layers appeared at base of Dogger Bank formation.
2. Improve the ability to penetrate into and through dense sand layers with tip resistances in excess of 100 MPa.

This objective has been met; seafloor penetration depth to 40-45m is now possible at Dogger Bank at most locations. The importance of this objective goes beyond the operational aspects of seafloor CPTs being more efficient than down hole CPTs in a borehole. It allows for reduced time from confirmed turbine layout to delivery of a geotechnical design basis "*by the speed with which the data can be acquired, processed and interpreted to provide geotechnical engineering parameters. This is advantageous for the development of offshore wind farm projects which may have 100 or more WTGs. For the Dogger Bank WTG locations, continuous seafloor CPT data permitted semi-automatic processing and analysis of data and thus:*

1) Rapid development of geotechnical design profiles (preliminary profiles available in a matter of minutes);

2) Early phase monopile driveability predictions for identifying the potential risk of refusal during installation." quote from companion paper (Tjelta et al 2022)

On a side note, the ability to penetrate into and through dense sand layers with tip resistance in excess of 100 MPa at more than 30m below seafloor is not trivial. It requires a significant reduction of rod friction. In doing so, the combined effect of a friction reducer and water injection as described in this paper is necessary, and it has taken time and efforts to arrive at a geometry

that works. The impact of altered geometry due to extreme wear on all parts in the CPT system complicates the feedback. Figure 7 indicates the changes taking place. Diameter changes, and friction reducers are ripped off by the continuous abrasion from dense quartz sand.

Figure 7. New rod with friction reducer 44mm left and to the right the wear has reduced diameter to 41 mm and in parts of the FR it is ripped off completely.

Outstanding challenges to be addressed are effective lubrication while the CPT string is being built, and effective lubrication in permeable sand layers.

The importance of the following elements has been recognized during the 3-4 years it has taken to develop a fully operational and efficient enhanced seafloor CPT system:

– Friction reduction and ideally removal along the entire rod by a combination of a friction reducer above the friction-sleeve and water injection
– Increased thrust force when stiff clays and dense sand layers are combined, like at Dogger Bank
– The importance of inclination measurement in the cone, both for operational purposes (abort the CPT if becoming excessive or to push deeper to compensate for rod inclination) and for final presentation of results with true vertical depth
– Special measures at the cone tip to tackle extremely dense sand layers with q_c above 100 MPa.

7   SUMMARY AND CONCLUSIONS

A seafloor CPT system with improved (enhanced) capabilities has been developed for the Dogger Bank field investigations in the period 2018-2021. The main objective of this development was to improve the depth range to more than 40m below seafloor in an environment where average penetration used to be in the low 20m's. This has been achieved through systematic development and adaption of techniques well known in the geotechnical industry (water lubrication and water injection). However, these techniques have never before been combined in an offshore CPT system to produce a machine capable of pushing through dense sand layers with $q_c >$ 100MPa and very stiff clays. The result has been a 100% increase in CPT penetration depth compared to a few years ago.

This performance enables fast and efficient development of a geotechnical design basis when combined with early boreholes strategically placed in geological units to build a ground model, as discussed in the companion paper (Yetginer-Tjelta et al., 2022).

ABSTRACT: The CPTU constitutes the main *in situ* offshore investigation tool for geotechnical site characterisation and provision of soil input for the design of wind turbine foundations. CPTUs are typically performed at all foundation positions. Thus, all obtained results of supporting geotechnical *in situ*, model and laboratory testing need to be confidently correlated to the CPTU parameters. Most of the interpretation methodologies available for industry practice consider the soil behaviour around the cone either as fully drained or undrained, and acknowledged and well-proven correlations between CPTU parameters and classification and engineering properties exist for sand and clay. However, for transitional soils, e.g. silty soils, which may exhibit partial drainage during standardized cone penetration, such robust interpretation schemes do not exist. This paper presents the background, the objectives, setup and early field results of a joint industry project into CPTUs in silty soils for developing schemes for planning, execution and interpretation.

1 INTRODUCTION

The Offshore Wind Industry is rapidly expanding across the globe. This expansion leads to the exploration of offshore wind sites that are characterized by thick layers of silty sand and silt mixtures. In contrast to sampling boreholes, CPTUs are performed on all wind turbine positions, which in many cases can be more than 100 positions covering large areas. The CPTU parameters must be confidently correlated to all supporting geotechnical tests to mitigate the following risks: a) site characterization and establishing facility position-specific soil parameters for foundation design, b) choice of foundation concept and relevant design methodologies, c) installation predictions, d) cable design and e) increased project maturation times and site investigation scopes. However, as opposed to sand and clays, the Industry finds it generally challenging to properly identify and capture the behaviour of transitional soil, e.g. silty sand, silts and silt mixtures, with standardized CPTUs. No simple, robust, and standardized testing approaches and interpretation methodologies have been calibrated to these types of soils.

A Joint Industry Project (CSi – CPTUs in Silty soils) is currently being executed within the Carbon Trust Offshore Wind Accelerator programme with the main objective to develop robust guidelines targeting the industry for planning, specification, execution, and interpretation of CPTUs in silty soils. Focus is especially paid to

- Soil classification and mechanical behaviour
  o New and/or revised soil classification and soil behaviour type charts
  o Identification of transition between drainage conditions including rate effects, i.e. of drained to partially drained to undrained conditions

- Correlations to engineering properties
  o Strength and stiffness.

- Guidelines for specifying and executing CPTUs for identifying silty soils and their behaviour.

The project targets mainly silty and transitional soils with low plasticity. This paper presents the background of the CSi project as well as the overall project set-up and early findings from a test site in Halden, Norway.

2 BACKGROUND

CPTUs carried out at a standard constant penetration rate (20 mm/s ± 5 mm/s according to ISO 2012) generally result in an undrained response in clay and a drained response in sand (Lunne et al. 1997). However, for silty soils partially drained conditions may prevail at the standard penetration rate, see DeJong et al. (2013). Understanding the drainage conditions around the penetrating cone is key to interpret CPTUs in silty soils (correlation with engineering parameters and classification charts).

2.1 Drainage conditions

In recent years the normalized penetration velocity V represents an often-used framework to indicate the drainage conditions around the penetrometer and to demonstrate how CPTU parameters change with penetration rate v, soil properties (horizontal coefficient of consolidation of the soil c_h) and cone penetrometer diameter d, see e.g. Randolph & Hope (2004), Kim et al. (2008) and Schneider et al. (2008). The normalized penetration velocity is defined as:

$$V = \frac{v\,d}{c_h} \qquad (1)$$

For contractive soils and a given cone diameter, the cone shoulder pore pressure u_2 increases, and the cone resistance decreases with increasing V, whereas the opposite may be observed for u_2 for dilative soils (Schneider et al. 2007 and Krage & DeJong 2016). Drained penetration is observed to occur for $V < 0.01$-0.3 and undrained penetration for $V > 20$-100 (Randolph 2004, Bihs 2021). v and d are parameters, which can be fully controlled and specified. Therefore, an accurate determination of c_h is important in the estimation of V. c_h depends on stress history, density and grain composition.

Determination of the operational value of the coefficient of consolidation of the soil is not straight forward, especially not for the more coarse-grained transitional soils. Most of the work to date, numerically and experimentally, is anchored in contractive clay-like soils and undrained conditions.

c_h can be determined from piezocone dissipation tests (PPDT) accounting for partial consolidation during cone penetration, and hence penetration rate, in the interpretation of the tests (DeJong & Randolph 2012). However, for transitional soils, the excess pore pressure measured at the cone shoulder u_2 does not always decay monotonically over time during dissipation and a dilatory response can be observed. Burns & Mayne (1998) and Paniagua et al. (2016) discuss different approaches to determine t_{50}, the time associated for 50% dissipation, dealing with both standard and non-standard (dilatory) dissipation curves. Carrol and Paniagua (2018) note that different interpretation methods can lead to significant differences in the estimated t_{50} and hence c_h.

The rigidity index I_r is required to interpret dissipation tests. However, the concept of I_r, developed for fully undrained conditions, may not be appropriate for partially drained conditions. Krage et al. (2014) provide guidance on how to determine I_r.

To overcome some of the challenges with the estimation of c_h, Schnaid et al. (2020) propose a modified version of the normalized penetration velocity depending on v, t_{50}, d and I_r.

CPTUs at variable penetration rates (VRCPTU) are traditionally performed to investigate the drainage conditions around the cone. Even with a robust methodology to estimate V, a link between V and engineering properties and soil classification need to be developed – also for engineering practice.

2.2 *Soil classification*

Soil behaviour type (SBT) charts, like Robertson (1990) and later updates or Schneider et al. (2008), are often used for classification purposes. The charts are based on standard CPTU geometries and a penetration rate of 20 mm/s.

Research (e.g. Schneider et al. 2008, Bradshaw et al. 2012) and practice support that silty soils can plot on a large range of zones in the SBT charts and thus the SBT charts alone can, at present, not be used to robustly identify grain composition or plasticity for a silt deposit. The reason is that the position in the SBT chart is a function of several parameters, including grain size, plasticity, *in situ* density, stress history and local geological history. Furthermore, partial drainage conditions affect where data plots on the SBT charts (DeJong & Randolph 2012) and use of additional data from dissipation tests and VRCPTUs may aid the identification of silty soils.

2.3 *Strength and stiffness*

Current practice in the offshore wind industry for assessing silty soils is to apply methods anchored in either clean sand (drained conditions, effective stress approach) or pure clay (undrained conditions, total stress approach).

The relation between cone resistance and the undrained shear strength through the cone factor N_{kt} has been investigated in the literature, e.g. Senneset et al. (1988), Blaker et al. (2019), Naeini & Moayed (2017) and Huang et al. (2021). For the effective stress friction angle Senneset et al. (1988) suggested an approach, which considers pore pressure build-up and is relevant for partially drained conditions. Bihs (2021) reports that both the drained and undrained strength depends on the choice of penetration rate. Senneset et al. (1988), Lunne et al. (1997), Robertson (2009) and Tonni & Simonini (2013) discuss constrained and small strain shear modulus.

Correlations between CPTU parameters and engineering properties are dependent on the quality of the samples tested in the laboratory for calibration purposes. Furthermore, for the strength correlations a unique failure criterion may not exist for undrained shear of especially dilative transitional soils (Blaker & DeGroot 2020). It is complicated to retrieve and prepare intact samples for testing and currently no robust and well-proved criterion for evaluating sample disturbance exists. Sampling and handling of silty samples are thus of importance to the CSi project.

3 CSI PROJECT SETUP

3.1 *CSi project scope and approach*

The CSi project includes a comprehensive scope of work, see Figure 1, on different scales and platforms to meet the project objectives and to exploit current and new methodologies and hypotheses for addressing the project challenges, cf. Sections 1, 2.

Initial studies in terms of a literature review and a project plan provides the background and detail the other activities. The guidelines, addressing the project objectives, are based on analyses of high-quality factual data gathered in a database. The data are extracted from different sources.

In situ tests, and parallel laboratory tests, will be performed on aged natural silty soils at two complementary onshore test sites (Halden, Norway and Voorne-Putten, the Netherlands). VRCPTUs with different cone sizes, dissipation tests, seismic CPTUs and sampling (the static hydraulic piston sampler and the static gel-push sampler) will be undertaken. The onshore test site data are supplemented by Partners' data from offshore projects across the world as well as data from other silt sites published in the literature, thereby increasing the applicability of the database.

Calibration chamber testing, centrifuge testing and associated standard element laboratory tests complement the onshore test site data by providing test results under well-defined and controlled conditions. Furthermore, they are also relevant for benchmarking to existing interpretation schemes for clean sand. VRCPTUs and dissipation tests are performed at different densities and consolidation stresses with full-scale and miniature cones in unaged non-plastic silty sand and reconstituted clean sands (Fioravante et al. 2022).

A state-of-the-art numerical model will expand the general applicability of the guidelines by validating and extrapolating the design space offered by the experimental data. Furthermore, recommendations with respect to numerical models for predicting CPTUs in transitional soils will be provided. The critical state based Norsand constitutive model along with large-deformation finite element and cavity expansion analyses will be used to calibrate and validate the model based on field, laboratory and model tests (calibration and centrifuge testing).
Figure 1. High-level strategy adopted during the CSi project.

3.2 CSi organisation

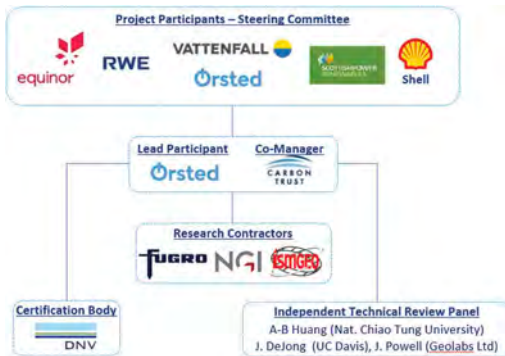
The CSi project is developed and led by Ørsted in partnership with five other offshore wind developers. The project is run as a discretionary project through the Carbon Trust's Offshore Wind Accelerator programme. The technical activities are managed and executed by the Norwegian Geotechnical Institute (NGI), supported by Fugro and ISMGEO. Selected activities are reviewed by an independent technical review panel to substantiate the developed methodologies. A certification body (DNV) ensures that the outcome is practically, applicable and relevant for industry practice and future standardization. Figure 2 illustrates the CSi organizational setup.


Figure 2. Schematic view of the CSi project setup.

4 FIELD TESTING AT HALDEN, NORWAY

4.1 Test site and test programme

The Halden site is located in southern Norway and is one of five sites within the Norwegian Geo-Test Sites program (NGTS). Extensive geophysical, *in situ* and laboratory testing have been carried out as part of the site characterization (see Blaker et al. 2019) and for subsequent research. Normally consolidated clayey silt is deposited between depths of five and 16 m and divided into two units, Unit II and Unit III, which are homogenous across the site.

The *in situ* testing programme (CPTUs and a borehole) was carried out in September 2021 and is summarized in Table 1 and Figure 3. The CPTUs were performed according to ISO (2012), except that non-standard penetration rates were also adopted. All tests were closely spaced but ensuring no interference with each other.

Efforts were made to ensure good saturation of the filters and cone chamber. At fast rate, the u_2 sensor must respond quickly and at slow rates, it shall ensure accurate measurements due to the small values of excess pore pressures measured. Plastic,

bronze and HPDE filters were used for the 5, 10 and 15 cm^2 cones, respectively. All filters and cones chambers were saturated with silicon oil. The filters were saturated under vacuum and placed in a container of saturation fluid before mobilization and until assembling with the cone. The cone chamber was first saturated with syringes and hereafter left submerged in a chamber with silicon oil along with the filters. Vacuum was also applied for up to 90 minutes for the 5 and 10 cm^2 cones. The penetrometer was assembled in submerged conditions and covered in a rubber membrane. The filters were replaced after each test.

Table 1. In situ testing scope, Halden campaign.

Item	Description
Cones	10 cm^2 single element (u_2)
	15 cm^2 dual element (u_1 and u_2)
	5 cm^2 single element (u_2)**
Scope per cone	1 CPTU benchmark*, 20 mm/s rate
	1 VRCPTU, 0.2 mm/s rate, 2 PPDT
	1 VRCPTU, 2.0 mm/s rate, 2 PPDT
	1 VRCPTU,200 mm/s rate, 2 PPDT

* 2 benchmark tests carried out for the 10 cm^2 cone
** Additional scope funded by the NGTS project
*** Dissipation tests (PPDT) as per Figure 3

Attention was also given to monitor the ground water table and thus the hydrostatic pressure (u_0-profile), since u_0 enters the calculation of e.g. B_q and is the baseline for dissipation tests. The ground water pressure was continuously monitored at four depths by means of standpipes permanently installed at the site, indicating hydrostatic conditions with the water table at 1.85 m depth.

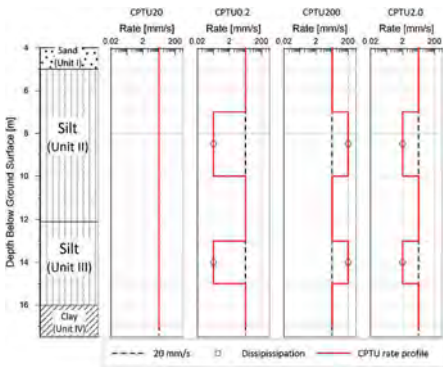
To investigate the drainage conditions around the cone through the normalized penetration velocity V, the chosen penetration rates cover four orders of magnitude (from 0.2 mm/s to 200 mm/s). The aim was to span from drained to undrained response during penetration. Furthermore, three cone sizes were used to investigate the effect of diameter. The u_1 sensor (located at the cone face) was used in addition to u_2 to study the differences in response during both variable rate penetration and during dissipation. The approach of having one long stroke at variable rate per soil unit at each location was preferred to the alternative twitch tests (see e.g. DeJong et al. 2013) because: (a) from VRCPTU tests performed earlier at Halden it was found that after changes in rate or dissipation tests, the length required to build up u_2 was in several cases up to 1.0 m and (b) shorter strokes can be affected by vertical variability and hence are thought to be less robust for future recommendations for offshore site investigations.


Figure 3. Specified penetration rate profiles for VRCPTUs.

4.2 Test results

Figure 4 shows selected results of standard rate CPTUs and VRCPTUs carried out with the 10 cm^2 and 15 cm^2 cones. The penetration rate profiles indicate that the rig accurately controls the speed in all tests.

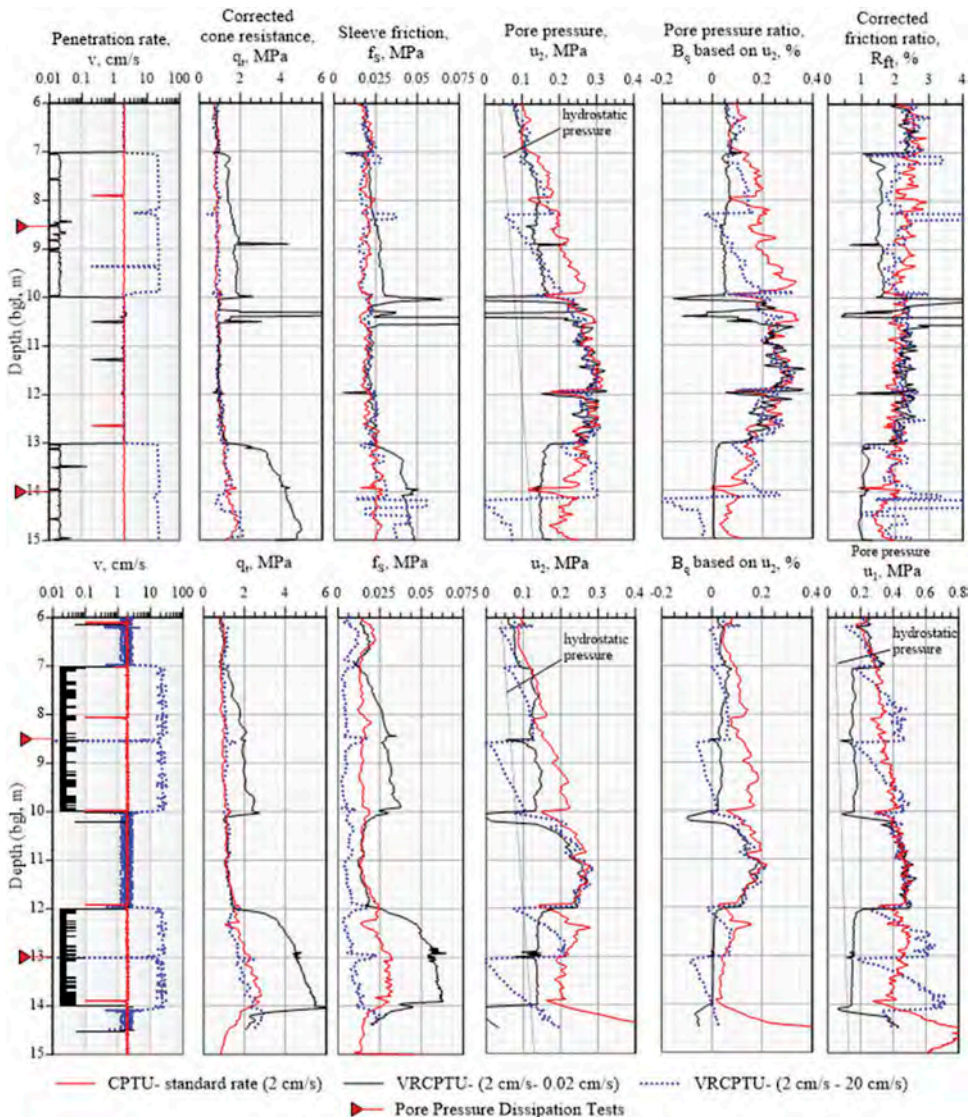
At depths of 10-12/13m all CPTUs are performed at standard rate. There is generally a good match of q_t, f_s and u_2 between the location with the CPTU at standard rate and the VRCPTU locations for both cones (10 cm^2 and 15 cm^2), respectively, indicating that (a) adjacent locations have similar soil conditions and hence the profiles at different rates at different locations can be directly compared and (b) the cones are performing consistently among different


Figure 4. Selected in situ test results, CSi Halden campaign. 10 cm^2 cone (upper figures) and 15 cm^2 cone (lower figures).

locations. The long strokes (up to 1.5 m before any stop, cf. Figure 3) allow for a clear identification of the changes in q_t, f_s and u_2 for penetrations at 0.2 mm/s compared to the standard rate. These aspects provide robustness to the VRCPTU interpretation approach.

During penetration at 0.2 mm/s both cones show an increase in q_t and f_s and a reduction in u_2 compared to the tests with standard rate. For example, q_t increases on average from 1.0 MPa to 1.6 MPa and B_q decreases from 0.2 % to 0.05 % for the 10 cm^2 cone in Unit II. In Unit III, the impact of a slower rate appears more markedly with q_t increasing from 1.5 MPa to 4.2 MPa and B_q decreasing from 0.08% to zero. This may be due to the less plastic and coarser nature of the lower unit.

In contrast, the VRCPTUs at 200 mm/s do not appear to affect q_t or f_s compared to CPTUs at standard rate (though for the 15 cm^2 cone the entire f_s profile is shifted at the location). Generally, after a prolonged stop in penetration, either for dissipation testing or for change in rate, u_2 increases smoothly and linearly with depth often starting with an abrupt negative increment in the pore pressure. These results will be further scrutinized during the project.

The u_1 profile for the 15 cm^2 cone shows similar trends to the u_2 sensor for both the highest and lowest rates noting that (a) the drop in pore pressure during slow penetration is more distinct and (b) at high rates u_1 appears to exceed u_1 for the standard rate CPTU after typically 50-70 cm of penetration after having changed rate or after a dissipation test.

Figure 5 shows the results of a representative dissipation tests performed with the 15 cm^2 cone. u_1 decays monotonically over time whereas u_2 exhibits a dilatory response. This response is similar to what has been reported for cases in overconsolidated clays (e.g. Lunne et al. 1997). The effect of this difference on the estimated coefficient of consolidation will be investigated.
Figure 5. Dissipation test at 8.5 m depth, 15 cm^2 cone.

5 CONCLUSIONS

Even with the landmark research undertaken over the last decades on CPTUs in silty soils, more research is needed to establish robust guidelines for use in engineering practice. The objective of the Joint Industry Project CSi is to provide such guidelines. The background, objectives, setup, and approach of the CSi project are described in this paper along with some initial results from the Halden test site. Field testing at the Voorne-Putten test site as well as centrifuge and calibration chamber testing are currently being performed in parallel with laboratory testing and numerical modelling. More Partners and Contractors are invited to join the project for the opportunity of investigating more innovative equipment and methods, such as partially drained triaxial testing and selected CPTU add-on sensors. Furthermore, field trials for validating the project outcome are essential and will add to the robustness and broaden the applicability of the project.

Numerical investigation of piezocone dissipation tests in clay: Sensitivity of interpreted coefficient of consolidation to rigidity index selection

A. Barati Nia, D.M. Moug & A.P. Huffman

ABSTRACT: Standard methods for interpreting the coefficient of consolidation (c_h) from CPTu dissipation tests require an estimation of the soil's rigidity index ($I_r = G/s_u$). For the Teh & Houlsby numerically derived dissipation solution, the values of shear modulus (G) and undrained shear strength (s_u) were straight forward to specify due to the use of the elastic-perfectly plastic Von-Mises soil constitutive model. However, estimation of appropriate G and s_u values is not as straight forward for field dissipation tests. The objective of this study is to examine the sensitivity of the interpreted c_h to various approaches for estimating I_r. The study is performed with an axisymmetric direct cone penetration model to simulate piezocone dissipation. Simulations are performed with the MIT-S1 constitutive model calibrated for Boston blue clay behavior. Analyses examine how the sensitivity changes for normally to lightly overconsolidated clay, and slightly to strongly anisotropic hydraulic conductivities. The results indicate that c_h interpretation is not highly sensitive to I_r estimation when I_r is within standard values for clay; however, the sensitivity appears to increase as the overconsolidation ratio increases.

1 INTRODUCTION

The piezocone (CPTu) dissipation test is often used as an in situ method to estimate the coefficient of consolidation in the horizontal direction (c_h) and hydraulic conductivity of fine-grained soils. The CPTu dissipation test records excess pore water pressure (Δu) at the cone shoulder (u_2 position) as porewater pressure returns to the hydrostatic condition during a pause in penetration. The dissipation response is primarily controlled by the initial distribution of Δu around the cone and c_h, among other factors.

Various researchers have proposed methods for estimating c_h; however, the Teh and Houlsby (1991) method remains widely used:

$$c_h = \frac{T^* r^2 \sqrt{I_r}}{t} \qquad (1)$$

where T^* is a modified time factor; r is the radius of the piezocone; I_r is the soil rigidity index; and t is the time to a degree of dissipation corresponding to T^*.

The Teh & Houlsby (1991) method was developed with the strain path method and Von-Mises soil model to estimate the initial Δu distribution, then Δu dissipation was modeled with Terzaghi consolidation theory. This method for interpreting c_h uses the square root of

I_r that was empirically determined to closely agree with the model data. The time to reach 50% dissipation at the u_2 position (t_{50}) is often used because it provides sufficient dissipation data without requiring large dissipation times in the field. An example estimation of t_{50} from a CPTu u_2 dissipation curve is shown in Figure 1. For t_{50}, T^* is equal to 0.245.
Figure 1. Comparison of a normalized field-measured u_2 dissipation curve in BBC and a simulated curve with MIT-S1 calibrated for BBC.

In addition to Teh & Houlsby (1991), other methods to interpret c_h from dissipation tests require an I_r value (e.g., Burns & Mayne, 1998, Chai et al., 2012). I_r is the ratio of shear modulus (G) to the undrained shear strength (s_u). Therefore, a single I_r value represents average G and s_u values for the complex loading, strain, and porewater conditions around the penetrating cone. For the Teh and Houlsby (1991) numerically derived dissipation solution, the values of G and s_u were straightforward to specify due to the use of the elastic-perfectly plastic Von Mises soil constitutive model. However, natural soil behaviors include strain softening, non-linear behavior, and anisotropic strengths. As a result, the selection of appropriate G and s_u values is not straightforward.

There are three standard approaches for estimating I_r: laboratories tests, CPT-based, and empirical relationships. Although laboratory shear testing on intact soil specimens is a direct method to estimate I_r, this approach typically requires the most effort and expense compared to CPT-based and empirical estimates. Accordingly, empirical methods or CPT-based approaches are frequently used to estimate I_r values. Given the various approaches, there remains uncertainty regarding how sensitive interpreted c_h values are to the estimated I_r.

For this study, different methods for estimating I_r will be presented and used to estimate I_r values for Boston blue clay (BBC). The various I_r values will be used to interpret c_h from simulated dissipation tests in normally and lightly overconsolidated BBC and for slightly anisotropic and strongly anisotropic hydraulic conductivities. The interpreted c_h values from the simulations will be compared to the c_h values estimated from assigned model properties.

2 SIMULATED PIEZOCONE DISSIPATION IN BOSTON BLUE CLAY

CPTu dissipation was simulated with the finite difference program FLAC (Itasca, 2019) and the MIT-S1 constitutive model (Pestana & Whittle, 1999). MIT-S1 is a bounding surface plasticity model that can capture the anisotropic undrained strength behavior of clays, which is advantageous for direct cone penetration simulations (Moug et al. 2019). To capture CPTu dissipation, first, undrained steady state penetration was simulated with MIT-S1 calibrated for BBC behavior. The penetration model is a direct axisymmetric model that uses an Arbitrary Lagrangian Eulerian rezoning and remapping algorithm to accommodate large deformations around the penetrating cone. A description of the model and implementation with the MIT-S1 model, including validation for undrained penetration in BBC, is published in Moug et al. (2019). After reaching steady-state stress and porewater pressure conditions, at approximately 25 cone diameters of simulated penetration, penetration is paused and brought to static conditions. Then, Δu

dissipation is simulated to capture the full response around the cone during a CPTu dissipation test.
Figure 2. Simulated u_2 dissipation for OCR = 1 with k_h/k_b = 2 and 10, and OCR = 2 BBC with k_h/k_v = 2.

Simulated u_2 dissipation for normally consolidated BBC is presented in Figure 1 and Figure 2. The initial conditions are vertical effective stress (σ'_{vo}) of 100 kPa, horizontal effective stress of 50 kPa, and hydrostatic porewater pressure of 100 kPa. A summary of these initial conditions and simulation results for undrained penetration are presented in Table 1. The horizontal hydraulic conductivity (k_h) for dissipation is 2×10^{-7} m/s, and is two times larger than the vertical hydraulic conductivity (k_v). Although these values of k_h and k_v are at least an order of magnitude higher than typical values for clayey soils (Kulhawy & Mayne, 1990), the objectives of this study are not compromised since dissipation is simulated from undrained conditions. In Figure 1, the u_2 dissipation curve is normalized by the initial Δu and t_{50} to compare it to a field-measured dissipation test in BBC (Baligh & Levandoux, 1986). The normalized simulated dissipation results in OCR=1 of BBC agree well with the field-measured results.

Table 1. Initial conditions and results for simulated undrained cone penetration in BBC with OCR=1.

	Value
Initial conditions	
Pore pressure, u_0	100 kPa
Vertical effective stress, σ'_{vo}	100 kPa
Horizontal effective stress, σ'_{ho}	50 kPa
Simulated penetration results	
Cone tip resistance, q_t	355 kPa
Pore pressure at the cone shoulder, u_2	259 kPa

3 RIGIDITY INDEX ESTIMATION METHODS

Estimation of c_h relies on estimated I_r values. Because I_r values for natural clay deposits may vary between

50 to 600, the c_h estimation can be different by a factor of up to 4 for a given clay (Schnaid et al., 1997). This variability of I_r may reflect changes due to OCR and PI; however, there may also be differences in I_r values depending on the method used to estimate the value. In the following subsections, different approaches for estimating I_r are briefly introduced and used to obtain I_r values for OCR = 1 BBC.

3.1 Laboratory test approaches

Laboratory testing of intact soil samples is a direct method for estimating I_r. However, uncertainties remain for estimating I_r from laboratory shear tests. s_u depends on initial stress state, loading conditions, loading rate, stress history, degree of fissuring, boundary conditions, etc. For example, one clay tested with isotropically consolidated undrained triaxial compression (CIUC) and anisotropically consolidated undrained triaxial compression (CAUC) will likely yield different s_u between the two tests, reflecting the different initial consolidation conditions. I_r interpreted from CAUC tests was used for several research studies that examined dissipation test interpretation (Krage et al., 2014; Schnaid et al. 1997); however, in practice, CIUC is a more common and simple to perform a test.

I_r values also depend on G estimation. The secant shear modulus at 50% of the yield stress (G_{50}) and 25% of the yield stress (G_{25}) were investigated by Schnaid et al. (1997) for dissipation test interpretation. G_{50} was considered by Schnaid et al. (1997) to reasonably represent the stress and strain levels in the vicinity of the cone.

For estimation of I_r in this study, CIUC and CAUC tests were simulated with single element models in FLAC and the MIT-S1 model calibrated for BBC. The simulated CIUC and CAUC results for deviatoric stress (q) versus deviatoric strain (ε_q) are shown in Figure 3. The values of I_r from the stress-strain paths in Figure 3 are summarized in Table 2. The G values for estimating I_r from CIUC and CAUC single element simulations were calculated at
Figure 3. Single element CIUC & CAUC simulations for OCR=1 BBC.

50% of the strain level required to reach the yield stress. Past researchers estimated G at 50% of the yield stress (Keaveny & Mitchell, 1986; Schnaid et al., 1997); however, this approach was overly stiff for the simulated results. This likely reflects sample disturbance effects from obtaining and preparing the sample that are not captured in the simulated response. An examination of published CIUC and CAUC tests for BBC (Landon, 2007) indicated there was about a 35% difference between I_r values estimated with 50% of strain and 50% of stress to yield stress. Consequently, 50% of the strain level to yield stress was considered for G_{50} to calculate I_r values from CIUC and CAUC.

3.2 CPT-based approaches

Several methods have been proposed to estimate I_r values from CPTu test data. These approaches have the advantage that the required data to estimate I_r are collected during the process of performing CPTu dissipation test.

Krage et al. (2014) analyzed a database of CAUC test results with corresponding CPTu data to develop two approaches to estimate I_r. The two approaches are called "method A" (I_{rA}) and "method B" (I_{rB}). Both methods use a functional reduction of G_{max} to approximate G_{50}, where $G_{50}/G_{max} = 0.26$ and G_{max} is estimated from V_s measurements obtained from the seismic CPT profile. Method A estimates s_u from laboratory testing. Consequently:

$$I_{rA} = 0.26 \times \frac{G_{max}}{s_u} \qquad (2)$$

Since this relationship was developed with CAUC laboratory test results, the simulated CAUC s_u value was used to estimate I_{rA} for this study.

Method B from Krage et al. (2014) generalizes Method A with a CPT-based approximation of s_u. The estimation of s_u is based on relationships between q_t and OCR (i.e., Chen & Mayne, 1994) and SHANSEP principles of s_u normalization by σ'_{vo} and OCR. The estimation of I_{rB} is:

$$I_{rB} = 0.26 \left(\frac{G_{max}}{\sigma'_{vo}} \right) \left(\frac{1}{0.33 \times \left[\frac{0.33(q_t - \sigma_{vo})}{\sigma'_{vo}} \right]^{0.75}} \right) \qquad (3)$$

Using the simulated q_t value from penetration in normally consolidated BBC resulted in OCR < 1. Therefore, the estimation of I_{rB} used OCR = 1 as opposed to the q_t-estimated OCR in the denominator of Equation 3. G_{max} was approximated from MIT-S1 stiffness parameters, which were selected in Moug et al. (2019) to be consistent with shear wave velocity data in BBC (Landon 2007).

Mayne (2001) developed a theory-based estimation of I_r with spherical cavity expansion and critical state soil mechanics (SCE-CSSM):

$$I_r = exp\left(\frac{q_t - \sigma_{v0}}{q_t - u_2} \times \left(\frac{1.5}{M} + 2.925\right) - 2.925\right) \quad (4)$$

in which M = (6sinϕ')/(3-sinϕ') and ϕ' is the effective friction angle. M was determined from the critical state ϕ' for the MIT-S1 calibration for BBC (Pestana et al., 2002), which resulted in an M value of 1.35.
Figure 4. Comparison of I_r values estimated with different methods for OCR=1 and OCR = 2 BBC.

The Mayne (2001) approximation of I_r resulted in a low value of 36. However, it should be noted that this estimate of I_r is relatively sensitive to changes in q_t and u_2. For example, a 10% increase in q_t results in an I_r value that is four times larger, or a 10% increase in u_2 results in an I_r value that is over 10 times larger than the original estimate.

3.3 Empirical relationships

Empirical relationships are used to estimate I_r from soil index properties and/or OCR. Keaveny & Mitchell (1986) observed that for ordinary clays, I_r increases by decreasing OCR and decreasing plasticity index (PI). Mayne (2001) provided an equation-based estimate of the Keaveny & Mitchell (1986) relationships with:

$$I_r = \frac{\exp\left(\frac{137 - PI}{23}\right)}{1 + ln\left(1 + \frac{(OCR-1)^{3.2}}{26}\right)^{0.8}} \quad (5)$$

The average PI of BBC was reported in Landon (2007) as 20. Therefore, for OCR = 1 BBC, I_r = 162 by the Keaveny & Mitchell (1986) estimation.

Młynarek et al. (2018) performed multivariate regression analysis to investigate relationships between I_r and PI, OCR, and liquidity index (LI) for different soil groups such as overconsolidated & aged clay, organic & young clay, aged till and young till. Although the analysis was performed with regionally-limited soils and one of the authors' conclusions was that I_r values and relationships should be regionally developed, the relationship for organic and young clays is included herein for comparison:

$$I_r = 4.73PI - 4.78OCR - 14.04LI + 151.74 \quad (6)$$

For OCR = 1 BBC, a LI of 1.14 was used based on data in Landon (2007), resulting in I_r = 226.

3.4 Summary of estimated I_r

A summary of the estimated I_r values for OCR = 1 BBC is provided in Table 2 and Figure 4. Generally, the values are consistent with typical I_r for OCR = 1 clay. The values estimated from single element simulations of CIUC and CAUC tests do not show a large difference: 212 and 261 for CIUC and CAUC, respectively. The I_r values estimated with Krage et al. (2014) methods are comparable between themselves but are larger than the laboratory-estimated values, with I_{rA} = 329 and I_{rB} = 315. As discussed above, the I_r value estimated with Mayne (2001) results in a notably lower value than the other estimation methods but is sensitive to small changes in q_t or u_2. I_r estimated with empirical methods yielded values of 162 and 226 for Keaveny & Mitchell (1986) and Młynarek et al. (2018), respectively. These estimates are consistent with typical values for clay; the Keaveny & Mitchell (1986) relationship estimates an I_r value lower than the laboratory-based estimates, while Młynarek et al. (2018) is consistent with the laboratory-based estimates.

Table 2. I_r values for OCR=1 BBC estimated with various methods.

Method	I_r
Simulated CIUC	212
Simulated CAUC	261
Krage et al. (2014) method A	329
Krage et al. (2014) method B	315
Mayne (2001)	36
Keaveny & Mitchell (1986)	162
Młynarek et al (2018)	226

4 INTERPRETED c_h SENSITIVITY To I_r

c_h values from a simulated CPTu u_2 dissipation test in OCR = 1 BBC are estimated using the various I_r values presented in the previous section and with Equation 1. The dissipation test was performed for BBC with a $k_h/k_v = 2$, representing slightly anisotropic hydraulic conductivity conditions. The simulated u_2 dissipation curve is shown in Figure 2, which has a t_{50} of 32 seconds. The c_h values interpreted from simulated u_2 dissipation ($c_{h,interpreted}$) are compared to c_h values assigned to the cone penetration model ($c_{h,model}$). This comparison is shown in Figure 5.

The range of $c_{h,interpreted}/c_{h,model}$ in Figure 5 is between 0.56 and 1.69 for the various I_r estimation methods. Generally, the sensitivity of $c_{h,interpreted}/c_{h,model}$ to the estimated I_r is low since $c_{h,interpreted}$ is proportional to $\sqrt{I_r}$ in the Teh & Houlsby (1991) relationship. It should be noted that estimating I_r with CIUC or CAUC does not significantly impact $c_{h,interpreted}$ indicating that there may not be a strong advantage of one test condition over the other for this application. Additionally, across the various I_r values, the variability of $c_{h,interpreted}$ appears to be within a typical range due to the variability of soil properties, estimation of t_{50}, and methods for interpreting c_h (e.g., Huffman & Moug, 2022).

5 THE EFFECT OF PERMEABILITY ANISOTROPY AND OCR ON c_h ESTIMATION

The sensitivity of c_h to I_r is further explored by examining dissipation in lightly overconsolidated and highly anisotropic BBC. To this end, u_2 dissipation tests were also performed for OCR = 1 with $k_h/k_v = 10$; and OCR = 2 with $k_h/k_v = 2$. These u_2 dissipation curves are shown in Figure 2. These simulated results show that although the k_h for both OCR = 1 and OCR = 2 models is the same, t_{50} decreases as OCR increases from OCR = 1 to OCR = 2. This may be attributed to a smaller Δu distribution around the penetrating cone as OCR increases and increasing soil stiffness as OCR increases and, therefore, less porewater pressure migration to dissipate the Δu field.

Estimated I_r values for OCR = 2 BBC are compared to those estimated in the previous section for OCR = 1 in Figure 4. Although the differences in I_r among different approaches are still considerable, the differences between OCR = 1 and OCR = 2 for every method are relatively small.

The comparison between $c_{h,interpreted}$ with the various I_r values and $c_{h,model}$ is shown in Figure 5. Comparing the ratio of $c_{h,interpreted}$ to $c_{h,model}$ for OCR = 1 with different hydraulic conductivity anisotropy, the differences between $k_h/k_v = 2$ and 10 across the various I_r estimation methods are similar. The ratio of $c_{h,interpreted}$ to $c_{h,model}$ for $k_h/k_v = 10$ ranged from 0.48 to 1.46. This indicates that c_h estimation using various I_r estimation methods is not strongly affected by hydraulic conductivity anisotropy.
Figure 5. Comparison of c_h estimated from simulated results and different I_r with c_h assigned to the dissipation models for OCR = 1, OCR = 2, and $k_h/k_v = 2$ and 10 BBC.

Comparing $c_{h,interpreted}$ to $c_{h,model}$ for OCR = 1 and OCR = 2, indicates that as OCR increases, the sensitivity of $c_{h,interpreted}$ to estimated I_r increases. The ratios of $c_{h,interpreted}$ and $c_{h,\ model}$ for OCR = 2 are in some cases twice as large as the ratio for OCR = 1 with the same hydraulic conditions, with the exception of $c_{h,interpreted}$ using the I_r values from Mayne (2001). For OCR = 2 the ratio of $c_{h,interpreted}$ to $c_{h,model}$ ranged from 0.44 to 2.45.

6 CONCLUSIONS

This study examined the sensitivity of CPTu dissipation test interpretation to estimated I_r values. For a given soil, there are various approaches to estimate I_r. Simulated CPTu dissipation tests in BBC were used to examine how the interpreted c_h from CPTu dissipation tests changes with different methods to estimate I_r. c_h was interpreted from simulated u_2 dissipation following undrained cone penetration using the Teh & Houlsby (1991) method, which requires an estimation of I_r. I_r was estimated with several approaches that represent laboratory test-based, CPT-based, and empirical-based approaches. The sensitivity of c_h to various I_r estimations was evaluated for BBC with OCR = 1 with slightly anisotropic hydraulic conductivity, OCR = 1 with strongly anisotropic hydraulic conductivity, and OCR = 2 with slightly anisotropic hydraulic conductivity. Ultimately, interpreted c_h was compared with the modeled c_h to assess the variability of estimated c_h over a range of reasonable I_r values. Although this study was performed for a single soil, it does provide some

insight into the role of I_r estimation on CPTu dissipation test interpretation. The results support the following conclusions:

1. Due to a square root of I_r in the Teh & Houlsby (1991) method (Equation 1), the sensitivity of c_h to I_r is relatively low. For OCR = 1 BBC, the range of I_r estimates was large: between 36 and 329. However, the $c_{h,interpreted}$ values ranged from 0.56 to 1.69 times the $c_{h,model}$ with slightly anisotropic hydraulic conductivity. When the hydraulic conductivity was strongly anisotropic, the $c_{h,interpreted}$ values ranged from 0.48 to 1.46 times $c_{h,model}$. However, it should be noted that c_h interpretation methods may also contribute to discrepancies between $c_{h,interpreted}$ and $c_{h,model}$, in addition to the estimated I_r value.

2. Increasing the OCR from 1 to 2 appeared to result in $c_{h,interpreted}$ values that were increasingly sensitive to the estimated I_r values. Estimated I_r values for OCR = 2 ranged from 11 to 343, and $c_{h,interpreted}$ values were between 0.44 and 2.45 times larger than $c_{h,model}$. The larger discrepancy between $c_{h,interpreted}$ and $c_{h,model}$ for OCR = 2 compared to OCR = 1 may be due to a smaller Δu distribution around the penetrating cone and increased soil stiffness, resulting in faster dissipation and a smaller t_{50}. The smaller t_{50} leads to more sensitivity to I_r even though the range of estimated I_r values was smaller.

3. Minor differences were observed between estimated c_h values using the I_r values from CIUC and CAUC testing in OCR = 1 and OCR = 2 BBC. Because CIUC is considered a more simple test to perform, with further investigation, it may be considered reasonable to estimate I_r values for CPTu dissipation test interpretation.

Correlation of CPT measurements and VibroCore penetration speed for medium, calcareous sands: A case study of the cable route survey at the North Sea

K. Bartczak & G. De Vries
Marine Sampling Holland B.V., The Netherlands

ABSTRACT: The Cone Penetration Test (CPT) is one of the most popular in-situ testing methods used in qualitative and quantitative research of characteristics of the subsurface sediments, both onshore and offshore. In offshore cable route surveys, CPT tests are often accompanied by VibroCoring (VC) boreholes. The article endeavours to verify whether there is a clear correlation between the relative density of cohesion-less soils and the VC penetration characteristics. The research has been based on an offshore site investigation campaign in the North Sea consisting of over 100 CPTs and VCs, supplemented by an extensive laboratory testing program. After a strict selection of locations, around one-fifth of those tests have been utilised in the correlation studies. The ultimate goal of this study was to demonstrate if processing data recorded during VC testing can increase certainty in the prediction of soil's strength parameters.

1 INTRODUCTION

VibroCoring is a technique of extracting a sediment core from the seabed, in which a steel tube with an inner plastic liner is vibrated into the seabed by the action of two counter-rotating eccentric weights driven by an electric- or hydraulic motor. To collect the fieldwork data used in this paper, a slightly modified VibroCorer Viking VKG-6 was used. The corer is characterized by 30 kN of vibrating force, vibrating frequency of 28 Hz, the inside diameter of the core barrel of 96 mm and its net length of 6.0 m. The penetration is measured employing sensors and magnets placed each 5.0 centimetres along the barrel. The data is logged with a frequency of 10 Hz. In common practice, a live view of the current penetration is used to determine if the penetration is properly succeeding and whether it should be already terminated.

This paper poses the question whether records of this data can add value to the data obtained from processing the cores and possibly other tests, such as CPTs, performed at the site. A database of over 100 CPTs and VCs, which were a part of the cable route survey in the North Sea, was utilised in this research. From all the tests, a lot of 33 locations characterised by homogeneous stratigraphy was selected for the studies. The soil profile mainly consisted of calcareous, medium sands in the medium-dense to very dense states. In two groups, there was an underlying clay layer starting at around 4.0 to 4.5 m deep. Field testing of each location comprised of both VC and CPT tests. Correlation of CPT results and relative density was

possible on the grounds of the laboratory testing program, which comprised both standard index tests and advanced testing.

2 EVALUATION OF RELATIVE DENSITY

2.1 Introduction

The chosen 33 locations create a triangle-shaped area around 7×10 km big. Elevation of around one-third of those was between −10 to −20 metres Lowest Astronomical Tide (LAT), while for the other two-thirds, the range was between −25 to −35 metres LAT. The usage of tests with highly varying elevations might be problematic when analysing and correlating the VC and CPT data. As each test starts at a slightly different elevation, using many tests is marked with noise and peaks in data, which affect the latter interpretation. Therefore, the analysis on CPT and VC data sets was made only as a function of depth. To simplify the analysis, the 33 picked locations were divided into seven groups in a manner to obtain the most uniform soil profile in each group.

2.2 Laboratory testing data

The determination of a lab-based Relative Density (RD) profile was made on a selection of lab testing results consisting of 22 minimum and maximum density tests and 161 dry density tests. The resulting mean (and standard deviation) of RD value was

equal to 69% (32%) for all 150 tests, while for the selected locations 73% (33%). The evaluated RD profile is shown in Figure 1 below.
Figure 1. Lab-based relative density in a function of elevation.

For plotting the depth-trend (solid line), the Python implementation (SciPy) of Savitzy-Golay (S-G) Filter (Savitzky & Golay 1964) has been used. For smoothing the VC data presented in the latter part of this paper, a polynomial interpolation algorithm had to be found. The S-G filter has been chosen as the best solution, and the same algorithm was proposed for the lab-based RD to avoid extra noise in further analysis. The window length (M), and the polynomial degree (N), were chosen via an iterative process of minimization values of the cost function, i.e. Mean Square Error (MSE) between the lab data points and smoothed values.

2.3 *CPT data*

In Figure 2, an average value of CPT-tip resistance is plotted for each of the seven groups. Several correlations for CPT-based RD have been tested to find the best fit with laboratory-based values. The one that provided the best fit was the one proposed for Ticino, Toyoura, Hokkusund Sand (Jamiolkowski, Lo Presti, & Manassero 2003) presented in Equation 1 below.

$$RD(\%) = \frac{100}{C_2} ln(\frac{q_c}{C_0(\sigma'_{vc})^{C_1}}), \qquad (1)$$

where: $C_0 = 0.175$; $C_1 = 0.500$ and $C_2 = 3.1$.

The fit between the correlation mentioned above and the laboratory-based data (visibly rougher curves) for two selected (and the biggest) groups is shown in Figure 3.
Figure 2. CPT Cone resistance in Depth.
Figure 3. CPT- and LAB-based RD in-depth for two selected groups.

3 VIBROCORE DATA INTERPRETATION

3.1 *Data clearing*

In these specific soil conditions, the core barrel's full penetration was reached after around 2 minutes of vibrations. The penetration data recording frequency was 10Hz, which gives over 1200 readings per 500 centimetres of penetration on average. As the resolution of depth measurement is 1.67 cm, this means that each centimetre of penetration has been logged 4 times, which results in high accuracy, but also a very high level of noise (penetration readings tend to "jump" up and down by over a dozen of centimetres). Other aspects that induced the need for rigorous data clearing include turning the vibrating motor off and on again in case of an obstacle or penetration hindrance and the free-fall penetration of the barrel when it touches the seabed.

Therefore, VC data had to be cleared from the top 20 centimetres of data classified as unreliable and then filtered according to the steps shown below. The clearing steps explained below correspond to the numbers of VC lines in Figure 4.

1. If the consecutive penetration reading is smaller than the previous one - the previous value is kept and the smaller one ignored. This prevents from appearing of any negative penetration speed values;
2. Exponential Smoothing (Statsmodels.org, Hyndman2018) of penetration readings with dumping factor $\alpha = 0.15$;
3. Applying the Savitzy-Golay Filter (SciPy) with $N = 7$ and M of 53 for VC penetration speed, S_P, above 0.075 m/s and 203 for penetration speed below 0.075 m/s along at least 50 consecutive readings.
Figure 4. CPT- and LAB-based RD and VC penetration speed in depth - chosen test from Group 3.

The reason for choosing the S-G filter was a trial-and-error process of testing several algorithms with decision criteria including lack of distortion of readings in-depth tendency, and correct depiction of average value at each depth with no severe over or underestimation. In addition, the S-G filter has two convolution coefficients, which iterative customisation allows reducing the MSE between the original data-set and the fitted curve.

3.2 Relationship between CPT-based RD and VC penetration speed

The relationship between the CPT and VC data sets is depicted in Figure 5, where the CPT-based RD and VC penetration speed are plotted together for the chosen group. The correlation between the mean in-depth values of those data sets is measured with Pearson's coefficient, ρ. The correlation studies are based only on the depth range between 0.20 and 5.00

m (3.70 m for the 5th and 7th group because of the underlying clay layer). The statistical relationship measured with the Pearson's coefficient has been summarised in Table 1 below.

Table 1. Correlation studies between CPT-based R_d and VC S_P.

Group	ρ (0.2 − 5.0m)	ρ (0.2 − 1.7m)	ρ (1.7 − 5.0m)
1	-0.59	-0.44	0.44
2	-0.91	-0.68	-0.27
3	-0.73	-0.20	-0.51
4	-0.75	0.04	-0.20
5	-0.68	-0.07	-0.51
6	-0.93	-0.76	-0.63
7	-0.78	-0.63	-0.62
AVG	-0.77	-0.39	-0.33

Based on the correlation studies of VC penetration speed, S_P, and CPT-based RD, R_d, an important conclusion has been drawn that the correlation is not constant in-depth. Although the correlation for the whole penetration dataset bracket together was strong ($\rho = -0.77$), it is not the case when the data is separated. The correlation is better in the upper section, apart from two groups that showed no correlation. In the upper section (until 1.7m of penetration on average), the strong negative correlation is severely affected by an initial uneven penetration speed of a "wavy" nature. Even though the data has been thoroughly cleaned and filtered, the noise generated by vibrations does not allow formulating a clear and undoubtful correlation in each test. The correlation in the bottom section could be improved by introducing an additional parameter, which could be based on, for example, a net surcharge or penetration depth.

3.3 VC-based RD formula

To verify what mechanisms govern VC penetration speed and whether it is possible to correlate it to the non-cohesive soils' RD, physical aspects linking those parameters need to be researched on.

The relationship between the cone tip resistance, q_c, and the relative density, D_r, was initially proposed by Lancellota (Lancellota 1983) as shown in Equation 2 below:

$$D_R = A_0 + B_0 \cdot X \qquad (2)$$

where: $X = ln[\frac{q_c}{(\sigma'_{v0})^\alpha}]$ A_0, B_0 and α = empirical correlation factors.

It is assumed that the VC-based RD should be formulated in the same way, but with the cone resistance, q_c, replaced by the VC Penetration Resistance q_{VC}. The q_{VC} parameter should depend on the depth of penetration and the penetration speed, which is mainly governed by:
Figure 5. CPT-based Relative Density and VC penetration speed and their correlation in Depth for Group 6.

– Liquefaction susceptibility, which mainly depends on relative density and grain size distribution and uniformity coefficient (Saikia & Chetia 2014);
– Vibrations frequency and intensity;
– Frictional resistance, which depends on the depth of the penetration, angle of friction at the interface between a cohesion-less soil and a steel core barrel, friction coefficient and water content (Mosaddeghi, Hosseini, Hajabbasi, Sabzalian, & Sepehri 2021), is assumed to be constant.

The intensity and frequency of vibrations generated by the motor are approximately constant; however, the vibrations transmitted along the barrel are dumped by the medium surrounding the barrel, i.e. firstly by the water and later the soil. Hence, the deeper the barrel is penetrated, the more vibrations dissipate to the soil above the cutting shoe at the bottom of the barrel, limiting the liquefaction occurrence.

The dependence of penetration resistance, F, on velocity for non-deforming projectiles is represented by the Poncelet equation (Bless, Omidvar, & Iskander 2018), which is a relatively similar problem in physical meaning and is shown below.

$$F = M \cdot \frac{dv}{dt} = A(C\rho v^2 + R) \qquad (3)$$

where M is a projectile mass, v is penetration velocity, ρ is the bulk density of sand, C is Poncelet drag, which ranges from 0.7 for loose to 1.1 for dense sand (Bless, Omidvar, & Iskander 2018), R is bearing strength (frictional resistance) that for the core barrel can be estimated with unit skin resistance equation:

$$R = \sum_{i=1}^{n} A_i \sigma'_h tan(\delta) = \sum_{i=1}^{n} L_i \pi d K_s \sigma'_v tan(\delta) \qquad (4)$$
Figure 6. Histograms of q_c and S_P from all 33 tests for depths from 0.20 to 5.00 m.

where L_i is incremental barrel penetration, d is barrel's diameter, K_s is coefficient of earth pressure, δ is angle of friction at interface and σ'_v is effective overburden pressure. Summing up all the relationships listed above, following dependency is proposed:

$$q_{VC} \sim D_2 S_P^2 \cdot f(L_i) + D_3 L_i \sigma'_v \qquad (5)$$

where D_2 is a correlation factor and is negative, $f(L_i)$ is a function that links difficulty in liquefying soil beneath the cutting shoe with the depth of penetration, and D_3 is an empirical factor that is positive. For a better understanding of those parameters' relationship, the distributions of the tip resistance and VC penetration speed are plotted in Figure 6.

The distribution of q_c is almost uniform, with approximately the same density in between 0 and 35 MPa. The distribution of penetration speed is

approximately log-normal. Therefore, the penetration speed cannot be incorporated linearly in the equation as the tip resistance is. After substitution of q_{VC} to Equation 2 and a preliminary verification process, which resulted in a few changes to the formula, the following relation is proposed:

$$D_{R,VC} = D_0 + \frac{100}{D_1} ln\left[\frac{D_2 S_P{}^2 \cdot f(L_i) + D_3 L_i \sigma_v'^{D_4}}{D_5 (\sigma_v')^{D_6}}\right] \quad (6)$$

where $D_{R,VC}$ is relative density in percents, S_P^2 is VC penetration speed in m/s, $f(L_i)$ is simplified to L_i, i.e. the penetration depth expressed in meters, σ_v' is effective vertical stress in kPa.

The proposed formula has been validated firstly with correlation factors same as in Equation 2, and employing iterative process, the constants were calibrated to the following values: $D_0 = 60, D_1 = 6.2, D_2 = -0.45, D_3 = 0.02. D_4 = 0.2, D_5 = 0.005, D_6 = 0.6$.

4 VC-BASED FORMULA VALIDATION

The formula proposed in the previous section has been tested along with all seven groups. The main problems that appeared in this process, and are limiting the reliability of the results, are as follows:

– The value of D_2 constant should be high to keep the meaning of S_P significant. However,if this value is too high compared to D_3 and D_4, the value in the logarithm becomes negative. This gives a small threshold of reasonable D_2 values;
– The constant of D_4 had to be introduced to minimise the value second phrase of the nominator - without it, the values of $R_{D,VC}$ in the deeper section of the test were unrealistic;
– There are limitations connected with the fact that S_P is to the power of 2. For low values of penetration speed, it results in practically no influence of S_P values on the computed value of $R_{D,VC}$.

The exemplary results are shown in Figure 7 for the same group as before. The correlation itself has visibly increased, but the accuracy of RD estimations are still very low. The results have been summarised in Table 2 below, analogically to the previous Table 1.

Table 2. Correlation studies between CPT-based R_d and VC-based $R_{D,VC}$.

Group	ρ (0.2 − 5.0m)	ρ (0.2 − 1.7m)	ρ (1.7 − 5.0m)
1	0.72	0.85	-0.64
2	0.94	0.90	0.29
3	0.90	0.84	0.55
4	0.69	0.15	0.14
5	-0.03	0.52	0.79
6	0.97	0.92	0.62
7	0.37	0.71	0.61
AVG	0.65	0.70	0.35

5 SUMMARY

5.1 Conclusions

This study was based on geotechnical data acquired from VC and CPT tests performed at 33 locations, which were divided into 7 groups with very selected, homogeneous stratigraphy consisting of medium-dense to very dense medium sand.

The main conclusion is that the penetration speed, together with the effective vertical stress and penetration depth, is not enough for the precise estimation of the relative density of cohesion-less soil. Studies presented in this paper have shown that there is a strong correlation between VC penetration speed and CPT-based relative density in the upper 1.50 - 2.00 meters of penetration. Furthermore, the Formula 6 provided relative density estimations of the correct order of magnitude and increased correlation in most of the groups. However, the reliability and accuracy of relative density estimation with the usage of VC data is very low and not enough for applications in geotechnical design.

The main aspects negatively affecting the estimations' accuracy are the erratic penetration speed in the upper section (between 0.0 - 1.7 m of depth) and the effects of exponentiation of penetration speed in the bottom section, which gives wrong estimations of relative density. One way of tackling those issues would be to divide the formula into two parts, i.e. one part for the penetration speed above 0.075 m/s and the other part for values below this threshold. Another way would be to incorporate acceleration into the equation instead of penetration speed or reduce the exponent from 2 to a smaller number.

5.2 Limitations

There are several limitations related to the derived correlation factors and formulas:

– Related to the coring technique and its physical meaning:

- Ignoring the friction of the core barrel in the calculations. The friction raises with penetration and should be incorporated in the calculations in the other way than it is in CPT-based formulas for relative density;
- The influence of the net surcharge has been calculated in the same way as in CPT-based formula;

– Related to the data processing:

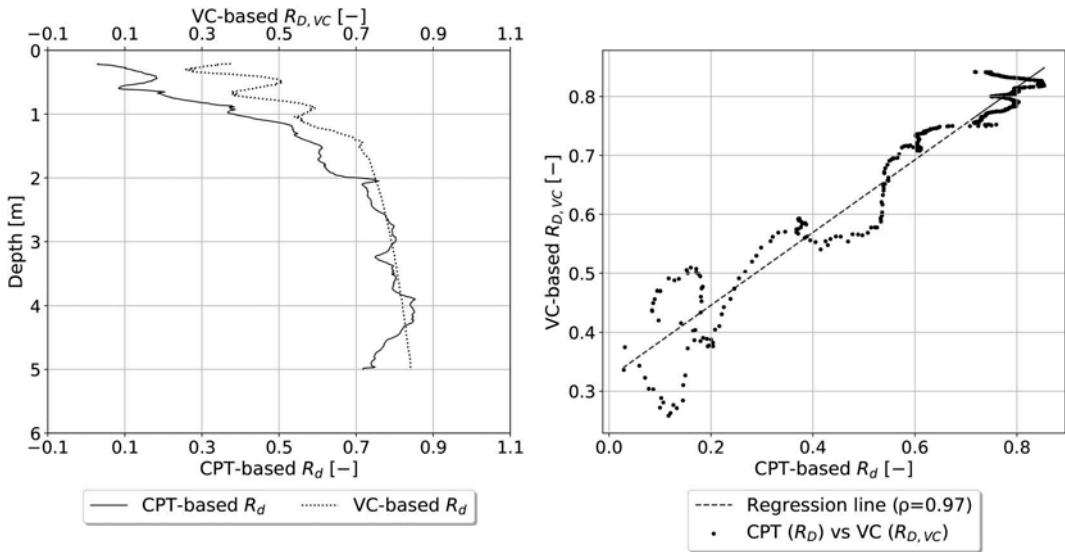
- The penetration data records have been cleared out of not-significant records. Whether the record is significant or not is up to the engineering judgments, which is ambiguous. Due to the high frequency of VC data logging (10 Hz), the records are noisy; hence, each user would end up with different cleared data sets;


Figure 7. CPT-based Relative Density and VC-based Relative Density and their correlation in depth for Group 6.

- The filtering technique presented in Subsection 3.1 has better performance for tests with penetration time longer than 30 seconds, while for quick sampling, the results are still prone to errors;
- All limitations, which apply to Savitzky-Golay Filter and its SciPy implementation, apply to the results of this analysis as well.

5.3 *Recommendations for further research*

As concluded above, the topic is promising in terms of increasing certainty in estimations of soil parameters; however, the literature and research on this subject are very limited. Therefore, the following concerns could be further elaborated on:

– The phenomenon of the vibration-induced liquefaction underneath the core barrel and its influence on the penetration speed of the core barrel;
– Studies on relating the relative density not only to the penetration speed but also the acceleration could bring new conclusions on the usage of VC data in the estimation of relative density;
– The relative and absolute error estimation should be incorporated into the correlation studies.
– Calibration of coefficients in the formula relating the VC penetration speed and relative density should be performed more thoroughly. An

optimisation algorithm integrating dynamic Bayesian networks could be of great help in this matter.

ABSTRACT: Post-depositional phenomena can produce significant changes in the geotechnical properties of soils. Although the identification of the effect of such phenomena on the soil structure may contribute significantly to the interpretation of the soil mechanical behaviour, their characterization is not routinely carried out in practice. In this context, the novel application of paleosol features in the definition of geotechnical stratigraphic models can result in improved characterization of soil deposits in alluvial sites. Sedimentology uses paleosols (i.e. fossil soils with peculiar geologic properties) as markers for stratigraphic correlations in alluvial areas at large scale. This paper outlines the main properties of these geological objects and investigates the strategies for their identification in cone penetration tests (CPT). The analyses are discussed with reference to boreholes and CPTs data in 3 well documented sites in the Po River Valley (Italy). First, sedimentological identification of paleosols from borehole corings is introduced; then, geotechnical interpretation of CPT is carried out on such a basis, showing how poorly developed paleosols (Inceptisols) found in the investigated sites, are difficult to be identified through CPT logs and how they plot in the well-established Robertson's classification charts.

1 INTRODUCTION

The Po Plain-Adriatic sea system is an elongated basin originated from the Po River catchment. It consists of a > 7km thick Pliocene - Quaternary sedimentary succession, with a 30m-thick Holocene succession that overlies Late Pleistocene deposits. The Holocene depositional history can be investigated through integrated stratigraphic, sedimentological and paleontological analyses. A total of 22 sedimentary facies, grouped into 5 main depositional systems, have been identified in the Po River catchment (Amorosi et al, 2017).

The present work focuses on three locations in the Po Plain, in Province of Ferrara (Figure 1), characterized by well-drained floodplain deposits, which belong to the alluvial plain depositional system. These deposits consist of different mixtures of clay and silt and show peculiar paedogenetic features: paleosols. The investigation started from the description of three continuous corings EM-S3, EM-S1 and EM-S5, located in Gaibana, Dogato and Ostellato, respectively. Then, three CPTU tests, each one performed in proximity to one coring, were analysed.

The stratal architecture of the Holocene succession of the Po coastal plain in Figure 2 shows the spatial distribution of the facies associations along the investigated section. The Holocene deposits, down to a depth between -10 and -20 m a.s.l, consist predominantly of a thick swamp clay succession that grades distally into

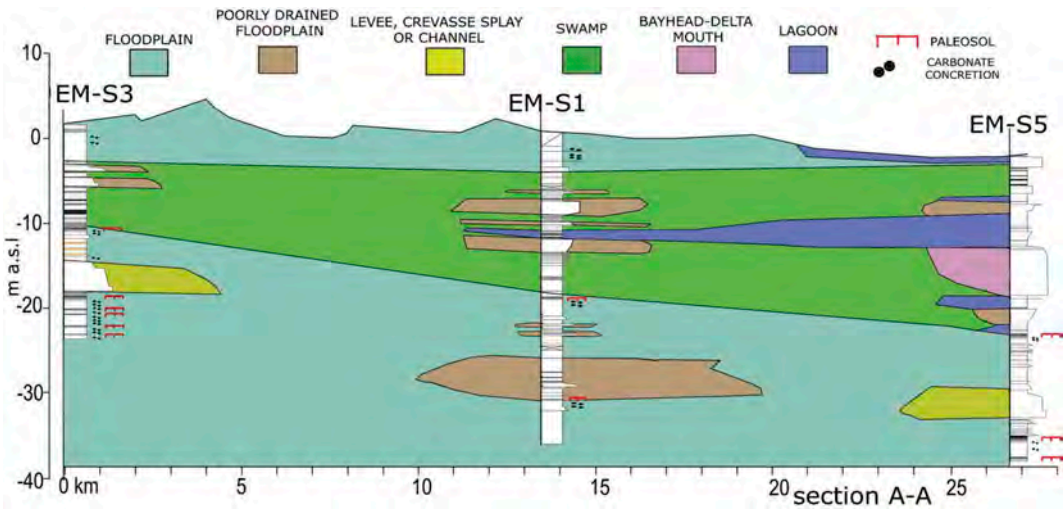
Figure 1. Location of the investigated site.


Figure 2. Stratal architecture with indication of the different facies association along section A-A in Figure 1.

lagoonal and bay-head delta deposits. Below the Holocene succession, Pleistocene deposits are predominantly well-drained floodplain silts and clays with subordinate fluvial-channel deposits (Amorosi et al, 2017).

2 PALEOSOL ORIGIN AND DEVELOPMENT

The floodplain facies association is characterized by the presence of paleosols, buried ancient soils formed on a ground surface of the past and subjected to physical, biological and chemical modifications caused by the interactions between soil, atmosphere and vegetation. Their development is strictly connected to fluvial activity which in turn depends on river sediment supply/discharge. A schematic representation of paleosol horizons (A_b, B_k, B_w) development is shown in Figure 3. When fluvial incision takes place in response to eustatic or climatic control, the adjacent interfluvial areas are prevented from river flooding and they experience soil development (paleosol 1 in Figure 3 top). In case of prolonged subaerial exposure, vegetation starts to grow on the top soil, enriching the A_b horizon in organic matter. Moreover, weathering in the vadose zone causes leaching of carbonates from horizon A_b and their precipitation into the underlying B_k, in form of millimetric to centimetric nodules. The horizon B_w is characterized by incipient weathering, while horizon C does not experience pedogenetic modifications. In case of high sediment supply/discharge, fluvial incision is rapidly filled by the transported sediments, and interfluvial areas experience frequent flooding events and crevasse lobe accumulation. Under these conditions, the water table is usually

close to the ground level and then, there is no vadose zone. Due to the fact that river continues to supply new sediments, soil formation is hindered. When the river enters a new stable phase of bed incision, renewed pedogenesis occurs on the interfluvial areas (paleosols 2 and 3 in Figure 3 top).

Holocene paleosols are more discontinuous and immature (Entisols, Amorosi et al., 2014). Paleosol identification is a valid help in the stratigraphic analysis of mud-dominated Late Pleistocene and Holocene deposits. For this reason, they are largely used as regional stratigraphic markers (Amorosi et al, 2017).

3 PALEOSOL IDENTIFICATION

In current practice, paleosols in floodplain deposits can be identified by the physical analysis of core samples (visual inspection). The A_b horizon usually exhibits a darker colour with respect to the illuvial B_k - B_w horizons, due to the higher quantity of organic matter. The B_k horizon typically shows carbonate nodules and often a microstructure created by calcareous cementation between particles. Figure 3 (bottom) shows a typical succession of horizons A_b-B_k-B_w. Considering the results of the pocket penetrometer, represented in Figure 4 for the EM-S3 borehole, it can be observed that A_b (whose top is identified with the paleosol symbol shown in the legend, just below the poorly drained floodplain) shows higher values of pocket penetrometer (PP) due to its overconsolidation state created by aging and pedogenetic processes, while B_k is characterized by medium-high values of PP, as a result of the carbonate accumulation and/or of the calcareous cementation between solid particles. In addition to the visual core inspection, simple
Figure 3. Top: schematic representation of development of paleosol horizons (A_b, B_k, B_w). Bottom: picture of the cores extracted at 20 and 25m depth from EM-S3 borehole.

laboratory tests have been performed in order to control experimental data that characterize the paleosols stratigraphy (Bruno et al, 2020).

In Figure 4, standard characterization tests have been performed on two samples of the A_b horizon of core EM-S3 (11.55m and 19.55m), on one sample of the B_k horizon (12.55m) and two samples of the C horizon (20.55m and 14.35m). The carbonate content showed low values (close to zero) for the A_b samples. The organic content determination confirmed that the highest values belong to the A_b horizon, which is coherent with the presence of a vegetation cover during soil development. An increase in particle grain size was observed from paleosol horizon A_b to B_k at the depth of 11.50-12.50 m. Indeed, the deposition in the B_k horizon of Fe and Mn oxides and the formation of secondary calcite nodules causes the enrichment in coarse grain material (recognized as sand in the laboratory procedure). On the other hand, the plasticity index is greater in the A_b horizon. A likely explanation is accumulation and mineralization of the organic matter and its association with clay minerals (Bruno et al, 2020). Samples from C horizons, not subjected to pedogenic processes, show an organic content close to 2.3%, *PI* around 16-17%, carbonate content ~20%, clay content of ~15% and silt content ~75%.

4 ROBERTSON'S CLASSIFICATION CHARTS

The observations of cores, extracted with a continuous perforating system, and, as additional tool, the results of classification tests carried out in the geotechnical laboratory, are a valuable aid for the identification of paleosol horizons in alluvial deposits. These types of investigations require a significant budget, especially when the study involves large areas. The economic effort, as well as the duration of the investigation campaign, could be significantly reduced by means of other geotechnical in situ tests. To this scope, CPTs, being rapid, cost-effective and widely used in practice, are taken into account as a possible additional investigation method, to be used with the aim of extending punctual information from boreholes to larger areas. In this paper, the application of CPT tests is analysed with respect to determination of the soil stratigraphy deduced from the soil behaviour type index (SBT) (Robertson, 2010). Paleosols are geological horizons with peculiar mechanical behaviour due to micro-structure creation as a consequence of pedogenetic processes and aging. A microstructured soil is characterized by a higher yield stress, peak strength and small-strain stiffness G_o with respect to an ideal soil. At large strain, the soil is subjected to destructuration and it may show a contractive behaviour (Leroueil and Hight, 2003). In order to investigate the effectiveness of this approach, the well-drained floodplain deposits identified in the three CPTU profiles, close to EM-S1, EM-S3 and EM-S5, were plotted on different soil classification charts available in the literature. Firstly, the Robertson (1990) chart was considered (Figure 5). Potentially, CPT-based charts could have the capability of recognizing paleosols since they rely on in situ mechanical behaviour and not directly on soil classification criteria based on grain size distribution and plasticity, such as the USCS (Unified Soil Classification System) (Tonni et al., 2019a, Tonni et al., 2019b). On the normalized Q_t-F_r chart the majority of records belong to SBT zone 3 (clay), on the right side of the normal consolidated central area, characterized by increasing *OCR*.

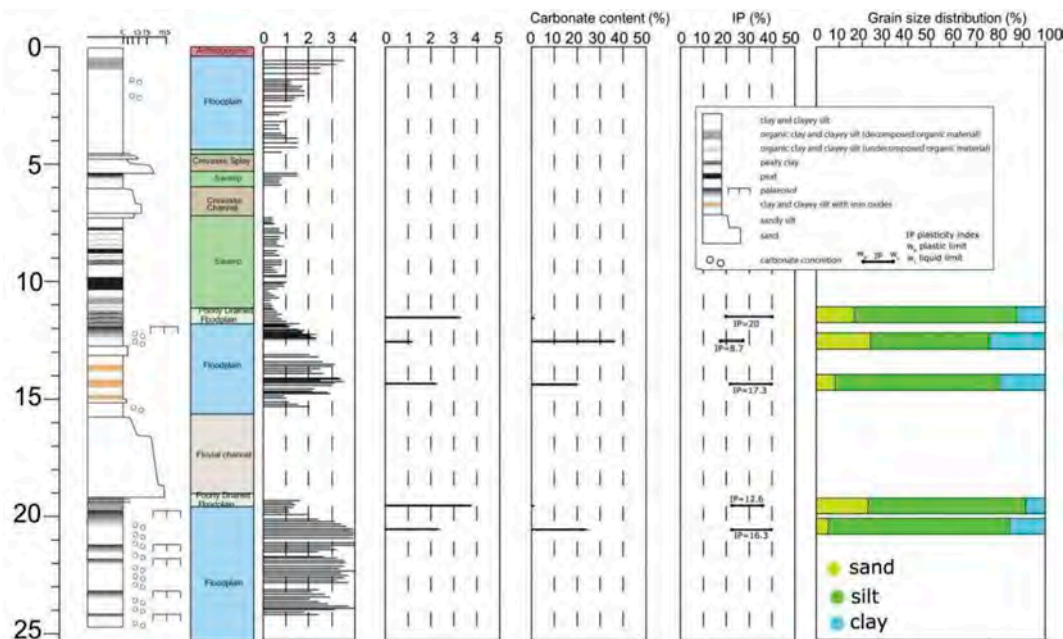
Data which have CPT-based SBT in either zone 4 or 5, could reflect the same soil (in terms of grain size), but stiffer, with higher *OCR* (horizon Ab), or a coarser layer as a consequence of a higher percentage of sand or carbonate nodules (B_k horizons). Similar results can be deduced from the Q_t-B_q charts (lower part of Figure 5), where the majority of the points are located in zone 3 (clay) and, to a lesser extent, in zones 4 (silty mixtures) and 5 (sand mixtures). Points showing SBT 4 and 5 plot around the vertical line $B_q = 0$. Comparing these groups of data (SBT 4 and 5) in the Q_t-F_r and Q_t-B_q charts, it can be noticed that a larger amount of points plots into zones 4 or 5 in the Q_t-B_q chart rather than in the Q_t-F_r chart. This likely reflects the presence of a significant silty component in this part of the deposits (see also grain size distribution in Figure 4 of samples EM-S3 and its


Figure 4. Physical characterization of five soil samples belonging to the continuous coring EM-S3. Two samples (11.55 and 19.55m deep, respectively) belong to horizon A_b; The sample at 12.55m belong to horizon B_k and the remaining two samples belong to horizon C.

Robertson's chart in Figure 5). These layers can be more effectively detected using the B_q parameter, which captures the dilatant behavior of silts (or paleosols) and the possible occurrence of coarser thin layers, not revealed by F_r. In a recent update of the classification charts, Robertson (2016) suggested to use CD = 70 line in the Q_{tn}-F_r chart (Figure 5) to recognize microstructured soils. Indeed, the CD = 70 line should separate contractive from dilative behaviours and it can be expressed with the following formula:

$$CD = 70 = (Q_{tn} - 11)(1 + 0.06 \, F_r)^{17} \quad (1)$$

With Q_{tn} normalized cone resistance and F_r normalized friction ratio.

In case of microstructured soils with contractive behaviour at large strains, but due to the increased strength and stiffness for cementation or aging, higher values of Q_{tn} may be recorded. As a result, cemented soils wrongly plot on the dilative region of the chart. In Figure 5 the majority of the points plots below the boundary line CD = 70 and only few points, that may show some microstructure, above it. On the Q_{tn}-F_r chart, the modified SBTn boundaries (black continuous lines) proposed by Schneider et al (2012) have been superimposed on the original SBT$_n$ zones (black dashed lines) by Robertson (1990). The modified contours are based on the Modified Soil Behaviour Index I_B expressed as follows:

$$I_B = 100 \frac{(Q_{tn} + 10)}{(Q_{tn}F_r + 70)} \quad (2)$$

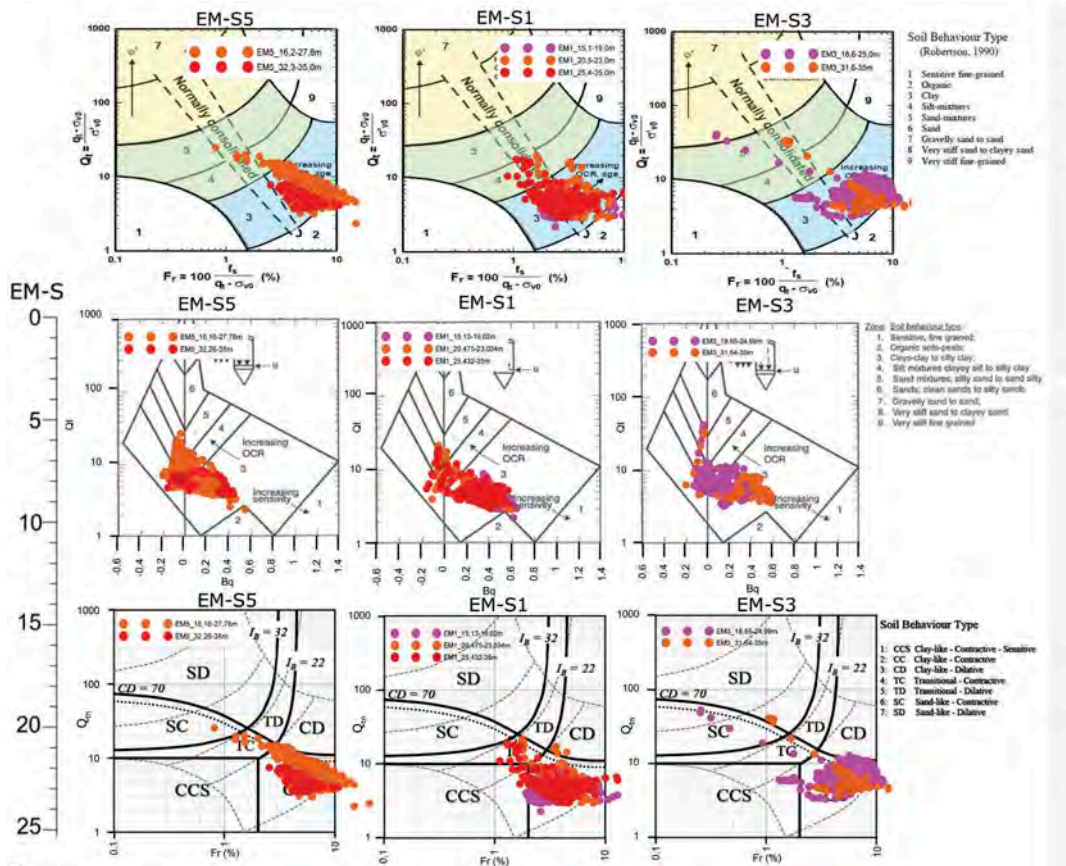
In addition to Robertson's approaches, a different classification system, proposed by Schneider et al (2008) was also taken into account. Its application showed that the investigated soils have a predominantly contractive behaviour, belonging to the clay like contractive soils (CC) and the transitional contractive soils (TC). Schneider et al (2008) also suggests that microstructured soils plot above a line of equation $Q_{tn} = -U_2 + 20$, where U$_2$ is defined as the ratio between the excess pore water pressure and the effective stress in the point. No points that satisfy this condition were found within the investigated depth. Figure 6 shows the results of the CPTU test performed in close proximity to EM-S5, in terms of corrected cone resistance q_t, f_s and u_2. Using the sedimentological characterization of facies in core EM-S5, and the SBT classification system, the geological-geotechnical stratigraphy was identified. It can be easily observed that the recognition of the different sedimentary facies starting solely from CPTU classification, in case no geological information is available, is not straightforward, as clearly shown by the comparison between central lagoon, crevasse splay and floodplain deposits. Focusing on the alluvial plain deposit (floodplain), it is interesting at this stage to compare how points plot with depth in the classification charts (Figure 6). The comparison


Figure 5. Soil Behaviour Type data plotted in the Robertson (1990) F_r-Q_t, and B_q-Q_t charts and in Robertson (2009) F_r-Q_{tn} chart for the floodplain deposits identified in EM-S5, EM-S1 and EM-S3 boreholes.

suggests that crevasse splay horizons, in particular those at a depth of 18 – 19.5 m and 22.5 – 23 m, show SBT 4 and 5 in almost all types of charts. This is due to the presence of cm-thick sandy layers that characterize this type of facies. On the contrary, the floodplain layers, where paleosol horizons have been identified, plot in SBT zone 4 only on the Q_t-B_q Robertson (1990)'s chart, while the other classification charts recognize them as homogeneous SBT 3. This peculiarity could be justified by the fact that in fine grained soils the B_q parameter is more sensitive than F_r to the presence of structure variations within thin layers, which cannot be detected through the F_r parameter.

5 CONCLUSIONS

In this paper, it has been shown how CPT data collected in floodplain deposits of the river Po plot on well-known classification charts (Robertson 1990; Robertson, 2009, Schneider et al, 2008).

Although CPTU classification charts proved to be a potential valuable help in the identification of

sedimentary facies in the alluvial Po Plain, they do not provide univocal identification of paleosol horizons without the support of their geological preliminary recognition. This evidence applies to low mature paleosols, peculiar horizons of the floodplain facies subjected in the past to microstructuration for cementation (B_k) or aging (A_b): they do not appear to be easily identified by using only information from cone penetration tests (q_t, f_s, u_2). Integrating the visual inspection of paleosols from cores with basic classification laboratory tests is crucial to a correct geotechnical-geological interpretation, especially in relatively homogeneous, mud-prone alluvial deposits, where sand bodies display strongly lenticular geometries.

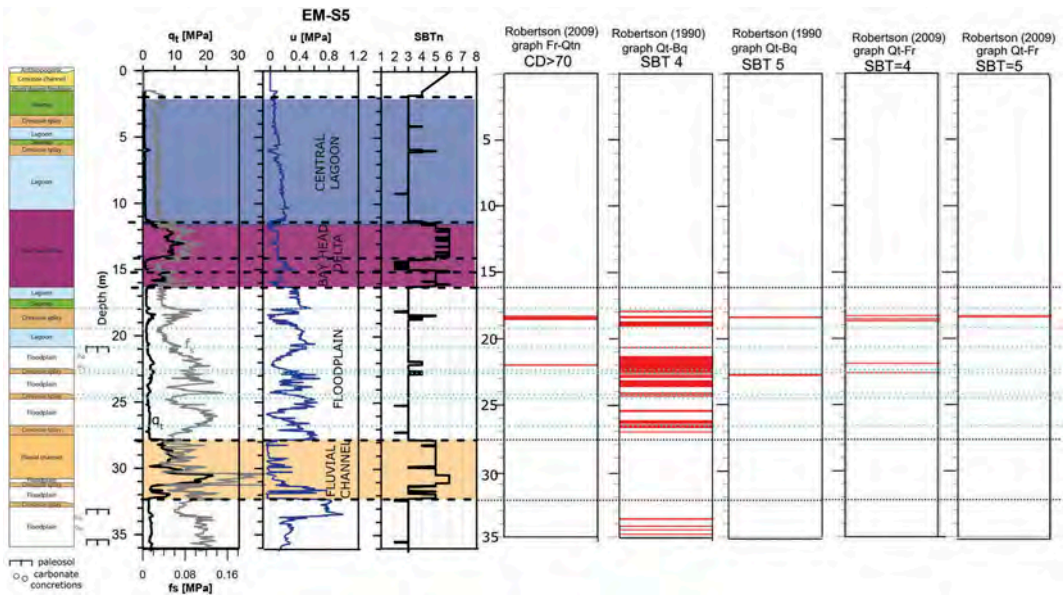
The paleosol horizons investigated in this study cannot be identified as microstructured soils in the classification charts available in the literature. This fact is probably a sign of the low maturity of these paleosols (Inceptisols), which only account for relatively short periods of subaerial exposure of the ancient topsoil. Nonetheless, a characteristic feature of paleosol horizons seems to be shown by the Q_t-B_q Robertson's (1990) chart, which


Figure 6. Left side: stratigraphic log of the continuous coring EM-S5. The final five columns represent with a red line the depth where SBT 4 or 5 have been found in the classification charts.

highlights the presence of SBT 4, where all the other charts provide SBT 3. Further investigations through dilatometer or other in situ tests will be carried out in the next future to expand the results of this study.

Application of CPT to the evaluation of permeability in a Po river embankment prone to backward erosion piping

Ilaria Bertolini, Guido Gottardi, Michela Marchi & Laura Tonni
University of Bologna, DICAM, Italy

Agnese Bassi & Alessandro Rosso
Interregional Agency for the Po River, AIPO, Italy

ABSTRACT: Backward erosion piping is one of the most critical issues for the stability of many river embankments worldwide. The article presents results from an extensive geotechnical campaign carried out on a section of the Po river embankments (Italy), prone to backward erosion piping. The aim of the investigations was twofold: firstly, identifying the stratigraphic arrangement of the river system causing favourable conditions for piping occurrence, and secondly determining the permeability of the aquifer and the finer top stratum (blanket) in their undisturbed state, as well as that of the preexisting eroded zone in proximity of the sand boil (i.e. the volume around the exit hole). Indeed, analytical and numerical approaches available in the literature are particularly sensitive to the value of permeability of the aquifer, which should therefore be determined in undisturbed conditions. CPT tests turned out to be suitable and economical to this scope. This study presents an integrated analysis of in situ testing data, collected from boreholes, piezocone test and Lefranc test, aimed at estimating the saturated permeability of the different soil units using different experimental methods and interpretation approaches. A comparison between alternative CPT-based methods and field permeability tests is proposed. A good agreement between the different methods was found, thus suggesting the suitability of CPT for the hydraulic characterization of soils.

1 INTRODUCTION

Backward erosion piping is an internal erosion process which may occur in stratigraphic contexts characterized by a shallow thin clayey layer ("blanket") overlying a highly permeable stratum (aquifer), where significant seepage flow can develop. Such stratigraphic conditions are typical of alluvial plains where major lowland rivers flow and of delta areas, protected by high-rise embankments. When the water level in the river rises, a high hydraulic head difference may be attained, resulting in an increase of the seepage flow in the aquifer. In such conditions, the water flow may concentrate towards local discontinuities where the hydraulic gradients increase, possibly creating flow exit pipes and the consequent initiation of the backward erosion process. The phenomenon could then progress eroding sand particles at the interface between the aquifer and the blanket, creating at the same time sand boils on the ground surface.

Backward erosion piping is recognized to represents a serious threat to dams and levees. Indeed, this phenomenon typically affects the surroundings of embankments of major lowland rivers in China, USA, and The Netherlands, among others. A widespread occurrence of sand boils has been also reported for the Danube. In Italy, along the Po River, more than 130 sand boils have been registered and the majority of them (80) reactivate periodically during high-water events (Merli et al., 2015; Aielli et al., 2019; Marchi et al., 2021).

An in-depth understanding of the mechanism and a reliable assessment of piping risk require both the preliminary development of a detailed stratigraphic model of the whole river embankment system and the accurate estimate of soil permeability. The different approaches, either analytical or numerical (e.g. USACE 2000; Sellmeijer et al. 2011; García Martinez et al., 2020), for the modelling of this phenomenon, are indeed based on a careful characterization of the hydraulic properties of soils. As a result, due to the significant extent of the areas to be investigated and to the fact that characterization involves coarse grain soils, field investigations turn out to be the only possible practical approach which can be adopted for the definition of the soil parameters required in the analyses. This paper discusses the determination of soil permeability from CPTU tests carried out in a piping-prone section of the Po river embankments.

2 THE STUDY AREA

The Po River is the main Italian watercourse. It flows across northern Italy from the Western Alps to the Adriatic Sea near Venice, for an overall length of 650 km. In the last two centuries, the height of Po river embankments has been progressively increased, with the obvious benefit of preventing overtopping while increasing at the same time the susceptibility to piping of the whole area. The higher the water level in the river, the greater the water head difference at the toe of the embankment landside, which, in turn, results in an increase of the probability of sand boil occurrence. In addition, the variation of flood dynamics, induced by climate changes, generates more recurrent and intense high-water events and consequently further aggravates the problem.

On that account, over the last years local authorities have launched a number of investigation campaigns on the most critical areas, with the aim of mitigating the flood risk connected to backward erosion piping.

This paper is based on the experimental dataset recently collected in one of the most investigated sections of the Po river, located in Guarda Ferrarese (Ferrara province) (Figure 1a). Here, an historical sand boil of remarkable size (the sand volcano reached an external diameter higher than 2.5 m), located landside of the riverbank section, at the bottom of a ditch, reactivates recurrently during high water events.
Figure 2. Stratigraphic model of Section A-A in Figure 1, with CPTU log profiles.

3 GEOTECHNICAL INVESTIGATIONS AND STRATIGRAPHIC MODEL

Figure 1 shows the location of the main in situ tests performed in the investigated river embankment section, in three different stages of geotechnical campaigns: in 2010, 2016 and 2021. During the 2016 investigation, dissipation tests have been performed in units B and C, in order to gain a better insight into the permeability characteristics of the subsoil, in terms of the horizontal permeability k_h. In 2021, the geotechnical campaign included continuous coring boreholes with execution of Lefranc permeability tests and SPT. In addition, Casagrande piezometers have been installed in the bored holes to monitor pore water pressures changes in both the confined and the phreatic aquifer (blanket), in relation to the variation of the water level in the river (PZ1, PZ2, PZ3, PZ4 and PZ5 in Figure 1).

The stratigraphic model in Figure 2 shows profiles of the corrected cone resistance (q_t) and the pore pressure (u_2) for the 2016 piezocone tests, which have been interpreted according to the classification framework proposed by Robertson (2009). Samples extracted during borings have been also taken into account to support stratigraphic modelling.

As evident from Figure 2, five different soil units have been identified. Unit A (aquifer) is the sandy layer where the erosion process takes place in case of piping. On the top of this unit, there are the continuous clayey and silty horizons C and B, creating favorable conditions for backward erosion piping initiation and progression. It is worth noting that the thickness of the ''blanket'' (comprising units B and C) tends to reduce in close proximity to the sand boil, as deduced from CPT1bis (2021) and CPT5 (2021). In particular, the thickness changes from 3.72m to 2.96m moving toward the ditch, being the CPT5 (2021) test closer to the longitudinal axis of the ditch. The reduction of the

blanket thickness approaching the ditch may give a reason for the position of the sand boil. Moreover, the thickness of the lesser permeable unit C, roof of the aquifer, decreases from 1.76m in CPT1bis to 1.2m in CPT5.

Laboratory tests have been carried out on 14 disturbed soil samples collected during borings. Samples have been tested to measure grain size distributions (Figure 3A) and plastic properties of the finer samples (Figure 3B). Unit A (no. 5 samples) turns out to have an average percentage of fine and coarse materials equal to 14% (standard deviation, *SD*, equal to 16%) and 86% (*SD* = 16%), respectively. The organic content is extremely low (0.28%) and the carbonate content equal to 10%. Unit C (no.3 samples) and E (no. 2 samples) are dominated by fine-grained soils, with a percentage of clay and silt equal to 52% (*SD* = 20%) and 60.8% (*SD* = 6.5%), respectively. Unit B, consisting of an alternation of silty mixtures, is composed of 39% silt and 8% clay, with plasticity index equal to 14% (SD = 7.8%) and organic content 0.72%. The samples of the investigated units B and C are located in the left side of the Casagrande chart (Figure 3) and therefore can be classified as low plasticity silts and clays.

4 DETERMINATION OF THE SATURATED PERMEABILITY

Estimates of the saturated permeability of the different soil units have been first obtained using the well-known CPTU-based empirical correlations proposed by Robertson (2010), given by:

$$1.0 < \text{Ic} \leq 3.27: \quad k = 10^{(0.952-3.04\,Ic)}\,[\text{m/s}] \quad (1)$$

$$3.27 < \text{Ic} \leq 4.0: \quad k = 10^{(-4.52-1.37\,Ic)}\,[\text{m/s}] \quad (2)$$
Figure 3. (Left) Particle size distribution of soil samples collected from boreholes; (Right) Soil classification according to the Plasticity Chart.
Figure 4. CPTU-based *logk* profiles in four different vertical alignments of the investigated river embankment section, in conjunction with permeability data deduced from Lefranc and dissipation tests.

Robertson's correlations are function of I_c, which generally relates well to soil grain size distribution, although this index is mainly intended to identify an in-situ soil behaviour.

The permeability profiles deduced using eqs. (1) and (2) are shown in Figure 4.

In addition, the frequency distributions of *log(k)*, as deduced from CPT data, are provided in Figure 5. This
Figure 5. Frequency distribution of permeability data (*log k*) from CPTU for each soil unit under investigation.

plot shows that the coarser layers A and D exhibit a bell-shaped distribution, typical of a normal distribution, while the heterogeneous unit B, characterized by alternations of silty-sands and sandy-silts, presents a bimodal distribution. In this case, the higher peak is found at *log(k)* = -4.75 (i.e. $k = 10^{-4.75}$ m/s), typical of silty-sands, whereas the smaller peak corresponds to *log(k)* = -6.8, consistent with sandy-silts. In unit C, the frequency distribution of *log(k)* is asymmetric, with a peak at -9.75 (thus low permeability clay) and mean value equal to -8.3, the latter value corresponding to a permeability typical of silty-clayey soils. This outcome reflects the fact that unit C is an alternation of clay and silty-clay materials.

The analysis of soil permeability was also developed using no. 7 dissipation tests, carried out in the 2016 CPTU tests. These data have been analysed using two approaches: the well-established Parez and Fauriel (1988) simplified formulation, which provides estimates of the permeability k_h from the time for 50% excess pore pressure dissipation (t_{50}), and the correlation based on the 1D constrained modulus M and the coefficient of consolidation in horizontal direction c_h, according to the following formula:

$$k_h = (c_h \cdot \gamma_w)/M \qquad (3)$$

where γ_w is the unit weight of water. In eq. (3), c_h has been approximated according to Robertson (2010):

303

Table 1. Mean values of soil permeability, as deduced from CPTU interpretation in terms of I_c and Parez and Fauriel (1988) method, and results from Lefranc tests (standard deviation given in brackets).

		log k (k in m/s) From dissipation	From CPTU (I_c)	Lefranc Test	k (m/s) From dissipation	From CPTU (I_c)
	Lefranc Test					
A	-6.05 (0.74)	-5.71 (0.38)	-5.04 (0.42)	8.91E-07	1.95E-06	9.12E-06
B	-5.79 (0.22)		-5.99 (0.79)	1.62E-06		1.02E-06
C		-8.33 (0.44)	-8.34 (0.79)		4.68E-09	4.57E-09
D			-6.54 (0.52)			1.62E-07
E			-6.08 (1.20)			1.17E-05

$$h = \left(1.67 * 10^{-6}\right)10^{(1-\log t_{50})} \quad (4)$$

whereas the constrained modulus M has been estimated using the Robertson (2009) formulation, suggested for soils with $I_c > 2.2$ and thus including a wide variety of soils such as sandy silts, silts and clays:

$$M = \alpha_M(q_t - \sigma_{vo}) \quad (5)$$

with

$$\alpha_M = Q_{tn}, \quad \text{when} \quad Q_{tn} \leq 14 \quad (6)$$

$$\alpha_M = 14, \quad \text{when} \quad Q_{tn} > 14 \quad (7)$$

being Q_{tn} the stress-normalized corrected cone resistance, as defined in Robertson (2009).

Results from the analysis of dissipation tests are shown in Figure 4. It is worth observing here that the indirect determination of k described above requires a reliable interpretation of dissipation tests, which could be affected by partial drainage effects when performed in predominantly silty sediments (such as unit B). In this case, the estimate of t_{50} and c_h from dissipation tests, using standard approaches, might be somewhat inaccurate (Tonni et al., 2019).

The latest site investigation campaign, performed in 2021, also included n° 7 Lefranc tests (LF). These tests consist in the injection of water by gravity into

a chamber filled with gravel located at the bottom of a borehole and then in the measurement of the water level lowering with time. The permeability can be calculated using information on the geometry of the internal chamber (area, length and diameter) and the measurements of the variable head during the test.

The determination of the permeability by means of Lefranc test is particularly suitable for soils having permeability higher than 10^{-7} m/s, which corresponds to units B and A of the investigated subsoil.

The estimates of k, as obtained from the different methods described above, are all shown in Figure 4. It can be observed that local determination of the permeability, provided by interpretation of dissipation tests or by Lefranc tests, are generally in good agreement with CPTU-based profiles of k predicted using eqs. (1) and (2). As regards the vertical alignment n° 4, located on the right side of the ditch, close to the sand boil, the permeability obtained from the Lefranc test, at 14.5 m in depth, could be only compared with the permeability profile computed from CPTU3_2016, which is the closest piezocone test though located on the opposite side of the road embankment. Table 1 summarizes the average values of permeability obtained from the different methods. The table confirms what previously observed in Figure 4, i.e. that minor differences exist between dissipation-based-values of k and CPTU-based predictions provided by eqs. (1) and (2).

An additional data analysis is provided in Table 2, where the average and the standard deviation of $log(k)$, as computed from piezocone tests, are reported for

Table 2. Mean values (standard deviation in brackets) of the permeability of each soil unit, as computed from each cone penetration test.

log k (k in m/s)	D	C	A	B	C2	B2	C3	E
CPTU1_2016_Berm	-6.86 (0.52)	-8.48 (0.51)	-5.11 (0.39)					
U277_2010_Crest		-8.57 (0.83)	-5.18 (0.54)	-6.54 (1.07)	-8.57 (1.06)	-5.25 (0.87)	-9.25 (0.29)	-6.08 (1.20)
CPTU02_2016_Outerslope	-6.59 (0.45)	-7.71 (1.22)	-5.06 (0.45)		-8.23 (0.52)	-6.80 (1.07)		
CPTU3_2016_BankToe		-8.48 (0.62)	-4.95 (0.41)	-6.11 (1.03)	-8.94 (0.76)		-8.91 (0.24)

every soil unit, taking into account the increasing distance of the test from the river course. In this analysis, the fine-grained unit C has been divided into 3 distinct sub-units, namely the upper unit C and the deeper soil units C1 and C2 (see Figure 6). Similarly, the predominantly silty unit B has been divided into the shallowest unit B and the deep unit B2.

The differences in the permeability values within each soil unit appear to be small, thus indicating a substantial homogeneity in the horizontal direction. Such condition facilitates the numerical modelling of the phenomenon (García Martínez et al., 2018).
Figure 6. Stratigraphic section of the investigated river embankment with indication of the different soil units specified in Table 2.

In particular, a minor variability is observed between the average values of permeability in the aquifer A. Moving from the centre to the toe of the embankment, a slight increase of k is observed, likely due to a reduction of porosity beneath the embankment due to its self-weight.

5 CONCLUSIONS

The assessment of backward erosion piping susceptibility of river embankment systems requires the accurate estimate of the permeability of the soil units affected by underseepage, irrespective of the approach (numerical or analytical) adopted for the analysis.

In this study, the well-known Robertson's (2010) empirical formulation, providing profiles of the permeability k as a function of the Soil Behaviour Type Index, I_c, has been used to estimate the permeability of an aquifer and the blanket forming the subsoil of a river embankment prone to piping, along the major Italian watercourse. The comparison with alternative determinations of k, based on dissipation tests or Lefranc permeability tests, showed a good agreement between the estimates provided by the different methods.

According to results presented in this paper, cone penetration tests have proven to be a valuable strategy for the definition of the saturated permeability of the soil layers underlying the embankment. The estimation of permeability from I_c results in a continuous profile of k with depth, which appears to be an important added value in comparison with a limited number of local measurements from dissipation or Lefranc tests.

In this study, the use of a few CPTU, performed in different locations of the river embankment section (namely the berm, the crest, the toe of the embankment and in proximity of the sand boil) has provided information on the spatial variability of permeability. A negligible variation of this parameter has been observed, especially for the aquifer. Such an evidence potentially simplifies the analysis of the phenomenon since a unique mean value can be assumed as representative of the permeability of each soil unit.

Such outcomes, though preliminary, appear to be very promising in view of an intensive application of the method for the assessment of piping susceptibility of the river embankments along the mid-lower stretch of the Po.

Dissipation tests to evaluate the equilibrium pore pressure

F.A.B. Danziger, G.M.F. Jannuzzi & A.V.S. Pinheiro
Coppe and Polytechnic School, Federal University of Rio de Janeiro, Brazil

ABSTRACT: Dissipation tests are carried out with two main purposes: the estimation of the horizontal coefficient of consolidation, c_h, and the evaluation of the equilibrium pore pressure. Regarding the first case, even in soft clays the duration of the test doesn´t need to be more than 40 minutes, in most situations. However, in the latter case a long time is needed to reach equilibrium, even when probes with small diameters are used. The present paper presents results of long-term dissipation tests performed in a soft clay layer, aiming at the decision of executing or not an underpinning of shallow foundations of a damaged warehouse which suffered significant settlements.

1   INTRODUCTION

According to Campanella & Robertson (1988), the pore pressure measurement during the penetration of a probe was carried out for the first time at the beginning of the 1970s, as described by Wissa et al. (1975) and Torstensson (1975). The main purpose of the Wissa et al.´s (1975) probe was to determine flow patterns through dams and pore pressure fluctuations due to waves and tides. However, this could only be achieved after the dissipation of the pore pressures generated during probe installation. Wissa et al. (1975) and Torstensson (1975) realized the enormous potential of the pore pressure measured during penetration, and Torstensson (1975) mentioned the possibility of assessment of the coefficient of consolidation from the time necessary to pore pressure dissipation.

It must be pointed out that Janbu & Senneset (1974) and Schmertmann (1974) also used a pore pressure probe and a Geonor electric piezometer, respectively, to investigate the pore pressure generation during the probe installation.

It is generally accepted that the piezocone was formally born (i.e., the joint measurement of cone resistance, q_c, sleeve friction, f_s, and pore pressure, u) at the beginning of 1980s, from the publication of several papers in the 1981´s ASCE Symposium on Cone Penetration Testing and Experience held in St. Louis, and the 1982´s II European Symposium on Penetration Testing held in Amsterdam.

Since then, dissipation tests have been used both to estimate the horizontal coefficient of consolidation, c_h, and the evaluation of the equilibrium (or hydrostatic) pore pressure.

However, in the latter case, a long time is needed to reach equilibrium when tests are carried out in soft clays, even when probes with small diameters are

used. The present paper presents results of long-term dissipation tests performed aiming at the decision of executing or not an underpinning of a damaged warehouse.

2   DISSIPATION TESTS

2.1   *General*

Pore pressure dissipation occurs as soon as the probe penetration is halted, even for a simple rod addition in the rod stem. In general, tests are carried out on specific depths of particular interest for the soil investigation. The time for dissipation depends on the coefficient of consolidation and the diameter of the filter, the higher the coefficient of consolidation and the smaller the filter diameter the faster is the dissipation (e.g., Torstensson, 1977). In most soil types and regular piezocone 10 cm^2 penetrometers, full dissipation can be achieved in less than one hour. However, when tests are performed in soft clays full dissipation may need a few days. Nevertheless, since most methods use t_{50} to evaluate the coefficient of consolidation, in most cases 30-40 minutes of test duration is enough for the estimation of the coefficient of consolidation.

There are some methods to estimate the coefficient of consolidation from dissipation tests (e.g., Torstenson, 1977, Levadoux & Baligh, 1986, Houlsby & Teh, 1988, Danziger et al., 1997). The methods based on the Strain Path Method seem to be more used in practice.

2.2   *The evaluation of the equilibrium pore pressure*

Some engineering applications require the measurement of the equilibrium pore pressure, both onshore

and offshore. In the offshore case, the verification of the presence of gas on sediments to estimate the safety of pile foundations of platforms was carried out by Lunne et al. (1996). The determination of the so-called "drilling window" for the installation of jetted conductors in clays (e.g., Jeanjean et al., 2015) also requires the equilibrium pore pressure measurement.

In the onshore case, the previously mentioned determination of flow patterns through dams and pore pressure fluctuations due to waves and tides (Torstensson, 1975) are possible applications.

In all those cases, since tests have been performed in clays, the time required for full dissipation is significant, thus probes with small filter diameters have been used. Figure 1 presents pore pressure probes used offshore (Peuchen & Klein, 2011).
Figure 1. Small diameter pore pressure probes (Peuchen & Klein, 2011).

Another increasing application is the determination of pore pressure equilibrium for tailings dams, however in such cases probes with small filter diameters are not required, because in most cases sandy silts or silty sands constitute the materials to be tested. The time for full dissipation is not significant in those materials, therefore regular 10 cm^2 penetrometers may be used.

In all cases, an issue with the measurement of the equilibrium pore pressure is the accuracy of the zero (reference) reading. Any possible variation must be avoided, since significantly influences the reliability of the measurements. A way to solve this issue is to use dual pore pressure penetrometers, which have been adopted by the Federal University of Rio de Janeiro since 1996 on regular basis (Bezerra,1996, Danziger et al., 1997). The use of two independent pore pressure sensors eliminates any doubts regarding the reliability of the measurements. An example is presented in Figure 2, in which a pore pressure smaller than the hydrostatic (u_0), assumed as the water unit weight multiplied by the distance between the water table position and the tested depth, is verified.
Figure 2. Dissipation test performed on the main Brazilian motorway with a dual pore pressure piezocone (Danziger et al., 1998, Danziger, 2007).

Since the material tested is dilative, the pore pressure u_2 at the onset of dissipation (time t=0), measured at the cone shoulder, recorded a negative excess pore pressure, because this position is dominated by the shear stresses. The pore pressure u_1, measured at cone face, however, recorded a positive excess pore pressure at t=0, because this position is dominated by octahedral stresses. After a certain time both u_1 and u_2 record the same pore pressure, below the hydrostatic pressure. If only one sensor was available, doubts regarding the reliability of the measurements would certainly exist, because at that time there was no apparent reason for such an event. However, the measurements carried out triggered an investigation which discovered that a beer factory (not close to the tested site) was taking water from the ground, generating a reduction in pore pressure in depth.

3 THE CASE

A warehouse of an industry in the state of Rio de Janeiro, Brazil, presented serious damages due to

excessive settlements. The warehouse is founded on shallow foundations constructed on an embankment overlying a soft clay layer. The company in charge of the repair wanted to know whether the settlements had already ceased or were still under development. If they had ceased, just repairing the damaged construction would take place, whereas underpinning with deep foundations in addition to repairing the structure would be necessary to significantly reduce further displacements of the structure.

The soil profile from a CPT is presented in Figure 3, where it can be observed an upper embankment until 10.2 m depth, followed by a soft clay layer until 15.0 m depth. The water table is approximately 5.3 m below ground level.
Figure 3. Soil profile.

It was not known whether the consolidation of the clay layer due to the embankment and surcharges on the ground had already ceased or not. Therefore, it was decided to verify whether the pore pressures generated by the loading had dissipated or not, by the measurement of the equilibrium pore pressures at different depths inside the clay material. Since the expected time for full dissipation would be significant, a pore pressure probe with a filter with a smaller diameter than a regular penetrometer (10 cm^2) would be used. The available probe has only one filter, 11.6 mm in diameter, made of sintered bronze (Figure 4), rather than two filters in the piezocone penetrometer routinely used by Coppe/UFRJ.

Since the interest of the measurements was only the soft clay layer, a casing borehole was executed until 8 m depth, which was filled with water. The probe was then inserted into the casing and pushed at a constant rate of 20 mm/s, the standard rate used for piezocone testing. It must be highlighted that: i) although several penetrometers are saturated with fluids like glycerin and silicon oil to keep saturation

when penetration is carried out on unsaturated material, the Coppe/UFRJ procedure is always to saturate the filter with water, following a procedure developed by NGI (Lacasse, 1980) in which vacuum is used; a parallel CPT is then carried out in the unsaturated soil; ii) the pore pressure is recorded during probe lowering inside the casing filled with water, which is then used to check the sensor calibration.
Figure 4. Pore pressure probe used for the determination of equilibrium pore pressure.

The pore pressure probe was pushed to 11.11 m, approximately 1 m below the top of the clay layer, then the dissipation was allowed to occur. The data acquisition system was kept inside a room adjacent to the test site, and the chart pore pressure versus time (in a log scale) was observed, and pictures were sent to the Coppe/Ufrj team, which had returned to the laboratory in Rio de Janeiro, to follow the

Table 1. Dissipation tests performed.

Test	Depth	Duration (day)
1	11.11	5
2	12.11	7

4	14.10	1
5	14.85	4

Figure 5. Picture showing a time close to the end of dissipation, 11.11 m test depth.
Figure 6. Dissipation tests performed.
Figure 7. Equilibrium pore pressure versus depth of all tests.

Figure 8. Pore pressure measured during installation and dissipation.

dissipation remotely. Figure 5 shows one of such pictures, in which dissipation was considered almost completed. When this occurred, a member of the team traveled to the test site and pushed the probe to the next depth. Table 1 presents the tested depths and the duration of each test until complete dissipation. Figure 5 presents some oscillations in the final part of the test, which was attributed to loading – unloading activities near the test. Those activities were requested to be interrupted to not disturb the tests, especially in its final part.

Figure 6 presents all dissipation tests, and Figure 7 shows the equilibrium pore pressure versus depth of all tests. The assumed hydrostatic pore pressure, based on the water depth on top of the soft clay, is also shown in the figure. It can be observed that there is still an excess pore pressure in the soft clay, especially in shorter depths.

Figure 8 shows the pore pressure measured during installation (including during lowering the probe inside the 8 m long casing) and the dissipation tests.

Based on the obtained results, it was decided to underpin the shallow foundations of the warehouse.

4 SUMMARY AND CONCLUSIONS

Long-term dissipation tests with a pore pressure probe have been carried out in a soft clay layer. The tests aimed at the evaluation of the equilibrium pore pressure to know whether the soft clay was still under consolidation due to an embankment. A few days were necessary to reach full dissipation, even with the small diameter of the probe (11.6 mm) used. An excess pore pressure was measured in three out of the five tests performed, indicating that the clay was still under consolidation.

Based on these measurements, it was decided that an underpinning of the shallow foundations with deep foundations was necessary, in addition to repairing the damaged warehouse.

Dynamic characteristics of the soils by Cone Penetration Tests (CPT)

A. Cavallaro
CNR-ISPC, Catania, Italy

ABSTRACT: A geotechnical project requires a site-specific investigation to collect data regarding the sub-surface conditions. Soil explorations must be made to determine the presence and identification of underlying strata, groundwater conditions, types of geomaterials, their depths and thicknesses, and the associated engineering parameters required for geotechnical design. The Cone Penetration Test (CPT) represents one of the most widely used on-site investigation methods in geotechnical engineering. This paper presents some empirical correlations available by Cone Penetration Tests (CPT) for determining the main geotechnical characteristics of soils. Moreover it aims to evaluate the small strain shear modulus by means of empirical correlations based on penetration tests results, CPT, Standard Penetration Tests (SPT) and Flat Dilatometer Marchetti Tests (DMT) or laboratory geotechnical investigations. It is aimed to achieve a better understanding of the obtained geotechnical parameters and the empirical correlations, justifying the investigation effort and enabling reliable input data for advanced dynamic analysis.

1 INTRODUCTION

Currently, CPT static sounding is one of the most popular field study as its specificity provides rich quasi-continuous data at depth. The CPT results enable to infer the soil profile as well as strength and stiffness parameters even at great depths in a cost effective way (Robertson et al., 1986, Kulhawy & Mayne, 1990; Fellenius & Eslami, 2000; Powell & Lunne, 2005; Robertson, 2009; Mayne, 2020).

The results presented in the article add new data to the documented knowledge. The results of field studies and guidelines on the soil of Noto area have been described in previous publications (Cavallaro et al., 2003a, 2003b; Cavallaro & Maugeri, 2003), and the data from soundings are the basis for determining soil parameters (Mayne, 2016) and engineering calculations.

In the light of the above, linking the numerical results of CPT static sounding to the genesis of soil will bring significant benefits to geotechnicians and engineering geologists in terms of data interpretation.

This paper intends to propose a critical evaluation of geotechnical parameters (Cavallaro, 2020) with special attention for small strain shear modulus G_o.

2 INVESTIGATION PROGRAM AND BASIC SOIL PROPERTIES

The Pliocene Noto deposits of Trubi Formation mainly consist of a medium stiff, over-consolidated lightly cemented silty-clayey-sand (Cavallaro et al., 2003a; Cavallaro & Maugeri, 2003).

The pre-consolidation pressure σ'_p and the over-consolidation ratio OCR $=\sigma'_p/\sigma'_{vo}$ were evaluated from the 24h compression curves of incremental loading (IL) oedometer tests.

Moreover, Marchetti's flat dilatometer tests (DMT) were used to assess OCR and the coefficient of earth pressure at rest K_o following the procedure suggested by (Marchetti, 1980).

For depths of about 15 m, DMT results show an OCR from 1 to 4.5 (K_o = 0.5 ÷ 1.0).

The OCR values inferred from oedometer tests (OCR from 1 to 3) are lower than those obtained from in situ tests.

One possible explanation of these differences could be that lower values of the pre-consolidation pressure σ'_p are obtained in the laboratory because of sample disturbance.

The value of the natural moisture content w_n prevalently range from between 12 - 37 %. Characteristic values for the Atterberg limits are: w_l = 37 - 69 % and w_p = 17 - 22 %, with a plasticity index of PI = 15 - 47 %. The obtained data indicate a low degree of homogeneity with depth of the deposits (Cavallaro et al., 2003b; Cavallaro & Maugeri, 2003).

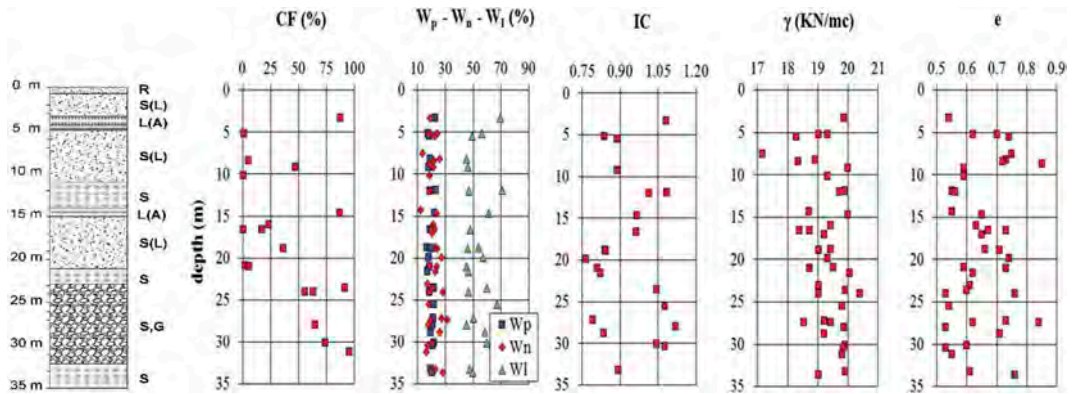
Shear modulus G and damping ratio D of Noto soil were obtained also in the laboratory by resonant column tests (RCT). These tests were performed on Shelby tube specimens retrieved from Noto site. The Resonant Column/Torsional shear apparatus were used for this purpose.


Figure 1. Borehole and index properties of Noto soil; where R: Landfill; S(L): Silty Sand; L(A): Clayey silt; S: Sand; S,G: Sand and Gravel.

3 EVALUATION GEOTECHNICAL PARAMETERS FROM CPT

CPT tests are widely used to investigate the subsoil in order to obtain information on the different physical-mechanical properties of the soils. Empirical laws are therefore available for determining the main geotechnical characteristics of soils.

The following geotechnical parameters have been determined:

- Total unit weight γ;
- Angle of shear resistance ϕ';
- Undrained resistance c_u;
- Shear modulus G_o.

It is possible to evaluate the total weight unit γ by empirical correlations of CPT in situ measurement:

- Mayne et al. (2010):

$$\gamma_t = 11.46 + 0.33\log(z) + 3.1\log(f_s) + 0.7\log(q_t) \tag{1}$$

where z = depth [m], f_s = sleeve friction resistance [kN/m²] and q_t = corrected cone resistance [kN/m²].

- Robertson & Cabal (2010):

$$\gamma/\gamma_w = 0.27\,[\log(R_f)] + 0.36\,[\log(q_t/P_a)] + 1.236 \tag{2}$$

where γ_w = water weight unit [kN/m³], $R_f = (f_s/q_t)$ = friction ratio [-], q_t = corrected cone resistance [kN/m²] and Pa = atmospheric pressure, expressed in the same unit of measurement of q_t.

- Mayne & Peuchen (2012):

a) $\gamma_t = 26 - 14/[1 + 0.5\log(f_s+1)]^2$ (3)

b) $\gamma_t = 12 + 1.5\ln(f_s+0.1)$ (4)

for clays and sands.
Figure 2. Total unit weight γ by empirical correlations based on CPT.

Figure 2 shows a comparison between the results obtained in the laboratory and those obtained by the empirical relationships proposed.

It is possible to observe that the results obtained are comparable even though the relationship proposed by Robertson & Cabal (2010) is better aligned with the experimental results.

Numerous empirical correlations have been proposed for the determination of ϕ':

- Meyerhof (1951):

$$\phi' = 17 + 4.49\ln(q_c) \tag{5}$$

where q_c = cone resistance [kg/cm²].

- De Beer (1965):

$$\phi' = 5.9 + 4.76 \ln(q_c/\sigma'_{vo}) \qquad (6)$$

where σ'_{VO} = effective vertical stress [kg/cm^2].

- Dourgunouglu & Mitchell (1975):

$$\phi' = 14.4 + 4.8\ln(q_c) - 4.5 \ln(\sigma'_{vo}) \qquad (7)$$

the terms q_c and σ'_{vo} are expressed in the same unit of measurement [kg/cm^2].

- Robertson et al. (1983):

$$\tan\phi' = 1/2.68 \, [\log(q_c/\sigma'_{vo}) + 0.29] \qquad (8)$$

the terms q_c and σ'_{vo} are expressed in the same unit of measurement [kPa].

- Kulhawy & Mayne (1990):

$$\phi' = 17.6 + 11 \log[q_c/(\sigma'_{vo}\cdot\sigma_{atm})] \qquad (9)$$

where $\sigma_{atm} = p_a$ = atmospheric pressure, expressed in the same unit of measurement of q_c [kPa].

- Marchetti (1997):

$$\phi' = 28 + 14.6 \log(K_D) - 2.1 \, [\log(K_D)]^2 \qquad (10)$$

where K_D = horizontal stress index by DMT ($q_c/\sigma'_{vo} \cong 33 \cdots K_D$).

- Jefferies & Been (2006):

$$\phi' = \phi_{cv} + 15.84[\log(Q_{tn})] - 26.88 \qquad (11)$$

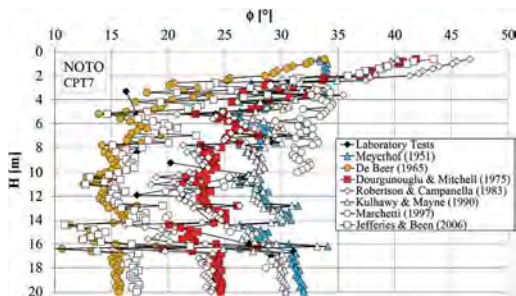
where ϕ_{cv} = constant volume friction angle and $Q_{tn} = (q_t - \sigma_{vo})/\sigma'_{vo}$ normalized cone resistance.


Figure 3. Angle of shear resistance ϕ' by empirical correlations based on CPT.

Regarding the results obtained for the angle of shear resistance ϕ', reported in Figure 3, it is observed that the values obtained in the laboratory by direct shear tests intersect all the empirical relationships proposed. Probably because these relations fail to, evaluate correctly the stratigraphic variations of the soil. High values of ϕ' were obtained in correspondence of the most superficial layers where no laboratory data is available. Overall, the Robertson & Campanella (1983) equation seems to approximate better the results of the direct shear tests.

As for the evaluation of the undrained resistance c_u the following empirical expressions were used:

- Lunne et al. (1976):

$$c_u = (q_c - \sigma_{vo})/(20.7 - 0.18 \, PI) \qquad (12)$$

where PI = plasticity index.

- Lunne & Kleven (1981) and Lunne at al. (1997):

$$c_u = (q_c - \sigma_{vo})/N_k \qquad (13)$$

where N_k = empirical factor for bearing capacity dependent on depth and opening angle of the penetrometer cone (11 - 19).

Figure 4 shows the c_u values obtained by laboratory tests and empirical correlations. The laboratory data aligns well with the c_u values derived from the correlations. High values of undrained resistance were obtained by the expression of Lunne & Kleven (1981) on the surface layers and at a depth of about 16 m.
Figure 4. Undrained resistance c_u by empirical correlations based on CPT.

4 EVALUATION G$_O$ FROM CPT

The small strain shear modulus G_o can be evaluated by laboratory Resonant Column Tests (RCT) (Capilleri et al., 2014; Castelli et al., 2016a) or in situ by Down Hole tests and SDMT (Castelli et al., 2016b; Cavallaro et al., 2012a, 2012b; Marchetti et al., 2008; Cavallaro

& Grasso, 2021) using the relationships: $G_o = \rho V_s^2$ (where: ρ = mass density) based on theory of elasticity.

An attempt was made to evaluate the small strain shear modulus by means of the following empirical correlations based on penetration tests results, CPT, SPT and DMT or laboratory results available in literature (Figure 5).

- Imai & Tomaichi (1990):

$$G_o = 28 \cdot (q_c)^{0.611} \qquad (14)$$

for any soil.
- Mayne & Rix (1993):

$$G_o = \frac{406 \cdot q_c^{0.696}}{e^{1.13}} \qquad (15)$$

for clayey strata;
where: G_o and q_c are both expressed in [kPa] and e is the void ratio. Equation (15) is applicable to clay deposits only.

- Simonini & Cola (2000):

$$G_o = 49.2 \cdot (q_t)^{0.51} \qquad (16)$$

It is also possible to evaluate the small strain shear modulus using the relation $G_o = \rho \cdot V_s$ by the following equations proposed by Ohta & Goto (1978) and Yoshida and Motonori (1988) for the shear waves velocity V_s:

- Ohta & Goto (1978):

$$V_s = 69 \cdot N_{60}^{0.17} \cdot Z^{0.2} \cdot F_A \cdot F_G \qquad (17)$$

where: V_s = shear wave velocity (m/s), N_{60} = number of blow/feet from SPT with an Energy Ratio of 60 %, Z = depth (m), F_G = geological factor (clays = 1.000, sands = 1.086), F_A = age factor (Holocene = 1.000, Pleistocene = 1.303)
- Yoshida and Motonori (1988):

$$V_s = \beta \cdot (N_{SPT})^{0.25} \cdot \sigma'vo^{0.14} \qquad (18)$$

where: V_s = shear wave velocity (m/s), N_{SPT} = number of blows from SPT, σ'_{VO} = vertical pressure, β = geological factor (any soil=55, fine sand=49).

- Hryciw (1990):

$$G_o = \frac{530}{(\sigma'_v/p_a)^{0.25}} \frac{\gamma_D/\gamma_w - 1}{2.7 - \gamma_D/\gamma_w} K_o^{0.25} \cdot (\sigma'v \cdot p_a)^{0.5} \qquad (19)$$

where: G_o, σ'_v and p_a are expressed in the same unit; p_a = 1 bar is a reference pressure; γ_D and K_o are respectively the unit weight and the coefficient of earth pressure at rest, as inferred from DMT results according to Marchetti (1980).
- Jamiolkowski et al. (1995):

$$G_o = \frac{600 \cdot \sigma_m'^{0.5} p_a^{0.5}}{e^{1.3}} \qquad (20)$$

The Jamiolkowski et al. (1995) method was applied considering a given profile of void ratio.

The values for parameters, which appear in equation (20), are equal to the average values resulting from laboratory tests performed on quaternary Italian clays and reconstituted sands.

Equation (20) incorporates a term, which expresses the void ratio; the coefficient of earth pressure at rest only appears in equation (19). However only equation (19) tries to obtain all the input data from the DMT results.

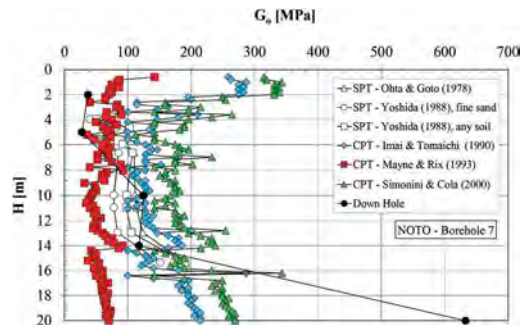
As regard Noto soil the G_o values obtained with the methods above indicated for CPT and SPT are plotted against depth in Figure 5.


Figure 5. Small strain shear modulus G_o by empirical correlations based on CPT and SPT.

The results obtained show a greater similarity between the G_o results obtained by the empirical correlations proposed for SPT, which, moreover, are quite close together. The G_o values, obtained through the correlation equations proposed for CPT are more dispersed and higher.

The lowest values of the shear modulus are obtained by the equation proposed by Mayne & Rix (1993). Only by the Down Hole test it is possible to identify the rapid increase of G_o at a depth of 20 m in correspondence with some layer characterized by higher mechanical characteristics that both CPT and SPT cannot identify.

The N_{60} values, experimentally determined during SPT, did not show any important variation in the transition zone at depth of 20 m, where the characteristics of the soil change from silty sand to sand and then to sand with gravel.

Standard Penetration Tests were performed at intervals from 1.5 to 3.0 m. The quite large interval used could explain why the thin sand layers were not detected. Consequently, the obtained G_o values, in the transition zone, resulted to be quite low.

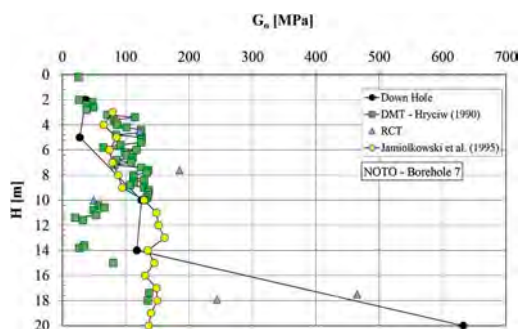
Unfortunately, the depth investigated by DMT is not able to intercept the most consistent layers of sand and sand with gravel. However, the method by Hryciw (1990) is the best one to follow the trend of the results obtained from the Down Hole tests, as can be seen in Figure 6.


Figure 6. G_o from Down Hole, empirical correlation and RCT.

From a comparison between Figure 5 and Figure 6 all the considered methods show very different G_o values of the Pliocene Noto soil. On the whole, Down Hole seem to provide the most accurate trend of G_o with depth even if the available data are unable to investigate the behavior of the soil for depths greater than 20 m. The method by Jamiolkowski et al. (1995) was applied considering a given profile of void ratio but while guaranteeing continuity of results, it fails to intercept the most consistent layers of sand and sand with gravel.

In Figure 6 the RCT results are also reported. The data obtained also show as the dynamic laboratory tests are able to interpret the G_o trend obtained from the Down Hole test.

Figure 7 reports a comparison between DH test measurements and the corresponding empirical correlations. Since the DH test was performed with an interval of about 5 m, it was necessary to interpolate the intermediate values. From the comparison obtained it is possible to observe a more disordered initial phase in correspondence with the more superficial layers while subsequently a horizontal linear relationship is highlighted with the exception of the depth of 16.20 m.

5 CONCLUDING REMARKS

A site characterization for a possible advanced dynamic response analysis has been presented in this
Figure 7. G_o from Down Hole vs G_o by empirical correlation.

paper. On the basis of the data shown it is possible to draw the following conclusions:

- empirical correlations between the small strain shear modulus and penetration test results were used to infer G_o from SPT, CPT, DMT and Down Hole. This comparison clearly indicates that a certain relationship exists between G_o and the penetration test results, which would encourage to establish empirical correlations for a specific site. This approach makes it possible to consider the spatial variability of soil properties in a very cost effective way.
- The values of G_o were compared to those measured with DMT and DH tests. This comparison indicates that some agreement exists between empirical correlations by DMT and DH test.
- relationships like those proposed by Jamiolkowski et al. (1995) seem to be capable of predicting G_o profile with depth only in the initial strata. The accuracy of these relationships could obviously be improved if the parameters, which appear in the equations, were experimentally determined in the laboratory for a specific site.
- Down Hole test only is probably able to investigate correctly the various layers of soil, identifying even the smallest variations in the mechanical characteristics.

Validating cone penetration test in partially drained conditions using a simplified numerical modelling method

R.W.L. Chia, Z.Z. Wang & S.H. Goh
Department of Civil and Environmental Engineering, National University of Singapore, Singapore

ABSTRACT: A simplified numerical modelling method, the Press-Replace Method (PRM), is applied to simulate the cone penetration process under conditions that range from fully undrained to fully drained. In this study, rigorous validations of the PRM technique for simulating the cone penetration test were performed. The results for a fully undrained and drained penetration are compared against published information using cone factor solutions. Coupled-consolidation analyses at different cone penetration rates were then carried out for a smooth cone, and the results processed to obtain the dimensionless backbone curves for comparison with published data. The consolidation analyses were further extended to a rough cone subjected to different penetration rates, for which there is little, if any, numerical simulation results reported in the literature. The results and computed backbone curves obtained using the smooth and rough soil-cone interfaces are presented and compared in this paper.

1 INTRODUCTION

The cone penetration test (CPT) is a widely used site investigation tool for the characterization of soil and the estimation of engineering properties through empirical and theoretical correlations. This method of testing provides a continuous profiling of the ground. The cone penetration in a clayey soil would typically be considered as an undrained process, whereas in a sandy soil, it is assumed as a drained process. Probable issues may arise when penetration occurs in intermediate soil layers whereby the penetration process is neither undrained nor drained. The majority of existing theoretical and empirical solutions to determine soil properties are based on the assumption of either a fully undrained or a fully drained condition. As such, partially drained conditions could complicate the interpretation of results.

In this study, finite element analysis is employed to model the penetration process in partially drained conditions, by simulating the penetration at different rates. Experimental studies in the published literature indicate that, when the rate of pore pressure dissipation is faster than the penetration rate, the soil near the cone consolidates during penetration. As a result, a higher tip resistance is expected as compared to undrained conditions (Lehane et al., 2009; Oliveira et al. 2011).

To model the large deformation scenarios like cone penetration, different types of modeling techniques (e.g. Updated Lagrangian, Arbitrary Lagrangian Eulerian (ALE) and Remeshing Interpolation Technique combined with Small-Strain (RITSS)) have been used to overcome the numerical issues associated with the large distortions of the discretized finite element mesh, many of which require additional subroutines. In this paper, a simplified method, the Press-Replace Method (PRM), is used to simulate the process of cone penetration. PRM can be easily implemented in standard small-strain finite element programs without the need for additional subroutines to execute remeshing or a mesh update.

PRM was first introduced to model suction anchors (Andersen et al 2004), and was refined and employed to model the installation of piles and spudcan (Engin et al., 2015; Sivasithamparam et al., 2015; Wang & Goh, 2018). A preliminary study of cone penetration was conducted by Engin et al. (2015) by comparing cone factors with other published literatures. Paniagua et al. (2014) compared numerical results obtained through PRM with laboratory scale cone penetration experiments. PRM was also used to simulate undrained cone penetration tests by Lim et al. (2018), who validated its performances in stress magnitude, principal stress direction and excess pore pressure against other existing numerical approaches such as LDFE, SSFE and MPM. More recent advances in PRM for cone penetration problems were presented by Paniagua et al. (2021), in which soil stresses and pore pressure measurements of a model scale penetration test with varying penetration rates were compared against the results from PRM back-analyses. However, the study only considered three different orders of penetration rates.

As the application of PRM to simulate cone penetration test in partially drained conditions has not been widely reported in the literature, an attempt to

rigorously validate its performance in partially drained conditions is presented in this paper. This paper first provides a concise summary of PRM and its implementation in the finite-element program PLAXIS 2D. Secondly, results obtained in partially drained conditions will be processed and compared against information from published literatures. Lastly, the influence of different soil-cone roughness on the penetration process under partially drained conditions will be briefly examined.

2 METHODOLOGY

PRM models penetration problems via a displacement control scheme (Engin et al., 2015), in which a prescribed displacement is first applied to the cone shaft to simulate the incremental pressing of the cone into the soil. This is followed by the replacement of that slice of the soil (through which the cone has incrementally penetrated) by the cone material. This systematic 'press-and-replace' process is presented in Figure 1. Figure 1 illustrates a standard 36mm diameter cone with some initial embedment. The intended downward incremental movements of the cone are represented by slices below the cone that are set up during the mesh generation process. The thickness of the slices is defined as t_s. Interface elements were added to the sides of these slices to model the interaction between the soil and cone. These interfaces were extended slightly beyond the corners of the slices; these interface extensions help reduce stress fluctuations around the angled corners of the cone. The length of these extensions is defined as $i_{int-ext}$.

The process starts with a prescribed downward displacement u_y (= 0.1D, where D is the cone diameter) of the cone over the thickness of one slice t_s (also equal to 0.1D). This represents a "press" phase. Within the same phase, the interfaces and the interface extensions bounding the cone are activated. Upon completion of this phase, the stress states of the soil elements in the deformed mesh will correspond to those caused by the pressing of the cone over the prescribed incremental depth. In the next phase, the soil material that was originally occupying the slice below the cone (in the preceding phase) will be changed to the cone material, thus making this the "replace" phase. To increase the penetration depth to 0.2D, the "press" phase is repeated and u_y is increased from 0.1D to 0.2D. As the cone advances downward, the cycle of "press" and "replace" is repeated. Accordingly, more slices must be created for greater penetration depths. To ease calculation time, after the initial "press" phase, successive "press" and "replace" phases can be combined into one phase. Negligible or little difference in the computed cone resistance was observed (Lim, 2017).

3 NUMERICAL MODELLING

3.1 Model dimensions and soil models

The FEM program used in this study is PLAXIS 2D CONNECT Edition V21. Investigations were carried using a standard cone diameter (D) of 36mm and a tip angle of 60° with an axisymmetric setup. As this paper involves a comparison study using published data from multiple sources (Yi et al., 2012; Sheng et al., 2014; Ceccato et al., 2016; Orazalin et al, 2018) with different model set-ups and assumptions, the following standardized procedures were adopted in all the PRM models of this study for simulating the different cases. These are: 1) As recommended by Engin et al. (2015), $\Delta u_y = t_s = i_{int-ext}$ of 0.1D will be adopted; 2) The initial setup begins with a soil body, which is followed by the first "press" that represents the embedment of the cone (Figures 2, 3) When required, the overburden stress in the soil will be modeled using a surcharge loading imposed by a 0.05m thick linear-elastic soil layer with the appropriate unit weight. The model dimensions adopted will follow those reported in the respective source literatures. Key details of these literatures and their soil models are summarized in Table 1. Figure 2 illustrates a typical finite element setup used in this study.

3.2 Soil-cone interface

Interfaces elements were used to model the interaction between the soil and cone surfaces. With each incremental advancement (Δu_y) of the cone, the interface elements bounding the entire penetrometer are activated. Interface elements allow for slippage (relative movement between the cone and the adjacent contacting soil) to occur as the cone displaces downwards.

Separate interface materials were created and assigned to the shaft and cone of the penetrometer. The general properties of the interface materials follow the neighboring soil; however, shear strength properties were varied depending on the desired roughness.

Table 1. Key set-up details of respective literatures used in this study.

4 RESULTS

4.1 Cone factor comparison for undrained and drained penetration

Using a case study from Yi et al. (2012), preliminary investigations for both undrained and drained conditions were carried out and compared. To achieve an undrained penetration, a penetration rate of 0.0278 m/s is selected (Yi et al., 2012). Similarly, to achieve drained penetration, a slow penetration rate of 1E-10 m/s was used (Yi et al., 2012).

For undrained penetrations, the results are presented in the form of the cone tip factor (N_c), which is calculated as $N_c = (q_c - \sigma_{v0})/s_u$, where q_c is the calculated cone tip resistance from the analysis, s_u is the equivalent undrained shear strength corresponding to the friction angle φ or friction coefficient M prescribed in the model, and σ_{v0} denotes the total overburden stress (Lu et al., 2004).

The calculated N_c values from the present PRM analysis are plotted against the normalized cone depth (H/D, where H is the penetration depth and D is the cone diameter), as shown in Figure 3. The results agree well with the data reported by Yi et al. (2012), with a stabilized N_c value of approximately 9. This stabilized N_c value also agrees well with other published solutions (Teh & Houlsby, 1991; Yu et al., 2000; Abu-Farakh et al., 2003; Lu et al., 2004; Walker & Yu, 2006).

For a drained penetration, the cone factor N_q is used for comparison. It is calculated as $N_q = q_c'/\sigma'_{v0}$ (Yu, 2004; Ahmadi et al., 2005), in which q_c' denotes the effective cone resistance obtained from the analysis and σ'_{v0} the effective vertical stress. Figure 4 shows the computed N_q values plotted against the normalized cone depth (H/D). The results obtained from the present PRM analysis agree well with the reported solution from Yi et al. (2012). The stabilized

N_q value of approximately 7.5 also falls within the range of 5 ~ 8 reported in other publications.
Figure 3. Comparison of calculated N_c with literature (Yi et al., 2012) and published solutions.
Figure 4. Comparison of calculated N_q with literature (Yi et al., 2012) and other published solutions.

4.2 Consolidation analysis of the penetration process at different cone penetration rates

In this section, the effect of different cone penetration rates is explored and validated. The effect of varying the penetration rates will result in partial drainage conditions (Suzuki and Lehane, 2014). Partial drainage occurs when there is concurrent generation and dissipation of excess pore pressures during the penetration process. In this section, the results from two published numerical case studies are adopted for comparison: (i) Sheng et al. (2014) and (ii) Ceccato et al. (2016) and Orazalin et al. (2018).

For both studies, the modified Cam-clay (MCC) model (Roscoe & Burland, 1968) is adopted to simulate the soil behavior in a more realistic manner.

The penetration rate is represented using the non-dimensional velocity V (= vD/c_v) proposed by Randolph & Hope (2004), in which v, D and c_v denote the cone penetration velocity, cone diameter and the soil's coefficient of consolidation respectively. The c_v value in the MCC model is given by Equation 1, in which e_0 is the initial void ratio, k and σ'_{v0} represents the hydraulic conductivity and effective vertical stress, λ denotes the virgin compression index and γ_w is the unit weight of water.

$$c_v = \frac{k(1 + e_0)}{\gamma_w \lambda} \sigma'_{v0} \qquad (1)$$

4.2.1 Comparison with Sheng et al. (2014)

Results obtained using PRM is presented in Figure 5. Sheng et al. (2014) associated an undrained and drained penetration in a soil body (with permeability 10^{-7}m/s) to a penetration rate of $v = 200$cm/s and $v = 0.0002$cm/s respectively. Figure 5 plots the variation of the net cone resistance (q_c-σ_{v0}) with normalized depth (H/D), in which good agreement was obtained between the results from the PRM analyses and those reported by Sheng et al. (2014) for the drained and undrained penetration conditions.

In the same figure, the results from consolidation analyses at various penetration rates proposed by Sheng et al. (2014) are also shown. At a penetration depth 10H/D, the net cone resistances of 213kPa and 137 kPa are achieved for the drained and undrained conditions respectively. Penetration velocities between $v = 200$cm/s and $v = 0.0002$cm/s resulted in the net cone resistances falling between the range of 137 to 213 kPa. The results from the various penetration rates were processed, following which the dimensionless backbone curve as illustrated in Figure 6 was obtained. In Figure 6, a normalized cone resistance (q_n) (Randolph & Hope, 2004) is plotted against a normalized penetration rate represented by v/k, where v and k denote the penetration velocity and hydraulic conductivity respectively. Instead of adopting the normalized velocity V proposed by Randolph & Hope (2004), Sheng et al. suggested the use of the normalized term v/k, which provides a more direct relationship that could facilitate the processing of data. The normalized cone resistance q_n is defined as:

$$q_n = \frac{q_c - \sigma'_{v0}}{q_{ref} - \sigma'_{v0}} \qquad (2)$$

in which q_{ref} is the reference cone resistance obtained from a fully undrained penetration. From the fitted dimensionless backbone curve of Figure 6, a stabilized q_n value at $v/k = 0.1$ can be obtained for the drained condition. The q_n values predicted by

PRM and Sheng et al (2014) at $v/k = 0.1$ are 1.56 and 1.68 respectively with a 7% difference in value. PRM predicts an undrained penetration response when $v/k > 200,000$ (approximately), whereas a drained behavior is observed when $v/k < 20$ (approximately). For intermediate values of v/k between 20 and 200,000, the effect of partial drainage is observed. A similar behavior was observed in the results of Sheng et al. (2014), for which the best fit curve showed partial drainage occurring between v/k values of 30 and 400,000 (approximately). Overall, there is good agreement between the PRM results and those reported by Sheng et al. (2014) in terms of the q_n values as well as the intermediate values of v/k (indicating partial drainage). For this example, these comparisons affirm the validity of the PRM to predict reasonable results under partial drainage conditions.
Figure 5. Comparison of undrained and drained net cone resistance between PRM and literature (Sheng et al., 2014).
Figure 6. Comparison of dimensionless backbone curve between PRM and literature (Sheng et al., 2014).

4.2.2 Comparison with Ceccato et al. (2016) and Orazalin et al. (2018)

In this section, the PRM results will be studied compared against those reported by Ceccato et al. (2016) and Orazalin et al. (2018). These two published works adopted different numerical techniques to simulate the same cone penetration set-up proposed by Ceccato et al. (2016). Both Ceccato et al. and Orazalin et al. adopted a MCC soil model to capture the soil behavior. However, for simulating the penetration process, Ceccato et al. (2016) used the Material Point Method (MPM), whereas Orazalin et al. (2018) adopted the Lagrangian finite element method with an automated remeshing procedure.

In this section, the normalized net tip resistance ($q_{n.net}$) is plotted against the normalized velocity V (Randolph & Hope, 2004) to obtain the dimensionless backbone curve. The normalized net tip resistance is defined as follows:

$$\text{Normalized Nettip Resistance } (qn.net) = \frac{q_{cnet}}{q_{ref.net}} = $$

$$\frac{q_c - \sigma_{v0}}{q_{ref} - \sigma_{v0}}$$

Using PRM, the cone penetration at different rates were modeled using consolidation analysis. A comparison of the computed cone resistances for the fast and slow penetration are presented in Figure 7 and Figure 8 respectively. These results plot the total cone resistance against the normalized penetration displacement in an undrained (fast) and drained (slow) penetration. The normalized penetration displacement is defined as the ratio of the penetration displacement to the cone diameter.

Figure 7 shows good agreement between the results reported by Ceccato et al. (2016) and Orazalin et al. (2018), while the PRM an undrained cone resistance which is about 7% higher. The results obtained by Lim (2017) are also plotted. Overall, the PRM results for the undrained response of this particular case study
Figure 7. Comparison of calculated total cone resistance with literature (Ceccato et al., 2016; Lim, 2017; Orazalin et al., 2018) in an undrained penetration.

compare favorably with those reported by Orazalin et al. (2018), Ceccato et al. (2016) and Lim (2017).

For a drained penetration, Figure 8 shows that PRM predicts a greater cone tip resistance of 263kPa compared to the MPM value of 210 kPa reported by Ceccato et al. (2016), which is a difference of about 25%. Despite the good agreement observed for the undrained response, the cone tip resistance obtained by Orazalin et al. (2018) for the drained response is about 250kPa, or about 20% higher than the MPM value. For the drained penetration, Orazalin et al.'s results are closer to those obtained using PRM.

The cone resistance results at different penetration rates obtained by Ceccato et al. (2016), Orazalin et al. (2018) and the PRM approach are processed and plotted, in the form of $q_{n.net}$ against the normalized velocity V, to produce the backbone curves shown on Figure 9. This figure shows that the PRM predictions of the normalized tip resistance $q_{n.net}$ are approximately the average of those predicted by Ceccato et al. (2016) and Orazalin et al. (2018).
Figure 8. Comparison of calculated total cone resistance with literature (Ceccato et al., 2016; Orazalin et al., 2018) in a drained penetration.
Figure 9. Comparison of dimensionless backbone curve between PRM and literature (Ceccato et al., 2016; Orazalin et al., 2018).

4.3 Effects of cone roughness

This section explores the influence of cone roughness with a case example taken from Yi et al. (2012). Cone roughness affects the stress-transfer interaction between the cone and soil surfaces, and are characterized by the friction angle φ_{int} and cohesion c_{int}' assigned to the interface elements.

For this study, the interface cohesion c_{int}' is assumed to be negligible, although a small value of 0.001 kPa is used to avoid numerical instability. Hence, the interface friction φ_{int} is the only parameter controlling the interaction between the 2 surfaces. The analyses are performed for φ_{int} values of 0, 8°, 16° and 23° to capture the transition from a perfectly smooth to a fully rough cone-soil contact.

Figure 10 plots the PRM computed undrained and drained responses for the perfectly smooth ($\varphi_{int} = 0°$) and fully rough ($\varphi_{int} = 23°$) interface conditions, in the form of the normalized depth (H/D) against q_c. For both the undrained and drained conditions, a higher q_c value is obtained when $\varphi_{int} = 23°$, the increase being much more significant for the drained response.
Figure 10. Illustration of cone tip resitance for an undrained and drained penetration, when $\varphi_{int}/° = 0$ and $\varphi_{int}/° = 23$.

Subsequently, PRM analyses are performed for different penetration rates with different values of φ_{int}. The results are summarized and presented in the form of backbone curves obtained by plotting $q_{n.net}$ against V, as shown in Figure 11 for 3 different depths (15H/D, 20H/D, 25H/D). Four distinctive back bones curves may be fitted to the data. These correspond to φ_{int} values of 0, 8°, 16° and 23°, with drained $q_{n.net}$ values of 2.38, 2.90, 3.4, 3.61 respectively. Figure 11 shows that increasing the cone roughness results in higher $q_{n.net}$ values across the whole spectrum of penetration rates. Further studies should be performed to examine the rate of increase of $q_{n.net}$, as well as the absolute cone resistance values (q_c), for different φ_{int} values at different penetration rates. This would provide a better understanding of the relationship between φ_{int} with $q_{n.net}$ and q_c.
Figure 11. $Q_{n.net}$ against non-dimensional velocity, V, for $\varphi_{int} = 0°$, 8°, 16° and 23°.

5 CONCLUSION

This paper presents a simplified approach, the Press-Replace Method (PRM), for modeling large deformation penetration problems using a small strain finite element program. The PRM approach was used in this paper to model cone penetration in soils under different drainage conditions. This paper compares the PRM predictions against the results of 4 examples taken from the published literature.

The PRM results from drained and undrained penetrations were presented and compared against the published results for the 4 examples (Yi et al., 2012; Sheng et al., 2014; Ceccato et al., 2016; Orazalin et al., 2018). In general, the PRM results (undrained and drained) are close to and within the range obtained by other researchers using different modeling techniques.

The effect of partial drainage was studied and validated in this paper by performing consolidation analysis with different penetration rates. The results, in the form of dimensionless backbone curves obtained by plotting normalized resistances against normalized velocity, compare favorably with those reported by Sheng et al. (2014) and Orazalin et al. (2018). Some discrepancies were observed when compared to the MPM results of Ceccato et al. (2016), which could be due to the use of a different tip geometry.

The effects of cone roughness were also explored in this paper. The results show an increase in q_c and $q_{n.net}$ values with the interface friction angle φ_{int}.

The University of British Columbia, Vancouver, Canada

K. Ziotopoulou & J.T. DeJong
University of California at Davis, Davis, USA

ABSTRACT: A reliable prediction of liquefaction-induced damage typically requires nonlinear deformation analyses with an advanced constitutive soil model calibrated to the site conditions. The calibration of constitutive models can be performed by relying primarily on a combination of commonly available properties and empirical or semi-empirical relationships, on laboratory tests on site-specific soils, on in-situ penetration tests, or a combination thereof. Chiaradonna et al. (2022) described a laboratory-based calibration approach of the PM4Sand constitutive model and evaluated the prediction accuracy against the response of a centrifuge experiment of a submerged slope. This paper addresses an alternate calibration approach in which the PM4Sand model is calibrated using centrifuge in-situ CPT data. The model performance for the resulting calibration is evaluated against the centrifuge experimental data and prior simulations from Chiaradonna et al. (2022). In this case, the CPT-based calibration resulted in more accurate estimations of the dynamic response and permanent displacements.

1 INTRODUCTION

A reliable prediction of liquefaction-induced damage usually requires performing nonlinear deformation analyses by adopting advanced constitutive soil models. Constitutive model calibration protocols have been developed to guide the selection of parameters, firstly driven by the goal to reproduce the soil element behavior as observed in laboratory element tests and, if tests are not available, against the broader body of data and engineering relationships in the literature. For larger scale experiments, the use of in-flight miniature Cone Penetration Tests (CPT) in centrifuge testing has provided system level soil properties and better definition of soil conditions before and after any applied shaking (Kim et al. 2016; Khosravi et al. 2018; Moug et al. 2019; Darby et al. 2019; Carey et al. 2020). Darby et al. (2019) used CPT soundings collected prior to multiple shaking events to define liquefaction triggering correlations in a centrifuge experiment. The cyclic resistance for the investigated sand in the experiment was lower than that inferred from case history-based liquefaction triggering correlations. Data from in-flight miniaturized CPTs strongly constrain several soil parameters, e.g., relative density D_R, and were therefore useful to define model calibration parameters.

Chiaradonna et al. (2022) modelled the dynamic response of a centrifuge experiment consisting of a submerged 10-degree slope of a poorly graded clean sand at a D_R of 63% (Carey et al. 2022a). Shaking was imposed by applying a 1 Hz at the base of the model container. CPTs were pushed using a 10 mm cone in the experiment prior to and following shaking, but were not considered in the calibration performed by Chiaradonna et al. (2022).

The critical state compatible, stress ratio-based, bounding surface plasticity constitutive model PM4Sand (Boulanger & Ziotopoulou 2017), implemented in the commercial finite-difference platform FLAC (Itasca, 2016) was adopted in the simulations. The primary input parameters of the model are the apparent relative density (D_R), the shear modulus coefficient (G_o), and the contraction rate parameter (h_{po}). A laboratory-based calibration was defined on the results of undrained cyclic direct simple shear tests performed on reconstituted samples (Humire et al. 2022). The simulation of the centrifuge test by adopting the laboratory-based calibration reasonably simulated the pore pressure and acceleration time histories, while the permanent horizontal displacements were overpredicted by a factor of three (Chiaradonna et al. 2022).

In this paper, the aforementioned simulation was revisited by calibrating PM4Sand parameters using the cone tip resistance as measured in the centrifuge by Carey et al. 2022a. The D_R is the target value of 63%, which was verified through a pre-shaking cone penetration test (Carey et al. 2022a). The soil behavior at small strains (i.e., G_o) was estimated by the measured cone tip resistance through the application of several literature relationships, whose efficacy was verified against the shear moduli based on the measured shear wave velocity. The cyclic resistance ratio (CRR), which is primarily controlled by the contraction rate parameter (h_{po}) in PM4Sand, was estimated through the normalized cone tip resistance measured in the experiment and the CPT-based empirical triggering liquefaction chart by Boulanger & Idriss (2014).

The comparison between simulated and experimental soil response is made to verify that in-flight CPT testing in the centrifuge experiments properly measures the cyclic strength of soils. In addition, the comparison between the CPT-based calibration and the calibration based on cyclic laboratory tests performed by Chiaradonna et al. (2022) is also discussed.

2 EXPERIMENTAL PROGRAM

2.1 Overview of centrifuge test

A 14 m-high submerged embankment with a 10-degree slope constructed with a uniform profile of sand was tested in a rigid container at 40g using the 9-m radius centrifuge at the Center for Geotechnical Modeling located at the University of California, Davis (Figure 1). The soil was a clean poorly graded sand, hereafter called 100A sand (Sturm 2019). The physical properties of the 100A sand are $e_{min} = 0.579$, $e_{max} = 0.881$, $D_{50} = 0.18$mm, $C_u = 1.68$, and $G_s = 2.62$. The embankment was dry-pluviated to a target $D_R = 63\%$, overlying a dense sand layer ($D_R > 90\%$) of the same soil. The model was saturated with methylcellulose pore fluid that had a viscosity that was 40x that of water (40 CSt).

Instrumentation within the model included pore pressure transducers and accelerometers, which enabled monitoring the coupled excess porewater pressures and acceleration responses. Piezoceramic bender element pairs were placed at two depths in the model to measure the shear wave velocity. Measurements were performed at 1 g and at 40 g, before and after shaking, for a total of 6 measurements. The processing of bender element time histories is reported by Carey et al. (2021). Horizontal displacement time-histories were measured using highspeed videos of the deforming embankment's cross-section recorded through the transparent side walls of the model container and GEOPIV image analysis software (Carey et al. 2022a).

The ground motion sequence included four shaking motions, all of which included a linear ramp to the maximum acceleration, a hold at the maximum acceleration for a certain number of cycles, and a non-linear decay. All motions had a prototype frequency of 1 Hz but varied in their number of cycles and amplitude of the hold cycles. Further details about the motion are given by Carey et al. (2022a, b). Herein the system response to the motion shown in
Figure 1. (a) Cross-section of the centrifuge model with accelerometers and porewater pressure sensors (length in prototype scale); (b) FLAC numerical grid used in the simulations overlaid on a photo of the centrifuge model test cross-section; and (c) recorded input motion from the centrifuge experiment used in this study.

Figure 1c with a maximum acceleration of 0.14g is analyzed. For brevity, only the shallowest sensors of the mid-slope array were analyzed (Figure 1a,b).

2.2 *Experiment characterization using a CPT*

A 10 mm-diameter cone penetrometer was pushed before and after the completion of the ground motion sequence. Cones were pushed into the soil 457 mm at the model scale at a penetration rate of 1 cm/s using a hydraulic actuator (Carey et al. 2022a). Figure 2a presents the CPT profile prior to shaking, measured in the upper bench of the slope.
Figure 2. (a) CPT sounding measured prior to the start of the shaking sequence; and (b) comparison of G_{max} values based on bender elements in the model test with predicted G_{max} profiles from literature.

Shown in Figure 2a is the pre-shake CPT penetrated to depths that exceeded an overburden stress of 1 atm. Hence, the depth of 10.45 m corresponds to an overburden effective stress of 1 atm and the cone tip resistance, referred to as q_{c1}, was 12.8 MPa. The q_{c1} measurement was sufficiently deep to avoid shallow penetration effects in the model (Kim et al. 2016; Sawyer 2020) and was used to calculate the normalized corrected cone tip resistance, q_{c1N}, as defined by Boulanger & Idriss (2014), which was rounded to 126.0 for the considered case. Since the considered soil has a fines content equal to zero, the 'equivalent clean sand' normalized and corrected cone tip resistance, q_{c1Ncs}, is also 126.0.

3 ESTIMATION OF MODULUS AND CRR

3.1 *Estimation of small-strain shear modulus*

The shear wave velocity measurements made prior to and following the shaking event were used to calculate the small strain shear modulus, with the values shown in Figure 2b. The small-strain shear modulus at the depth of the atmospheric pressure, $G_{max,1}$, was calculated according to $G_{max,1} = \rho V_S^2$, where ρ is the soil saturated density of 1,958 kg/m³ at the $D_R = 63\%$.

Several literature relationships expressing the normalized shear wave velocity, V_{S1}, as a function of the cone tip resistance measured in sands were selected and applied using q_{c1N} and are given in Table 1. The laws are expressed by an exponential function:

$$V_{S1} = m\, q_{c1N}^{n} \tag{1}$$

where m and n are the coefficients listed in Table 1. The vertical profile of G_{max} as a function of the mean effective stress, p', is expressed as:

$$G_{max} = G_o P_a \left(\frac{p'}{P_a}\right)^{0.5} \tag{2}$$

where P_a is the atmospheric pressure (101.3 kPa) and G_o is the shear modulus coefficient calculated by imposing $G_{max} = G_{max,1}$ in Eq. (2) for an effective vertical stress, σ'_v, equal to the atmospheric pressure (Table 1). The mean effective stress, p' is related to the depth, z, as follows:

$$p' = \left(\frac{1+K_0}{2}\right)\sigma'_v = \left(\frac{1+K_0}{2}\right)\gamma' z \tag{3}$$

where K_0 is the coefficient of earth pressure at rest, assumed equal to 0.5, and γ' is the unit weight of the submerged soil. Eq. (2) can be expressed as a function of the depth. As evident in Figure 2b, the bender element-based G_{max} values were generally consistent with the predicted G_{max} profiles.

Table 1. Considered $V_{S1} - q_{c1N}$ relationships.

Relationship	m	n	V_{S1}	G_o
	m/s		m/s	
Baldi et al. 1989	110	0.13	206	964
Robertson et al. 1992	60.3	0.23	183	762
Hezagy & Mayne 1995	72.8	0.192	184	769
Andrus et al. 2004	62.6	0.231	191	830

3.2 *Estimation of the cyclic resistance ratio*

The estimation of the CRR for the 100A sand was obtained through the normalized cone tip resistance q_{c1Ncs} and the CPT-based triggering liquefaction relationship developed by Boulanger & Idriss (2014), as shown in Figure 3. For the q_{c1Ncs} of 126.0, the CRR was equal to 0.186.
Figure 3. Estimation of CRR from the CPT-based liquefaction triggering curve by Boulanger & Idriss (2014).

4 PM4Sand CALIBRATION

The PM4Sand model calibration based on the experimental CPT data is referred to as "CPT calibration". The calibration focused on defining the three primary input parameters, D_R, G_o, and h_{po}. The secondary parameters were left to their default values (Boulanger & Ziotopoulou 2017). Specifically, D_R was set to 63%, controlled by the centrifuge test design, and G_o was set to 863, the average of the upper (964) and lower (762) bounds of the G_o relationships in Table 1. The h_{po} parameter of 0.21 was iteratively calibrated via single element undrained cyclic stress-controlled direct simple shear (DSS) simulations until a satisfactory match between the Cyclic Stress Ratio (CSR) and CRR of 0.186 was reached for a triggering criterion of 3% shear strain in 15 cycles.

Figure 4 Illustrates CSR versus number of cycles to liquefaction for a 3% single amplitude shear strain triggering criterion for the "CPT calibration". This curve is generated from a series of single element DSS simulations using the calibrated PM4Sand primary variables, subjected to a range of CSRs. Experimental points as measured through cyclic DSS tests (green points) for two different overburden effective vertical stresses are also plotted for reference. The data for a σ'_{vo} = 50 kPa were used as the dataset for the laboratory-based calibration ("Lab calibration") in Chiaradonna et al. (2022).

The cyclic strength at 15 cycles is 0.186 for the "CPT calibration" and 0.133 for "Lab calibration", implying that the soil resistance to liquefaction as estimated by the in-situ CPT is 1.4 times higher than that measured by direct simple shear tests.
Figure 4. Cyclic resistance curves used in the simulations (CPT calibration) vs calibration based on direct simple shear data (Lab calibration) and experimental data.

5 NUMERICAL SIMULATION RESULTS

The centrifuge test was numerically simulated with the finite difference program FLAC (Itasca, 2016). The geometry of the analysis domain was based on the centrifuge prototype dimensions (Figure 1a). The discretized domain is shown in Figure 1b, with further details available in Chiaradonna et al. (2022).

The predicted and observed time histories of the horizontal displacement at the surface of the mid-slope (Figure 1b) are shown in Figure 5. The experimental trend exhibits a progressive accumulation of displacements, with a final permanent value of 7 cm.
Figure 5. Comparison of horizontal displacement measured at the surface of the embankment slope and numerical simulations from the CPT and Lab calibrations.

The magnitude of the displacement oscillations per cycle is relatively minor, resulting in a clear ratcheting of downslope displacement. The CPT calibration predicted displacements that were practically identical to the experiment with a permanent horizontal displacement was 5 cm. The oscillations in displacements for the CPT calibration are larger compared to the

experiment and predict a dynamic upslope movement. For context, the lab calibration-based simulation predicted significantly higher displacements, with the accumulation primarily occurring during the last two cycles of shaking at full acceleration amplitude and during the decay.

The agreement between the experimentally measured and CPT Calibration simulation of the mid-slope displacement also extended to the global deformation patterns across the centrifuge experiment. This is evident in Figure 6 where contours of horizontal displacement of the experiment are presented. The magnitude and spatial distribution of the displacement field is nearly identical.

While the agreement of the displacement fields is central for performance-based design, examining the pore pressure and acceleration time histories as well as the response spectra at the mid-slope during shaking, is also insightful. Figure 7 presents the pore pressure and acceleration time histories of the upper two locations on the mid-slope. The pore pressure generation time histories for P7 and P8 show different patterns of accumulation, as well as different residual values at the end of shaking. Excess pore pressure ratio, r_u, peaks in P7 are better captured by the "Lab calibration" compared to the "CPT calibration". The experiment reached an r_u of 1 after several cycles, while the simulation did not. However, at the end of shaking both the experimental and the CPT calibration simulation have a r_u value less than about 0.7, implying that resedimentation and re-establishment of the effective stress profile has been partially taking place.
Figure 6. Contour fields of displacement from the shake measured in the centrifuge experiment, and the numerically predicted contours using the CPT and Lab PM4Sand calibrations.

The acceleration time histories between the measured experimental response and the CPT calibration simulation are nearly identical for the lower AH9 accelerometer, time history, and in the first part of the AH10 time history. However, later in the AH10 time history the predicted accelerations in the simulation are lower. These trends are also evident in the clear agreement in the spectral acceleration plots for AH9, with show consistency across all periods. For AH10 the higher spectral acceleration at the predominant period of 1 Hz is evident. For periods less than 0.7 s, spectral accelerations are better captured better by the "Lab calibration" due to the dilation spikes in the time histories of acceleration; however, these high frequencies have a minor contribution to the overall movement of the embankment.

The agreement in deformation, acceleration, acceleration response spectra, and excess porewater pressure trends stand in clear contrast to the trends for the "Lab Calibration" simulation. As evident in Figures 6 and 7 the displacements that accumulate near the end and after shaking are significantly larger at the mid-slope surface and throughout much of the model. The primary reason for these differences is attributed both (1) to the lower cyclic resistance ratio (CRR) of the laboratory data which contributes to an early onset of liquefaction and its associated deformations, and (2) the continuing deformation after the end of shaking due a high excess pore pressure.

6 DISCUSSION

The numerical simulation presented in this paper demonstrates the utility and value of CPT measurements in centrifuge experiments. Simulations based on a CPT-based calibration of the PM4Sand constitutive model provided a very satisfactory match to the observed system level responses. Past parametric investigations by Chiaradonna et al. (2022) had shown that a CRR higher than the one obtained from DSS tests would likely justify the observed responses.

However, that study was inconclusive as to whether the higher in-situ CRR was an artifact of arching or sloping ground conditions or that in general the DSS data in this case had misrepresented the in-situ centrifuge conditions. The present study demonstrated that the CPT measurements provided a significantly improved characterization of the cyclic resistance of the centrifuge model and thus a more successful validation of the response, particularly with respect to displacements.

Future work will investigate the (i) influence of other contributing factors such as 3D effects and arching, (ii) effect of sloping ground conditions on cyclic strength, and (iii) reasons between the dis-crepancy of the DSS-based CRR and the CPT-based CRR.

7 CONCLUDING REMARKS

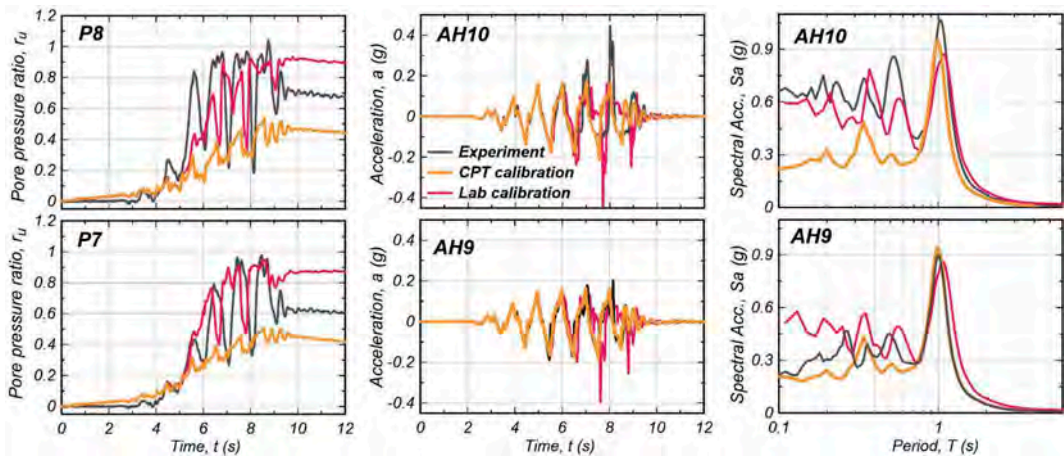
This paper addressed the calibration of a critical state compatible, stress ratio-based, bounding surface plasticity constitutive model aiming at


Figure 7. Comparison of the measured experimental and numerically simulated responses for 'CPT Calibration' vs. 'Lab Calibration'. Results are for the select sensors (Figure 1) in terms of porewater pressure ratio, acceleration time histories, and response spectra (5% damping).

numerically simulating the dynamic behavior of a poorly-graded sand slope. While deficiencies in the horizontal displacement prediction were highlighted by a calibration obtained from cyclic laboratory tests (Chiaradonna et al. 2022), the use of CPT data as a calibration basis produced a better prediction of both displacements and accelerations. The reliability of the simulation can be ascribed mainly to two principal reasons: (i) the cyclic strength of the soils is directly estimated by combining the measured cone tip resistance of the soil tested in centrifuge with the CPT-based triggering liquefaction chart, and (ii) the small-strain shear modulus is well reproduced by the applied literature relationships for clean sands. This study strengthens the importance of in-flight CPT measurements in centrifuge tests and represents a step forward in the calibration of advanced constitutive models using measurements from in-situ CPT tests. Further applications to available centrifuge tests with different relative densities and gradation of soils will be performed to generalize the obtained results.

Probabilistic delineation of soil layers using Soil Behavior Type Index

S. Collico & M. Arroyo
Universidad Politécnica de Cataluña, Barcelona, Cataluña, Spain

M. DeVincenzi, A. Rodriguez & A. Deu
Igeotest s.l. Figueres, Cataluña, Spain

ABSTRACT: CPTu-based soil profiling has become a key component in the geotechnical design process. However, this is an interpretative process, affected by the inherent variability of soil properties, measurement noise and subjective heuristics. These are difficult to communicate to other interpreters or, even for the same interpreter, to transfer across profiles. A semi-automated tool for CPTu data interpretation is presented as an aid in this interpretation process. A probabilistic-based algorithm is employed to elicit the implicit heuristics in CPTu-based soil profiling and facilitate transference. Univariate normal distributions fit Soil Behavior Type Index data. Soil class boundaries, taken from a conventionally accepted chart, are sequentially activated with user-specified refinement. Thin layers under cone resolution are merged using well-established criteria. An application to CPTu records on finely interlayered deltaic deposits is illustrated, in which output delineations resulting from different analyst choices are compared among themselves and with one based on core description.

1 INTRODUCTION

Differentiation of ground units by means of stratigraphic profiling is a key step of site characterization for geotechnical design. Among all the in-situ tests, Cone Penetration Tests CPTu are widely employed for layer's identification based on the soil response to the probe. An aid for CPTu postprocessing results is given by Soil Behavior Type (SBT) charts (Douglas & Olsen, 1981; Robertson, 1990, 2009) that allow every reading to be classified. Analysts can then establish boundary layers by inspecting the profile of soil class assignment derived from these charts.

This is an interpretation task, and as such is strongly affected by analyst knowledge, experience and heuristics. The interpretation process followed is sometimes difficult to explain and might appear arbitrary and be a subject of disputes if other parties are involved. Even if that is not the case, the same analyst may find it difficult to ensure coherence of interpretation across different soundings of a site.

As an example, when a thin silt layer (e.g., 20-30 cm) is embedded in two thick sand units, the analyst, based on his experience, may or may not consider relevant the presence of such layer. An additional and more sensitive issue arises when dealing with multiple CPTu sounding records and the so called cross-site variability (Zhang et al., 2004). Layer's identification, by accounting for information of different locations, is an even more complex process since both

vertical and horizontal inherent variability and measurements errors, that might differ during each test, intervene. Therefore, such lack of transparency and not methodical process of layers' identification, should be addressed.

Different probabilistic methodologies have addressed the problem of stratigraphic profiling based on CPTu. Some works (Jung et al., 2008; Wang et al., 2013) put the focus on the basic classification scheme applied. They point that generally established soil class boundaries are inherently inaccurate to derive site-specific soil profiling and address this issue by updating the classification scheme according to site-specific observations.

Another line of thinking is the one that enable the integration geological unit's information to CPTu data (Depina et al., 2016; Krogstad et al., 2018). These works employ SBT charts only as a reference template, and CPTu soil class assignment refers to geological units identified from retrieved core samples and/or previous studies.

This work follows a different line of thinking and it is based on a more modest approach, manly oriented for practical use. SBT charts− here Robertson, (2009) −←are considered as conventionally accepted template for soil classification with given (not uncertain) class boundaries. The probabilistic approach is applied only to assess inherent variability and measurements error of CPTu readings. The probabilistic parameters introduced are then oriented to quantify the degree of internal coherence of each

identified layer, and, at the same time, eliciting analyst heuristics and interpretation criteria.

The tool fits a univariate normal distribution to interpret data originated from one or various CPTu probes, which are gradually plotted on Robertson (2009) chart, identifying soil units in a probabilistic manner. Class boundaries are sequentially activated with user-specified refinement. Thin layers (layers below a specified minimum thickness resolution) are assessed through a practical merging scheme. This work applies the methodology previously proposed by Collico et al., (2020) to Robertson, (2009) SBT chart. In Collico et al., (2020), a bivariate normal distribution approach was applied to fit CPTu observations on Robertson, (1990) SBT chart. The flexibility of such work is here exploited to fit Soil Behavior Type Index observations according to Robertson, (2009) class boundaries.

As illustrated section 2, the proposed methodology consists of three main parts: a probabilistic model to CPTu data; a staged classification procedure and an option for automated thin layer consolidation.

2 METHODLOGY

2.1 *Soil behavior type index I_c*

Among all SBT charts, one of the most popular is the Robertson (2009) chart (Figure 1). Based on the work of Douglas & Olsen, (1981) and Jefferies & Davies (1991), Robertson (2009) highlighted how Robertson (1990) class boundaries could approximate by a concentric circle whose radius can be defined by a unified parameters denoted as soil behavior class index I_c which combine both normalized CPTu parameters as:

$$I_C = \left[(3.47 - log(Q_{tn}))^2 + (log(F_R) + 1.22)^2 \right]^{0.5}$$
(1)

with:

$$Q_{tn} = \left[(qt - \sigma_{v0})/p_a \right] \left(p_a/\sigma'_{v0} \right) \right]^n$$
(2)

$$n = 0.381 I_C + 0.05 \left(\sigma'_{v0}/p_a \right) - 0.15$$
(3)

where $n \leq 1$ is a soil-type dependent exponent which normalizes for the effect of stress level on tip resistance.

Robertson (2009, 2016) highlighted that despite being a single-valued index, by including the stress exponent n, I_C based soil delineation might provide more useful information on soil behavior than one based on Robertson (1990) classes.
Figure 1. Soil Behavior Type chart based on Soil behavior Type Index I_c.

2.2 *Statistical model for CPTu data*

When plotting CPTu observations classified by SBT, inherent variability and measurements errors, generate some data scatter (Figure 2). In this study a univariate normal distribution is fitted to SBT data of a given stretch of CPTu:

$$f\left(I_{C_i} \right) = \frac{1}{\sigma_{I_C} \sqrt{2\pi}} \exp\left(-\frac{1}{2} \frac{\left(I_{C_i} - \mu_{I_C} \right)^2}{\sigma^2_{IC}} \right)$$
(4)

with μ_{I_C}, σ_{I_C} mean and standard deviation of I_C data sample. An example of 3D representation of fitted univariate normal distribution for a 5m I_C profile (Figure 2b) is reported in Figure2b. The area of color, under the density function, indicate the extent of an interval pre-established representative data interval. As explained below, the interplay between this interval and SBT class boundaries is exploited to obtain a systematic procedure for layer identification.
Figure 2. a) Synthetic I_C record. b) Corresponding univariate distribution and pre-established representative interval plotted on Robertson (2009) chart.

2.3 *Class assignment criteria*

Once the CPTu SBT values corresponding to a particular stretch are fitted to a univariate normal distribution, the fitted data will be assigned to the soil class in which the distribution mean is found. Two user-specified acceptance thresholds (i.e.,

model parameters) are used to divide the CPTu record into different stretches:

- Noise-threshold parameter, $P(\sigma_{I_C})$
- Class-mixture tolerance parameter, m

The meaning of these two parameters is rather intuitive. The P parameter (Figure 2b), expressed in term of standard deviations, establishes the width of the representative data sample interval ($P = \mu_{I_C} \pm \sigma_{I_C}$). It is introduced to account for the possibility of extreme values of I_C within the dataset (e.g., shelly inclusions in clays). As an example, by considering a value of $P = 2$, the representative interval would contain 95% of the underlying data and 5% will be considered as noise.

The class-mixture tolerance parameter m is introduced so that the user can modulate the relevance of the underlying classification system in the soil profiling exercise. The value of m is defined as the area proportion of specified representative interval that is allowed to cross soil class boundaries. In other word, the m value explicit how strictly adhered to are pre-established class boundaries when the CPTu is subdivided into layers. Parameter m expresses the degree of belief on the underlying classification adopted.

2.4 Classification levels

The original Robertson (2009) chart introduces six different soil classes. In some circumstances simpler classifications might appear more suitable to the analyst. This possibility has been enabled in this work introducing a staged classification procedure, in which SBT-based classifications of progressive refinement are introduced sequentially.

The coarser level uses a dual classification, distinguishing only between:

- Clay-like behavior (C-L)
- Sand-like behavior (S-L)

These two soil classes, representative of undrained and drained response for C-L and S-L respectively, are identified by the I_C boundary value 2.6 (Figure 3), (Robertson 2009). That boundary is here onwards designed as a primary boundary. A second, more refined, level of classification introduces a soil-mixture class to account for partially drained soil response to the cone probe, along with a sand-like and clay-like classes. The boundaries separating these three classes (Figure 3) are designed as secondary boundaries. Finally, the most refined classification level introduces all six soil classes of the original Robertson, (2009) proposal. The limits between them and here designated as tertiary boundaries.

The analyst might choose directly a particular classification level or might run sequentially through all levels.
Figure 3. Class boundary at first and second staged classification on Robertson (2009) chart.

2.5 Thin layer treatment

Any semi-automated analysis of CPTu records is liable to end identifying thin layers (e.g., thinner than 20 cm). It is well recognized that the cone diameter employed limits the ability of CPTu to resolve thin layers, as the measured cone tip resistance is affected by both development and sensing distances (Boulanger & Dejong, 2018). Due to those two limits, the measured soil resistance does not coincide with that of the material at the tip location, i.e., measured soil resistance in absence of both development and sensing distances. Therefore, the cone is only able to unambiguously identify layers above a minimum layer resolution of 150- 200 mm. A simplified practical approach to deal with this difficulty is to merge layers below the minimum thickness with adjacent ones of similar soil behavior type (Ganju et al. 2017).

This strategy is also adopted here, with details slightly dependent on the classification level selected. At the first and second refinement levels thin layers are merged based on the closeness on mean value of I_C. At the third level, when using the full (Robertson, 2009) classification chart, the situation is analogous to that of Ganju et al. (2017) and the same auxiliary criteria based on class groupings are applied.

2.6 Single CPTu analysis workflow

The main workflow steps are reported in Figure 4. The analyst has to feed in a CPTu record to analyze and select the level of classification, minimum layer resolution and the P and m values. The code can then start analyzing the CPTu input record by selecting a segment of CPTu data pairs long enough (e.g., 10 points) to fit an initial PDF (I_C). The PDF(I_c) is then updated by adding the next CPTu data point, moving downwards through the record. Such updating allows the I_C density to move on the SBT line until the representative interval (given by P) surpasses any class boundaries by a larger proportion than that allowed

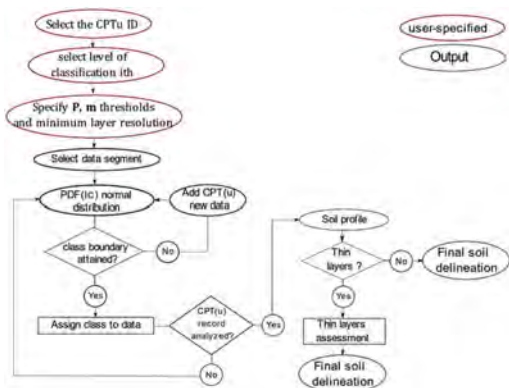
by *m*. At that time, data that fed the univariate density are assigned to the identified layer, whose soil class is assigned depending on location of the mean value of the univariate distribution. The procedure resumes by analyzing the next segment in the CPTu record until all the record is analyzed (Figure 4). An example of layer identification is depicted in Figure 5 for a synthetic I_c profile and $P = 1.5$ and $m = 0$ using a first level (binary) classification.


Figure 4. General workflow of single CPTu analysis.

2.7 *Multiple CPTu analysis*

The same methodology can be applied to multiple CPTu records. The aim is to identify common layers at different locations according to a pre-established depth correspondence criterion between the records. This may just be a hypothesis of layers parallel to the ground level, or following a linear trend throughout the site or any other criteria.

Once selected the depth criterion, the univariate density is now initialized by $n_{CPT(u)}$ length (initial data segment) data points, with $n_{CPT(u)}$ number of CPTu records analyzed (Figure 6a). The univariate density is then updated by $n_{CPT(u)}$ data (one for each sounding record analyzed) until the boundary condition is attained according to *P* and *m* threshold (Figure 6b). After stoppage, to ensure that identified layers belong to the same soil type, data assigned to the layer for each CPTu sounding is analyzed separately, and n_{CPTu} univariate density distributions are computed. A common soil layer is identified only if the n_{CPTu} mean values are within the same class boundaries, (Figure 6b). The procedure then resumes until all the CPTu records are analyzed.

Qualitative considerations on layer lateral continuity may be then inferred depending on thickness of identified common layers and relative distance of CPTu locations. As an example, if a thick common soil layers is identified and the relative distance of C-

PTu locations is less than typical value of horizontal scale of fluctuation (e.g., $40 - 80m$, Phoon & Kulhawy 1999) lateral continuity could be assumed.

3 ILLUSTRATIVE EXAMPLE

3.1 Case study

The proposed methodology is tested on CPTu records obtained at Barcelona harbor (Spain). Two adjacent CPTu sounding profiles (CPTu74, CPTu73), each up to 21m depth from seabed surface (Figure 7) are analyzed. An independently established soil layer profile was available for the site, which was derived from cores retrieved at the same location where CPTu74 was performed. Laboratory samples were retrieved each 5 m depth and core description followed UNE-EN ISO 14688-1 from which a detailed soil profile was derived. The boundaries identified (Figure 7a) carried significant uncertainty due to the complex structure and strong heterogeneity of the site. The layering of Figure 7a was directly checked against cone results. For each layer, CPTu74 data were assigned to one of the six classes of Robertson (2009). Percentages of I_C data are reported in Table 1. Up to 15.5 it is evident how core-based layers are mainly composed by soil-mixture class (class 3 and 4 of Robertson, 2009). However, a significant heterogeneity is evident within each layer.

3.2 Case study-single CPTu record

The procedure previously described was applied to the CPTu74 record. The P and m model parameters were varied to try to match the core-based delineation. A third staged delineation was initially selected due to the detailed core-based description. By considering $P = 1.8$ (e.g., about 92% representative interval) and 5% threshold mixture, all core-based boundaries (except one at 17.4 m depth) were identified (Figure 7). However, several additional layers were detected as expected from the results in (Table 1). To illustrate the effect of varying the fitting control parameters, the same record is reanalyzed using the $m = 0.2$ value and $P = 1$ (i.e., representative interval of about 68%) (Figure 7c). The parameters of the reanalysis result in a simpler profile, but it is noticeable that the layers disappearing are not simply the thinner ones (e.g., at 6 m depth) but others (e.g., at 19 m depth) that were less statistically contrasted with their neighbors.

An alternative route to profile simplification is to use a coarser classification level. This is explored in Figure 8a, b using the same CPTu74 record and maintaining the same control parameters as in (Figure 7b). Most boundaries established by core inspection are recovered by the binary classifier, whereas that is not the case for the second level profile. It is interesting to observe how the coarser binary classification results in very fast layer alternance in the first 14 m, Figure 8a whereas the introduction of the "mixtures" class results in a rather homogenous profile (Figure 8b).

This result is also clear when another CPTu is analyzed using the same control parameters (Figure 9). Comparing the different profiles obtained, the analyst can decide which set of choices (classification level, P and m values) results in the level of detail that is more meaningful for engineering design process. Once the analyst heuristics are thus elicited, they can be systematically applied at all site locations.

3.3 Multiple CPTu records

As an example of simultaneous analysis, the two CPTu records discussed above were considered. Based on previous study on this area a depth correspondence criterion parallel to the seabed surface was selected. By assuming the same P and m value, 2D cross sections for three different level of classifications are reported in Figure 10. For identified common layers, lateral continuity was assumed due to the relatively close distance between CPTu (e.g., about 50 m). At first level 15% of data was classified as S-L, 59% as C-L, and 26% corresponded to "not common" layers. Increasing the classification refinement level at every profile the continuity between different site investigation points is reduced. Using second and third level classifications, the percent of data in "not common" layers increase to 40% and to 58%, respectively.

4 CONCLUSION

This work describes a novel probabilistic procedure for soil delineation based on CPTu sounding records aiming to facilitate communication in the process of layer delineation. Subjective heuristics, applied within CPTu records interpretation, are elicited and quantified facilitating consensus in the soil delineation process. The proposed methodology is application to multiple CPTu records to help discern continuous layering. Although the method has been illustrated using SBT it is easily adaptable to any other chart-based classification procedure (Collico et al. 2020).

ABSTRACT: Accurate estimates of soil unit weight are fundamental for correctly post process CPTu data and making use of Soil Behavior Type-based classification systems. Soil-specific and global regressions have been proposed for this purpose. However, soil-specific correlation might pose a problem of pertinence when applied at new sites. On the other hand, global correlations are easy to apply, but generally carry large systematic uncertainties. In this context, this work proposes a data clustering technique applied to geotechnical database aiming to identify hidden linear trends among dimensionless soil unit weight and normalized CPTu parameter according to some unobservable soil classes. Global correlations are then revisited according to such data subdivision aiming to improve accuracy of soil unit weight prediction while reducing transformation uncertainty. A new probabilistic criterion for soil unit weight prediction is also obtained. The potential benefits of the proposed procedure are illustrated with data from a Llobregat delta site (Spain).

1 INTRODUCTION

CPTu interpretation is almost always based on stress normalized cone readings. For instance, soil classification charts (Robertson, 1990; Been & Jefferies, 2006; Schneider et al., 2008) use stress normalized tip resistance, friction and excess pore pressure parameters. Total soil unit weight γ_t is thus a necessary input in any CPTu interpretation exercise.

Soil unit weight is measured on undisturbed samples from boreholes. Such samples are not always available, particularly for granular soils and/or in early stages of site investigation. As a simpler alternative, total soil unit weight can be estimated indirectly from piezocone and seismic piezocone readings. In the last decades several proposals have been presented to achieve this purpose (Mayne, 2009; Mayne et al., 2010; Robertson & Cabal, 2010; Mayne, 2014; Lengkeek, 2018).

These proposals are all based on empirical regression using databases in which cone readings are paired with soil unit weight measurements. A trade-off typically arises between coverage (the scope of the original soil database) and precision (the predictive power of the regression). Global regressions, usually described as applicable to soils with a "normal" or common mineralogy, are widely applicable but less precise than regressions developed only for a certain class of soil (i.e., soil specific). On the other hand, soil specific regressions are more difficult to

apply at a particular site because they have less coverage and require a previous soil classification step, which may introduce additional uncertainty. One possible way out of this problem is to develop soil-specific regressions for unit weight using a global database that is segmented into soil classes for regression purposes. How to define those classes?

In this work we employ a Gaussian Mixture Model (a.k.a., GMM) technique to identify hidden classes in a global database described by Mayne, (2014) with the purpose of establish more accurate regressions. GMM have been previously applied to CPTu data analyses (Depina et al., 2016; Krogstad et al., 2018) to identify soil classes for stratigraphic delineation. In those studies, a Bayesian perspective was introduced, as having the possibility of updating the stratigraphic groups as more information was gathered was deemed essential. In the present work a fixed database in considered and therefore the Bayesian updating aspect has been omitted.

A key step of applying such data clustering technique is to express the reference database, including soil unit weight and CPTu data, as a multivariate normal distribution before GMM is applied. To this end we use a methodology laid out by Ching et al., (2014), to rationally account for predictor co-dependence and to establish or revise correlations between different variables.

In what follow, key steps to construct valid multivariate distribution are reported followed by a brief

description of finite Gaussian Mixture Models. In the results section, an example of data subdivision and assignment to identified hidden classes is reported using dimensionless soil unit weight and normalized CPTu parameters. Existing correlations are re-examined using the new soil classes and a new one is proposed.

2 METHODOLOGY

2.1 *Setting up a multivariate distribution*

Ching et al., (2014) and Phoon & Ching, (2018) proposed a systematic cumulative transform procedure to build standard multivariate normal distributions for multivariate databases. Such approach is adopted in this study to treat the Mayne, (2014) database.

Essentially the steps involved are:

1. For a given set of selected observations $\underline{\Omega}$ (e.g., $\underline{\Omega} = [\Omega_1, \Omega_2]$ with $\Omega_1 = [nx1]$ and n number of observations) define marginal distributions Ω_i for each of the component variates in the database;
2. Transform the different marginals into standardized normal distributions $\mathbf{X}_i$
3. Assume that transformed observations $\underline{\mathbf{X}} = [\mathbf{X}_1, \mathbf{X}_2]$ follow a multivariate normal distribution $f(\underline{\mathbf{X}})$;
4. Obtain a random sample from $f(\underline{\mathbf{X}})$, and transform it back to the non-normalized space, obtaining the simulated set $\underline{\Omega}_{sim}$
5. Check by inspection the overlap between $\underline{\Omega}_{sim}$ and $\underline{\Omega}$.

A key step in the procedure is the definition of marginal distributions for the different variates in the database (in this case dimensionless soil unit weight and normalized CPTu parameters). Lognormal distributions have been frequently used in geotechnical applications (Phoon & Kulhawy, 1999). The lognormal is included in the Johnson system of distributions (Ching et al., 2014), which has three main families: the lognormal system S_L, the bounded system S_B and unbounded system S_U. Choosing between the whole system of Johnson distributions offers versatility while maintaining the interesting property of having analytical expressions to transform into standard normal variables and back (Ching et al. 2014).

The selection of an appropriate Johnson distribution for a particular dataset is based on the first four moments of a sampling distribution (George & Ramachandran, 2011). Examples of Johnson distributions fitted to different variates of the Mayne, (2014) global database are given in (Figure 1).

2.2 *Multivariate as a gaussian mixture*

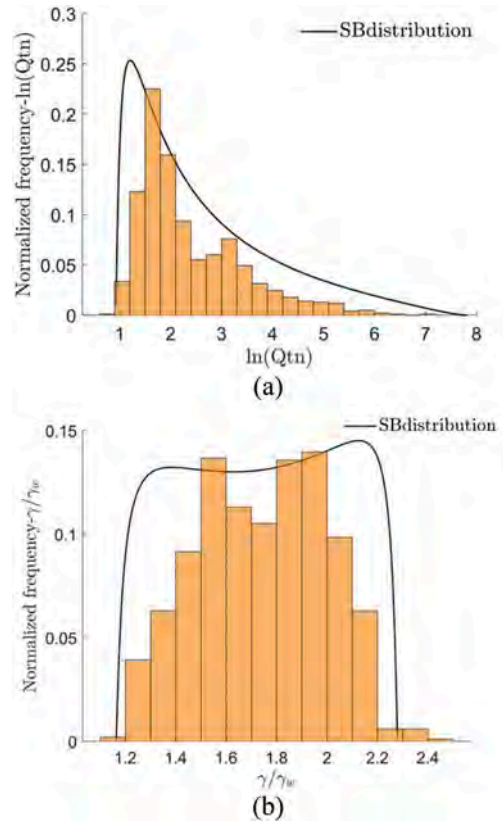
The multivariate distribution that represents the database might be conceived as a combination of several


Figure 1. Fitting Johnson probability density function to a) $\ln(Q_{tn})$; b) γ_t/γ_w data of Mayne, (2014) database.

underlying components (the hidden classes that we are trying to identify). This is formalized using a Gaussian Mixture Model, (Depina et al., 2016; McLachlan & Peel, 2000), that expresses the transformed -standardized- multivariate distribution as a linear combination of K multivariate gaussians:

$$f(\underline{x_i}|\zeta) = \sum_{j=1}^{K} \pi_j \phi_j(\underline{x_i}|\Theta_j) \qquad (1)$$

Each ϕ_j represents a component of the mixture and is a multivariate normal probability density function with the same structure as $f(\underline{\mathbf{X}})$. Therefore, each component has its own statistical parameters, denoted by Θ_j. In our case they include a vector of means and a covariance matrix (i.e., $\mu_j, \underline{\sum}_j$). The collection of all the Θ_j is denoted by Θ. Each component has a weight π_j (proportion of data assigned to ϕ_j); weights are chosen so that they add up to one and are collected in a vector $\underline{\Pi} = (\pi_1,.., \pi_K)$. $\zeta =$ collection of all the unknown parameters of the mixture model (i.e., $[\Theta; \underline{\Pi}]$).

Depending on the values that ζ finally takes each observation $\underline{x_i}$ would have a certain probability p_{ij} of belonging to a particular component ϕ_j.

Gaussian Mixture analysis consists of estimating the most probable ζ, $\widehat{\zeta}$. This is generally done through the Expectation-Maximization (EM) algorithm (Samé et al., 2011; Huang et al., 2017; Liu et al., 2019) which alternates an expectation step in which observations are assigned exclusively to a particular gaussian component and a maximization step, in which the log-likelihood function for the incomplete dataset is maximized.

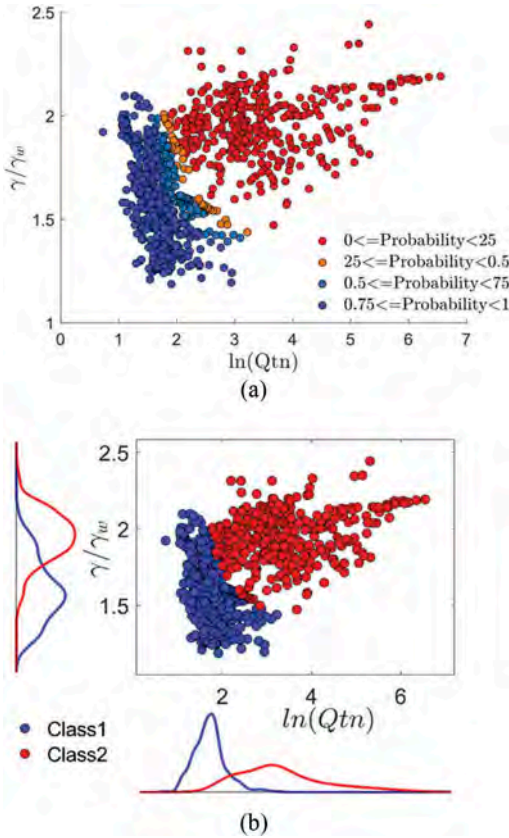
The concept of GMM could be also formulated in a Bayesian framework, by integrating prior knowledge p (ζ) and observations $\underline{\Omega}$ to obtain posterior estimates of ζ. Due to lack of previous studies, this work only applies GMM. For more detailed information about the Bayesian formulation, analysis about optimal number of hidden classes to consider and most plausible normalized CPTu parameters to be considered, the reader is referred to Collico, (2021).


Figure 2. A) Assigned probability of belonging to component 1 of the GMM b) Scatter and marginal distributions of observations for the two hidden classes identified.

3 RESULTS

3.1 *Cluster definition and analysis*

There are six variates in the Mayne, (2014) database. To illustrate the methodology proposed in a simple setting, we consider only two of them, namely dimensionless unit weight γ_t/γ_w and normalized tip resistance, $ln(Q_{tn})$. After fitting a bivariate distribution to all the data pairs $\gamma_t/\gamma_w - ln(Q_{tn})$ we run the expectation-maximization algorithm to identify a GMM with two components.

An example illustrating the probabilities of data belonging to a particular component of the Gaussian mixture is given in Figure 2a. Clustering is based on such probabilities. A simple choice is to assign data to the component in which they have the largest probability of belonging. For two components this is equivalent to enforcing a probability threshold of 0.5 as clustering criteria. The result of doing so in this case is reported in Figure 2b, while statistics for the two clusters in the $\underline{\Omega}$ space are reported in Table 1.

To understand the meaning of this newly identified soil classes, the clustered data is plotted in Soil Behavior Type charts (Robertson, (2016); Schneider et al. (2008) (Figure 3). Results show that the first hidden class identified is dominated by Clay-Like-Contractive soils ($C - C$, Figure 3a), while the second hidden correlation identified is represented by a wider range of conventional soil types.

Table 1. Covariance matrix and mean vector of γ_t/γ_w-$ln(Q_{tn})$ hidden classes identified.

Class	Mean			Covariance	
1	μ_{γ_t/γ_w}	$\mu_{ln(Q_{tn})}$		γ_t/γ_w	$ln(Q_{tn})$
	1.59	1.71	γ_t/γ_w	0.04	-0.036
			$ln(Q_{tn})$	-0.036	0.125
2	μ_{γ_t/γ_w}	$\mu_{ln(Q_{tn})}$		γ_t/γ_w	$ln(Q_{tn})$
	1.95	3.32	γ_t/γ_w	0.025	0.04
			$ln(Q_{tn})$	0.04	0.94

3.2 *Generating cluster-based correlations*

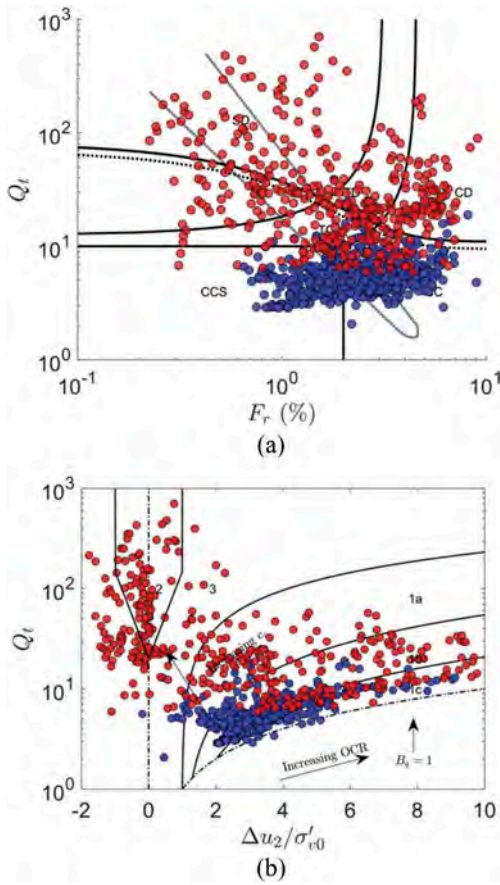
The clustered data can be used to generate new correlations. Such correlations need not be based on the same restricted subset of the global database that was used to generate the clustering. For instance, we use here correlations that follow a template proposed by Mayne, et al., (2010) (i.e., γ_t=a+ b·log(z) + c·log(f$_s$)+ d·log(q$_t$)). Results in terms of coefficient of determination, R^2 and regression standard error, σ_{ε_T} are reported in Table 2, while regression coefficients are reported in Table 3. The standard error, after GMM subdivision, is at least 13% smaller than the one of global database. The coefficient of determination R^2 is also smaller for the clusters than for the global database. These effects are particularly strong for Hidden class 2.


Figure 3. Scatter plot of data belonging to each hidden cluster identified on SBT charts: a) Robertson, (2016); b) Schneider et al., (2008).

Table 2. Coefficient of determination and regression standard error before and after database subdivision.

	R^2	σ_{ε_T}
Global	0.66	1.44
Hidden class1	0.6	1.25
Hidden class 2	0.39	1.22

However, those comparisons are somewhat misleading, as the statistics are computed using different observations. The improvement of predictive strength after clustering is more clearly identified through a cross-validation procedure. To this end we run a simulation exercise in which we randomly selected 85% of the data in each cluster and used them to fit cluster specific correlations, as well as a global one in which no cluster distinction was made. Then we applied those correlations, to the remaining 15% of the dataset -the validation data. The sum of squared residuals $||SS_{res}||$ was

computed at each trial, for each one of the correlations (global, cluster 1, cluster 2). 500 such simulations were performed. Results, reported in Figure 4 for both Hidden classes, highlight the benefit of the GMM as the distribution of error norms is clearly shifted towards lower values.

Table 3. Coefficient of the regression for linear form of Mayne (2010) after BMA subdivision.

	a	b	c	d
Global	8.78	-0.67	2.24	1.457

Class2	15.34	0.052	0.02	1.94
Figure 4. Cross validation of revisited regression and comparison with global literature correlation for a) Hidden class1. B) Hidden class 2.

3.3 Application to new sites: Decision boundary

To assign CPTu observations at a new site to a cluster, we use the (non- normalized) Robertson, (1990) SBT chart. Plotting the clustered data in that chart we apply discriminant analysis (Ghojogh & Crowley, 2019) to establish a user-friendly separation criteria for new CPTu observations. The decision boundary (Figure 5) obtained takes the shape of a quadratic in Robertson (1990) chart. This boundary line between the two clusters has the following expression:

$$2.37 + \left[0.2\ln(R_f) - 1.58\ln(q_t)\right]^2 \pm \sigma_{boundary} = 0 \quad (2)$$

with $\sigma_{boundary}$ systematic uncertainty associated with decision boundary ($\sigma_{boundary} = 0.13$).
Figure 5. Mean estimate and 95% Confidence Interval of decision boundary.

3.4 Illustrative example

The cluster-based correlations just developed are now applied to results of a particular CPTu campaign performed at a Llobregat site (SW Barcelona-Spain). Several infrastructures have been developed around this site during the last decades, requiring extensive onshore-nearshore geotechnical investigation. Along with in-situ investigation, laboratory tests were performed on selected sub-samples from undisturbed Shelby tubes recovered every 5m in each borehole. For this study we consider data from 20 CPTu and 44 total soil unit weight measurements. More detail on this campaign is given by Deu et al., (2021).

All the CPTu data were plotted on Robertson graph, showing that the site is dominated by silty soils. Then each CPTu observation was assigned to class 1 or 2 according to the mean value of the decision boundary (Figure 6a). Most of the data were assigned to Hidden class 2.

The cluster-based correlation was applied to the 20 CPTu data and the results are plotted in (Figure 6b), indicating the mean and spread of the predicted values.

The same is done using the global correlation, obtained using the whole database, without clustering. Summary results are also presented in Table 4. They include the

Table 4. Statistics of mean value of total unit weight prediction.

	μ_{γ_t}	$\sigma_{\mu_{\gamma_t}}$
Global correlation	17.47	0.48
Cluster-based correlation	18.1	0.42
Laboratory	19.45	0.66

(a)

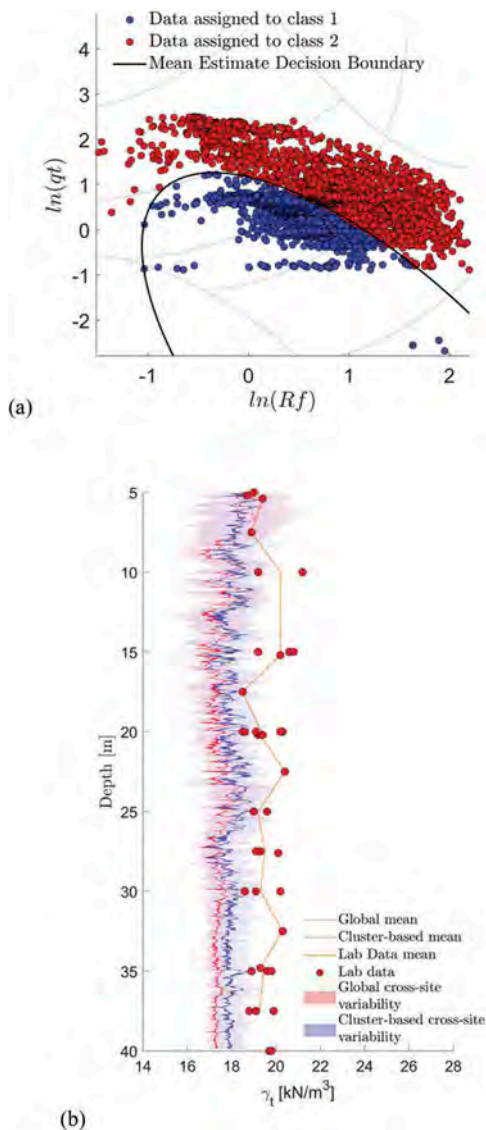
(b)


Figure 6. A) CPTu data assigned to class 1 and class 2 according to the proposed criterion. b) Profile of total unit weight prediction for cluster-based and global correlations and laboratory observations.

overall predicted mean estimate as well as the standard deviation of the means evaluated at different depths.

The cluster-based correlation clearly exhibits an improvement of total unit weight prediction at the site (Figure 5b), when compared global correlation. It has a lower dispersion and its mean is closer to that of the laboratory measurements. It is clear, however, that even the cluster-based correlation under-estimates the laboratory mean. There are several possible explanations for this discrepancy. One is that samples of silty soils generally tend to be densified upon sampling (Lim et al. 2018). The other is that the reference database is somewhat scarce in the silt area were most datapoints in the example lie (compare Figures 6a and 3a).

4 CONCLUSION

This study describes a first attempt to apply GMM clustering to geotechnical database.

The clustering technique has been applied in a space parametrized by dimensionless soil unit weight and normalized cone tip resistance, assuming the existence of two unobserved classes, selected at 50% probability. One of emerging hidden classes can be associated to Clay-Like-Contractive class, while the second is representative of a wide range of soil types. Assignation of new data to the hidden classes is based on a discriminant line generated on nonnormalized SBT charts (Robertson, 1990). CPTu data subdivision according to such classes has been shown to increase the predictive strength of correlations. This has been illustrated using a correlation template from Mayne et al., (2010) in which unit weight is predicted from shaft friction, depth and tip resistance.

Beyond the particular application explored here, the technique presented here may prove useful to improve accuracy and precision of empirical CPTu based correlations established using global databases.

ABSTRACT: The north Irish Sea is earmarked for the development of several offshore wind farms. The complex Quaternary history of this area has resulted in a legacy of geotechnically challenging deposits, including heterogeneous glacial deposits, soft sediments and gas-charged sediments. Multichannel Analysis of Surface Waves (MASW) is commonly used onshore to produce shear wave velocity (V_s) profiles and is increasingly being used offshore (UMASW). When used in tandem with *in-situ* Cone Penetration Testing (CPTU) profiles it is a powerful tool for characterising offshore deposits. UMASW profiles were obtained from sites across the north Irish Sea coincident with CPTU profiles. V_s profiles from UMASW show good agreement with CPTU parameters in a range of geological settings. The purpose of this paper is to present a characterisation of geological deposits using a combined approach of CPTU and UMASW. By doing so the aim is to further develop classification charts that can give reliable characterisations of offshore deposits by combing non-invasive geophysical techniques and traditional CPTU.

1 INTRODUCTION

1.1 *Background*

The use of the Multichannel Analysis of Surface Waves (MASW) technique is used extensively in onshore geotechnical investigations, providing a profile of shear wave velocity (V_s) against depth. Additional geotechnical parameters, such as the small strain stiffness (G_{max}), can be derived using this V_s profile and subsequently used as input for foundation design. Typically, measurement of G_{max} requires high-quality undisturbed samples for laboratory-based testing, which are challenging to acquire and only measure discrete sampling locations. In this way, *in-situ* geophysical testing like UMASW offers a rapid method of measuring the bulk response of undisturbed sediment (Long & Donohue, 2007). When combined with other *in-situ* testing, such as Cone Penetration Testing (CPTU), V_s profiles derived from the Underwater MASW (UMASW) have been shown to be powerful complimentary tools in characterising marine sediments (e.g. Long & Donohue, 2010) and in offshore geotechnical site investigations (Long et al., 2020).

The north Irish Sea has experienced a complicated geological history comprising of ice-sheet advance and retreat coupled with marine transgression and complex sea-level rise (e.g. Scourse et al., 2021; Ward et al., 2016). As a result, glacial deposits have been deposited on bedrock, which in turn are over-laid by marine sediments that are known to host shallow gas (Coughlan et al., 2019). These geological conditions create a number of potential geohazards and geotechnical constraints that may inhibit the extensive development of offshore wind planned for the area (Coughlan et al., 2020; Guinan et al., 2020).

Shear wave velocity (V_s) profiles were acquired using the UMSAW technique from a number of locations where CPTU data existed. This paper presents V_s and CPTU data in order to characterise challenging ground conditions, such as heterogeneous glacial deposits and soft marine sediments hosting shallow gas.

1.2 *Site location and description*

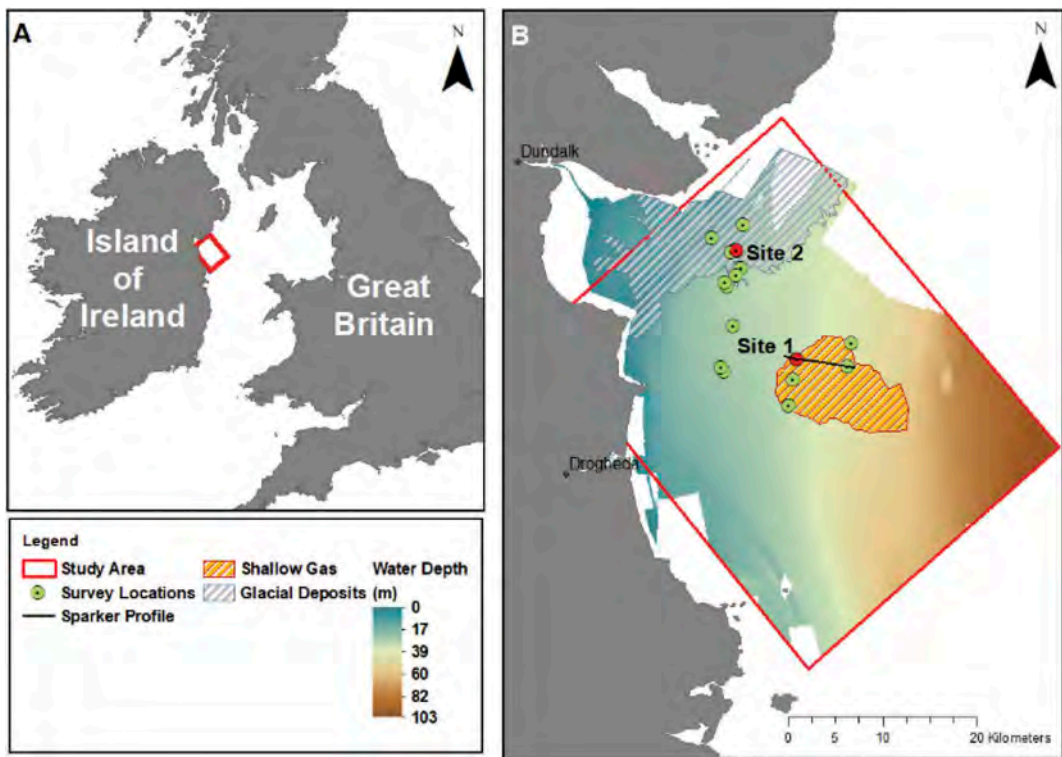
The study area is outlined in Figure 1. In this area UMASW data were collected at 19 locations, corresponding with locations where previous geotechnical


Figure 1. Study area map with data site locations. Areas of shallow gas and glacial deposits are from Coughlan et al. (2020).

data had been acquired. The data presented in this paper were obtained at 2 locations representing differing geological conditions: soft sediments with shallow gas (Site 1) and glacial deposits (Site 2). Site 1, located in an area known as the Western Irish Sea Mud Belt (WIMSB: Belderson, 1964). Coughlan et al. (2019), identified four stratigraphic units. These consist of a basal subglacial (lodgement) till emplaced by the Irish Sea Ice Stream (ISIS) as it advanced across the area, underlain by irregular bedrock. As the ISIS retreated during deglaciation,, ice-proximal outwash gravels, sands and silts were deposited in a glaciomarine to glaciolacustrine. As deglaciation continued, the area became increasingly ice-proximal and dark muddy sands were deposited in a glaciomarine to marine environment. Finally, Holocene marine muds varying in thickness lie above an erosive horizon marking the base of the Holocene (Woods et al., 2019), and form the contemporary seabed. These Holocene sediments are known to host shallow gas (Coughlan et al., 2021; Yuan et al., 1992).

At Site 2, to the north and north-west, the Holocene muds and silts thin out and coarsen to sands with the underlying glacial units out- and subcropping at the seafloor. In the vicinity of Dundalk Bay, a large arcuate moraine ridge is evidence of a readvance of the Irish Ice Sheet eastward (Callard et al., 2019). This feature is correlated with ice

margins mapped onshore and is likely correlative to the Clogher Head and/or Killard Point Stadial, both of which are exposed in onshore sections, in a period spanning 18.2 to 16.5 ka BP (McCabe et al., 2005).

2 MATERIALS AND METHODS

2.1 *Cone Penetration Testing (CPTU)*

CPTU data was acquired in the study area in 2014 onboard the *RV Celtic Explorer*, using the University of Bremen developed Geotechnical Offshore Seabed Tool (GOST) system. The hardened stainless steel cone tip had a cross-sectional area of 5 cm^2 and sleeve area of 75 cm^2 recording tip resistance, sleeve friction and differential pore pressure with a sampling frequency of ~30 Hz, resulting in a vertical resolution of ~2 mm with a maximum tip resolution of 0.06 MPa and a range up to 120 MPa. The GOST system has an operational weight of between 2 and 8 tonnes depending on the addition of weighted plates for extra stability. It has 8 tonnes of hydraulic push power with variable hydraulic pressure of 0-20 MPa. Exact control on push velocity during penetration allows for data to comply to the highest international including DIN 4904 and ISO 22476-1:2012

requirements. The interface was a digital one of industrial RS485 BUS using direct A/D converting of a measured variable with overvoltage and reverse protection. Raw CPTU data were calibrated using standard methods according to (Lunne et al., 1997).

2.2 Underwater Analysis of Surface Waves (UMASW)

UMASW data were acquired as part of the Developing Site Investigation Methodologies and Constraint Mapping Products for Offshore Renewable Energy (DeSIRE) Survey in 2020. The set-up comprised two Geometrics Model DHA-7 bay cables, each consisting of 24 hydrophones moulded onto the receiver cable, that was deployed onto the seabed from a main vessel (*Ocean Navigator*) using a smaller auxiliary vessel (*Fionn MacCumhaill*). Hydrophone spacing on the cable was 3.125 m and it was attached to a mooring weight at the *Ocean Navigator* end, whilst a clump weight deployed by the *Fionn MacCumhaill* secured it at the other end. The *Fionn MacCumhaill* also acted as a gunboat for the seismic source, which comprised a Sercel 12 cu.in. Mini G. Gun, allowing for shots to be taking at different positions along the cable (McGrath et al., 2016).

Processing of UMASW data involved the Fourier transform of time series shot data to produce phase velocity (c) – frequency (f) intensity plots, often referred to as dispersion curves images. The method relies on the dispersive nature of surface waves where different frequencies sample different depths within the ground travelling at different velocities.

Surfseis software developed by the Kansas Geological Survey was used for the processing and analysis of the surface wave data (Park et al., 1999, 2007). Once the surface wave response has been isolated and the high semblance curve picked the software carries out a least squares inversion of the data to produce a 1D V_s profile. The UMASW data were processed using a default 10-layer variable thickness model based on the input picked dispersion curves. These parameters are routinely used to give a good approximation of the seismic layer thickness and resulting V_s profile. The frequency content resolved

from the dispersion curves defines both the upper and lower depth limits of the inversion process (Figure 2). The shallowest resolvable depth is approximately 1/3 to 1/2 of the maximum phase velocity wavelength (c/f). The maximum resolvable depth is defined in the same way by the minimum phase velocity wavelength. In this instance the range of reliable Vs values is typically between 3 and 25 m.

3 RESULTS

3.1 Site 1

CPTU and UMASW for Site 1 is shown in Figure 3. The data show 2.5 m to 5 m of a Very Soft clayey silt (Unit 1) overlying a Soft to Firm clay layer to circa. 18 m (Unit 2). At 18 m there is a transition to a Firm to Stiff clayey Silt/sandy Silt (Unit 3), with a corresponding drop in u_2. The transition from the base of Unit 2 into Unit 3 at Site 1 correlates with the presence of shallow gas as determined by seismic sparker profiles in Coughlan et al. (2019) and Figure 4.

During the acquisition of seismic sparker profiles the presence of shallow gas, predominantly contained within the Holocene fine-grained sediments, results in high acoustic reflectivity at the top of the gas unit. This reduces the signal to noise ratio manifesting itself as acoustic turbidity within the gas and acoustic blanking below the gas. These effects result in a lower resolution of the underlying units, reducing the ability to identify and pick horizons from the seismic profiles. (e.g. Judd and Hovland, 1992; Tóth et al., 2014). In the DeSIRE study area, shallow gas had previously been mapped by Coughlan et al. (2019, 2021; Figure 1).

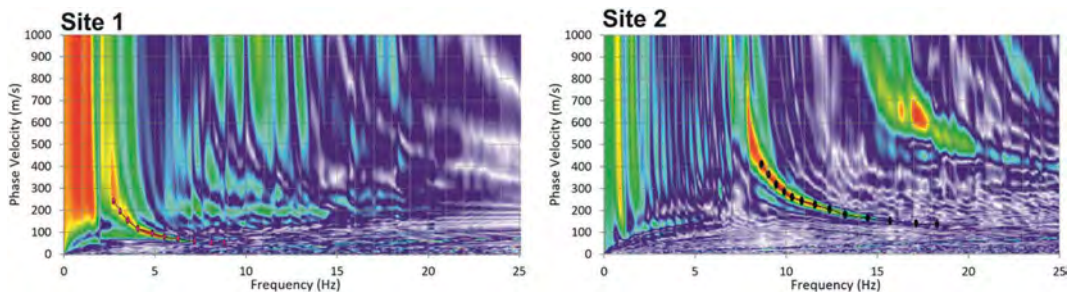
The division between Unit 1 and 2 is most clear from the u_2 data, where the pore pressure picks up in the clay but can also be seen from the change in slope of the q_t and f_s profiles. The division between units 2 and 3 is clear from all 3 sets of CPTU data. As the cone penetrates from the clay to the more coarse material, q_t increases, f_s (and R_f) reduces and u_2 drops back towards the hydrostatic value.


Figure 2. Dispersion curves produced in 45 m water depth at Site 1 and Site 2 in 25 m water depth.
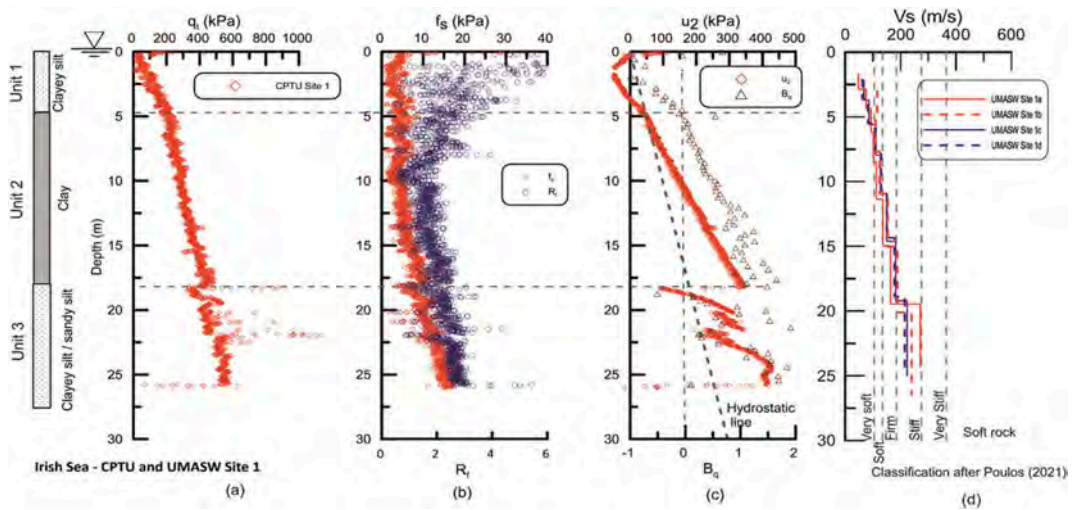

Figure 3. CPTU data for Site 1 is presented in the form of (a) corrected tip resistance (q_t), (b) sleeve friction (f_s) and friction ratio (R_f) and (c) pore pressure generated in the u_2 filter position and normalised pore pressure parameter (B_q) versus depth (Lunne et al., 1997). In addition the parallel UMASW profiles for Site 1 are shown in (d).
Figure 4. Seismic profile for line highlighted in Figure 1 (see Coughlan et al. (2019) for further details).

The UMASW profiles (Figure 3d) are consistent with the CPTU data, correlating well with the q_t values. The profile identifies Very Soft sediments (< 100m/s) to the base of Unit 1 at c. 5 m increasing from Soft to Firm to Stiff (100 – 180 m/s) at the base of Unit 2 at c. 18 m. Unit 3 corresponds to Stiff material (>180 m/s) below this depth. Stiffness designations according to the classification system proposed by Poulos (2021).

The Robertson et al. (1986) soil behaviour type chart (SBT) for Site 1 is shown on Figure 5 and is consistent with the findings presented above. Both the B_q/q_t and R_f/q_t components of the chart work well for this case. The data for the upper 5 m of the sediment (Unit 1) is close to the boundaries of the charts but suggests that the material is an organic-type material. The 5 m to 18 m clay sediment (Unit 2) is classified correctly as a sensitive fine-grained material or a clay. Finally, the deeper material (Unit 3) is classified as either a clay or a silty clay.

3.2 Site 2

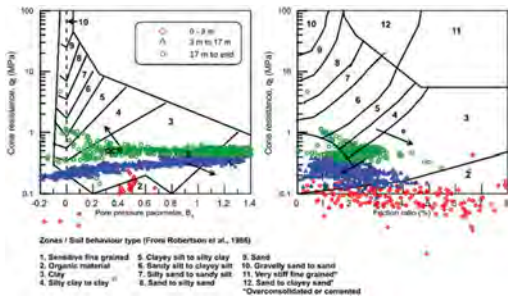
Data for Site 2 is shown on Figure 6. Only limited CPTU data is available here as no f_s and u_2 data were recorded. The q_t values confirm that the material is highly competent with q_t values increasing rapidly with depth up to a value of about 18 MPa with refusal at 3.25 m. However, the UMASW data was


Figure 5. Soil behaviour type classification for Site 1 CPTU data (from Robertson et al., 1986).
Figure 6. CPTU data for Site 2 is presented in the form of (a) tip resistance (qt) (Note the different x-axis scales from Figure 3). In addition, the corresponding UMASW profile is shown in (b).

able to resolve data to c. 15 m. The classification system proposed by Poulos (2021) suggests the material designation as increasing Firm, through Stiff and Very Stiff to Hard with depth.

4 CONCLUSIONS

The area of the north Irish Sea studied here exhibits a lateral variability of complex deposits, which are potentially challenging to the deployment of offshore renewable energy infrastructure such as foundations. These deposits include soft, fine-grained Holocene sediments, gas-charged sediments, and heterogeneous glacial deposits. Previous efforts at CPTU data acquisition in these sediments had mixed results, with limited penetration in particular in glacial deposits. The use of SBT based on Robertson et al. (1986) is considered suitable here due to the relatively shallow depths and nature of the sediment known in the area. Future work will include comparison with updated charts (e.g. Robertson, 2016) and cross-

checking across profiles and with available lab data.

In this study the UMASW technique was successfully applied across this variety of geological conditions and a range of water depths from 17 to 45 m, obtaining reliable V_s profiles to c. 25 mbsb. The two sites presented in this paper highlight the presence of soft Holocene sediments with shallow gas (Site 1), as well as glacial deposits (Site 2).

UMASW proved effective at Site 2 in characterising heterogenous glacial deposits at depths below CPTU refusal. At Site 1 MASW showed good correlation with CPTU to similar depths, however both methods were ineffective in determining the presence of shallow gas, which was identified using seismic sparker profiles. V_s and CPTU profiles show good agreement and can be used to develop classification charts for offshore deposits in complex geological areas.

The UMASW application is shown to be a proven method of providing geotechnical parameters for sub-seabed characterisation. When used in combination with other complimentary methods such as CPTU and seismic reflection a more robust ground model can be delivered.

Cone factor from CPTU tests in very soft clays at the east of Mexico's valley

J.M. De La Rosa R. & F.A. Flores López
Ingenieros Geotecnistas Mexicanos. S.C., México.

ABSTRACT: From the results obtained during an exploration campaign, the correlation between CPTU resistance and the undrained shear strength of soft clays at the valley of Mexico, is evaluated in this paper. This campaign consisted of 50 piezocone penetration tests, 50 soil sampling borings and laboratory tests carried out on more than 300 undisturbed soil samples recovered along 10 square kilometers. The samples were tested by means of unconfined compression and unconsolidated undrained triaxial compression tests. The correlation of the determined undrained shear strength and the experienced CPTU results was evaluated and the empirical cone factor (Nkt) was determined for all tests. The main innovation lies in the fact that for the eastern zone of the Valley of Mexico, the geotechnical characterization is not abundant and there are information gaps for this and other design parameters.

Keywords: CPTU, Nkt, Undrained shear strength, Valley of Mexico

1 INTRODUCTION

1.1 *Origins of Mexico's valley*

Mexico City is located on a lacustrine plain in the Basin of Mexico that occupies an approximate area of 9,600 km2 and is located at 2,250 m above sea level. This basin remained open (exoreic) until 700,000 years ago, when extensive volcanic activity formed the Sierra de Chichinautzin, which closed the basin (Mooser, 1963) and obstructed drainage to the Balsas River. For this reason, the water was stored and gave rise to several lakes. At the foot of the mountains and due to the sudden change in the slopes of the rivers, large alluvial deposits of highly variable composition and cross-stratification are located, evidence of an erosive dynamic due to periods of intense rain. This area of the city was enabled as a flood control zone through the creation of artificial lagoons causing surface depressions by pumping. Texcoco Project (1969). The soils found in this zone correspond to very soft and saturated lacustrine clays, subject to a regional subsidence process due to the extraction of water by deep pumping. The use of CPTU is a common option to know the stratigraphic sequence for the determination of settlements magnitude.

Currently, the urban development of the city has been pushing towards the east, driven by a new airport under construction which was canceled three years ago. However, during its execution this project triggered the infrastructure needs of the area, so it is necessary to expand the knowledge about its geotechnical characterization. This situation makes this publication necessary and useful.

2 BACKGROUND

2.1 *Empirical cone factor*

The many existing formulations to correlate Cone penetration tip resistance (qc) from CPT/CPTU, results with the undrained shear strength of clays (Su) are summarized in many publications. Most of those investigations found Su linearly proportional with the corrected tip resistance of the cone as shown in equation (1):

$$S_u = \frac{q_c - \sigma_{v0}}{Nkt} \tag{1}$$

Where,
   Su: Undrained shear strength.
   q_c: Tip resistance of the cone/piezocone.
   σ_{v0}: Total overburden pressure.
   Nkt: Empirical cone factor.

2.2 *Previous research and typical values*

Most of the research aimed at estimating the value of (Nk) that correlates CPT/CPTU with Su. Variation ranges has been estimated between 11 and 19 by Lunne & Kleven (1981) for normally consolidated Scandinavian marine clays, also Jorss (1998) estimated values ranging from 15 to 20 for marine y boulder clays, respectively. Mexico City's clays present Nk values between 5 and 11, according to Santoyo et al. (1989). Some values range between 5 and 28 for different types of soils, according to Chen (2001) and

Gebre-selassie (2003). Also, Ovando (2011) related Su = qc/Nk with Nk values of 13 for Mexico City. Typically, Nk is between 10 and 18, with an average of 14 (Robertson & Cabal, 2015). The marine clays of the Gulf of Mexico present Nk values between 12 and 20, according to Cruz et al. (2019).

2.3 Geotechnical input information

2.3.1 Field exploratory survey
Based on the dimensions of the project structures, a geotechnical exploration campaign was executed to define the stratigraphic profile, from which the laboratory program was planned. The exploration campaign consisted of boreholes between 25 and 50 m deep (SPT/SHB mixed, SM and piezocone tests, CPTU), in addition to a surface exploration campaign, consisting of 150 open-pit wells (PCA), 100 plate load Tests (PP) and strategically located piezometric stations.

The exploratory drilling was carried out according to the corresponding ASTM standard, in the case of mixed SM drilling, the SPT technique was combined with the selective recovery of undisturbed samples using a thin-walled tube (Shelby) and the Electronic Friction Piezocone Test was performed using a digital equipment that complies with the ASTM D5778-20 standard and that allows the measurement of resistance to tip penetration (q_c), lateral friction (fs) and pore pressure behind de cone (u2).

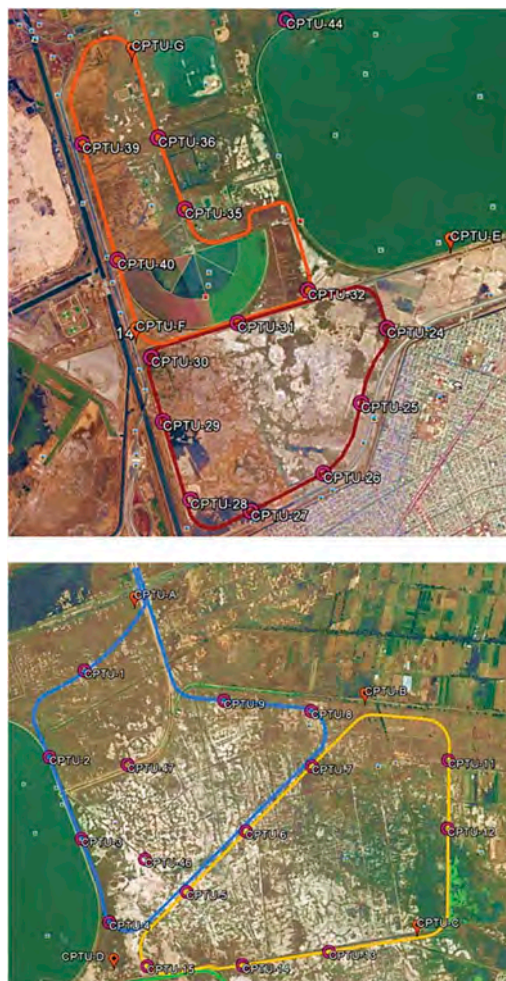
Figure 2. Location of CPTU tests.


Figure 1. Location of SM boreholes.

2.3.2 Laboratory tests
All the samples obtained in the exploration work were macroscopically identified and classified both in the field and in the laboratory, according to the Unified Soil Classification System. Tests

were carried out to determine the following index properties: Natural water content (150 to 400%). Limits of consistency (liquid limit, plastic limit) and plasticity index (100 to 300%). Grain size analysis. Percentage of fines (90 to 100%). Relative specific weight and density of solids (2.30 in average, maximum of 2.65 and minimum of 2.15).

The mechanical properties were determined based on the following tests: Unconfined compression shear resistance. Triaxial compression test UU with determination of Young's Modulus (E). Triaxial compression test CU. Compressibility in one-dimensional consolidation tests.

2.4 Analysis of parameters

The fulfillment of the objective for geotechnical characterization is not easy due to the variability of the results obtained in the field and laboratory tests. Another difficulty that causes uncertainty in representative soil results is the considerable size of the study area and the relatively large distances between boreholes and measurement points. To achieve a satisfactory description of the properties and stratigraphic characteristics of the subsoil, the use of descriptive statistics tools was used. In the next section, the analysis criteria and selection of parameters used are presented.

2.5 Criteria for quantitative analysis and variability of the parameters

By having a soil property measured repeatedly, we get a data set called a "data sample" that can be analyzed quantitatively using statistical parameters. For the values obtained in the project, although there are many parameters that can be estimated, the following were evaluated: Mean, median, mode, variance, standard deviation.

The analysis of variability of the soil properties was graphically complemented by means of a histogram calculating its corresponding probability distribution in order to select the data to be considered to describe the geotechnical parameters.

3 RESULTS OBTAINED

3.1 Mechanical properties

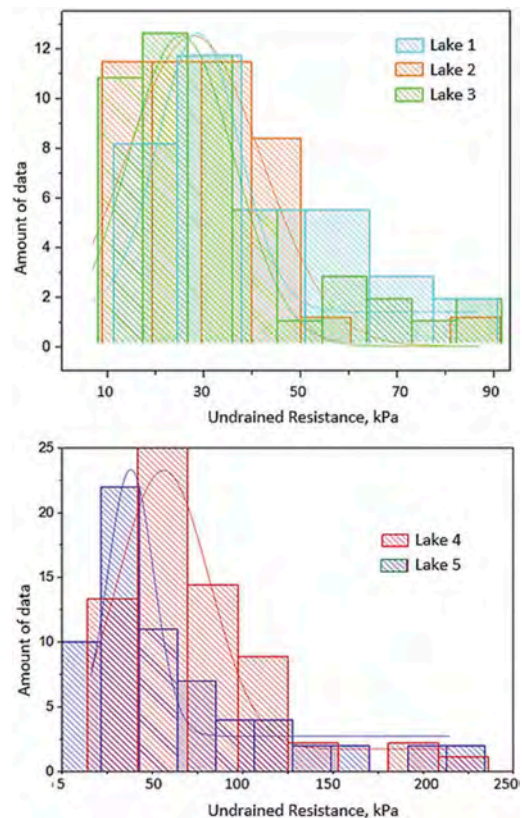
Based on the analysis of variability and the selection of representative values, the results of the CPTU tests on site and the laboratory results were correlated. For this project, the results obtained from the electrical cone (tip resistance) are more representative, since the SPT tests


Figure 3. Histogram of simple and triaxial compressive strength UU and its normal probability function.

mostly obtained the number of blows N equal to zero, which does not provide relevant data for characterization purposes. The histogram of all the correlated data was generated and the normal logarithmic probability distribution function that best fit the measured values was obtained (Figure 3). Figure 4 shows the results obtained by correlating the tip resistance with the laboratory results for the UU resistance of the soils, where a linear increase can be seen as a function of depth, it is also observed that there is more variation near the soil surface associated with the surface crust.

Figure 5 shows the average values of Undrained Resistance obtained in the laboratory and Tip Penetration Resistance, obtained on site for all samples.

3.2 Cone factor values

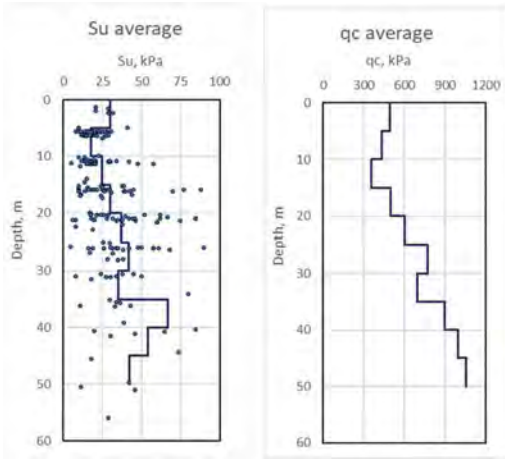
Once the corresponding analyzes had been carried out and the results obtained in the field and laboratory correlated, the average values of
Figure 4. Undrained resistance obtained by correlating laboratory tests and electrical cone results.
Figure 6. Average Cone Factor Nkt, depending on the depth range analyzed.


Figure 5. Average values of Soil Undrained Resistance (Su) and Tip Penetration Resistance along the explored depth for all samples.
Figure 7. Average Cone Factor Nkt, for each CPTU analyzed.

4 DISCUSSION AND CONCLUSIONS

4.1 Variability of results

Nkt, shown in Figure 7, were obtained for the 38 most representative CPTU. The results obtained range between 8 and 21 with an average of 14; while Figure 6 shows the average Nkt values obtained by depth range every five meters, also for the 38 most representative CPTU.

The results obtained during the analysis for this research, indicate that in 87% of the cases, the cone factor Nkt is between 10 and 20, *with an average of 14* of the 12,500 data analyzed, the maximum value found was 25 and the minimum 7. Figure 6 shows a progressive variability of the Nkt factor as a function of depth during the first 25 meters of depth, with

values between 11 and 16, while for greater depths a stabilization around values higher than the average is observed (16 to 19). Figure 8 shows the variability analysis between the proposed cone factor Nkt average and the results from the direct correlation of the Tip Resistance (qc) and the laboratory UU resistance (Su). Excluding the values obtained near the surface, due to what is mentioned in section 3.1, an R = 86% is obtained in the adjusted regression line.
Figure 8. Nkt average/correlated vs depth.

The variability of Nkt shown in Figure 6 with respect to depth is due in part to clay samples obtained with water contents between 50% and 450%. For extreme cases, sample recovery becomes challenging and results in non-representative samples. This variability as function of depth is a typical behavior for marine clays, and the lacustrine nature of the virgin, high-salinity clays to the east of the valley is consistent with this trend.

4.2 Future lines of research

In addition to the results obtained so far, there is sufficient data to establish correlations between Su and Index properties. Data consist of Atterberg limits from 500 samples and elastic Young's modulus from 200 samples.

4.3 Current trends in the valley of Mexico

The current trends among the predominant players of Mexican geotechnics can be observed with a tendency to promote the use of automated equipment to control the driving speed of the tip with the valid argument that there is some relevant variation between the parameters obtained in an automated way by comparing them with those derived from rudimentary field estimates, such as the most common practice of drawing division marks of predetermined length on the drilling rods and maneuvering the drill so that the guide adapts to the required speed of penetration.

In addition, the application spaces for nationally produced equipment have decreased because, although they comply with ASTM or similar standards, they do not usually include temperature and verticality sensors, which have proven necessary to guarantee the quality of the results obtained.

These trends, point to a less widespread use of the electric cone due to the costs involved in this modernization, as well as more accurate results in cases where this technique is applied. However, these improvements are unlikely to replace or lessen the need for laboratory testing, while the main objective of using the electric cone will remain unchanged: to determine the stratigraphic sequence in previously explored areas where the stratigraphy is partially known in advance.

ABSTRACT: Soft and sensitive clays are widespread in Scandinavia. Piezocone correlations for Norwegian clays have been previously proposed based on high-quality block samples from several sites. Recently, a large database of Finnish soft clays was compiled by Tampere University from piezocone measurements as well as high-quality laboratory tests on specimens from large tube samples. Finnish and Norwegian clays exhibit some differences in terms of basic properties. Norwegian clays show lower water content, lower organic content, higher silt content and lower plasticity than the clays from Finland. This may be linked to the source of the materials, their depositional and post-depositional processes that in turn impact on the mechanical behaviour.

This paper aims to compare piezocone Norwegian and Finnish data with focus on strength and stress history. The database trends are compared for relevant engineering parameters. The data and its variability are critically discussed considering differences in geological history, basic properties, sampling techniques and disturbance.

1 INTRODUCTION

Piezocone (CPTU) testing is one of the most reliable site investigation tools in soft clays, as it has proven repeatability of measurements and can be used to detect soil layering and derive a large number of geotechnical parameters (e.g., Lunne et al. 1997a, Robertson 2009, Di Buò 2019). During cone penetration, the standard CPTU equipment measures cone tip resistance q_c, sleeve friction f_s and excess pore pressure above the cone tip u_2.

The use of CPTU is widespread in Norway, regardless of the project size. CPTU correlations for Norwegian clays derived from high-quality laboratory data on block samples (Karlsrud et al. 2005, Paniagua et al. 2019) have been in use for nearly two decades. On contrary, CPTU testing is still on the rise in Finland, where weight soundings, dynamic penetration testing and field vane testing are among the most preferred site investigation tools. This is mainly a consequence of the lack of local correlations as well as limited experience by the operators. Nevertheless, in recent years the Tampere University (TUNI) has

carried out studies on CPTU testing and correlations in Finnish soft clays (Di Buò et al. 2016, Di Buò et al. 2018, Selänpää et al. 2018, Di Buò 2020, Di Buò et al. 2020, Selänpää 2021). The calibration database includes testing on large tube samples retrieved with a Laval-type tube sampler developed by Tampere University (Di Buò et al. 2019). Both the Norwegian and the Finnish databases include laboratory index tests, constant-rate-of-strain (CRS) oedometer tests, undrained triaxial compression (CAUC) and extension tests (CAUE) and direct simple shear tests (DSS).

The scope of this paper is to compare the Norwegian and Finnish clay data to better understand how the basic clay properties impact on the CPTU response in these clays. The database trends are compared for two key engineering parameters, i.e. undrained shear strength and overconsolidation ratio. The observations in terms of cone factors and calibration coefficients are critically discussed, considering differences in basic properties, geological history, sampling techniques and features of the databases.

2 GEOLOGICAL HISTORY OF NORDIC CLAYS

A detailed study on the geological formation of fine-grained sediments in Finland was conducted by Gardemeister (1975). Fine-grained soil sediments in Finland originated in the late Pleistocene, during the retreat of the continental ice sheet in the Weichselian ice age (11,700 years ago). The entire Scandinavian region was covered by a large ice sheet named Fenno-Scandian that spread out from the Scandinavian Mountains to Northwest Russia, UK, and The Netherlands. The stratigraphy of Finnish soil deposits is the result of a series of processes that occurred at the end of the last glacial period when the Fenno-Scandian ice sheet retreated and during the Holocene (i.e. c. last 10,000 years ago). The glacier meltwater accumulated between the front of the ice sheet and the southern shores, giving rise to what currently is the Baltic Sea. This area underwent four environmental stages in the postglacial progression of the Baltic basin, known as Baltic Ice Lake, Yoldia Sea, Ancylus Lake, and Littorina Sea. (Gardemeister 1975)

Despite the extensive studies conducted on this topic, the process of the formation of the Baltic Sea is not completely clear. Its connection with the Atlantic Ocean during the different phases made the salinity vary with location, depth, and time. The complex origin and development of this area may explain the different geotechnical properties characterizing the clay deposits located in Finland and Sweden compared with the Norwegian ones. The Baltic Ice Lake originated during the retreat of the Weichselian glacier, when meltwater accumulated and formed a freshwater lake. At this stage, the connections with the North Sea and the Atlantic Ocean were closed because the ground on the entire depression rose faster than the sea level. However, a short connection with the sea across central Sweden occurred during the Yoldia Sea stage. At the early stage, the depositional environment was still characterized by low salinity owing to the heavy water flow from the continental ice sheet. The salinity increased after 200 years of the ingression of salt water, creating the condition for a brackish depositional environment. Afterward, the isostatic uplift of the Baltic basin closed the connection with the Atlantic Ocean and the Yoldia Sea turned into Ancylus Lake. This stage lasted until a new connection with the North Sea was established owing to the continuous rising of the water level of Ancylus Lake, forming the Littorina Sea. Finally, the continuous land rise made the connection with the Ocean shallower, thus creating the conditions for the formation of the current Baltic Sea, which is characterized by brackish water. (Gardemeister 1975)

It is evident that the combination of the sea water intrusion and freshwater flow from the melting glacier created a heterogeneous depositional environment characterized by variable salinity content. Although the salt leaching process is considered as the main factor explaining the high sensitivity of Scandinavian marine clays, further studies are needed for Finnish clays.

3 EVALUATION OF ENGINEERING PROPERTIES OF CLAY FROM CPTU

3.1 CPTU parameters

Engineering properties of clays are derived from both measured and normalized CPTU parameters. Among these:

- Normalized cone resistance $Q_t = (q_t - \sigma_v)/\sigma'_v$
- Normalized excess pore pressure $Q_u = (u_2 - u_0)/\sigma'_v$
- Normalized effective cone resistance $Q_e = (q_t - u_2)/\sigma'_v$
- Pore pressure ratio $B_q = (u_2 - u_0)/(q_t - \sigma_v)$

where q_t is the corrected cone tip resistance, σ_v is the total overburden vertical stress, σ'_v the vertical effective stress, u_2 the pore pressure measured above the cone tip, u_0 the in-situ pore pressure.

In addition, $(q_t - \sigma_v)$, $(u_2 - u_0)$ and $(q_t - u_2)$ are commonly referred to as q_{net}, Δu and q_e, respectively.

3.2 Overconsolidation ratio

The over-consolidation ratio (OCR) is defined as the ratio of effective preconsolidation stress σ'_p and the vertical effective stress σ'_v. Several authors verified the dependence of σ'_p and OCR on the cone tip resistance and excess pore pressure parameters, with σ'_p and OCR increasing with increasing q_{net}, σu, q_e and Q_t, Q_u, Q_e respectively. (e.g. Chen and Mayne 1996, Lunne et al. 1997, D'Ignazio et al. 2019).

In practice, the relationship between σ'_p and q_{net} is the most used (Equation 1). The relationship between OCR and Q_t is used in the same way as (Equation 2):

$$\sigma'_p = k(q_t - \sigma_v) = kq_{net} \qquad (1)$$

$$OCR = k\frac{q_t - \sigma_v}{\sigma'_v} = k\frac{q_{net}}{\sigma'_v} = kQ_t \qquad (2)$$

where k is an empirical parameter. Similar equations are found in the literature for Δu, q_e and Q_u, Q_e. An average value of $k \approx 0.32$ is suggested by Chen and Mayne (1996) based on statistical analysis of piezo-cone-oedometer data involving a variety of different clays. D'Ignazio et al. (2019) found k in the range 0.15-0.5 for clays with OCR $\approx$ 1-5. Paniagua et al. (2019) found $k = 0.20$-0.75 for Norwegian clays, while Di Buò (2019) suggested $k = 0.28$ with coefficient of variation (COV) ≈ 0.1 for Finnish soft clays.

3.3 Undrained shear strength

The net cone resistance q_{net} is related to the undrained shear strength s_u by means of the cone factor N_{kt} as:

$$s_u = \frac{q_{net}}{N_{kt}} \qquad (3)$$

Similarly, Δu and q_e are related to s_u by means of the cone factors $N_{\Delta u}$ and N_{ke} respectively as:

$$s_u = \frac{\Delta u}{N_{\Delta u}} \qquad (4)$$

$$s_u = \frac{q_e}{N_{ke}} \qquad (5)$$

For low OCR offshore and onshore clays, Low et al. (2010) reported N_{kt} = 8.6-15.3 and $N_{\Delta u}$ = 3.3-8.8 for triaxial compression (CAUC) and N_{kt} = 11-20 and $N_{\Delta u}$ = 4.8-11.9 for field vane test (FVT). Paniagua et al. (2019) found N_{kt} = 5-16 and $N_{\Delta u}$ = 5-10 for CAUC in onshore Norwegian clays with OCR less than 6. Paniagua et al. (2019) further observed N_{ke} ≈1,5-10 for CAUC decreasing with increasing B_q. Selänpää (2021) suggested N_{kt} = 9.1, $N_{\Delta u}$ = 7.7, and N_{ke} = 4.5 with COV ≈ 0.1 for CAUC in Finnish soft lightly overconsolidated clays. D'Ignazio & Lehtonen (2021) observed $N_{\Delta u}$ ≈ 11 for FVT in a soft organic sulphate rich lightly overconsolidated clay from Finland. D'Ignazio et al. (2020) found N_{kt} = 20-32 (CAUC) for an overconsolidated North Sea clay with OCR ≈ 4-20, with N_{kt} increasing with increasing OCR.

4 HIGH-QUALITY CLAY DATABASES

4.1 Norway

The Norway CPTU database is presented in detail by Paniagua et al. (2019). The database consists of 61 high-quality block samples data points collected from 17 Norwegian clay sites located all over the country. For these points, both CPTU and laboratory measurements are available. The laboratory tests were carried out on specimens obtained from large diameter (Ø250 mm) block samples and mini-block (Ø150 mm) Sherbrook samples (Emdal et al. 2016). For Norwegian clays, block samples seem to ensure higher quality than the more traditional Ø54 mm or Ø72 mm piston samples (e.g., Lunne et al. 2006, L'Heureux et al. 2018).

The database includes laboratory index tests, constant-rate-of-strain (CRS) oedometer tests, anisotropically consolidated undrained triaxial compression (CAUC) and extension tests (CAUE) and direct simple shear tests (DSS).

Sample quality was assessed according to the Lunne et al. (1997b) criterion based on the normalized change in void ratio $\Delta e/e_0$ from CAUC tests. Data points fall within sample quality categories "Very good to excellent" and "Good to fair".

Soil properties were measured from specimens collected down to a maximum depth of 22 m. The clay properties cover a wide range of plasticity index, with I_p varying between 4 (low plastic) and 49 (very high plastic), a wide range of water content (w = 28–72%), a wide range of sensitivity (S_t) values

(S_t = 2–240). The OCR ranges from 1 to 6, while the clay content varies between 21 and 65%.

4.2 Finland

The Finland TUNI's CPTU database in summarized in the works carried out by Di Buò (2019), with focus on preconsolidation stress, and Selänpää (2021), with focus on undrained shear strength. Data was collected from 5 test sites located in Southern Finland. Both CPTU and laboratory measurements are available from the test sites.

The laboratory tests were carried out on specimens obtained from large diameter (Ø132 mm) Laval-type sampled designed by Tampere University and presented in detail by Di Buò et al. (2019). Some of the tests were performed on specimens obtained from a mini-block (Ø150 mm) Sherbrook sampler (Emdal et al. 2016).

The database includes laboratory index tests, n.99 constant-rate-of-strain (CRS) oedometer tests, n. 17 anisotropically consolidated undrained triaxial compression (CAUC) and n. 14 extension tests (CAUE), n. 14 direct simple shear tests (DSS) and n. 14 field vane tests (FVT).

Sample quality was assessed according to the Lunne et al. (1997b) criterion based on the relative void ratio change at reconsolidation $\Delta e/e_0$ from CAUC as well as CRS tests. CAUC data points from Ø132 mm samples fall within sample quality categories "Very good to excellent", while the CRS data points and fall within "Very good to excellent" and "Good to fair" sample quality categories.

Soil properties were measured from specimens collected down to a maximum depth of 9 m. The clay properties cover a plasticity index I_p varying between 16 (low-medium plastic) and 59 (very high plastic), a wide range of water content (w = 66–127%), a wide range of sensitivity (S_t) values (S_t = 16–98). The OCR ranges from 1 to 2, while the clay content varies between 40 and 100%.

5 COMPARISON OF CPTU DATABASES OF NORWEGIAN AND FINNISH CLAYS

5.1 Overconsolidation ratio

Figures 1, 2 and 3 show plots of OCR versus the normalized values of cone resistance Q_t, pore pressure Q_u and effective cone resistance Q_e. The plots suggest a well-defined trend line for the Finland data, while the Norway data appears to be characterized by higher scatter.

Even though the uncertainty associated with OCR for Finnish clays appears to be lower than that for the Norwegian clays, it must be noted that the Finland data is obtained from 5 sites all located in the Southern part of the country; while the Norwegian data is collected from 17 sites spread all over the country,

where areas might have undergone different geological histories. However, the OCR range of the Finland data (OCR = 1-2) is lower than that of the Norway data (OCR = 1-7). For OCR < 2, the mean trends of the two databases appear to be consistent, despite the larger scatter in the Norway data. Consistency is also found between the OCR based on mini-block samples and Ø132 mm samples of Finnish soft clays.

The coefficient k of Equation 2 is ≈0.3 in Figure 1 for Finnish clays. Such a value is often assumed in practice in absence of site-specific oedometer tests.

Figure 3. OCR vs Q_e.
Figure 1. OCR vs Q_t.
Figure 2. OCR vs Q_u.

Data in Figures 1, 2 and 3 show a remarkable variability of the calibration coefficients, particularly for the Norwegian database. Figure 4 shows the variation of k (=OCR/Q_t) with plasticity index (I_p). The coefficient k appears to vary as a function of plasticity, decreasing with increasing I_p. Such a trend could not be observed when treating the two databases separately. Nevertheless, for I_p < 20%, the data from Finland is consistent with measurements at larger I_p.
Figure 4. K = OCR/Q_t vs plasticity index.

5.2 Undrained shear strength

The undrained shear strength from triaxial CAUC tests (s_{uC}) is taken as a reference and used for comparison of the Finland and Norway databases.

Figures 5, 6 and 7 illustrate the variation of s_{uC} with q_{net}, Δu and q_e respectively. The s_{uC} from Finnish clay deposits is generally lower than that of Norwegian clays. It must be noted that the sampling depths are limited to 9 m below ground level for the Finland data, while depths reach up to 22 m for the Norway data. Therefore, the deeper samples in the Norway database experienced larger stress relief than the samples from Finland. Nevertheless, for the depth range 0-9 m, s_{uC} of Norwegian clays is in the range 26-62 kPa, while s_{uC} of Finnish clays is 12-24 kPa. One possible explanation for this is the variation of OCR with depth. As shown in Figure 8, the range of OCR is larger for the Norwegian data. Given that s_u increases with increasing OCR (e.g. D'Ignazio et al. 2016, Selänpää 2021), this explains the higher strength of Norwegian clays at shallow depths.

The cone factor values for Norwegian and Finnish clays are discussed in detail by Paniagua et al. (2019)

359

and Selänpää (2021). Cone factors N_{kt}, $N_{\Delta u}$ and N_{ke} present some variability as illustrated in Figures 5, 6 and 7. As for the OCR, the variability appears to be the lowest for the Finland data. The variability of cone factors for Norwegian clays was discussed by Karlsrud et al. (2005) and Paniagua et al. (2019). These studies suggested a dependency of cone factors on OCR and lightly on index properties, although the proposed correlations are characterized by a non-negligible scatter.

Figure 9 presents the variation of the normalized CAUC strength s_{uC}/σ'_v with OCR. In agreement with previous analyses, the Finland data shows overall a well-defined trend and a lower scatter. For OCR < 2, the normalized s_{uC}/σ'_v of Finnish clays appears to be higher than that of the Norwegian clays, with the Miniblock samples data from Finland showing slightly higher values than the Laval Ø132 mm samples. This may result from the fact that the lower OCR points in the Norway database are observed at greater depths than in the Finnish database (Figure 8). This may be an indicator of the stress dependency of the normalized shear strength of clays.
Figure 5. Q_{qnet} vs s_{uC}.
Figure 6. Δu vs s_{uC}.
Figure 7. Q_e vs s_{uC}.

Karlsrud & Hernandez-Martinez (2013) and Paniagua et al. (2019) discussed how the variability of Norwegian clays in Figure 9 may be captured by the variability of water content. Considering that the Finland data is characterized by higher water content, this may further support the results of these studies.
Figure 8. OCR vs depth.
Figure 9. s_{uC} vs OCR.

6 DISCUSSION AND CONCLUSIONS

This study has compared two high-quality clay databases from Finland and Norway. Both databases include piezocone (CPTU) measurements and laboratory testing from different sites. Laboratory specimens were mainly retrieved from large diameter block sampler (Norway) and large diameter Laval-type tube sampler (Finland). Constant-rate-of-strain (CRS) oedometer tests results and undrained triaxial compression (CAUC) tests were used as reference tests to compare the overconsolidation ratio (OCR) and undrained shear strength from triaxial compression tests (s_{uC}) and their trends with respect to CPTU parameters.

The study showed that the shear strength of Finnish clays is lower than that of Norwegian clays. This is mainly due to the stress histories of the soils, i.e., the OCR of Finnish clays is generally lower when comparing samples from the same depth interval.

The larger scatter in both OCR and s_{uC} observed for the Norwegian data might be related to the fact that the Finnish data is collected from 5 sites all located in Southern Finland, while the Norwegian database comprises 17 sites spread all over Norway, where areas might have experienced different depositional histories and relative fall of sea level. Furthermore, the Finnish data has been collected using the same piezocone and sampling equipment for all sites, while the Norwegian data has been acquired over a period of 30+ years using different equipment. Even though data has been collected according to best practice, differences in measured CPTU parameters may be observed when using different cones (Lunne et al. 2018).

Future research shall focus on the mineralogy of clays. Mineral composition can have a large effect on the flocculation potential and building of strength of the soil (e.g. Torrance 2014). Depositional and post-depositional processes for both countries are also important aspects to investigate in depth. For a more thorough comparison, it is recommended to add data from Central and Northern Finland to the Finnish database.

ABSTRACT: Although various empirical models have been proposed to predict the resilient modulus (M_r) from laboratory test parameters, less effort has been made in developing reliable empirical models using piezocone penetration test (CPTU) data. Moreover, the prediction accuracy of the existing empirical models is not high enough. In the present study, a novel empirical model was proposed to predict the M_r from CPTU data based on the polynomial neural network. To this end, a comprehensive database comprising 16 different sites in Jiangsu province, China, was firstly compiled, which contains 124 sets of M_r, cone tip resistance (q_c), sleeve friction (f_s), pore water pressure (u_2), moisture (w), and dry density (γ_d) values at the in-situ stress condition. Taking the in-situ M_r values as reference values, three empirical models was developed using the group method of data handling (GMDH) neural network. The results show that proposed GMDH model 3 (GMDH method) with the input parameters of q_c, f_s, w, and γ_d can accurately predict the M_r. The obtained specific expressions for prediction of M_r further prove the reliability of the GMDH model. Overall, the new GMDH method can more accurately predict the M_r of subgrade soil and guide engineering practice.

1 INTRODUCTION

The properties of subgrade soils are the key contents in the design and performance of a pavement structure (Liu et al., 2016; Ghorbani et al., 2020). Among these properties of dry density, moisture content, stress state, the resilient modulus (M_r), and so on, the M_r is

an important index that describes the nonlinear stress-strain behavior of soil materials with respect to repeated traffic loading. The definition of M_r can be expressed as the ratio of the repeated deviator stress to the recoverable axial strain. The most usually used method to determine such property of M_r is using the repeated load triaxial test with a closed loop servo

pneumatic loading system (AASHTO, 1993; NCHRP, 2004). However, most of the results from laboratory tests generally run into difficulties: size limitations, disturbance, and actual maintenance effects (Duan et al, 2019). Instead, the in situ tests can provide more direct and accurate results, thus, several attempts were made to determine and understand the behavior of resilient modulus property based on different soil properties (Mohammad et al. 2002; Tarawneh et al. 2014; Liu et al., 2016; Heidaripanah et al., 2017; Ghorbani et al. 2018).

In fact, some empirical correlations between M_r and other test indices such as undrained shear strength, unconfined compressive strength, and California Bearing Ratio (CBR) has been established. Additionally, the in situ testing indices are also very well-received when related the indices to M_r. Among these in situ tests, the cone penetration test (CPT), especially for the piezocone penetration test (CPTU) is treated as the most accurate method that have the advantage of near-continuous, repeatable measurements that provide a detailed profile of the subsurface soil layers (Ghorbani et al. 2018). The past studies have confirmed that the M_r is a function of CPT measured parameters (cone tip resistance (q_c), sleeve friction (f_s)), moisture content (w), applied stress and confining pressure (Mohammad et al., 2007). several empirical correlations have been proposed that related to M_r to soil properties, stress states, and CPT testing indices (Mohammad et al. 2002; Liu et al. 2016; Ghorbani et al., 2020). However, the it appears that most prior studies suggested the empirical correlations may be limited to site-specific conditions due to rather selective and limited in-situ data obtained from only a few sites. Moreover, the studies related to CPTU indices are very limited (Liu et al. 2016; Ghorbani et al., 2020).

With recent advances in computational software and hardware (Zhao et al., 2021a), the use of the artificial neural network (ANN) method as a statistical regression technique to approximate input-output relationships in geotechnical engineering has gained impetus for its ability to effectively deal with the complex relationships in recent years (Juang et al., 1999; Zhao et al., 2021b). However, the major drawback of ANN is that the detected dependencies are hidden in the ANN structure, and the correlations are often not expressed intuitively (Duan et al., 2021a). The group method of data handling (GMDH) type neutral network is a polynomial neural network that using a powerful identification technique to model complex relationships between multiple variables (Moayed et al., 2017). Hence, in the present study, the GMDH model is proposed for predicting M_r based on these parameters of cone tip resistance (q_t), sleeve frictional resistance (f_s), dry density (γ_d) and moisture (w).

In this present study, the feasibility of the GMDH algorithm to predict the M_r of cohesive subgrade soils has been conducted. Details of the development of various GMDH-type network models for in-situ

M_r evaluation have been presented. A comparison of the predictions from the existing empirical correlations are presented in detail. Salient findings and conclusions are shown based the above results and analysis.

2 GMDH ALGORITHM

The GMDH algorithm an inductive self-organizing approach to estimate black-box models with an unknown correlation between variables. The kernel of GMDH is to build an analytical function in a feed-forward network based on a quadratic node transfer function and use regression technique to determine the coefficients of partial quadratic polynomials (Duan et al. 2021a). Assume y_i and $\hat{y}_i$ represent the actual output and predicted outputs of GMDH neural network, respectively.

For a given input vector $x_i = [x_{i1}, x_{i2}, \ldots, x_{in}]^T$, $i = 1, 2, \ldots, M$, the mathematical relationship between the input and the output variables of GMDH neural network can be simplify expressed by a system of partial quadratic polynomials consisting of only two variables (neurons) as

$$\hat{y} = G(x_i, x_j) = a_0 + a_1 x_i + a_2 x_j + a_3 x_i x_j + a_4 x_i^2 + a_5 x_j^2 \tag{1}$$

The coefficients of each quadratic function (G) can be obtained for an optimal fit for the output in the input-output data pairs. The optimal fit is based on the least root mean square error (RMSE) described as:

$$\text{RMSE} = \sqrt{\frac{1}{M} \sum_{i=1}^{M} (\hat{y}_i - y_i)^2} \tag{2}$$

The purpose of GMDH neural network is to determine the coefficient a_i in Eq. (1) to minimize the RMSE by regression techniques. A number of partial descriptions are formed based on all possibilities of obtaining the output variable from two independent variables to construct the regression polynomial that best fits the dependent observations (y_i, $i = 1, 2, \ldots, M$). The normal equations can be solved using the least squares method as follows:

$$\boldsymbol{a} = (A^T A)^{-1} A^T Y \tag{3}$$

where $\boldsymbol{a} = [a_0, a_1, a_2, a_3, a_4, a_5]^T$ is the vector of unknown coefficients of the quadratic polynomial in Eq. (1); $Y = [y_1, y_2, y_3, \ldots, y_M]^T$ is the vector of output values from observation. The best estimation of the coefficients in Eq. (1) from the whole set of M data triples can be determined through the Eq. (3).

3 DATABASE

3.1 *Site description*

Geotechnical investigations were conducted in Jiangsu Province, China and sixteen (16) different test sites are investigated and considered in this study as shown in the Figure 1. The geological formations of Quaternary clays mainly contain Marine, Yangtze River Delta, Floodplain of Long River, Floodplain of Abandoned Yellow River, Lagoon of Lixia River and Lagoon of Taihu Lake. Based on the previous analysis, the subsoil profile in these test sites mainly clay deposits.
Figure 1. Location of the testing sites.

3.2 *Laboratory tests and field CPTU tests*

Based on the soil samples from the testing sites, laboratory tests were performed to obtained the w, γ_d and M_r properties. The resilient modulus tests were conducted on the soil samples by repeated load triaxial tests. The CPTU soundings have been conducted at the adjacent locations near the boreholes where the soil samples were collected to ensure the predicted M_r value with the in-situ stress level. In the next section, the CPTU technique along with representative profile is presented.

CPTU field tests were conducted using a light-weight truck with a 20-ton-capacity hydraulic system, which is in accordance with international standards (Lunne et al., 1997; ASTM D5778, 2012; Duan et al., 2021b). The sizes of the CPTU probe are as follows: The section area of the cylindrical cone penetrometer is 10 cm^2 with a tip angle of 60°, the surface area of the friction cylinder is 150 cm^2. The penetration rate was set as 20 mm/s, and nearly continuous data were produced at intervals of about 50 mm. Compared with CPT, the pore pressure can be measured simultaneously and the ground water table (GWT) can be identified based on CPTU test. Based on the test results, the GWT value varied with the range of 0.4 m to 4.5 m. Figure 2 shows a typical profile of the SCPTU sounding. Thus, a database of 124 data sets

including q_c, f_s, w, γ_d and M_r is compiled and used for the following analysis.
Figure 2. Typical profiles of piezocone penetration test.

4 CONSTRUCTION OF GMDH MODELS

4.1 *GMDH models development*

The data points can be separated into three subsets in the ratios of 7:2:1 for training, testing, and validation. Actually, the subsets of testing and validation are always merged into one. Thus, the data sets separated with a ratio of 7:3 for the training and testing (including validating), respectively. Of the 124 data sets, 87 data points were randomly selected for the training while 37 data points were used only for validating the developed models. In the present study, four variables (q_c, f_s, w, γ_d were considered to demonstrate the prediction ability of the GMDH network. Three categories are considered as follows: i) w, γ_d; ii) q_c, f_s; iii) q_c, f_s, w, γ_d. The relative root mean square error (RRMSE), absolute fraction of variance (R^2) are utilized for the performance evaluation of GMDH models.

4.2 *GMDH models results*

The values of the RRMSE, and R^2 for each model are listed in Table 1. It can be observed that all developed GMDH models have shown relative good performance. Comparing the performance of model 1 using soil indices from laboratory tests, the predicted performance has been improved using the CPT parameters based on the results of model 2. The CPT parameters seems to be more useful in predicting M_r values. From the perspective of performance evaluation, model 3 was found to be the best among other GMDH models. This is not surprise because the input parameters are comprehensive and GMDH has strong predictive ability. Thus, the accuracy of predictions can be consistently improved if more indices are involved in the GMDH model.

Table 1. Performance of GMDH models in predicting M_r in testing dataset.

Model	Inputs	RRMSE	R^2
1	w, γ_d	0.5571	0.6896
2	q_c, f_s	0.4730	0.7762
3	q_c, f_s, w, γ_d	0.1314	0.9827

Based on the analysis, the specific equations are presented subsequently.

1) Model 1

$$M_r = 140.9416 - 8.3239\gamma_d - 2.3476\omega$$
$$+0.02757\omega \cdot \gamma_d + 0.3018\gamma_d^2 + 0.01661\omega^2 \quad (4)$$

2) Model 2

$$M_r = 9.7980 + 386.2597f_s - 0.5083q_c + 65.5731q_c \cdot f_s$$
$$- 1902.9274f_s^2 + 2.0608q_c^2 \quad (5)$$

3) Model 3

$$M_r = 27.5607 + 0.7400X_2 - 4.3630\gamma_d + 0.02173\gamma_d \cdot X_2$$
$$- 0.001522X_2^2 + 0.1606\gamma_d^2 \quad (6-1)$$

$$X_2 = 2.8207 + 0.3640X_1 + 89.3235f_s + 2.08785f_s \cdot X_1$$
$$+0.003977X_1^2 - 26.5075f_s^2 \quad (6-2)$$

$$X_1 = 44.5084 - 1.1459\omega + 21.8014q_c$$
$$- 0.09932q_c \cdot \omega + 0.009240\omega^2 - 1.6703q_c^2 \quad (6-3)$$

Taking model 2 as an example, the targeted values (scatter points in red) and predicted curved surface values (colored) using Eq. (5) is shown in Figure 3. It can be observed that the data points of targeted values are closed to the curved surface and they are uniformly distributed on both sides of the predicted curved surface, indicating the ease and practicability of the GMDH model using CPT parameters (q_c, f_s). Thus, under the condition that the accuracy requirement is satisfied, model 2 can be chosen as an option for its simplicity, whereas model 3 is a better choice when high precision is required.

The points scatter of predicted (calculated by GMDH model 3 along with model 1 and model 2) versus targeted ψ values has further demonstrated the accuracy of resilient modulus evaluation using
Figure 3. Correlation of M_r with q_c and f_s using GMDH model 2.
Figure 4. Comparison between targeted M_r and predicted M_r.
Figure 5. Variation in the relative errors obtained from GMDH method (Model 3).

GMDH model 3 (Figure 4). Compared with model 1 and 2, the predicted points by GMDH model 3 are closer (near 1:1 line) to those targeted values. Thus, the GMDH model 3 was considered as the GMDH method for predict the resilient modulus of subgrade

soils. Overall, the predicted values by the GMDH models are smaller than the targeted values, which will lead to conservative engineering design.

Figure. 5 Plots the relative errors (defined as the percentage difference between the GMDH predicted and the targeted values) for the training and testing sets. Observely, most of the GMDH estimations of the data patterns for model 3 fell within $\pm12\%$ of the targeted values. Overall, it is feasible to apply GMDH method to evaluate the resilient modulus of subgrade soils.

5 CONCLUSIONS

In this study, the feasibility of GMDH polynomial neural networks in modeling a regional database containing Quaternary clay from different geologic formations in Jiangsu province, China. Three GMDH models using all or part of the parameters including M_r at the in-situ stress condition, CPTU indices (q_c, f_s), and laboratory indices (w, γ_d).

The relative good prediction results are obtained from all GMDH models and it is confirmed that the GMDH is capable of effectively capturing the non-linear relationships. The most significant advantage for GMDH is that specific expressions can be given in predicting geotechnical parameters. Among three types of GMDH models, model 3 including q_c, f_s, w and γ_d is selected as the GMDH method for its high accuracy.

Effect of sand bio-cementation on cone tip resistance: A numerical study

M.El Kortbawi, K. Ziotopoulou & J.T. DeJong
University of California, Davis, CA, USA

D.M. Moug
Portland State University, Portland, OR, USA

ABSTRACT: Understanding the effect of soil cementation on cone measurements is important for the identification of naturally cemented soil deposits and for the verification of soil improvement achieved by various forms of artificial cementation, including bio-cementation. This paper presents the results of an effort to connect cone tip resistances with fundamental, constitutive level, bio-cementation-induced changes in soil behavior. To this end, a direct axisymmetric cone penetration model using the Mohr-Coulomb constitutive model and grid rezoning and remapping algorithms is used to model cone penetration in bio-cemented sands. By connecting the results of cone penetration simulations in a Mohr-Coulomb material to real data and established relationships, this work will guide selection of equivalent strength properties of these challenging materials. More specifically, the apparent cohesion, peak friction angle, dilation angle, and small-strain shear modulus within the Mohr-Coulomb constitutive model are varied parametrically across a reasonable range of parameter values informed by past laboratory, bench-scale, and centrifuge tests. Results show that cone penetration resistance in bio-cemented sands is mostly influenced by the interconnected apparent cohesion and the small-strain shear modulus, while other parameters play a secondary role.

1 INTRODUCTION

The cone penetration test (CPT) is a widely used field test for soils in subsurface explorations due to its ability to provide continuous information on the stratigraphy, and to be correlated to physical and engineering properties of the subsurface strata (e.g., Robertson & Campanella 1983, Lunne et al. 1997, Robertson 2016). While the CPT has been mostly used for the characterization of sands and clays, it may also be used for the identification of naturally cemented soils deposits (e.g., Puppala et al. 1995, Roy 2008) and artificially cemented and improved soils, including bio-cemented ones (e.g. Gomez et al. 2018, Darby et al. 2019).

Bio-cementation is a relatively new ground improvement technique in which microorganisms present in the soil are stimulated under specific conditions to precipitate calcite which coats and bridges soil particle contacts. The artificially precipitated calcite is analogous to natural cementation and can be considered as a proxy for naturally cemented sands (e.g., DeJong et al. 2006, DeJong et al. 2010). To date, the characterization of bio-cemented sands and, similarly, naturally cemented sands in the field remains a challenging task due to difficulties in sampling and its high cost.

Classification and characterization approaches for bio-cemented sands developed to date have been primarily derived through empirical analyses of field data obtained in cemented soils, although some full scale 1-g and reduced scale centrifuge modeling data are also available. Therefore, the CPT has been proposed as a field test able to overcome the limitations of sampling and to provide direct indications of the presence of the cementation in the field. In general, the cone tip resistance and the shear wave velocity both increase with cementation, which suggests the development of a framework relating these two parameters as an indicator of possible cementation. Currently, such a framework is not available for the interpretation of the CPT data and their correlation to soil strength parameters for bio-cemented sands.

This paper presents the results of an effort to connect cone tip resistances with fundamental, constitutive level, bio-cementation-induced changes in soil behavior. To this end, a direct axisymmetric cone penetration model using the Mohr-Coulomb constitutive model and grid rezoning and remapping algorithms (Moug 2017) is used to model cone penetration in bio-cemented sands. By connecting the results of cone penetration simulations in a Mohr-Coulomb material to real data and established relationships, this work will guide selection of equivalent strength properties of these challenging materials. More specifically, the apparent cohesion, peak friction angle, dilation angle,

and small-strain shear modulus within the Mohr-Coulomb constitutive model are varied parametrically across a reasonable range of parameter values informed by past laboratory, bench-scale, and centrifuge tests.

The axisymmetric penetration model is briefly introduced, followed by a summary of the equivalent Mohr Coulomb input parameters. Simulation results are presented, interpreted, and compared against a published soil behavior type chart as well as experimental data from a reduced scale centrifuge model test. Conclusions pertaining to the validity of the proposed framework and the results are drawn.

2 NUMERICAL INVESTIGATION

2.1 *Axisymmetric penetration model*

The axisymmetric model presented in Figure 1 simulates the steady-state penetration of a standard 10 cm^2 (3.57 cm-diameter) cone into the soil column. Boundary conditions are imposed for a soil flowing into the bottom of the model upwards relative to a fixed cone. Mohr-Coulomb interface elements are applied at the interfaces between the cone and soil to represent an interface roughness factor of 0.60, which is the ratio of the interface friction angle to the soil friction angle. Stresses and Mohr-Coulomb material properties are initialized for a "wished-in-place" condition at the depth of interest. Initial stress conditions correspond to an at-rest K_o condition and a fully drained penetration is simulated. The cone penetration is velocity-controlled at the gridpoints across the top boundary. The right radial boundary is far enough from the cone to avoid any boundary effects and is thus defined as an infinite elastic boundary. The bottom boundary is sufficiently far from the cone's zone of influence to maintain the prescribed in-situ stress conditions. Large deformations are handled with a user-implemented Arbitrary Lagrangian-Eulerian (ALE) algorithm which performs grid rezoning and remapping during the cone penetration. Penetration is simulated until a steady state penetration resistance is achieved (Moug et al. 2019), which is approximately 25 cone diameters of penetration.

2.2 *Input parameters and calibration*

The application of bio-cementation treatment to sands, as well as the geologic-time scale process where sand is gradually cemented, induce changes in the stiffness and strength. While difficult to characterize in the field, coupling the simulated cone tip resistance in a Mohr-Coulomb type of material and established relationships can guide the selection of equivalent strength parameters for these challenging geomaterials. The Mohr-Coulomb constitutive model was selected because it defines a failure envelope with a cohesion intercept and a peak friction angle which can be representative of bio-cemented sands. More broadly, it is a simple

model with few parameters and nicely describes a broad range of responses without unnecessary complexities. Based on numerous bench-scale and large-scale experiments on bio-cemented sands, a linear relationship between the "apparent" cohesion (c) and the change in shear wave velocity (ΔV_s) was developed to estimate the value of cohesion from the measured post-cementation in-situ V_s (El Kortbawi et al., under review).

$$\Delta V_s = 18.9c \qquad (1)$$

where ΔV_s = the change in shear wave velocity in m/s and c = the "apparent" cohesion in kPa.

Following an extensive literature review on bio-cemented sands (e.g., Nafisi et al. 2019, Nafisi et al. 2020, Wu et al. 2020) and using the above empirical relationship, the values for the input parameters in Table 1 was defined.
Figure 1. Geometry and boundary conditions of the numerical cone penetration model (Moug, 2017).

Table 1. Variables for parametric study.

Variable	Tested values
Cohesion, c (kPa)	0, 10, 20
Friction angle, ϕ (degrees)	30, 35
Dilation angle, ψ (degrees)	0, 10
"Functional" shear modulus, G_{sec} (kPa)	Based on the relationship between ΔV_s and cohesion
Confining stress, σ_{vo} (kPa)	35, 100

Due to the large strains around the penetrating cone, the small-strain shear modulus (G_{max}) as an input model parameter does not reflect the complex deformations and strain softening in the plastic region near the cone tip which would result in an overestimation of the cone tip resistance (Teh & Houlsby 1991, Lu et al. 2004). Therefore, a reduction factor is applied to G_{max} (where $G_{max} = \rho V_s^2$ and ρ is the density) to account for the shear modulus softening and a secant shear modulus (G_{sec}) is used, where $G_{sec} = G_{max}/F$ and $F = 0.15\ c + 3$ based on a calibration process and comparison of simulated cone penetration with experimental results (El Kortbawi et al., under review). The chosen initial V_s ($V_{s,ini}$) values normalize with respect to the varying confining stresses of 35 and 100 kPa, hence the results of these simulations are examined in absolute terms such as q_c instead of incremental terms (Δq_c).

The input to each set of simulations is summarized in Tables 2 and 3 for the confining stresses of 35 and 100 kPa, respectively.

Table 2. Simulation input parameters for $\sigma'_v = 35$ kPa.

	Cohesion (kPa)		
	0	10	20
$V_{s,ini}$ (m/s)	150	150	150
ΔV_s (m/s)	0	189	378
Reduction factor F	3	4.5	6
G_{sec} (kPa)	12,750	43,149	78,262

Table 3. Simulation input parameters for $\sigma'_v = 100$ kPa.

	Cohesion (kPa)		
	0	10	20
$V_{s,ini}$ (m/s)	200	200	200
ΔV_s (m/s)	0	189	378
Reduction factor F	3	4.5	6
G_{sec} (kPa)	22,667	56,814	93,783

3 RESULTS

The focus of the subsequent analyses and illustrations is the cone tip resistance q_c. Open and closed symbols correspond to confining stresses of 35 and 100 kPa, respectively. Circle and square symbols correspond to friction angle of 30 and 35 degrees, respectively. Figure 2a presents the variation of the absolute q_c with an increasing shear stiffness (proportional to V_s according to $G_{max} = \rho V_s^2$), friction angle, and confining stress at a dilation angle

of 0°. Figure 2b illustrates the change in q_c with the change in V_s due to the presence of a cohesion (Eq.1) for the given combinations of stress states and friction angles. Figure 2c illustrates the effect of the confining stress on q_c by normalizing it according to $Q_t = (q_t - \sigma_{vo})/\sigma'_{vo}$. Collectively, these figures confirm that: (1) the cone tip resistance increases considerably with the increase in the cementation level, (2) the change in q_c is due to the changes in cementation only, and (3) the "cemented" friction angle may have an effect on the increase in q_c but to a lesser extent than the shear stiffness.

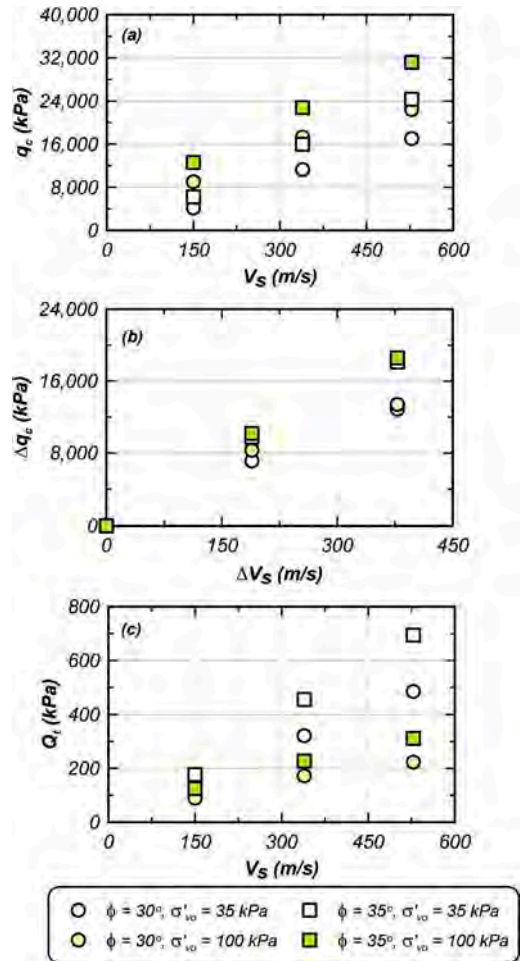
Figure 3 Presents the variation of the tip resistance as a function of the confining stress with varying strength parameters, cohesion from 0 to 20 kPa, and friction angle from 30 to 35 degrees. Circle and


Figure 2. (a) Variation of q_c as a function of V_s, (b) variation of Δq_c with varying ΔV_s, and (c) variation of normalized Q_t as a function of V_s, for varying ϕ of 30° and 35° and different confining stresses at ψ of 0°.

square symbols correspond to friction angles of 30 and 35 degrees, respectively, whereas the shading corresponds to increasing the cohesion from 0 to 20 kPa.

Similar to Figure 2, a positive trend exists between q_c and σ_{vo} where the following observations are made: (1) for σ'_{vo} =35 kPa, q_c for c = 20 kPa is around 4 times the q_c for c = 0 kPa, whereas for a higher σ_{vo}= 100 kPa, this ratio decreases to 2.5 times regardless of the friction angle, (2) for c = 0 kPa, q_c for σ'_{vo}= 100 kPa is around twice the q_c for σ'_{vo}= 35 kPa, whereas for c = 20 kPa, this ratio decreases to 1.3 times regardless of the friction angle, and (3) for σ_{vo}= 35 kPa, q_c for ϕ = 35º is around 1.5 times q_c for ϕ = 30º whereas for σ'_{vo} =100 kPa this ratio slightly decreases to 1.4 times, regardless of the cohesion. These observations suggest that: (1) cohesion is the major contributor to the enhanced tip resistance, followed by the confining stress, and then followed by the friction angle, and (2) the effect of the cementation is more significant at low confining stress.
Figure 3. Variation of q_c as a function of σ_{vo} for varying ϕ and c at ψ of 0º.

Figure 4 Incorporates, in addition to the cohesion, friction angle and confining stress, the effect of the dilation angle ψ. Figures 4a and 4b correspond to ϕ = 30º and 35º, respectively, and the diamond and triangle symbols correspond to a ψ of 0º and 10º, respectively. The results show that the increase in the dilation angle leads to a larger cone tip resistance, due to stronger dilation of the soil which in turn results in a higher resistance of the soil to shearing. The q_c with a ψ = 10º (a limit for bio-cemented sands suggested by the literature e.g., Wu et al. 2020) is 3 to 4 times higher relative to q_c with a ψ = 0º, depending on the strength parameters with this ratio increasing for a higher confining stress (σ_{vo} of 100 kPa).

The current state of practice uses previously established charts for the interpretation of CPT data

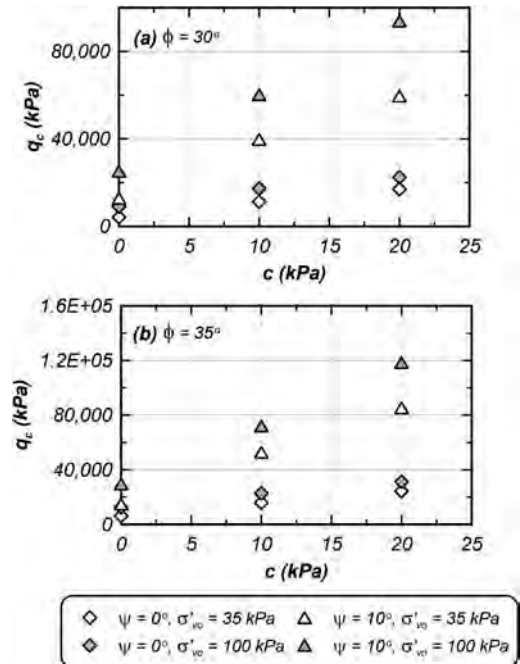
and classification of soils which include cemented sands. As the change in shear stiffness plays a major role in the behavior of bio-cemented sands and cemented sands in general, the small-strain shear modulus G_{max} and the stress-normalized cone tip resistance Q_t can be correlated to guide the soil behavior type and extend it to these cemented soils. Figure 5a presents the simulation results for the different scenarios. In addition to the simulation results from this work, experimental data obtained from cones pushed in a bio-cemented specimen in a centrifuge model (Darby et al. 2019) are plotted. Several levels of cementation were established by the experimentalists targeting light, moderate, and heavy cementation levels. The datapoints from the cones pushed in treated sands plot reasonably within the region corresponding to soils with "ageing cementation", with few datapoints plotting close to the "uncemented" region due to their light level of cementation (Darby et al. 2019). Specimens with higher levels of cementation follow the trend discussed earlier. Moreover, Figure 5a shows that the simulation results for σ'_{vo}= 35 kPa fall within the range of the experimental data from Darby et al. (2019) with a similar confining stress of 35 kPa, hence validating the proposed approach.


Figure 4. Variation of q_c as a function of c for varying ψ and σ'_{vo} at, (a) ϕ of 30º, and (b) ϕ of 35º.

The CPT-based classification chart according to Q_t and G_o/q_t is reproduced in Figure 5b and the simulation and experimental results are overlaid.

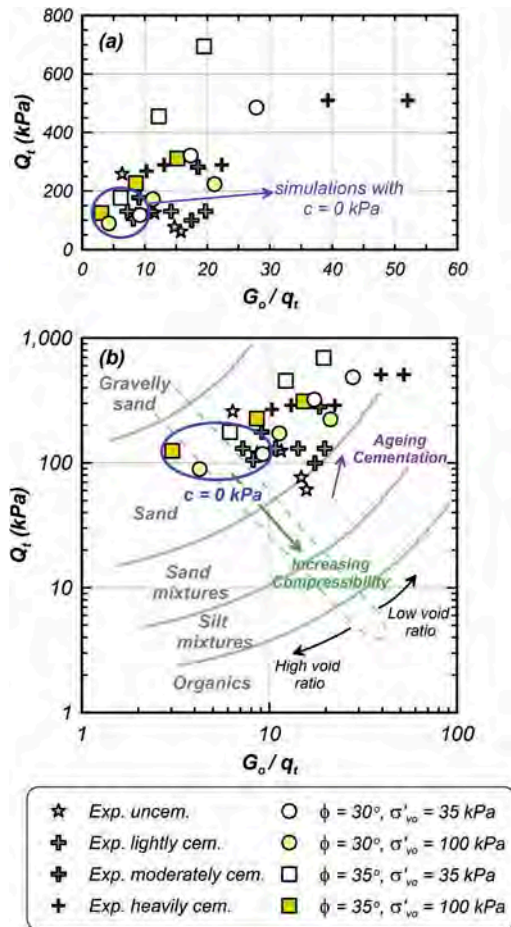
Figure 5b shows a reasonable agreement between the expected soil behavior from the input parameters (i.e., uncemented sands with zero cohesion versus cemented sands with nonzero cohesion) and the suggested soil behavior from the chart. For example, the simulations with $c = 0$ kPa plot in the "sand" behavior type on the chart as expected for a cohesionless uncemented sand. Similarly, the simulations with $c > 0$ kPa plot in the region corresponding to soils with "ageing cementation" on the chart. Moreover, the aforementioned relative magnitude of Q_t and G_o/q_t between the cemented sands and the uncemented sand is also evident on the soil classification chart.


Figure 5. Soil classification chart based on normalized cone resistance and small-strain shear modulus, reproduced from Lunne et al. (1997), and overlaid with simulation results from this work and experimental data from the centrifuge test from Darby et al. (2019).

The results suggest that as cohesion increases, i.e., the level of cementation precipitated at the particle contacts increases, the soil moves vertically towards a higher normalized tip resistance and laterally to a higher normalized stiffness. When other parameters remain constant, increasing the friction angle results in a larger q_c hence the soil moves vertically towards a higher normalized tip resistance but horizontally towards a smaller normalized stiffness due to the normalization with q_c.

4 CONCLUDING REMARKS

The cone penetration test has been commonly used in soils to indicate the soil behavior type and to assess the soil's resistance in bearing capacity and liquefaction mitigation applications. Its use can be extended to bio-cemented or cemented sands. Some limitations are associated with pushing cones in cemented sands, such as the inability of the cone to detect light cementation (equivalent to calcite content less than 3%) and the destructive nature of the test to any pre-existing cementation in the soil. However, it is still a common and valuable test able to provide proxies of the expected soil behavior and its degree of cementation in the absence of more viable exploration methods.

In this paper, a parametric study on the input parameters to an axisymmetric cone penetration model for sands was presented in the context of its application to bio-cemented sands. The numerical model implemented the Mohr-Coulomb constitutive model which was used to estimate equivalent "cemented" strength parameters. Although the Mohr-Coulomb constitutive model prescribed constant strength parameters to strain-dependent soil conditions, the approximation with a "functional" shear modulus allows the model to reasonably predict the elastic-plastic behavior of bio-cemented soils in the failure zone near the cone tip. The input parameters varied in this paper are the cohesion, friction angle, dilation angle, and confining stress. The results were analyzed in terms of cone tip resistance, and the study confirmed that it increased with increasing the level of cementation, and suggested that the cohesion value is the main contributor to this improvement in the soil resistance. The dilation and friction angles also affect the soil's resistance but to a lesser extent. Simulation results were also compared to experimental data from CPTs pushed in bio-cemented sands and to previously established soil behavior type charts for "unusual" soils. The simulation results fell within the range of the experimental data and they both plotted in the "ageing cementation" region of the chart. Hence the proposed framework appears reasonable to estimate the soil's strength and overcome the challenges in sampling cemented sands.

Oftentimes, considerable effort is put into the selection of input parameters for numerical models. The above observations related to the effect of input parameters on the cone tip resistance are insightful for prioritizing the choice of input parameters and

can be potentially used to guide parameter selection for numerical models, based on CPT data, to represent cemented materials in numerical simulations.

The ranges of input parameter values used in this study reflect the typical ranges found in the literature for lightly and moderately bio-cemented sands. The trends presented here may be cautiously extrapolated to reasonably higher strength parameters and confining stresses; however, the relative magnitudes may warrant further exploration.

In the developing field of bio-cemented sands, numerical models that are validated and calibrated against existing data can be leveraged to populate and synthesize data that are not yet available. While some approximations such as the estimation of the cohesion value and the reduced secant shear modulus are made herein, the numerical model is still a valuable tool to, in the first stage, study the sensitivity of the results to input parameters and, in the second stage, synthesize data needed to develop correlations between these various parameters. El Kortbawi et al. (under review) extend this work to develop a correlation between the cone tip resistance and the cohesion in order to implement it in a plasticity constitutive model for bio-cemented sands.

Adding to the importance of the CPT in indicating the behavior of the present soil, it can and should be a preferred method for post-cementation verification in the field. The CPT can thus serve as a tool in the design of ground improvement methods and in the QA/QC of the final improvement, especially in the field of bio-cementation ground improvement techniques.

A data-driven approach to predict shear wave velocity from CPTu measurements

I. Entezari & J. Sharp
ConeTec Group, Burnaby, British Columbia, Canada

P.W. Mayne
Georgia Institute of Technology, Atlanta, Georgia, USA

ABSTRACT: The use of machine learning modelling to predict shear wave velocity (V_S) from piezocone penetration tests (CPTu) is presented. A large dataset of paired V_S-CPTu data (n = 104,054) compiled from seismic piezocone (SCPTu) soundings completed in a wide variety of soil types with various stress histories and geological environments was used to develop machine learning models to directly estimate V_S from CPTu data. The impact of soil microstructure on the results was investigated and separate models were developed to predict V_S in cemented and uncemented soils. The results of machine learning models outperformed the existing widely used CPT-based relationships to predict V_S.

1 INTRODUCTION

Shear wave velocity (V_S) is an important property of geomaterials and is widely used to evaluate the dynamic and elastic properties of soils in geotechnical design. V_S measurements provide the fundamental stiffness of the ground in terms of the small-strain shear modulus (G_o), specifically: $G_o = \rho V_S^2$, where $\rho = \gamma_t/g_a$ = soil total mass density, γ_t = soil total unit weight, and g_a = gravitational acceleration constant.

V_S measurements can be obtained using a variety of test methods. The value of V_S can be measured in the laboratory using high quality undisturbed samples and special equipment (resonant column, bender elements), which is costly and restricted to a limited number of samples. In-situ measurements of V_S are preferable to preserve site-specific conditions and minimize errors due to sampling disturbance and stress release.

In-situ measurements of V_S can be obtained through downhole and crosshole tests, seismic piezocone tests (SCPTu), spectral analysis of surface waves (SASW), and multichannel analysis of surface waves (MASW). SCPTu method is often preferred as it is a rapid and cost-effective technique to measure in-situ wave velocities in conjunction with CPTu parameters, including cone tip resistance (q_t), sleeve friction (f_s), and dynamic porewater pressure (u_2) in a single direct push sounding.

Although performing site-specific testing is the preferred method to determine shear wave velocity, several empirical relationships have been developed to estimate V_S from the basic CPTu for lower risk projects. When actual measurements of V_S are not practical, estimates can still provide useful additional information. Existing empirical CPT relationships for V_S have been developed using statistical approaches. This paper explores the use of a data-driven approach via machine learning modelling to predict V_S from CPTu. Machine learning requires little or no priori assumptions to be considered and thus are more flexible than statistical models.

The development dataset used in this study is comprised of V_S-CPTu data pairs from ConeTec SCPTu soundings collected from 2017 to early 2021. The soundings have been completed in a wide variety of soil types with various stress histories and are from geological environments around the world. The dataset is tested with a random forest algorithm to develop a model for the prediction of V_S from CPTu data. The results of the machine learning models are compared to empirical equations proposed by Mayne (2006) and Robertson (2009). Furthermore, the impacts of soil microstructure and cementation on estimated V_S results are discussed and separate models are developed for the categories of uncemented and cemented soils.

2 BACKGROUND

2.1 Seismic Piezocone Tests (SCPTu)

The SCPTu is similar to the CPTu probe with the addition of one or more geophones or accelerometers located behind the cone tip. As shown in Figure 1, the equipment required to perform SCPTu includes the
Figure 1. Schematic of seismic CPTu equipment.

seismic source on the ground surface, seismic sensors behind the cone probe, a data-acquisition system, and a data recording trigger circuit (Styler et al. 2016).

The seismic testing is conducted at selected depth intervals (typically every 1m), while the penetrometer is pushed into the ground. The shear waves are generated by striking a horizontal beam pressed firmly against the ground. Paired left-and right-strikes are used to define either the first arrival time of shear waves, or first crossover, or both. V_S is calculated using the difference in arrival times of the shear wave traces between the source and geophone at two successive depths. The SCPTu has several advantages including cor-related V_S and CPTu results, the capability to do deep tests, the ability to measure compression wave velocity (V_P), and availability of soil prop-erty interpretations based on small-strain rigidity index ($I_G = G_o/q_{net}$, where q_{net} is cone net tip resistance).

2.2 Existing CPT relationships

Relationships between CPT data and V_S have been studied previously by various researchers. Hegazy & Mayne (1995) developed various expressions to esti-mate V_S using parameters including tip resistance (q_c), sleeve friction (f_s), vertical effective stress (σ'_{vo}), and in-situ void ratio (e) for Quaternary clays, sands, and mixed soils. Various relationships have also been pro-posed by Piratheepan (2002) for the estimation of V_S based on tip resistance (q_c), sleeve friction (f_s), vertical effective stress (σ'_{vo}), depth (z), and soil behaviour type index (I_c) for Holocene clays, sands, and other soils. Mayne (2006) showed a relationship where the V_S is a function of the sleeve friction (f_s) for Quater-nary soils. Another correlation developed by Andrus et al. (2007) for Holocene and Pleistocene soils is based on tip resistance (q_t), depth (z), soil behaviour type index (I_c), and a time factor depending on the soil

age. Robertson (2009) also developed a generalized soil relationship where V_S is a function of net tip resistance ($q_{net} = q_t - \sigma_{vo}$), total vertical stress (σ_{vo}), atmospheric pressure (σ_{atm}), and soil behaviour type index (I_c). An overview on some of the CPT relation-ships to predict V_S has been provided in Wair et al. (2012).

In this study, the estimated V_S results from the machine learning models are compared to the results obtained by the empirical expressions proposed by Mayne (2006) and Robertson (2009), shown in Equations 1 and 2, respectively:

$$V_s = 118.8 \log(f_s) + 18.5 \qquad (1)$$

$$V_s = \left[\left(10^{0.55 I_c + 1.68}\right)\left(q_t - \sigma_{vo}\right)/\sigma_{atm} \right]^{0.5} \qquad (2)$$

where V_S is in m/s in both equations, f_s is in kPa in Eq. 1, and σ_{atm} is in same units as q_t and σ_{vo} in Eq. 2.

2.3 Impact of soil microstructure

The existing empirical correlations developed for interpretation of CPT results have been generally developed using silica-based uncemented soils with little or no microstructure (Robertson 2016). There-fore, caution should be exercised when CPT based relationships are used in soils with microstructure. According to Robertson (2016), the empirical par-ameter, K^*_G, can be used to determine whether soils are cemented or not. K^*_G is calculated as $(G_o/q_{net})(Q_{tn})^{0.75}$ (Robertson 2016), where Q_{tn} is the normalized tip resistance. Soils with K^*_G of less than 330 are likely young and uncemented with little or no microstructure, while soils with K^*_G of greater than 330 can be classified as cemented and micro-structured soils.

The cemented versus uncemented soils are con-sidered in this study for the evaluation of the per-formance of the machine learning model. Furthermore, individual models are developed spe-cifically for uncemented and cemented soils.

3 DESCRIPTION OF DATASET

To investigate the potential of a data-driven approach to estimate V_S from CPTu data, a dataset of paired V_S-CPTu data was compiled using Cone-Tec's geospatial database. The database was queried to find the relevant information that resulted in 14,855 SCPTu tests worldwide with more than 248,500 V_S-CPTu data pairs. For this study, sound-ings collected after 2016 were selected in order to only utilize modern tests with increased quality con-trol. Procedural changes in ConeTec's SCPTu meth-odology yielded slightly higher accuracy in V_S measurements due to signal enhancement and signal

stacking after this date (Styler & Weemees 2016). Consequently, the dataset was reduced to 104,809 V_S-CPTu data pairs from 7171 independent SCPTu soundings worldwide. Most of the soundings are from North America, with additional contributions from various sites in South America, Australia, Europe, and Asia. To pair the CPTu parameters with V_S measurements at a given depth, the median of CPTu parameters over a window size equal to the V_S depth interval was calculated. Only depth intervals equal to or less than 1 m were considered to minimize variations due to potential soil heterogeneity. The CPTu parameters paired with V_S included corrected tip resistance (q_t), sleeve friction (f_s), porewater pressure (u_2) and depth (z) at each V_S measurement. Additional parameters including normalized tip resistance (Q_{tn}), normalized friction ratio (F_r), normalized porewater pressure (B_q), net tip resistance (q_{net}), total stress (σ_{vo}), and effective stress (σ'_{vo}) as well as small-strain shear modulus (G_o), small-strain rigidity index (I_G), and K^*_G were also calculated.

Calculation of a number of these parameters required the soil unit weight (γ). The machine learning model based on corrected tip resistance (q_t), sleeve friction (f_s), porewater pressure (u_2) and depth (z) developed by Entezari et al. (2021) was used to estimate unit weight at each depth. The measured equilibrium pore pressure profile of each SCPTu sounding, combined with the estimated unit weight profile, was used to determine in-situ vertical stresses.

Data points with net tip resistance (q_{net}) of less than 100 kPa were screened out to remove fluid-like tailings from the dataset. Also, data points with sleeve friction (f_s) of less than 1 kPa were screened out in order to remove data where the soil-sleeve friction was less than internal o-ring friction. The final dataset used included 104,054 V_S-CPTu data pairs. Table 1 lists the summary statistics of the paired dataset.

Table 1. Summary statistics of the V_S-CPTu dataset.

	Min	Max	Mean
V_S (m/s)	9	1000	251
q_t (MPa)	0.1	94.1	8.4
f_s (kPa)	1.0	1577	117.6
u_2 (kPa)	-87.2	5489	245.0
z (m)	0.3	129.6	17.3
σ'_{vo} (kPa)	0.1	2185	215.4

Total number of data pairs = 104,054.

3.1 Soils with microstructure

The plot of normalized tip resistance (Q_{tn}) versus small-strain rigidity index (I_G) for the dataset is shown in Figure 2. Accordingly, 63,740 data points

fall in the young and uncemented soils category (soils with little or no microstructure), where K^*_G is less than 330 (green points in Figure 2). Another 40,314 data points fall in the cemented soils category (soils with microstructure), where K^*_G is greater than 330 (blue points in Figure 2).

3.2 Training and test datasets

The dataset was split into training and test sets. The training set was used to calibrate the model whereas the test set was used to evaluate the model performance. The data collected from 2017 to 2019 was used as the training set and data collected in 2020 and early 2021 provided the test set. This allows for an unbiased performance evaluation of the model (a blind test) where the potential errors due to variation in stress histories and geological environments are taken into account. The number of paired V_S-CPTu data points for the training and test sets are listed in Table 2.
Figure 2. The dataset plotted in the Q_{tn}-I_G chart.

Table 2. Number of data pairs in the training and test sets.

	All	Uncemented	Cemented
Training set	73,010	45,386	27,624
Test set	31,044	18,354	12,690

4 MACHINE LEARNING MODELLING

Machine learning models acquire information from prior data, allowing the computers to discover predictive rules applicable for future data. Machine learning models are generally data-hungry and need large

datasets for training. In general, as more data become available, the more accurate and robust the predictions become. Machine learning is widely used in numerous disciplines and has gained interest in geotechnical engineering. Example applications of machine learning for CPT interpretations can be found in Erzin & Ecemis (2016), Reale et al. (2018), Wang et al. (2019), Erharter et al. (2021), Rauter & Tschuchnigg (2021), and Entezari et al. (2020, 2021).

In this study, the random forest algorithm (Breiman 2001) was employed to calibrate CPTu data to V_S measurements. It is one of the most widely used machine learning algorithms for classification and regression tasks. Random forest is an ensemble of several decision trees and thus overcomes the shortcomings of traditional decision trees, predominantly overfitting. The models here were trained using four input parameters including corrected tip resistance (q_t), dynamic porewater pressure (u_2), sleeve friction (f_s), and depth (z).

4.1 Performance evaluation

The performance of the random forest models is evaluated using the properties of the cumulative distribution function (CDF) of errors on the test set. The error is calculated as the discrepancy between the measured V_S from SCPTu and predicted V_S from the random forest models. The 50th percentile in the CDF is taken as the bias of the prediction. Assuming the errors follow a normal distribution, the CDF values at 15.9% and 84.1% correspond to ±1 standard deviation. The average of the two CDF values at 15.9% and 84.1% is considered as the overall error of the model.

To compare the performance of the machine learning models to existing CPTu expressions, similar performance evaluation is performed on the test set using the predicted V_S obtained from the equations proposed by Mayne (2006) and Robertson (2009).

5 RESULTS

5.1 All-soils model

An all-soil model was developed using the random forest model trained with all data points in the training set. The relationship between measured V_S from SCPTu and the estimated V_S from the random forest model is shown in Figure 3. This relationship is shown for the test set. The R^2 of the model on the test set was observed to be 0.58. The error analysis using CDF of errors showed that the bias and error of the estimated results are –8.5 and 49.5 m/s, respectively. The bias –8.5 m/s means that random forest model overestimates the measured V_S by 8.5 m/s overall. The error of 49.47 m/s means that 68.2% of the estimated V_S values fall within ±49.5 m/s of the measured V_S from SCPTu testing.

The performance of the model was also assessed on uncemented and cemented soils. When only uncemented soils were considered in the test set, the bias and error of the estimated V_S results are –23.4 and ±34.8 m/s, respectively. For cemented soils, the bias and error of the estimated V_S were observed to be 27.2 and ±62.8 m/s, respectively.

5.2 Uncemented and cemented soils models

Using the uncemented and cemented soil categories in the training set, two separate models were developed for the estimation of V_S in these types of soils. Figure 4 shows the relationship between the SCPTu measured and random forest predicted V_S for the fraction of the test set in uncemented soils. As can be seen, the correlation between estimated and measured V_S significantly improved compared to the all-soils model shown in Figure 3 (R^2 of 0.79 compared to 0.58). The bias and error of the estimated results were observed to be 0.6 and 28.2 m/s, respectively.
Figure 3. Relationship between measured and random forest estimated V_S on the test set using all soils.

Evidently, the random forest model is far better able to model the relationship between V_S and CPTu parameters in uncemented soils, compared to the all-soil scenario.

The results of the random forest model developed for cemented soils are also shown in Figure 4. The bias and error were observed to be -12.3 and 54.1 m/s, respectively. Compared to the all-soil model, this model performs better on cemented soils, but the bias and error are still high. This is presumably because microstructure can have a variety of impacts on CPTu parameters. Thus, the learnt relationship between V_S and CPTu parameters in

cemented soils of the training set may not be applicable on the cemented soils of the test set.

5.3 Existing relationships

Figures 5 shows the relationships between the estimated V_S calculated using the methods of Mayne (2006) and Robertson (2009) with the measured V_S using SCPTu on the test set. For the Mayne (2006) model, the bias and error were observed to be 12 and 68.6 m/s, respectively, when error assessment was done on all soils. When only uncemented soils were considered, the bias and error were dropped to -7.2 and

Figure 4. Relationships between measured and random forest estimated V_S of the uncemented (top) and cemented soils (bottom) in the test set when separate models were trained using uncemented and cemented soils in the training set.

52.5 m/s, respectively. The bias and error were calculated to be 51.1 and 82.8 m/s, respectively, on cemented soils.

In case of Robertson (2009) model, the bias and error were 21.5 and 64.3 m/s, respectively, on all soils in the test set. The bias and error were observed to be -6.1 and 50.3 m/s, respectively, for uncemented soils, compared to 69.2 and 57.8 m/s for cemented soils. Overall, it can be seen that these expressions perform better on uncemented soils, as expected. A summary of model performances is presented in Table 3. It should be noted that no limits were applied to the two existing methods because the intent was to compare the results to those obtained from the random forest models developed using a wide range of soil types. Limiting the range of applicable data to be used in the existing methods would be prudent and may result in a better average correlation and error.

Table 3. Performance of different models.

| Model | Bias±Error (m/s) | | |
	All Soils	Uncemented	Cemented
RF-All Soils	-8.5±49.5	-23.4±34.8	27.2±62.8
RF-Uncemented	NA	0.6±28.2	NA
RF-Cemented	NA	NA	-12.3±54.1
Mayne (2006)	12.0 ±68.6	-7.2±52.5	51.1±82.8
Robertson (2009)	21.5 ±64.3	-6.1±50.3	69.2±57.8

5.4 Example SCPTu Vs profile

An example SCPTu profile of V_S estimated using the random forest models developed in this study is shown in Figure 6. The estimated V_S values from the expressions of Mayne (2006) and Robertson (2009), as well as the measured V_S profile, are displayed along with the results of this study. The SCPTu sounding is from 2020 and is thus part of the test set. As evident, both all-soils and uncemented models are in agreement with the measured V_S. The uncemented model, however, shows less fluctuations and a better performance compared to the all-soils model. Both of these models appear to outperform the Mayne (2006) and Robertson (2009) models. The analysis of K^*_G revealed that the soils are uncemented for the whole profile except for depth ranges between 3.5-9 m and 15-17.5 m.

Figure 6. Example profile of V_S estimated from models developed in this study and existing relationships.

Figure 5. Relationships between measured vs. estimated V_S using Mayne (2006) (top) and Robertson (2009) (bottom) methods.

When a priori information on soil categories is available, the soil-specific models developed in this study could lead to better results than the all-soils model and the equations proposed by Mayne (2006) and Robertson (2009).

In future work, the dataset compiled in this study will be used to investigate the potential of machine learning algorithms to classify and identify cemented and uncemented soils from CPTu parameters. However, K^*_G of 330 as a threshold to distinguish cemented from uncemented soils has been determined empirically and may not be an absolute metric.

In addition to the models developed and presented in this paper, random forest models were trained by adding normalized tip resistance (Q_{tn}), normalized friction ratio (F_r), normalized porewater pressure (B_q), and effective stress (σ'_{vo}) to the input variables, but no significant improvements were observed.

6 DISCUSSION

In practice, a priori information on the soil microstructure is required in order to be able to employ soil-specific models developed in this study to estimate V_S (uncemented and cemented soils models). Determining the soils categories based on K^*_G is not practical without knowing V_S. Therefore, information on soil categories should be available from other sources such as previous SCPTu testing in the region under investigation or information on the geology of soils.

When such information is not available, the results of this study showed that the developed all-soils model performs better than the Mayne (2006) and Robertson (2009) models when CPTu is pushed in regions with both cemented and uncemented soils.

7 CONCLUSIONS

Machine learning models using a random forest algorithm were developed to directly predict V_S from CPTu data. A dataset of paired V_S-CPTu data compiled from 7171 SCPTu soundings completed at various sites with a wide variety of soil types, stress histories, and geological environments was used to develop machine learning models. Results showed that the all-soils model developed using random forest algorithm can estimate V_S with ±49.5 m/s error. The model developed for uncemented soils showed a significant improvement and could predict V_S with ±28.2 m/s error. The model developed for cemented soils achieved an accuracy of ±54.1 m/s. All the developed machine learning models outperformed the studied existing relationships from literature. Although actual measurement of V_S is always

preferrable, it appears to be more crucial when dealing with soils that have microstructure. The models developed are from a very large dataset compiled from SCPTu soundings from various geological regions and are therefore considered to be robust, however engineering judgement should always be exercised when using any empirical statistics or models.

Interpretation and comparison of CPT derived soil properties to static and cyclic laboratory tests on unique fine-grained soils in Western Washington and Oregon

B. Exley, A. Pyrch, J. Jacoby & B. Thunder
Haley & Aldrich, Inc., USA

ABSTRACT: CPT interpretation methods are evaluated against laboratory and in-situ methods to identify and evaluate the soil properties of multiple non-textbook soil deposits located in Western Washington and Oregon. These deposits include unique glacially overridden soils which are widespread in the Puget Sound region, as well as younger soils which vary widely in depositional history and stress history.

The glacially overridden deposits can be very thick and are heavily overconsolidated, often showing signs of fissures and slickensides when they are fine-grained, with SPT blowcounts frequently much larger than N=100 in coarse grained deposits. Based on the CPTs included in this paper, the fine-grained overconsolidated materials are typically identified by the CPT as sand-like and dilative, and generally have I_c values between 2.0 and 2.6 despite frequently having index properties which classify the soils as stiff to hard high plasticity clay. This paper documents the characteristics of these soils to facilitate identification of them by the CPT.

Additionally, the correlated strength, preconsolidation pressures, and cyclic resistance of the younger fine-grained soils are evaluated against laboratory testing methods. This includes documenting a site in Beaverton, Oregon with several CPTs paired with constant rate of strain consolidation laboratory tests and both monotonic and cyclic direct simple shear tests in the fine-grained Missoula Flood Deposits as part of a study on the susceptibility of the silt to liquefaction or cyclic softening.

1 INTRODUCTION

Western Washington and Oregon each consist of soil conditions which generally do not fall under the classical soils. The Puget Sound Lowlands in Western Washington generally are a deep basin that has been glacially overridden several times, with the most recent occurring approximately 15,000 years ago during the Vashon Stade of the Fraser glaciation (Booth & Goldstein, 1994). The glacially overridden soils were subjected to approximately 5,000 feet of ice (Easterbrook 1969), resulting in very dense and very hard soil deposits that engineers generally do not attempt to push CPTs in.

Holocene age deposits tend to be interlayered due to depositional environment and frequently consist of relatively silty sands or low plasticity silts. These characteristics generally make them difficult to collect and test using high quality undisturbed samples. When silt-rich, these soils do not behave like classical sand-like or clay-like materials.

2 GLACIALLY OVERRIDDEN SOILS

2.1 Fine-grained material

The glacially overconsolidated fine-grained soils in the Puget Sound Lowlands are known to widely vary in strength due to the presence of blocky texture and slickensides in zones. However, when intact, they exhibit significant strength and stiffness. Unfortunately, the soils are also brittle and easily sheared due to the rotary action of a pitcher barrel when undisturbed sampling is attempted. Accordingly, being able to reliably estimate the soil properties using the CPT presents significant value where the soils are intact. However, initial Soil Behavior Type screening tools generally describe the soils as having a more coarse-grained behavior than would be measured by traditional index testing.

This trend has been observed on multiple sites, with observed tip resistances in the fine-grained material often about 100 tsf or more with SBT index values of approximately 2 to 2.2. Documented on

Figure 1 are three CPT sounding results from a site which was located along Interstate 405 south of Bellevue, Washington (Site 1). Three CPTs were pushed into a likely glacially overconsolidated fine-grained material. However, the materials had lower q_t values than previously mentioned, ranging from about 50 to 75 tsf. The I_c index was generally about 2.2.
Figure 1. Site 1 basic CPT results.

The CPTs were advanced near existing borings which had index testing completed on the samples that identified the fine-grained soil as a high-plasticity clay (CH). A qualitative screening of the sounding shows large positive excess pore pressure values with B_q values generally between 0.3 and 0.5. Evaluating the soil type using a technique which considers pore pressure response (Schneider 2008), the CPT correctly identifies the material as a clay. An example of this is interpretation is shown on Figure 2 for HC-CPT-2-20.
Figure 2. Example schneider plot interpretation of HC-CPT-2-20.

Correctly identifying the material as a clay facilitates the use of appropriate methods to estimate design properties. The use of the modified Norwegian Institute of Technology (NTH) method (Ouyang & Mayne 2019) results in an interpreted friction angle of approximately 35 degrees, which is consistent with the results of consolidated undrained triaxial tests on undisturbed samples of similar clays in the region. This friction angle can then be used to refine the estimated preconsolidation pressure, resulting in a refined estimate as documented in Mayne and Miller (2021).

3 SUSCEPTIBILITY TO LIQUEFACTION OR CYCLIC SOFTENING OF RECENTLY DEPOSITED FINE-GRAINED SOILS

As previously noted, the Holocene aged fine-grained soils in the Pacific Northwest are commonly silt-rich with relatively low plasticity, and are characterized as "transitional" soils when using the SBT Index. This causes significant difficulties for consultants in identifying whether the material has a "sand-like" or "clay-like" behavior when subjected to cyclic loading. These soils do not consistently identify with an I_c>2.6, further confounding identification of them through traditional filtering methodology when assessing sand-like behavior. An in-depth study of these soils in the Pacific Northwest has been completed and is documented by the Oregon Department of Transportation (Dickenson et. al 2021). The study includes a publicly accessible database that is being continually updated with new data. Currently, the database includes over 300 cyclic tests targeted at evaluating the response of these silty materials to cyclic loading. In general, their findings show that the materials do not exhibit the significant degradation of shear stiffness and strengths that sands do as the porewater pressure increases. Gingery (2014) showed that, for sands with relative densities of less than 40%, sands tend to exhibit post-liquefaction accumulation of shear strains per cycle of approximately 2% per cycle. Conversely, while silts do accumulate shear strains during cyclic loading, the accumulated shear strain per cycle is typically much smaller. For example, a sample of the Columbia River Silt with a PI = 1 and an OCR = 1 accumulates approximately 0.7% shear strain per cycle for single amplitude shear strains larger than 3% (Dickenson et. al 2021). Further, unlike sands, these soils do not tend to show the large loss of strength following cyclic loading which imposes large pore pressure ratios (R_u) or single amplitude shear strains larger than 3%. Accordingly, the term "liquefaction" is misleading when used to describe response to cyclic loading of these soils. Documented herein is a case study of Willamette Silt encountered in Beaverton, Oregon (Site 2) with evaluation of the cyclic resistance of those soils relative to traditional liquefaction triggering methods.

Site 2 is a well-documented site that has had 19 CPTs advanced through the soil profile, as well as 21 traditional SPT borings and 24 test pits. In support of a recent seismic assessment of the site, several CPTs and borings were advanced (included in the totals above), the latter of which included undisturbed

samples used for advanced laboratory testing. The samples were collected and extruded using methods generally consistent with those recommended by Ladd & DeGroot (2003), including cutting and delaminating the soil from the tube to minimize sample disturbance during preparation of the sample for testing. In addition to index testing, constant rate of strain (CRS) consolidation testing, static direct simple shear testing (DSS), and cyclic direct simple shear testing (CDSS) was completed. The DSS and CDSS tests were completed using a SHANSEP type testing methodology to explicitly evaluate the effects of overconsolidation on the samples and attempt to overcome some of the impacts of sample disturbance that may have occurred during testing.

Fill materials, if encountered, ranged between approximately 2 and 15 feet thick and generally consisted of either reworked native silty/clayey soils or imported gravels. More significant thicknesses of fill were encountered on the south end of Site 2 in proximity to Cedar Mill Creek. Materials interpreted as native alluvium generally consisted of very soft clays underlying thicker fills in proximity to Cedar Mill Creek. The generally silty Missoula Flood deposits were encountered in all of the explorations near the surface or at depths of up to approximately 35 feet below ground surface (bgs) underlying fill and alluvium. All of Haley & Aldrich's explorations encountered high- to low-plasticity clay interpreted to be the Hillsboro Formation underlying the Missoula Flood deposits at approximately 22 to 75 feet bgs. All the explorations terminated in materials interpreted as the Hillsboro Formation down to approximately 101.5 feet, the maximum depth explored. While the layering is generally consistent across the site, there is significant intra-deposit variation across the site. Therefore, the assessment of an individual CPT is presented to simplify the case study. However, the results were broadly applicable across the site.

The basic results of CPT-6 are presented on Figure 3. The I_c index in the fine-grained soils is on average about 2.5. Interestingly, the index appears to be insensitive to index properties of the soils, however the pore pressure ratio was more responsive to transitions between silt and clay.
For a preliminary evaluation of the susceptibility to liquefaction of the fine-grained soils encountered at the project site, we used Bray & Sancio (2006) criteria based on soil index tests. According to the findings in Bray & Sancio (2006), the amount and type of clay minerals in the soil best indicate liquefaction susceptibility, which can be quantified by PI and the ratio of water content and liquid limit (wc/LL). Based on the available soil index tests for the project site, 9 out of 22 samples (41%) tested in the depth range of 5 to 55 feet bgs are considered to be susceptible or moderately susceptible to liquefaction by the Bray & Sancio (2006) criteria.

The use of a typical I_c cut-off for the transition between sand-like and clay-like behavior of 2.6 would result in analyzing most of the profile as a sand, calculating a magnitude 7.5 normalized cyclic resistance ratio ($CRR_{7.5}$) of approximately 0.15. However, as noted, Dickenson et. al and others have observed that these materials behave in a manner more similar to clays. An assessment of the profile using a methodology similar to that presented by Idriss & Boulanger (2006) results in an improved assessment of the soil's response to cyclic loading.

3.1 Overconsolidation ratio profiling

The use of the generalized expression for stress history (Agaiby & Mayne 2019) with dependency on I_c did not adequately reflect the laboratory test results. This is due to the insensitivity of the I_c index to changes in soil type in these soils. Agaiby & Mayne presented alternative relationships to estimate the exponent m' on D_{50} and fines content. However, these generally did not provide consistent differentiation between the silts and clays, and a relationship associated with B_q was observed. As such, a modified m' exponent was developed as a function of the pore pressure ratio. The preconsolidation pressure was estimated according to Equations 1 and 2, which are modifications of the methods presented by Agaiby & Mayne (2018):

$$\sigma_p' = 0.33(q_{net})^{m'}\left(\frac{\sigma_{atm}}{100}\right)^{1-m'} \qquad (1)$$

$$m' = 1 - \frac{0.28}{1 + (Bq/0.05)^{25}} \qquad (2)$$

The resulting overconsolidation ratios calculated for CPT-6 are presented on Figure 4, with nearby CRS results from nearby borings. There was a general trend on the site that the clays had significantly larger OCR's than the silts and sands, which is reflected in the reduction of OCR with the drop in B_q that reasonably fits the trends observed in the lab tests. Some differences in elevation of the transitions between silts and clays is expected between the borings and the CPT. This likely explains the depth offset between the CPT predicted OCR for B7-S6 and B9-S12. This trend was observed in other CPTs as well.

Figure 3. Site 2 basic CPT results for WHQ CPT-6.
Figure 4. OCR profile for WHQ CPT-6.

3.2 *Shear strength profiling*

The undrained shear strength of the materials can be calculated using critical state soil mechanics for the appropriate stress path (Mayne 2005). The effective stress friction angle can be calculated by the modified NTH method (Ouyang & Mayne 2018). Equation 3 can be used to calculate the undrained shear strength for the direct simple shear (DSS) stress path. When calculating the undrained shear strength, it was found that using a Λ=0.7 works well for these silty soils.

$$\left(\frac{S_u}{\sigma'_{vo}}\right)_{DSS} \approx 0.5 \sin \Phi' OCR^\Lambda \qquad (3)$$

The laboratory test results from DSS testing for depths between 10 and 30 feet deep are presented on Figure 5. Figure 6 provides a comparison of the CPT derived properties with the laboratory-based model fit.

3.3 *Cyclic resistance profiling*

Dickenson et. al (2021) presents the cyclic resistance ratio (CRR) of silts in the Pacific Northwest according to Equation 4, where N is the number of cycles:

$$\frac{CSR}{OCR^{0.8}} = a \times N^{-b} \qquad (4)$$
Figure 5. DSS undrained shear strength ratios.
Figure 6. CPT-6 calculated normally consolidated shear strength ratios compared to lab test model fit.

The "a" coefficient can be described as a function of the normally consolidated undrained shear strength ratio. Using model parameters of a = 0.8*S_u/σ_v = 0.213 and b = 0.15 results in a reasonable fit for the soils as tested for a single amplitude shear strain of 3%, as shown on Figure 7. The model fit may be increased by approximately 0.05 for larger shear strain amplitudes up to approximately 7%. The model fit results in a CRR at 30 cycles equivalent to 50% of the undrained shear strength, which can be used in
Figure 7. Cyclic shear strain accumulation as a function of undrained shear strength and number of cycles.
Figure 8. Peak R_u generation normalized to shear strength and cyclic loading.

combination with the values presented in Figure 6 to develop a $CRR_{7.5}$ profile. This fit is less than the CRR $= 0.8*S_u$ recommended by Idriss and Boulanger (2006) for clays, but results in a significantly larger CRR than the sand-like behavior presented previously for soils that are overconsolidated. This reduction may be due to the use of SHANSEP-like testing methodology to directly control the sample OCR, resulting in a loss of the in-situ soil stiffness.

The "a" coefficient is generally less than the coefficients presented by Dickenson et. al for other soils in the Pacific Northwest. This is consistent with observations that under cyclic loading these soils tend to generate more excess pore pressures than most of the silts in the Pacific Northwest database, with max R_u values of approximately 0.9, as shown on Figure 8, suggesting the silts on Site 2 are more sand-like than many other silts in the region.

When the CRR is exceeded, resulting in an R_u greater than 0.8, the post cyclic shear strength was approximately 50% of the undrained shear strength.

4 CONCLUSIONS

When evaluating the behavior of glacially overconsolidated soils in Western Washington, it has been shown that penetration of the CPT through the overconsolidated fine-grained soils of the Puget Sound Lowlands can be readily accomplished. When evaluating those soils, practitioners should consider the use of Schneider plots to facilitate identification of fine-grained soils that may otherwise not be identified by SBT.

Additionally, the assessment of cyclic resistance ratios of transitional soils in the Pacific Northwest is documented. The soils generally have an I_c less than 2.6, resulting in most practitioners using sand-like liquefaction assessment methods. This significantly underestimates the soils cyclic resistance ratio. Classic liquefaction behavior was not observed in any of the cyclic laboratory tests in soils associated with an I_c index as low as 2.2. I_c values generally ranged from 2.3 to 2.6 for depths in the soils tested with plasticity index values as low as 5.

A methodology was presented to assess the cyclic resistance to cyclic softening of the transitional soils that is consistent with other soils in the Pacific Northwest that can be used in combination with existing stress history and shear strength profiling techniques. Further refinement to OCR profiling methods in soils other than clay would be beneficial. An example of such refinement would be the development of a unified approach which provides a theoretical framework for both drained and undrained materials, which also addresses the impact of site-specific shear strength parameters in a consistent manner.

ABSTRACT: An extensive geotechnical investigation was performed on an oil terminal site located in a seismically active field. Combination of *in situ* and laboratory tests were performed including Piezocone Penetration Tests (CPTu), some of which were adjacent to the borehole locations, providing a detailed stratigraphic soil profile and different physical and mechanical parameters. In this paper, the application of the CPTu test for analyzing cyclic liquefaction is evaluated and discussed. Both "liquefaction" and "cyclic softening" potentials are evaluated depending on the magnitude of I_c factor. A clayey silt layer was identified having an I_c factor of about 2.5 between 12 and 19 m of depth. The average q_c of this layer was 6 MPa and friction ratio (RF) was 2.5. The induced pore pressure, u, was measured between 300 to 1800 kPa from 12 to 19 m of depth. The equivalent SPT counts from correlations with CPT were 15 while the real SPT counts were about 50 or higher. According to CPT data, the factor of safety of liquefaction was calculated having an average of 0.56 for a 0.49g earthquake with M=7. Undisturbed samples were taken from the layer onto which cyclic undrained liquefaction tests were carried out. The results, however, revealed that specimens were resisting the cyclic liquefaction with sufficiently high factor of safety. The soil classification in the laboratory showed that the soil was clay and not silty clay. Detailed analyses and interpretations are carried out to find out the reasons of the differences between CPTu correlations and real response of the specimens to cyclic loading. The results show that modifications might be required at times in interpretations of soil classification as well as liquefaction potential evaluation for soils at the borderline of low plasticity clay and silty clay.

1 INTRODUCTION

Liquefaction can be defined as a loss of strength and stiffness in soils, divided into "cyclic liquefaction" and "cyclic softening" categories. The terms "sand-like" and "clay-like" were introduced to refer to soils whose stress-strain behavior under undrained monotonic and cyclic loading is similar to that of sands and clays, respectively (Boulanger & Idriss 2004). Soils like gravels, sands, and very low plasticity silts that are recognized as "sand-like" can experience some level of cyclic liquefaction. However, the term "clay-like" is reserved for clay and plastic silts which can experience cyclic softening (Robertson 2009).

Developing high positive pore pressure under undrained cyclic loading can reach the "sand-like" soil at the state of zero effective stress causing a condition under which the initial soil structure is lost, and large deformations occur. Alongside the size and duration of the imposed cyclic loading, *in situ* state parameters and soil structure, including relative density, effective confining stress, age, fabric, and

cementation, affect "sand-like" soil response to the cyclic liquefaction (Robertson 2009). Generally, loose, young, uncemented "sand-like" soil is known to be highly susceptible to cyclic liquefaction. In contrast, "clay-like" soils do not reach zero effective stress due to the developed pore pressure under the same undrained cyclic loading condition. In "clay-like" soil, the buildup pore pressure is controlled by key features, including *in situ* state, sensitivity, age, fabric, and cementation. Soft normally to lightly overconsolidated and sensitive clays are considered to tolerate significant shear strains. They are susceptible to cyclic softening that cause lateral and vertical deformations.

Monotonic and cyclic undrained loading tests data show that soil transition from sand-like to clay-like behavior appears over fine-grained soils on a fairly narrow range of plasticity indices (Boulanger & Idriss 2006). To distinguish between fine-grained soils that may exhibit sand-like behavior versus clay-like behavior, researchers have developed several criteria. The Chinese criteria have been widely for evaluating the liquefaction susceptibility of silts

and clays (Boulanger & Idriss 2006). Based on Atterberg limits for those reported data from sites in China, Seed & Idriss (1971) categorized clayey soils having less than 15% finer than 5 μm, LL<35, and w_c>0.9 LL as vulnerable to severe strength loss as a result of earthquakes (Seed 1982). Andrews & Martin (2000) reviewed a few case histories, concluding that soils are susceptible to liquefaction if they have 10% finer than 2 μm and LL<32. Soils are not susceptible to liquefaction if they have 10% finer than 2 μm and LL>32. Further study is required for soils that meet one, but not both, of these criteria (Andrews & Martin 2000). Bray et al. (2004) provided new liquefaction criteria for soils containing significant fine contents. The criteria are considered fine-grained soils with plastic index, PI<12 and w_c >0.85 LL as susceptible to liquefaction. Boulanger & Idriss (2006) suggested that for practical purposes, fine-grained soils exhibit clay-like behavior if they have PI≥7. If a soil plots as CL-ML, the PI criterion may be reduced to PI≥5. Fine-grained soils that do not meet these criteria should be considered sand-like liquefiable, unless appropriate *in situ* and laboratory testing have shown otherwise (Bray et al. 2004).

The most common CPT-based classification systems are based on behavior characteristics and are often referred to as a soil behavior type (SBT) classification (e.g., Robertson, 1990). The SBT charts are behavior-based descriptions, while the general soil classification is textural-based (Robertson 2016). The charts proposed by Robertson (1990) and the present update (Robertson 2009) have become very popular, in which cone resistance, q_c, and sleeve resistance, f_s, are normalized to account for *in situ* stress level with depth. Since then, many CPT soil behavior type charts have been developed (e.g., Jefferies & Davies 1993, Ramsey 2002, Schneider et al. 2012). Robertson & Wride (1998) had suggested that I_c = 2.6 was an approximate boundary between soils that were either more sand-like or more clay-like. The Robertson SBTn chart works well in ideal soils but can be less effective in structured soils. The term "ideal soil" describe soils with little or no microstructure that are predominately young and uncemented. The term "structure" is used to describe features either at the deposit scale, macrostructure, e.g., layering and fissures, or at the particle scale, microstructure, e.g., bonding and cementation (Robertson 2016). Older natural soils tend to have some microstructure due to the post-deposition. Many researchers have contributed to developing the CPT-based models to evaluate liquefaction based on cyclic liquefaction case histories that were limited to predominately silica-based ideal soils (e.g., Robertson & Wride 1998). The updated method proposed by Robertson (2009) is the most widely used method to assess the potential for liquefaction. The method was initially developed for clean sands and it proposed a unified approach, in which two sets of equations are created for sand-like and clay-like behavior in liquefaction.

An industrial site on northern shorelines of Gulf of Oman was lately developed where boreholes and CPTu tests were carried out. At a small zone of this site near sea, the CPTu tests identified a clayey silt to silty clay with I_c factor of slightly below 2.5 (average of 2.497). The Robertson classification chart used correlations of the sand-like soil with I_c <2.5 for this layer and concluded that this layer is highly liquefiable with a factor of safety, FS=0.54 for the 0.49 g peak ground acceleration, PGA, of the field. This is while SPT correlations indicate a much greater FS=0.9 to 1, also assuming that the soil is sand-like. Cyclic triaxial tests were carried out on undisturbed specimens revealing that the soil is not liquefiable.

In this paper, the geotechnical condition of the site is characterized presenting the CPTu and SPT data along with blow count profile of a precast concrete pile driven in this zone. The soil classification results from CPTu data and soil sampling and lab data are compared and attempts are made to account for the contradictions between CPTu data and other methods.

2 STUDY SITE

2.1 *Location and morphology*

The study site is located near Jask in Hormozgan Province, southern Iran, on the northern shorelines of Gulf of Oman. The site is approximately 300 m away from sea. This area is located in the Zagros orogenic zone and generally consists of marl, sandstone, and silty/clayey sediments. The site area is situated in a seismically active zone. The PGA with a return period of 475 years is estimated equal to 0.49g on the basis of a site-specific seismology study carried out by Pars GeoEnviro Consulting Engineers.

2.2 *Geotechnical conditions*

An extensive geotechnical investigation was performed at the study site. A combination of *in situ* and laboratory tests were carried out including Piezocone Penetration Tests, CPTu, some of which were adjacent to the borehole locations, providing a detailed stratigraphic soil profile and different physical and mechanical parameters. Total of 12 CPTu points as well as 6 boreholes were considered for the geotechnical investigation objectives.

Subsurface layers across the site mostly consist of cohesive soil containing clay and silty clay, and non-cohesive soil containing silty sand to sandy silt. After processing all data from field exploration, *in situ* tests including CPTu and SPT, as well as lab tests, the site area has been divided into three main zones in terms of geotechnical characteristics and subsoil conditions as shown for BH5. Zone b, which is the focus of this paper, mainly consists of a 6 m thick layer from

non-plastic silt and sand categorized as medium dense to dense starting from ground surface; underneath this layer, a layer consisting of plastic lean clay is located down to depth of around 12 m and categorized as firm stiff to stiff. Third layer starts from depth 12 m and extends down to the end of investigated BHs and CPTs consisting of clay and silty clay with PI=10-11; this layer is categorized as very stiff.

In most locations across the site, there has been a good compatibility between geotechnical data obtained from borehole sampling and the ones obtained on the basis of CPTu processed data and soil classification charts. However, in Zone b in which two CPTu tests as well as one borehole were executed, some incompatibilities are observed, especially between the results from CPT6 and BH5. BH5 which was continuously drilled down to 20 m is located adjacent to CPT6 penetrating to 19.1 m. Below 11 m, incompatibilities were more severely observed in classification, equivalent SPT numbers, and most significantly, liquefaction/cyclic softening potential analyses.

3 CPT DATA INTERPRETATIONS

3.1 *Soil classification*

Among proposed SBT charts on the basis of CPT data, the updated unified approach by Robertson (2009) is employed. The effective overburden stress is used to normalize tip and sleeve friction resistances as Q_t and F_r, as shown in Eqs. 1 and 2, respectively.

$$Q_t = \left[\frac{q_t - \sigma_{v0}}{\sigma'_{v0}} \right] \tag{1}$$

$$F_r = \left[\frac{f_s}{q_t - \sigma_{v0}} \right] 100\% \tag{2}$$

where q_t is CPT corrected cone resistance, $q_t = q_c + u_2 (1-a)$. The "a" is net area ratio of the cone determined from laboratory calibration for the cone, with a typical value between 0.7 and 0.85, f_s is CPT sleeve friction, σ_{v0} and σ'_{v0} are *in situ* total and effective vertical stresses, respectively. The primary ground water table is evaluated from site observations and rechecked from drilled adjacent borehole as 5 m from the surface at the CPT location. Figure 1 also shows the recorded data of CPT6 in Zone "b". Profile of soil behavior classification based on Roberson (2009) method is plotted next to the CPT data alongside of the profile of soil classification from laboratory test.

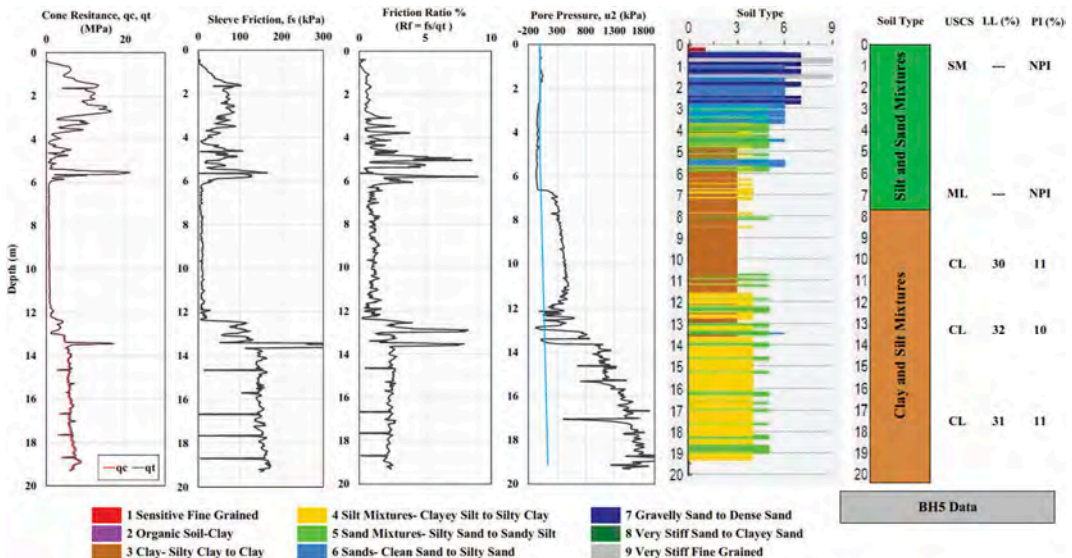
The data points scattering over the Q_t–F_r chart are plotted in Figure 2. The soil layering according to CPT classification are three layers: Layer I: the top 5 m can be categorized as "clean sand to silty sand", Layer II: between 5 to 12 m, dominantly "clay to silty clay", and Layer III: between 11 to 19.5 m, classified as "silt mixtures, clayey silt to silty clay". Layer III is categorized as a transition layer in the SBT chart. To further evaluate and verify the classification, another chart proposed by Eslami & Fellinius (1997) was attempted as shown in Figure 3.


Figure 1. CPT6 cone resistance, sleeve friction, friction ratio, and pore pressure profile accompanied by soil classification profile based on Robertson (2009) and soil classification based on laboratory tests on adjacent borehole BH5.

Considering plotted data on Figures 2 and Figure 3, the two proposed classification SBT charts show an accumulation of points over 12 to 19 m representing by red squares. The accumulation of points is mainly categorized as clayey silt to silty clay over the SBT chart proposed by Robertson (2009) on Figure 2. These points have I_c value close to the suggested boundary, $I_c=2.6$, distinguishing between sand-like or clay-like behavior by Robertson & Wride (1998). The proposed boundary $I_c=2.6$ is the approximate boundary between soils that can be either claylike or sandlike, however, it is not always a good fit, except for predominately young uncemented, and normally consolidation soils referred to as ideal soil (Robertson, 2016). Also, the other CPTu tests performed at the site in different locations show the existence of this behavior type layer which is recognized as a transition layer between sand-like and clay-like behavior.
Figure 2. Scattered data points on Qt-Fr soil behavior type chart proposed by Robertson (2009) for CPT6.
3.2 *Liquefaction & cyclic softening*

A procedure suggested by Robertson & Wride (1998) is used to evaluate the potential for cyclic softening and cyclic liquefaction. The procedure used the basic methodology, developed by Seed & Idriss (1971), calculating cyclic stress ratio, CSR, induced by the earthquake, and cyclic resistance ratio, CRR of the soil. If CSR>CRR, then liquefaction can occur. The proposed procedure estimates CRR based on the "sand-like" or "clay-like" classification, separated by the defining boundary of $I_c=2.6$. The updated procedure is well established by Robertson (2009).

To get an outlook of the potential for cyclic liquefaction, Robertson (2009) presented a SBT Qt−Fr chart by defining "dilative" and "contractive" zones as a guide. Figure 4 shows the plotted data points over the chart for CPT6. The I_c boundaries of 2.5 and 2.7 are plotted with dashed lines. The red dots of the layer 12-20 m are dominantly in the transition zone and some points slightly below 2.5. The plots indicate that the points are at the "dilative" zone of the chart.

In all assessments, the earthquake magnitude, M, is estimated 7 with PGA equal to 0.49 g. Figure 5 shows the profile of safety factors for cyclic liquefaction for sand-like soil classification and cyclic softening for claylike soil classification with depth. The calculations demonstrate that the soil beneath the performed location has potential for either of the cyclic liquefaction and cyclic softening. In layers with clay-like behavior, $I_c>2.7$, green points, FS is approximately around 0.73 in cyclic softening. While in sand-like layers, $I_c<2.5$, red points; I_c between 2.5 and 2.7, yellow points, the average safety factor against cyclic liquefaction is 0.56.

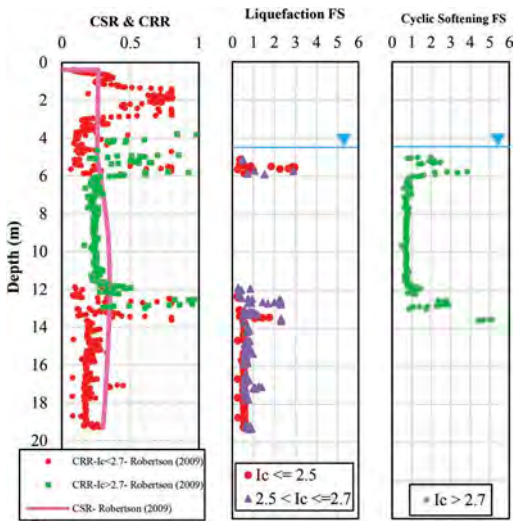

Figure 5. Liquefaction analysis of layers at location of CPT6; "liquefaction: is for sand-like (Ic<2.5) and transition zone (2.5<Ic<2.7); "cyclic softening" is for clay-like (Ic>2.7).

Figure 6. Comparison between direct results and correlated results: (a) N-SPT from actual SPT test and correlated from CPT, (b) blow count values from actual pile tests program.

4 COMPARISON WITH BOREHOLE SAMPLES

4.1 *Atterberg limits and classification*

The results of Atterberg Limits tests performed according to ASTM D-4318 shows that a thick plastic layer is situated with PI=10-11 extended between 12 to 20 m (Figure 1). CPTu results show that in this layer, silt mixtures containing clayey silt to silty clay are dominant. According to I_c value, this layer is located in sand-like zone as far as classification is concerned (Ic≤2.6). It seems that lab testing shows more dominant clayey soil than CPT classification.

SPT test was carried out with intervals of 2 m in soil layers as well. N-SPT obtained from SPT test in BH5 is shown in Figure 6. In addition, N-SPT is estimated from available correlations proposed by Robertson (2012) as well as Jefferies and Davies (1993) based on CPTu test results, as shown (Figure 6). Comparing actual SPT number with correlated values from CPT shows that in upper 6 m sand, there is fairly good compatibility between SPT and CPTu data; in deeper depths consisting of clay, N-SPT values from SPT test are somewhat greater than values correlated from CPTu down to 10 m within the firm clayey layer. Below this, the N-SPT from the tests is significantly higher than CPT correlation, highlighting a very stiff layer. The blow count data of a 400 mm precast concrete square pile is also plotted in Figure 6 versus depth to further validate the soil stratification. Good correlations exist in layers I and II, while the blow counts rapidly reached 20 blows per 100 mm penetration and beyond and pile driving was stopped. The blow count record further confirm the trend of N-SPT counts rather than N-SPT correlated from CPT.
Figure 7. Assessments of liquefaction: (a) CSR values from SPT numbers based on Youd et al. (2001) and CRR values based on Seed & Idriss (1971), (b) factor of safety against liquefaction.

An evaluation of liquefaction is also performed based on SPT results according to the method proposed by Youd et al. (2001). The SPT-based assessments for cyclic liquefaction is presented in Figure 7. The results show that both CPT and SPT confirm the probability of liquefaction occurrence in the layer at the depth of 12 to 20 m. However, SPT-based assessment generally shows higher FS values close to unity.

4.2 *Cyclic triaxial tests*

The liquefaction resistance could be evaluated using undrained cyclic triaxial tests with two-way, symmetrical loading in compression and extension (Yang & Sze, 2011). For the mode of cyclic mobility, the usual

approach is to define failure criterion as the point that is accompanied by the occurrence of 5% double-amplitude (DA) axial strain (Toki et al., 1986; Ishihara, 1996).

A series of cyclic triaxial tests were carried out for the assessment of liquefaction and cyclic softening occurrence of the 3rd layer. An undisturbed sample extracted from depth 12 m was studied by cyclic triaxial test. Assuming peak ground acceleration of a_{max}=0.49g, the average stress for liquefaction triggering was calculated equal to CSR=0.37 based on the method proposed by Seed & Idriss (1971). After saturating the soil sample and being consolidated under σ_{3c}= 120 kPa, cyclic deviatoric stress considering CSR=0.37 varying in the range of ±100 kPa has been applied on the sample. The results show that no sign of failure exist (Figure 8). For an earthquake with M=7, according to Boulanger & Idriss (2004), the number of cycles equivalent to an earthquake for triggering liquefaction is 25 for clay-like soil samples. Figure 8 shows that at cycle No. 1000, DA axial strain is equal to 3.4%, which is much less than the proposed criterion. Thus, although CPTu correlated results for assessing cyclic liquefaction shows high risk of cyclic softening at the layer between depth of 12 and 20 m, the performed triaxial test shows no evidence of liquefaction under assumed seismic condition.

5   CONCLUSIONS

The layer between 12 to 19 m is classified using two classifications systems as clayey silt to silty clay.
Figure 8. Cyclic triaxial test results at the end of 1000th cycle: (a) loops of deviator stressaxial strain, (b) Effective stress paths on Cambridge p'-q diagram.

The lab testing on the specimens classified the soil as CL with PI=10-11 and relatively high shear strength under cyclic loading. The SPT N-value is greater than the N-value correlated with q_c. CPTu results show very high induced pore-water pressure for the subject layer even up to 1800 kPa, therefore, the layer is highly compressible. This is while the SBC has recognized the soil as dilative. Cyclic triaxial test confirm that soil is not liquefiable even after 25 cycles.

It looks like that an Ic value of slightly below and above 2.5 mandated using "cyclic liquefaction" correlations of CPTu. This is while the soil is in fact clay-like and "cyclic softening" correlations should have been used instead. When the soil is classified at the transition zone, special cares are required in adopting correlations with CPTu data to evaluate liquefaction.

ABSTRACT: The geographical and geological spatial variabilities raise challenges for geotechnicians to devise globally applicable subground stratification models working based on cone penetration testing (CPT). Recently, a novel CPT-based stratification and classification model was proposed in Tampere University, Finland. It combines the soil behavior type (SBT) classification chart proposed by Robertson (1990) with a novel integrated Game Theory-optimization subground stratification model (denoted herein as RIGTOSS). The model has already been verified based on few test sites results from Taiwan and the U.S. Therefore, in this paper, the RIGTOSS model is developed further, and it is evaluated based on the stratification profiles provided by CPT experts for the Venetian Lagoon deposits. The test site has been selected because of high variability of CPT measurements and the thin transient soil layers in the area. The results indicated comparable stratification profiles from the developed model(s) and the profiles by experts, derived based on field and laboratory tests.

1 INTRODUCTION

Stratifying and classifying the soil behavior type (SBT) based on loads of sampling and laboratory testing can be currently in conflict with the sustainable design of a project. Furthermore, it may not finally lead to a desirable stratification-classification profile due to the probable discontinuities and soil disturbances in sampling. This problem is more challenging in highly variable and stratified soils. Then the thin transient layers may not be determined accurately. A solution can be sought in the advantageous continuous measurements of cone penetration test (CPT). Although, there are already challenges in the interpretation of the CPT measurements, and consequently in stratifying soils based on them.

In the past, much investigation has triggered the SBT classification and stratifying soils based on the CPT measurements. Several SBT classification charts have been successfully proposed based on data sets from around the world (Douglas 1981, Robertson 1990, Schneider et al. 2012, Eslami et al. 2017); although, in several studies, their applicability has been criticized for several soil types and geographical regions (Ricceri et al. 2002, Gylland et al. 2017). Besides, stratification models have

been recently appealed to researchers, and several models have been proposed (Wang et al. 2013, Ching et al. 2015, Wang et al. 2019). They often recognize strata based on computing a consistency factor among the succeeding CPT measurements in depth. A probable problem of this approach has been with the recognition of thin strata. There have been recent improvements, though. On the other hand, several methods are proposed which seek the change points in the succeeding CPT measurements, as the boundaries of strata. They may discover the thin strata better, compared to the former approach. Following the latter approach, a novel model is proposed in Tampere University, Finland, named herein integrated Game Theory-optimization subground stratification (-IGTOSS) model (Farhadi & Länsivaara 2021).

The -IGTOSS model has been previously combined with the classification chart proposed by Robertson (1990), so called RIGTOSS. In this study, it is developed further, and applied to the CPTu ('-u' indicates the pore water pressure measured in CPT) measurements at the highly nonhomogeneous deposits of the Venetian lagoon, Italy. Herein, the modified model is explained briefly, and the resulting stratification profiles of the site are compared with the ones suggested by experts.

2 STRATIFICATION MODEL

The basics of the utilized stratification model are described in (Farhadi & Länsivaara, 2021). In general, the proposed model consists of the following steps:

1. Importing and interpreting CPTu measurements
2. Denoising interpreted measurements
3. Stratifying and classifying soils based on integrated Game Theory-soil classification charts
4. Illustrating stratification profile

In the Game Theory model, the previously optimized parameters are utilized herein as well. The steps 1 and 3 are briefly explained below.

2.1 Classification charts and data interpretation

The previously published model contained only the F_r-Q_t Robertson SBT classification chart (1990). It is developed in this study, and currently, three other CPTu-based classification charts are implemented in the model. Hence, the modified model consists of:

a. RIGTOSS$_{Fr-Qt}$ (sub)model: stratification based on the F_r-Q_t classification chart, proposed by Robertson (1990).
b. RIGTOSS$_{Bq-Qt}$ (sub)model: stratification based on the B_q-Q_t classification chart, proposed by Robertson (1990).
c. SIGTOSS$_{Fr-Qt}$ (sub)model: stratification based on the F_r-Q_t classification chart, proposed by Schneider et al. (2012).
d. SIGTOSS$_{(\Delta u2/\sigma'v0)-Qt}$ (sub)model: stratification based on the $(\Delta u_2/\sigma'_{v0})$-$Q_t$ classification chart, proposed by Schneider et al. (2012).

The initial R/S letters of the mentioned (sub)models names represent either of the employed charts proposed by Robertson (1990) or Schneider et al. (2012).

In the classification charts, several normalized parameters are used, which are interpreted from the CPTu measurements as:

- Normalized cone tip resistance, Q_t:

$$Q_t = \frac{q_n}{\sigma'_{v0}} = \frac{q_t - \sigma_{v0}}{\sigma'_{v0}} \quad (1)$$

- Friction ratio, F_r:

$$F_r = \frac{f_s}{q_n} \times 100 = \frac{f_s}{q_t - \sigma_{v0}} \times 100 \quad (2)$$

- Pore pressure ratio, B_q:

$$B_q = \frac{\Delta u_2}{q_n} = \frac{u_2 - u_0}{q_t - \sigma_{v0}} \quad (3)$$

- Normalized excess pore pressure, $\Delta u_2/\sigma'_{v0}$, which equals $B_q Q_t$;

where, q_n is the net corrected cone tip resistance, σ'_{v0} is effective vertical stress, q_t is total corrected cone tip resistance, σ_{v0} is total vertical stress, f_s is sleeve friction, u_2 is pore pressure measured at the cone shoulder, u_0 is the in-situ pore pressure prior to cone penetration, and Δu_2 is the excess pore pressure measured at the cone shoulder in penetration. As generally utilized, q_t is the corrected measured cone tip resistance, q_c, based on water content and unequal end effect of the piezometer: $q_t = q_c + u_2(1-a)$, where, a is the cone area ratio.

For computation of the in-situ vertical effective stress, σ'_{v0}, unit weight of soil, γ, is computed based on the equation by Robertson & Cabal (2010), which provides a continuous profile in depth:

$$\frac{\gamma}{\gamma_w} = 0.27\left[\log R_f\right] + 0.36\left[\log\left(\frac{q_t}{p_a}\right)\right] + 1.236 \quad (4)$$

where, friction ratio, R_f, equals $(f_s/q_t)\times100$, γ_w is the unit weight of water in same unit as γ, and p_a is the atmospheric pressure in the same unit as for q_t.

2.2 Digitized classification charts

In order to implement the charts in computations, different equations have been fitted to the boundary lines of each classification chart. The fitted equations for the F_r-Q_t chart of Robertson (1990) is previously published in Farhadi & Länsivaara (2021). The fitted equations for the other used charts are presented in Figures 1-3.

In Figure 1, the SBT zones in the B_q-Q_t chart of Robertson (1990) are defined as:
1. Sensitive, fine-grained soils
2. Organic soils and peat
3. Clays (clay to silty clay)
4. Silt mixtures (silty clay to clayey silt)
5. Sand mixtures (sandy silt to silty sand) or cemented soil
6. Sand (silty sand to clean sand)
7. Sand to gravelly sand
8. Sand (clayey sand to 'very stiff' sand)
9. Very stiff, fine-grained, overconsolidated

Note that the SBTs of 8 and 9 only exist in the F_r-Q_t chart, not in the B_q-Q_t chart.

Figures 2-3 illustrate the classification charts proposed by Schneider et al. (2012) and the fitted equations to the boundary lines. In these two charts, the SBTs are defined as:

1a. Low-I_R clays ($I_R=G/S_u$; where, I_R, G and S_u represent rigidity index, shear modulus, and undrained strength, respectively)
1b. Clays
1c. Sensitive clays
3. Silts and transitional soils

2. Essentially drained sands and sand mixtures

3 TEST SITE

The data of the CPTu measurements are derived from a long-lasting project in the Venetian lagoon basin, Treporti test site, Italy. The importance of studying the Treporti site originated from the regional land subsidence in 1970s, and designing submersible gates to protect Venice from recurrent flooding in 1990s. There exist predominantly Pleistocene silty sediments of the Venetian lagoon basin with a high variability of strata (Tonni & Gottardi 2019), which can be a challenging soil condition to stratify.
Line	Equation

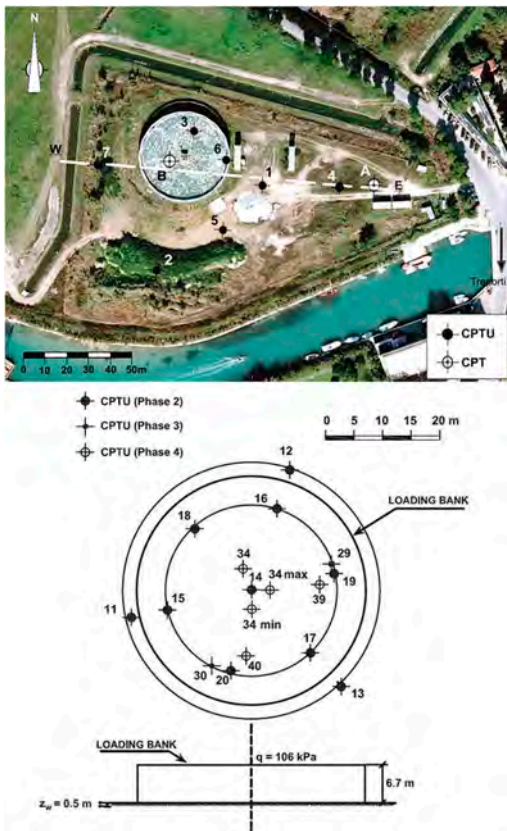

Figure 4. Location of CPTu tests at Treporti test site (TTS), from Tonni & Gottardi (2011). The diameter of the loading bank is 40 m.

bank. In this study, the CPTu measurements before the bank construction are utilized, which are indicated as 'Phase 2' in Figure 4.

4 RESULTS AND DISCUSSION

4.1 Stratification profiles

The (R/S)IGTOSS models were applied to nine CPTu measurements: CPTu 11-CPTu 19.

In the first step, data were imported into the model and were interpreted.

In the second step, the interpreted data were denoised using the locally estimated scattered smoothing (LOESS) method. The results of the smoothing for the four interpreted parameters of test CPTu14 (performed at the center of the loading bank) are presented in Figures 5a-5d. As can be observed, the benefit of the smoothing has been denoising the outliers (for instance, the abrupt large fluctuations at depths of 10-17 m), such that the general trends of variations would be preserved.

The solid lines in Figures 5f-5i show the identified SBT versus depth after using directly the classification charts of F_r-Q_t and B_q-Q_t by Robertson (1990) and F_r-Q and $(\Delta u_2/\sigma'_{v0})$-$Q$ by Schneider et al. (2012), respectively. It can be observed that the succeeding data points are highly variable on the charts and too many SBTs/strata are identified. Thus, it may be really challenging for a geotechnician to decide on the number of strata and their boundary depths in highly heterogeneous soils, such as in the Venetian lagoon. In this regard, (R/S)IGTOSS models facilitate the stratification procedure. Their resulting stratification profiles (illustrated with colored contours) for the test CPTu14 can be compared with the profiles resulting from direct use of classification charts in Figures 5f-5i. In the colored stratification profiles, the tone of colors varies from blue to yellow; where yellow means the highest probable SBT, and vice versa. Then, it is observed that after applying the (R/S) IGTOSS models, less strata can be detected generally.

Figure 5j illustrates the distribution of all CPTu measurements points on the used classification charts. As observed, especially in the F_r-Q classification chart of Schneider et al. (2012), numerous points are located out of the boundary lines of the chart, indicated by SBT='f' in Figure 5h. They may result from different factors, such as uncertainties in measurements, interpretation methods and parameters, or incompatibility of the chart with the soils at the Treporti site. However, Figures 5f-5i unveil that after application of (R/S)IGTOSS models, a large number of the data points close to the boundary lines have been regarded within the zones. It evidences that the model considers the proximity of the succeeding points in detecting strata.

4.2 Spatial variability of sediments

Figure 6 illustrates the highly horizontal variability of deposits in the Venetian lagoon for tests CPTu11, CPTu12 and CPTu13, located around the perimeter of the loading bank. Although the (R/S)IGTOSS models have identified the strata based on each CPTu (Figures 6b-6m), it is still challenging to find similar layers with almost the same boundary depths at the test site. This is due to the highly spatial variability of soils at the Treporti site.

4.3 Comparison of classification charts

Despite the spatial variability of deposits at the Treporti site, and highly alternation of different grain-sized sediments, Gottardi & Tonni (2005) reported the following strata (as illustrated in Figures 5e and 6a):

- very soft silty clay, from ground level to 2 m in depth,

397
Figure 5. Illustration of CPTu measurements, experts stratification profile, RIGTOSS and SIGTOSS stratification profiles, and distribution of CPTu measurements on classification charts, for test CPTu14: a-d) smoothed versus unsmoothed inter-preted CPTu parameters, e) expert-based stratification reported for Treporti site (Tonni & Gottardi 2011), f-i) directly chart-based stratification profile, presented by solid line, versus the profiles by the RIGTOSS$_{Fr-Qt}$, RIGTOSS$_{Bq-Qt}$, SIGTOSS$_{Fr-Q}$ and SIGTOSS$_{(\Delta u2/\sigma'v0)-Q}$ models, respectively, and, j) distribution of measurements points on the classification charts (the color of data points gets darker with depth). In (R/S)IGTOSS stratification profiles, SBTs of '10′' and 'f' mean that the data points located out of the boundaries of the classification charts.
Figure 6. The expert-based stratification profile (a) by Tonni & Gottardi (2011) compared with the profiles from RIGTOSS and SIGTOSS models for tests: b-e) CPTu11, f-i) CPTu12, and, j-m) CPTu13. Every four profiles, i.e. a-e, f-i, and j-m, are derived from RIGTOSS$_{Fr-Qt}$, RIGTOSS$_{Bq-Qt}$, SIGTOSS$_{Fr-Q}$ and SIGTOSS$_{(\Delta u2/\sigma'v0)-Q}$, respectively.

- medium-fine sand (to approximately 8 m in depth),
- silt with thin layers of sandy to clayey silt, from 8 to 20 m in depth,
- dense clean sand (interbedded within the silty unit, though not everywhere),

- silty sand,
- alternate layers of silty sand, sandy silt, and clayey silt, with occasional presence of peat, at depths greater than 24 m.

Figures 5-6 indicate highly variable behaviour of soil at depths less than 2 m. However, they are

mostly silt, or silty clays, which is almost similar to the observation of Gottardi & Tonni (2005).

At the depth range of approximately 2-8 m, an almost homogeneous layer is identified with SBT of 6, that means sand (silty sand to clean sand) according to the Robertson chart, and based on the Schneider et al. chart, SBT is 2, that means essentially drained sands and sand mixtures. Although the SBT from two charts are almost similar, the thickness of the layer based on each chart is a little different. For example, Figure 6h shows SBT of 2 from surface to approximately 7.5 m deep, while Figure 6f indicates SBT of 6 for 1-8.5 m deep.

From 8 to 40 m in depth, highly variable deposits are identified. Their SBTs based on the Robertson charts are 3 or 4 and at some depths it is 5. Generally, they range from clay/silty clays to sandy silts/silty sands. On the other hand, the chart by Schneider et al. (2012) indicates almost all SBT classes from *1b* to *3*, which means from clays and sensitive clays to drained sands and sand mixtures. Therefore, using each chart leads to different profiles of stratigraphy. Such observations may lead to the necessity of a site-specific classification chart, such as the B_q-F_r chart by Ricceri et al. (2002).

5 CONCLUSIONS

In this study, a stratification-classification model is modified and employed for the highly variable deposits of Venetian lagoon, Treporti site, Italy. The model classified soil behavior based on four classification charts. It was observed that the model was capable of stratifying highly variable deposits. Generally, the obtained stratification profiles have been comparable with the profile provided by experts, which have been not only based on CPTu tests, but also based on the field and experimental tests.

The differences between the model and experts stratification profiles originate from numerous factors, such as the incompatibility of the classification charts with the testing site condition, uncertainties in measurements, or different criteria in classifying soils in contrast to those of the available classification charts.

ABSTRACT: Two novel CPTu-based stratification models are applied to the measurements at four Norwegian sites, including a broad range of soil behavior types (SBTs). The two models, called RIGTOSS and SIGTOSS, are developed based on the recently proposed integrated Game Theory-optimization subground stratification (-IGTOSS) model. The RIGTOSS model includes two submodels classifying the SBTs based on either the F_r-Q_t or B_q-Q_t charts by Robertson (1990); and similarly, the SIGTOSS model includes two submodels classifying the SBTs based on either the F_r-Q_t or $(\Delta u_2/\sigma'v_0)$ Q_t charts by Schneider et al. (2012). The resulting stratification profiles of the four submodels were compared with the ones provided by experts, derived from extensive field and experimental testing. Similarity was observed and the results are promising. Differences at this stage can be attributed to incompatibility of the classification charts with the Norwegian soils and more specifically soil heterogeneities at the Øysand test site.

1 INTRODUCTION

A significant advantage of cone penetration test is the continuity of measurements in depth. This valuable feature can contribute to a better understanding of subground, which may not be obtained only from sampling. As an example, it can lead to one of the main applications of CPTu testing, which is the stratification and classification of the soil behaviour type (SBT). Currently, the stratification-classification needs combining CPTu measurements with experimental and probably other field tests. However, it is desirable to stratify and classify soils only based on the CPTu measurements, which is targeted in this study.

The CPTu-based stratification-classification has been extensively investigated. Initially, a generally applicable method was sought to classify soils based on the CPTu measurements, which resulted into several classification charts (Robertson 1990, Schneider et al. 2012, Eslami et al. 2017). Despite the breakthroughs, the observed inaccuracies of the charts for different sites have left the question open, and researchers are still proposing soil-type- or site-specific classification charts (Ricceri et al. 2002, Gylland et al. 2017). However, using only the classification charts could not provide accurate stratification profiles while they represented largely high number of strata especially in highly variable soils. Therefore, several researchers focused on combining

classification charts with computational methods for stratifying soils based on CPTu measurements (Ching et al. 2015, Wang et al. 2019, Shuku et al. 2020).

In Tampere university, Tampere, Finland, a novel CPT-based stratification-classification model, named -IGTOSS here, is proposed integrating several computational models: a Game Theory model, the evolutionary Grey Wolf Optimizer (GWO) and the classification chart proposed by Robertson in 1990 (Farhadi & Länsivaara 2021). It was previously evaluated based on several CPTu tests in Taiwan and the US. In this study, the model is developed further including three other SBT classification charts. Then, it is applied to several CPTu tests from Norway containing a broad range of SBTs.

2 -IGTOSS MODEL

2.1 *Normalized CPTu parameters*

The utilized normalized parameters interpreted from the CPTu measurements are (Schneider et al. 2012):

i) Normalized cone tip resistance, Q_t:

$$Q_t = \frac{q_n}{\sigma'_{v0}} = \frac{q_t - \sigma_{v0}}{\sigma'_{v0}} \qquad (1)$$

ii) Friction ratio, F_r:

$$F_r = \frac{f_s}{q_n} \times 100 = \frac{f_s}{q_t - \sigma_{v0}} \times 100 \qquad (2)$$

iii) Pore pressure ratio, B_q:

$$B_q = \frac{\Delta u_2}{q_n} = \frac{u_2 - u_0}{q_t - \sigma_{v0}} \qquad (3)$$

iv) Normalized excess pore pressure, $\Delta u_2/\sigma'_{v0}$, which equals $B_q Q_t$;

where, q_n is the net corrected cone tip resistance, σ'_{v0} is the effective vertical stress, σ_{v0} is the total vertical stress, q_t is the total corrected cone tip resistance, f_s is sleeve friction, u_2 is the pore pressure measured at the cone shoulder, u_0 is the in-situ pore pressure prior to cone penetration, and Δu_2 is the excess pore pressure measured at the cone shoulder in penetration. As generally utilized, q_t is the measured cone tip resistance, q_c, corrected based on water content and unequal end effect of the piezometer: $q_t = q_c + u_2(1-a)$, where, a is the cone area ratio.

2.2 Developed stratification model

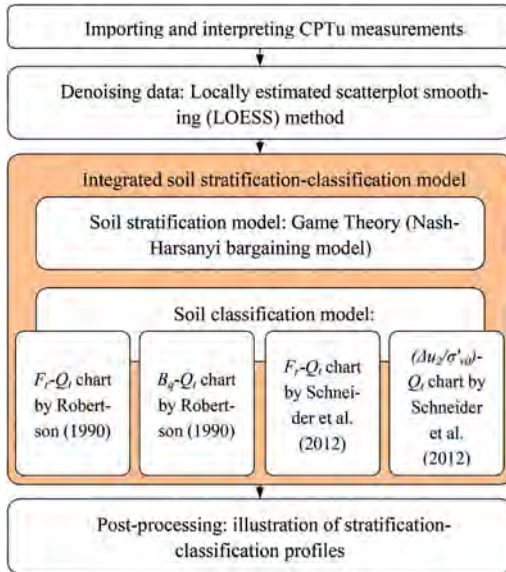
The basics of the stratification model are described in Farhadi & Länsivaara (2021). In this study, it has been developed further containing three other classification charts. A concise flowchart of the modified model is presented in Figure 1.


Figure 1. Concise flowchart of the proposed (R/S)ITGOSS model(s).

As illustrated in Figure 1, in the *first step*, the CPTu data are imported and interpreted. A constant soil unit weight, γ, for the whole depth of cone penetration is used to interpret Q_t, F_r, B_q and $\Delta u_2/\sigma'_{v0}$.

In the *second step*, the interpreted data is smoothed using a spatial regression method, called locally estimated scatterplot smoothing (LOESS). 1% of data is used as the spatial regression range.

In the *third step*, the integrated stratification-classification model specifies the strata boundaries depths, using a Game Theory model, as described in Farhadi & Länsivaara (2021). Then, the SBT is determined from a classification chart, in each of the following submodels:

a) RIGTOSS$_{Fr-Qt}$ based on the F_r-Q_t chart by Robertson (1990),
b) RIGTOSS$_{Bq-Qt}$ based on the B_q-Q_t chart by Robertson (1990),
c) SIGTOSS$_{Fr-Qt}$ based on the F_r-Q_t chart by Schneider et al. (2012),
d) SIGTOSS$_{(\Delta u_2/\sigma'_{v0})}$ − Q$_t$ based on the $(\Delta u_2/\sigma'_{v0})$− Q_t chart by Schneider et al. (2012).

The introductory R or S letters in the names of the RIGTOSS and SIGTOSS models indicate the utilized classification charts.

In the charts by Robertson (1990), the SBTs are defined as:

1. *Sensitive, fine-grained*
2. *Organic soils - peats*
3. *Clays - clay to silty clay*
4. *Silt mixtures - clayey silt to silty clay*
5. *Sand mixtures-silty sand to sandy silt*
6. *Sands, clean sand to silty sand*
7. *Gravelly sand to sand*
8. *Very stiff sand to clayey (heavily overconsolidated or cemented) sand*
9. *Very stiff fine-grained*

In the charts by Schneider et al. (2012), the SBTs are defined as:

1a. *Low-I_R clays ($I_R = G/S_u$; where, I_R, G and S_u represent rigidity index, shear modulus, and undrained strength, respectively)*
1b. *Clays*
1c. *Sensitive clays*
3. *Silts and transitional soils*
2. *Essentially drained sands and sand mixtures*

In the *final step*, the identified SBTs of the strata are plotted three-dimensionally with colored contours, as explained in Farhadi & Länsivaara (2021).

The interested readers may contact the first author for the MATLAB code; which will be probably described further in a separate paper in future.

3 TEST SITES

The developed (R/S)IGTOSS models are applied to the CPTu data from four sites in Norway (Figure 2):

Figure 2. Location of the test sites in Norway (provided by MATLAB, hosted by Esri, and Google Earth Pro).

Table 1. Soil properties of the test sites, in brief (Blaker et al. 2019, Gundersen et al. 2019, Quinteros et al. 2019, and L'Heureux et al. 2019).

Property	Halden		Onsøy		Øysand		T-F*

** w_n: natural water content; γ: unit weight; FC: fines content; CC: clay content; LL: liquid limit; I_p: plasticity index; S_t: sensitivity; OC: organic content; and SC: salt content.

a silt site at Halden, a soft clay site at Onsøy, a medium dense sand site at Øysand, and a quick clay site at Tiller-Flotten (L'Heureux & Lunne 2019).

The Halden site consists of a natural fjord marine deposit including mostly a low plasticity silt. A majority of bulky angular grains was observed at the scanning electron microscope (SEM) test: 41% quartz and 42% feldspar (Carroll & Paniagua 2018). Water table was 2.5 m below the surface. Further soil properties for all sites are presented in summary in Table 1.

The Onsøy site consists of a marine clay deposit with similar behaviour as that observed in Canada, Japan, Southeast Asia, Sweden, and Finland. The site has a thick layer of uniform very soft to soft clay.

The Øysand site consists of a 20 m thick glacio-fluvial mostly sandy deposit. The site includes several strata of gravelly sand (fluvial deposit), fine silty sand (deltaic soils), and clay-and-silt. The sand layer includes fine to medium uniform sand, predominantly of quartz minerals, some plagioclase and micas.

The Tiller-Flotten site consists of marine and glaciomarine sediments with a thick layer of sensitive clay from 8 m below terrain.

4 RESULTS AND DISCUSSION

4.1 Denoising data

Figure 3 shows the interpreted smoothed F_r, Q_t, B_q and $\Delta u_2/\sigma'_{v0}$ parameters for tests HALC19 and HALC20. It can be observed that the major variations are preserved after smoothing, and the minor sharp variations are smoothly approximated. Thus, the smoothing rarely impacts the resulting stratification profile while the model finds the strata boundaries
Figure 3. Illustration of the smoothing impact on the parameters interpreted from the CPTu tests at the Halden site.

mostly based on the large change points. However, most importantly it removes the outliers in data, such as those caused by stopping the cone penetration.

4.2 Stratification-classification profiles

4.2.1 Halden

Figure 4 illustrates the stratification-classification profiles for test HALC19.

Figures 4a-4d show that the interpreted parameters look similar before and after smoothing; although, several abrupt changes are removed. For
Figure 4. Illustration of CPTu measurements, experts stratification profile, RIGTOSS and SIGTOSS stratification profiles, and distribution of CPTu measurements on classification charts, for test HALC19, from Halden investigation site: a-d) smoothed versus unsmoothed interpreted CPTu parameters, e) expert-based stratification reported for Halden site (Blaker et al. 2019), f-i) directly chart-based stratification profile, presented by a solid line, versus the profiles provided by the RIGTOSS$_{Fr-Qt}$, RIGTOSS$_{Bq-Qt}$, SIGTOSS$_{Fr-Qt}$ and SIGTOSS$_{(\Delta u2/\sigma'v0)-Qt}$ models, respectively, and, j) distribution of measurements points on the classification charts (the color of data points gets darker with depth). In (R/S)IGTOSS stratification profiles, SBTs of '10' and 'f' mean that the data points located out of the boundaries of the classification charts. [In profiles, the yellow color shows higher probability of the SBT.].

example, in Figure 4a, two sudden changes at approximate depths of 0.5 and 1.4 m are removed after smoothing.

Figure 4e illustrates the experts' judgement based on the in-situ and laboratory tests performed by Norwegian Geotechnical Institute (NGI). Four main soil deposits are identified: a loose to medium dense silty clayey sand from 0 to 5 m (Unit I), two clayey silt layers with the same geologic origin and almost the same material (Units II and III), and a deeper unit consisting of medium stiff clay (Unit IV) (Blaker et al. 2019).

In Figures 4f-4i, the solid lines show the stratification profiles after using directly the classification charts. A large number of thin layers can be identified with dissimilar SBTs, compared with the (R/S) IGTOSS contoured profiles (Figures 4f-4i) and the experts' profile (Figure 4e). The identification of numerous strata originates from the location of the CPTu measurements points on a classification chart; which may be located close to the SBT boundary lines, but on different sides.

The colour-contoured profiles in Figures 4h-4i show that the SIGTOSS$_{Fr-Qt}$ and SIGTOSS-$_{(\Delta u_2/\sigma'v0)-Qt}$, models indicate three thick strata. However, the RIGTOSS$_{Fr-Qt}$ and RIGTOSS$_{Bq-Qt}$ models indicate approximately 5 thick strata

(Figures 4f-4g). Thinner layers can be observed with different probabilities at these thick strata.

Figure 4j illustrates the location of the CPTu measurements on the classification charts. The colour of the points gets darker with depth. They show the variability of the soil at the Halden site. In addition, comparing them with Figures 4f-4i showed that the (R/S)IGTOSS profiles are correctly determined.

4.2.2 Onsøy
Figure 5 shows the (R/S)IGTOSS results for tests ONSC19, ONSC20, and ONSC21, performed at the south-east corner of the Onsøy site. The distances between their locations were less than 2.1 m.

Figures 5a-5d indicate the impact of the smoothing method, and an appropriate repeatability of CPTu tests; although, the ONSC20 measurements deviate from the other two tests at some depths.

Comparing Figures 5e with two sets of Figures 5f-5i and 5j-5m indicates a generally appropriate similarity in recognizing the soil type as clay; although, the strata identified by experts are more than the strata identified by the (R/S)IGTOSS models. On the other hand, several thin layers are identified by the (R/S)IGTOSS models.
Figure 5. Comparison of the CPTu measurements at the Onsøy test site: a-e) smoothed and unsmoothed measurements of tests ONSC19, ONSC20, and ONSC21, f-i) respectively, RIGTOSS$_{Fr-Qt}$, RIGTOSS$_{Bq-Qt}$, SIGTOSS$_{Fr-Qt}$ and SIGTOSS$_{(Δu2/σ'v0)-Qt}$ profiles for ONSC19, and, j-m) respectively, RIGTOSS$_{Fr-Qt}$, RIGTOSS$_{Bq-Qt}$, SIGTOSS$_{Fr-Qt}$ and SIGTOSS$_{(Δu2/σ'v0)-Qt}$ profiles for test ONSC20.
Figure 6. Comparison of (a) experts' stratification profile with the (b) RIGTOSS$_{Fr-Qt}$, (c) RIGTOSS$_{Bq-Qt}$, (d) SIGTOSS$_{Fr-Qt}$, and (e) SIGTOSS$_{(Δu2/σ'v0)-Qt}$ models profiles, for test OYSC40, Øysand site. In the experts' profile, Unit I is sand (silty, fine; layers and seams of medium to coarse sand), Unit II is sand (fine to coarse, gravelly), Unit III is sand (fine, traces of organic material), Unit IV is sand (fine to medium, silty), Unit V is sand (medium to coarse, gravelly), Unit VI is sand (fine to medium, silty), Unit VII is silt (sandy, clayey), and Unit VIII is sand (fine to medium, silty) (Quinteros et al. 2019).

4.2.3 Øysand

Figure 6 shows the experts' stratification profile (Quinteros et al. 2019) compared with the (R/S)IGTOSS profiles for test OYSC40. The experts recognized several strata of sandy soils for the whole depth, except for Unit VII, which is mainly silty. Similarly, the (R/S) IGTOSS models identified mostly sand mixtures; except SIGTOSS$_{Fr-Qt}$ that identified silts and transitional soils, i.e. SBT=3, but at depths different from Unit VII. In general, the strata boundaries recognized by the models differ significantly from the experts'
Figure 7. Comparison of (a) experts' stratification profile with the (b) RIGTOSS$_{Fr-Qt}$, (c) RIGTOSS$_{Bq-Qt}$, (d) SIGTOSS$_{Fr-Qt}$, and (e) SIGTOSS$_{(Δu2/σ'v0)-Qt}$ models profiles, for test TILC17, Tiller-Flotten site (L'Heureux et al. 2019).

judgement at Øysand; although, the SBT characterization is quite similar.

4.2.4 Tiller-Flotten

Figure 7 compares the SBT profiles by the experts (L'Heureux et al. 2019) and (R/S)IGTOSS models for test TILC17. It is interesting that only the SIGTOSS$_{(Δu2/σ'v0)-Qt}$ model has clearly recognized the sensitive clays. Albeit, in the SIGTOSS$_{Fr-Qt}$ model the SBT has been mainly either 1c, sensitive clay, or 3, i.e. silts and transitional soils. Besides, the RIGTOSS model could not recognize the sensitive clays, i.e. SBT = 1, well; however, it found them as clays or silt mixtures. Further, it can be observed that the strata change depths are recognized differently by the models and the experts.

4.2.5 Comparison of classification charts

Comparing the RIGTOSS$_{Fr-Qt}$ and RIGTOSS$_{Bq-Qt}$ profiles in Figures 4-7 for each test, indicates almost similar stratification profiles. However, differences can be due to the different numbers of SBT zones on the classification charts, and different interpreted parameters used in each of them.

Similarly, comparing the SIGTOSS$_{Fr-Qt}$ and SIGTOSS$_{(\Delta u2/\sigma'v0)-Qt}$ profiles in Figures 4-7 indicates almost similar profiles with respect to the strata boundaries depths; but the SBT differences are visible. Besides, data points may be located out of the boundaries of the SIGTOSS$_{(\Delta u2/\sigma'v0)-Qt}$ chart, i.e. SBT='f' in the profiles. This may originate from several factors, such as the incompatibility of the chart with the Norwegian soils, using different interpretation methods in this study in contrast to the ones used in Schneider et al. (2012), and the small zone of '1c' on the chart.

Figures 4-7 indicated that judging based on the Schneider's chart might have advantage over using the Robertson chart for the Norwegian fine-grained soils; although, it can be confusing to differentiate clays from silts based on the Schneider's chart.

On the other hand, comparing the RIGTOSS and SIGTOSS profiles, less strata are determined based on the charts proposed by Schneider et al. (2012), while they include less SBT zones. Then, it may affect the precision of stratification and the recognized number of strata; which can be observed in Figures 5 and 6, as examples.

5 CONCLUSIONS

A stratification-classification model by Farhadi & Länsivaara (2021) is developed further in this study to include different CPTu-based soil classification charts. The developed models are applied to four Norwegian soils. As observed, the stratification profiles of the models are comparable with the profiles presented by experts –which resulted from extensive field and laboratory experiments. However, there are still differences between them, principally originating from:

- using different soil classification viewpoints or parameters implemented in the available classification charts,
- incompatibility of the used classification charts with the Norwegian soils, especially for fine-grained soils, and,
- spatial variability of soils, resulting into almost different stratification profiles for the CPTu tests performed close to each other.

In addition, it was observed that the CPTu measurements points may be located out of the bounds of the Schneider's $\Delta u_2/\sigma'_{v0} - Q$ chart, which could be caused by the incompatibility of the chart with the Norwegian soils.

ABSTRACT: In this paper, Hardening Soil model with small-strain stiffness (HSsmall) and Delta-Sand model are used as constitutive soil models to simulate the Cone Penetration Test (CPT) using the Material Point Method (MPM). Both models are formulated within the double hardening framework, in which independent yield surfaces represent mechanical behavior of soil under deviatoric and volumetric loadings. DeltaSand is a new advanced state-dependent constitutive model in which the relative density is incorporated in the formulation to represent the mechanical behavior of soil under deviatoric and volumetric loading in different stresses and relative densities. The numerical simulations are compared with CPTs in Cuxhaven Sand in a calibration chamber. Both constitutive soil models are compared with each other and DeltaSand is found to be capable to capture the soil behavior during quasi-static CPT.

1 INTRODUCTION

The Cone Penetration Test (CPT) is a widespread tool in both onshore and offshore for soil characterization, (Lunne 2010) due to repeatability, accuracy, and simplicity. Simulating CPT, as a mean to further interpret and understand the CPT results, is challenging because of the large deformation near the cone and complex behavior of soil under various type of loading. Different numerical approaches have been used to simulate CPT, considering the large deformation calculations, such as the Particle Finite Element Method in Geomechanics (G-PFEM) (Monforte *et al.* 2017, 2018, Schweiger & Hauser 2021, Carbonell *et al.* 2022), Finite Difference Method (FDM) (Moug *et al.* 2019), Finite Element Method (FEM) (Goodarzi *et al.* 2018), Discrete Element Method (DEM) (Khosravi *et al.* 2020), and the Material Point Method (MPM) (Ghasemi *et al.* 2018,

Martinelli & Galavi 2021). Each of these approaches has its pros and cons. For instance, investigation of the interactions of the soil particles with each other and with the cone is possible through DEM simulation in a precise manner. However, a high number of particles and, followed by that, a significant amount of time is required for a realistic boundary value problem. FEM has the ability to model realistic boundary value problems and lower computational time but suffers from mesh distortion in the simulation of large deformation problems. On the other hand, MPM discretizes the continuum medium in material mass points and has the ability to simulate large deformations' problems without mesh distortion. MPM utilization in different geotechnical problems is comparatively new (Coetzee *et al.* 2005, Zabala & Alonso 2011, Sołowski & Sloan 2015, Goodarzi & Rouainia 2017, Ghasemi *et al.* 2018, Galavi *et al.* 2019).

In addition to the numerical approach to simulate CPT, employing an appropriate constitutive soil model to predict the soil behavior in different soil states is indispensable. Various soil models have been used to predict the soil behavior in CPT simulations, such as Mohr-Coulomb (Huang *et al.* 2004), Drucker–Prager (Susila & Hryciw 2003), Hardening Soil (HS) (Tolooiyan & Gavin 2010), and Hypoplastic with intergranular strain (Fan *et al.* 2018). However, either they need recalibration for different relative densities or face several issues pertaining to the numerical stability.

In this paper, the Material Point Method, along with Hardening Soil model with small-strain stiffness (HS-small) and DeltaSand model (Galavi 2021), is used. The latter model is a new advanced state-dependent constitutive soil model, which is an elasto-plastic constitutive model formulated based on the double hardening framework. The simulation outcomes are compared with CPT tests in the MARUM Calibration Chamber (MARCC) in order to evaluate the capability of the new constitutive model in capturing the soil response throughout the simulation of CPT.

2 NUMERICAL MODEL

2.1 *MPM formulation*

The benefits of combined point-based and mesh-based strategies in MPM is the avoidance of mesh distortion and collecting the history of simulation in material points. (Sulsky *et al.* 1994).

The entire domain of the problem is covered by computational mesh similar to FEM. Additionally the continuum body is divided into a set of Material Points (MPs), which can relocate in the whole computational mesh contrary to the fixed position of Gaussian integration points within elements in FEM.

In the material point method, the momentum balance equations are solved in the computational mesh nodes, and constitutive equations and mass conservations are solved in MPs. The required information for solving balance equations in the mesh is transferred from MPs to the degrees of freedoms at nodes in the beginning of each calculation step. After solving the balance equations at nodes, the position of MPs, acceleration, and velocity at the MPs will be updated. The computational grid does not store any permanent information; therefore, all nodal data are discarded at the end of each calculation step.

A contact algorithm is employed to model the frictional contact between the cone and the soil. In order to enhance the precision of the contact algorithm and simulate the cone penetration into the soil, the moving mesh concept (Al-Kafaji 2013) is utilized here. In this concept, the deformable mesh is located between the fixed boundary and the moving mesh part, adjusting its dimensions with time. The refined mesh at the contact will always stay around the cone in this concept.

In standard MPM, MPs inside elements are used as integration points. Therefore, the accuracy of the integration depends on the location and numbers of MPs. The Gauss integration method, in contrast, utilizes a fixed number of integration points in a perfectly suited location to obtain accurate integration similar to FEM (Beuth & Vermeer 2013). Beuth *et al.* (2007) suggested a combination of both integration methods to mitigate stress oscillations in elements due to MPs crossing between elements. This is based on an assumption that stresses of MPs in a fully-filled linear element are identical, and therefore, stress calculation and integration can be performed on one Gauss Point in the elements. This numerical scheme leads to less computational effort than the standard material point integration (Martinelli & Galavi 2021). This mixed integration method is used in this study.

In problems in which the inertia effect is insignificant, mass scaling can reduce the computational cost by scaling the density. This scheme increases the time step size by a factor of $\sqrt{MS}$:

$$\Delta t_{critical}{}^{MS} = \frac{L_{min}}{\sqrt{E/MS \times \rho}} = \sqrt{MS} \times \Delta t_{critical} \quad (1)$$

where Δt_{crit} is the critical time step; L_{min} is the smallest element length; E is young modulus; ρ is density, and MS is the mass scaling factor. Sensitivity analysis is required to determine the amount of mass scaling factor such that it does not lead to inaccurate results. More information about the MPM formulation can be found in (Martinelli & Galavi 2021).

2.2 *Constitutive soil models*

This paper uses two constitutive soil models, HS-small and DeltaSand, to model the cone penetration into the soil. The list of parameters for the HS-small model and their values for the Cuxhaven sand for different relative densities are given in Table 1 and 2.

The full description of HS-small model can be found in (Benz 2007). The parameters of the HS-small model are calibrated for the Cuxhaven Sand based on laboratory experiments (Kluger 2014). Since the state dependency is not implemented in the HS-small model, unrealistically high dilation during shearing might occur. The maximum dilation angle is, therefore, decreased to stop unrealistic volume increase during extensive deformations (Martinelli & Galavi 2021).

DeltaSand captures the soil behavior under volumetric and deviatoric loading in different soil states (Galavi 2021). Deviatoric, volumetric, and tension cut-off yield surfaces are incorporated in the model. The deviatoric part in DeltaSand includes three deviatoric yield surfaces such that two of which are implemented to reproduce the cyclic behavior of sands. An extended Marsouka-Nakai criterion

Table 1. Description of HS-small model parameters.

parameters	Units	Description
E_{50}^{ref}	[kPa]	The secant stiffness from triaxial test when the ratio of deviatoric stress to the deviatoric stress at failure is 0.5
E_{oed}^{ref}	[kPa]	The tangent stiffness obtained from oedometer tests
E_{ur}^{50}	[kPa]	Unloading/reloading stiffness
v_{ur}	[−]	Unloading/reloading Poisson's ratio
φ'	[°]	Effective friction angle
c'	[kPa]	Effective cohesion
ψ	[°]	Dilation angle
m	[−]	Rate of stress dependency in stiffness behavior
$\gamma_{0.7}$	[−]	Shear strain at which the shear modulus decreases to almost 70% of its initial value
G_0^{ref}	[kPa]	Shear stiffness at small strains
R_f	[−]	Failure ratio q_f/q_q (ratio of deviatoric stress at the failure to an asymptotic value of deviatoricstress)

Table 2. HS-small model parameters.

parameters	Units	Relative Densities (%)			
		83.48	85.63	86.85	92.53
E_{50}^{ref}	[kPa]	83000	85500	86500	92500
E_{oed}^{ref}	[kPa]	83000	85500	86500	92500
E_{ur}^{50}	[kPa]	249000	256500	259500	277500
v_{ur}	[−]	0.2	0.2	0.2	0.2
φ'	[°]	41.4	41.7	41.8	42.4
c'	[kPa]	1	1	1	1
ψ	[°]	0.01	0.01	0.01	0.01
m	[−]	0.439	0.432	0.429	0.411
$\gamma_{0.7}$	[−]	0.00012	0.00011	0.00011	0.00011
G_0^{ref}	[kPa]	116700	118200	119000	122900
R_f	[−]	0.896	0.893	0.891	0.884

(Matsuoka & Nakai 1974) is used for the deviatoric yield surfaces. The hardening-softening rule that is used in this model is given in Eq. (2):

$$\sin \varphi'_{mob} = \sin \varphi'_i + \frac{\varepsilon_q^p f_d(e)}{A + \varepsilon_q^p} \left(\sin \varphi'_{cv} - \sin \varphi'_i \right) \quad (2)$$

where $f_d(e)$ is a function to connect the hardening-softening rule to the current void ratio; φ'_i and φ'_{cv} are initial effective and critical friction angles, respectively; A is a parameter to control plastic stiffness.

The volumetric section of DeltaSand is an elliptical yield surface with an associated flow rule. This yield surface is expressed as follows:

$$f_v = \frac{q^2}{M_v} + p'^2 - p_c^2 \quad (3)$$

where q and p' are Von Mises deviatoric stress and mean effective stress, respectively; p_c is effective pre-consolidation stress; M_v is a shape factor that is acquired from a 1D consolidation loading. A full explanation of the constitutive relations of the DeltaSand model can be found in (Galavi 2021).

2.3 The schematization of CPT in the calibration chamber

The calibration chamber was developed in the Marine Engineering Geology working group of the Center for Marine Environmental Sciences (MARUM), University of Bremen (Fleischer *et al.* 2016, Stähler *et al.* 2018). MARCC samples have a diameter of 30 cm and a height of 55 cm. A piezocone with a diameter of 12 mm is used in the chamber. This chamber has the capability of conducting the tests under "BC5" boundary conditions (Fleischer *et al.* 2016).

The numerical model geometry used as equivalent to MARCC BC5 (simulated field boundary condition) is shown in Figure 1. BC5 presumes that the specimen is in an infinite soil volume with known horizontal stiffness (Kluger *et al.* 2021). The ratio of chamber diameter to cone diameter in the numerical model is 125 for field conditions to avoid boundary effects. A thin layer of 5 cm is modeled with a linear elastic material to simulate the vertical effective stresses in experiments. Vertical effective stress equals 200 kPa, and the K_0 value is 0.45 as it was in the laboratory experiments. Due to the symmetry of the geometry, a 2D axisymmetric material point formulation (Galavi *et al.* 2019) is employed. The meshes are fine near the cone, and their size increase as they get close to the far-field boundary. Quadrilateral elements are used in all simulations.

The mini-cone is modeled as a rigid body that penetrates into the soil under drained condition with a prescribed velocity of 2 cm/s like in the laboratory experiments. The initial position of the cone is below the soil surface, and it is pushed into the soil until it reaches a steady-state for measuring the cone resistance q_c. The contact friction angle of 15 degrees is chosen as the cone surface is smooth (Al-Mhaidib 2005). At the beginning of the simulations, the MPs' positions are defined uniformly in rectangular clusters in the whole domain. This uniform distribution is independent of the elements' size and type. In order to avoid the formation of unrealistic empty elements, the number of material points was chosen so that they fill all elements throughout the penetration.
Figure 1. Schematic illustration of the model geometry. Yellow: cone, green: soil, blue: elastic layer as a surcharge.

Table 3. DeltaSand parameters.

parameters	Unit	Description
f_G^{ref}	[−]	Reference elastic stiffness
n	[−]	Power stiffness parameter
h_s	[stress]	Hardness parameter
C_{oed}	[−]	Oedometer parameter
α	[−]	Parameter to control peak friction angle
β	[−]	Parameter to control volumetric behavior
A_{mat}	[−]	Plastic stiffness parameter
e_{min}	[−]	Minimum void ratio
e_{crit}	[−]	Critical void ratio
e_{max}	[−]	Maximum void ratio
φ'_{cv}	[°]	Friction angle in constant volume

γ_r	[−]	Reference shear strain at $G_{ratio} = 0.722$

*$G_{ratio} = G_0/G$

3 RESULTS

3.1 *Calibration of DeltaSand*

Prior to the simulation of CPT in the calibration chamber, the parameters of the DeltaSand model for Cuxhaven sand were obtained from experiments. The oedometer tests with four relative densities and triaxial tests with three relative densities are used to cover medium-dense to dense sand samples (Kluger 2014). In this study, the kinematic hardening parts of the model, implemented in the model to capture the mechanical behavior of soil under cyclic loadings, were ignored. Therefore, only parameters related to the isotropic hardening parts of the model are calibrated and presented here. A brief description of DeltaSand parameters is presented in Table 3. The calibration procedure was conducted using the SoilLab feature of PLAXIS (Plaxis 2021). The results of the calibration are depicted in Figure 2 and Figure 3, and the final set of parameters is given in Table 4. Detailed explanations and steps for calibrating the DeltaSand model are represented in (Galavi 2021).

3.2 *Simulation results vs. laboratory tests*

In this section, the capabilities of the constitutive soil models are shown by comparing the numerical outcomes with laboratory test results. The same geometry, boundary conditions, number of elements, number of material points are used for comparing the constitutive soil models. The steady-state cone resistance was reported here obtained from averaging the values of cone resistances for depths between 18-32 cm, similar to the experiments.

Table 4. Set of parameters used in all numerical simulations.

f_G^{ref} [−]	n [−]	h_s [MPa]	C_{oed} [−]	α [−]	β [−]	A_{mat} [−]	e_{min} [−]
920	0.3	30	1.1	1.65	0.95	0.016	0.47

e_{crit} [−]	e_{max} [−]	φ'_{cv} [°]	G_{ratio} [−]	γ_r [−]
0.8	0.85	32	5	0.0001

Figure 3. Simulation (DeltaSand and HSsmall) and experimental results of drained monotonic triaxial tests on medium dense and dense sand.

3.2.1 *DeltaSand constitutive model*

A sensitivity analysis to identify the optimum mesh size was conducted for DeltaSand. The results of simulations for fine, medium-fine, and coarse mesh

Fine mesh   Medium-fine mesh   Coarse mesh
Figure 4. Different mesh size adjacent to cone.
Figure 5. Mesh size effect on qc-Dr results (Black: Dr = 83.48%, red: Dr = 86.85%, and blue: Dr = 92.53%).
Figure 6. Comparison of experimental and numerical results using DeltaSand and HSsmall model (Upper bound obtained using φ_{peak} and lower bound using $\varphi_{critical}$ in HSsmall model).

were compared to each other. The obtained averaged q_c regarding depths between 18-32 cm for fine and coarse mesh are within 2% and 5% of the ones obtained with fine mesh. The number of elements for coarse mesh is 929 and for medium-fine and fine mesh are 2463 and 3680, respectively. The average element size exactly beneath the tip for coarse mesh is 4 mm and for medium-fine and fine mesh are 1.7 mm and 1.1 mm, respectively. Therefore, the medium-fine is an optimum choice for analysis, considering that the results do not differ tremendously

from the ones obtained from finer mesh. Moreover, using medium-fine mesh is computationally more efficient. Figure 4 shows different mesh sizes adjacent to the cone. Figure 5 illustrate the results of q_c in different depth for different mesh sizes. Besides, the experiment result for relative density 83.48% is included in this figure.

Figure 6 illustrates the q_c – D_r curve for both numerical and experimental data under BC5 condition. The obtained results with DeltaSand match well with the experimental data. A set of parameters is used for all relative densities, which demonstrates the capability of DeltaSand.

3.2.2 *HS-small constitutive model*
The input parameters for HS-small model are calibrated based on relative density for the Cuxhaven sand and were presented in Table 2 and Figure 3. Figure 3 represents the calibration results based on two different friction angles- peak and critical friction angles are shown by solid and dashed lines, respectively. Figure 6 compares the obtained qc – Dr curve from numerical modeling with laboratory tests under the BC5 condition. Contrary to the DeltaSand model, the Hardening Soil has no state-dependent parameter. It should be noted that the simulations are run with two different friction angles, the critical friction angle as lower bound and the peak friction angle upper bound, while other parameters are constant. The experimental data are located between the lower and upper bound numerical simulations. Another shortcoming of the HS-small soil model is that different sets of parameters have to be used for each relative density.

4 CONCLUSION

In this study, the cone penetration in a small volume calibration chamber MARCC was simulated using two different constitutive soil models, namely Hardening Soil with small-strain stiffness and DeltaSand.

Prior to simulations, material parameters were calibrated for both constitutive soil models based on the laboratory tests. The results showed that Delta-Sand can capture the sand behavior better than the HSsmall.

The result of simulations showed that the Delta-Sand model can capture the soil behavior around the cone for different relative densities with one set of parameters. Simulating CPT with HS-small soil models, however needs recalibration of material parameters for different relative densities and neither calibration of the model at peak strength nor at critical state strength could reproduce the experimental results for a complex problem like CPT. Moreover, the effect of element size on simulation outcomes was analyzed in this study. The simulations showed that the mesh size has a negligible effect on the results for fine and medium-fine meshes, while a coarse mesh can affect the results.

ABSTRACT: When dealing with unsaturated soil conditions, the influence of matric suction on cone tip resistance of the soil above the ground water table is typically neglected in engineering practice, with consequent possible misinterpretation of soil features. In the last decades, various researchers have investigated the influence of suction on cone resistance for sands, whilst still little is known for silty materials, whose contribution can be significant and extended for many meters above the groundwater table. Such issue is especially relevant for compacted earth structures, like river embankments, typically made of a heterogeneous mixture of intermediate soils. With the aim of providing a contribution and stimulating its correct implementation into geotechnical practice, a set of miniature piezocone tests have been carried out in a centrifuge on both saturated and partially saturated silty sand models. The interpretation of CPT results is discussed, highlighting the effect of partial saturation on cone tip resistance.

1 INTRODUCTION

Due to its reliability and time and cost effectiveness, the cone penetration test (CPT) represents a valuable tool for continuous stratigraphy profiling and geotechnical soil properties estimation. Most of the existing approaches for analyzing CPT results are based on fully saturated or dry conditions, for which interpretation methods are well established and have a solid theoretical background (Robertson and Campanella 1983a, b; Lunne et al. 1997; Mayne 2007; Robertson 2009). However, in several cases CPT soundings may cross a vadose zone, conventionally extended from the ground level to the water table, where partially saturated soil states are very likely to occur. Thus, a reliable interpretation of CPT data in unsaturated soil layers is of pivotal importance for the design, optimization and management of the engineering works interacting with soils at shallow depths (e.g. foundations, road pavements) or influenced by infiltration, evapo-transpiration and transient groundwater flow, such as river embankments, earth dams or backfill of retaining walls.

As observed by Yang and Russell (2016), for an accurate analysis of CPT results in partially saturated soils, the in-situ stress state needs to be accurately evaluated, taking into account the variations with depth of the matric suction and the effective degree of saturation of soils. In the current practice, instead, the

contribution of suction to the effective stress is frequently neglected, due to difficulties in assessing the in-situ moisture content and in obtaining a reliable pore water pressure distribution, often resulting in excessively conservative design approaches and in the incorrect evaluation of soil features (Russell and Khalili 2006). Various studies have been recently carried out to gain insights on the influence of unsaturated conditions on CPT data, mostly limited to sandy soils (Hryciw and Dowding 1987; Bolton et al. 1999; Russell et al. 2010; Pournaghiazar et al 2013; Jarast and Ghayoomi 2018), all showing evidence that the cone penetration resistance, q_c, can be significantly increased by suction. Conversely, limited research has been carried out on CPTs in unsaturated silty materials (Silva and Bolton 2005; Tan 2005; Yang and Russell 2016), due to the intrinsic complexity related to partial drainage, occurring during penetration at the standard rate of 20 mm/s (Paniagua et al. 2014), and to the microfabric of intermediate soils. Most of these studies have been performed on reconstituted samples, under the controlled laboratory environment of calibration chambers or centrifuges, in order to eliminate the typical uncertainties related to soil heterogeneity and parameters estimation, while only few field tests have been performed so far to evaluate the effect of soil moisture content on the cone resistance, q_c (Lehane et al. 2004; Collins and Miller 2014; Giacheti et al. 2019). The

present paper aims at contributing to a better understanding of the effect of matric suction on CPT results interpretation. For this purpose, a set of piezocone tests have been carried out on a compacted mixture of sand and finer material in the 240 g-ton geotechnical centrifuge facility at the Experimental Institute for Geotechnical Modelling (Italian acronym: ISMGEO) of Seriate (Bergamo, Italy), in both saturated and partially saturated conditions. The use of monitoring sensors allows to clearly define the pore pressure distribution of the models under different water table depths. Furthermore, implications of using various assumptions on the calculation of the effective stress states during penetration, starting from matric suction measures, are preliminarily discussed and CPT calibration in the centrifuge is attempted.

2 EXPERIMENTAL CAMPAIGN

2.1 Equipment, tested material and test procedure

A scheme of models tested is presented in Figure 1. The testing soils are Ticino sand (TS, Baldi et al., 1982, 1986, Fioravante, 2000, Jamiolkowski et al., 2003, Fioravante & Giretti, 2016) and Pontida clay (PON, Ventini et al. 2021). TS is a coarse to medium, uniform silica sand, of alluvial origin, mainly composed by angular grains; PON is a low plasticity kaolinitic clayey silt, deposited in a post-glacial lake environment. The overall experimental campaign has been performed considering different mixtures of TS and PON. However, in this contribution, only the results of a test carried out on a mixture of 85% by weight of TS and 15% by weight of PON are discussed. The main physical properties of the mixture, obtained from an accurate laboratory characterization, are listed in Table 1. In particular, the minimum and maximum dry density have been obtained following ASTM 4254 - Method A (2016) and ASTM D1557 - 12e1 (2012) - Modified Proctor method, respectively. Figure 2 compares the grain size distribution of TS, PON and the mix.

Table 1. Main physical properties of the mixed soil 85% TS+15%PON.

SOIL	G_s	d_{50}	C_U	C_C	$\gamma_{d,min}$	$\gamma_{d,max}$
	-	mm	-	-	kN/m³	kN/m³
85%TS+15% PON	2,695	0,499	13,2	10,9	13,92	18,15

The ISMGEO miniaturized piezocone used in the tests has a diameter d = 11.3 mm and a total cone area of 100.3 mm². It incorporates a 60° cone tip with a load cell to measure tip forces up to 9.8 kN and a 36.9 mm long shaft, which connects to an upper

section containing a second 9.8 kN load cell, used to measure tip resistance plus sleeve friction. In addition, the cone has a 35-bar capacity Druck PDCR pressure transducer for interstitial pressure measurements. Physical models were reconstituted in layers of prescribed height to obtain a 1g dry density of 90% of $\gamma_{d,max}$ and using an initial water content of about 17%. The container was a cylindrical box, 400 mm in diameter. With a ratio D/d (D is the container diameter) equal to about 36, boundary side effects were minimized. During the reconstitution, pore pressure transducers (ppts M, P, Q, N, R) and tensiometers (tens 1, 2, 3) were embedded in the model at prescribed heights (Figure 1) and at a distance of 50 mm from the box axis. Once the total height was achieved, the soil saturation was completed applying to the model a continuous vacuum pressure of about -70 kPa for 12 hours. Then a rigid frame which holds a linear displacement transducer to monitor
Figure 1. Sketch of the cylindrical strongbox containing details of geometry, transducers and in-flight miniature probe.
Figure 2. Grain size distribution of the tested soils.

the soils surface settlement, the miniaturized piezocone and the actuator was fixed to the top of the container.

The container was loaded onto the centrifuge and accelerated to the target (50g at the soil surface). After the in-flight consolidation, a first CPTU was carried out in the central axis of the model. At the end of penetration, the penetrometer was lifted, the centrifuge was stopped, the equipment was moved 70 mm from the original position and the model was re-accelerated. When the pore pressure equilibrium was achieved again, as identified by real-time pore pressure monitoring data, an outflow was imposed to the soil model by opening a hydraulic valve placed at the bottom of the cylindrical box. The outflow was interrupted when the water table reached almost mid depth. Following pore pressure stabilization, a second CPTU was carried out in a model partially saturated in the upper part and saturated below, with matric suction and pore pressure data continuously recorded. It has to be noticed that, due to settlement induced by saturation, centrifuge accelerations and desaturation of the model, the soil sample underwent a progressive increase in density, with an average void index value equal to 0.480 (at the beginning of the test in saturated conditions) and to 0.475 (at the beginning of the test in partially saturated conditions).

3 CENTRIFUGE TEST RESULTS

The data recorded during the piezocone advancement in both fully saturated soil conditions (continuous lines) and with the phreatic surface below the ground level (dotted lines) are presented in Figure 3. To take into account the progressive mobilization of the cone resistance from the free model surface (Schmertmann, 1978), the data registered in the first

10 d of penetration from the ground level were removed (Gui and Bolton 1998). The plot shows the variation with the dimensionless depth (i.e. the ratio between penetration depth, z, and cone diameter, d) of the sleeve friction resistance, f_s, and of the corrected cone tip resistance, q_t, this latter expressed as:

$$q_t = q_c + u_2(1 - a) \qquad (1)$$

where q_c is the measured cone tip resistance, $a = 0.785$ is the net area ratio, determined from laboratory calibration, and u_2 is the pore pressure generated during cone penetration and measured just behind the cone. In addition, the pore pressure values measured by ppts (in the positive range) and tensiometers (both in positive and negative ranges) are also plotted, with circles and triangles, respectively, together with u_2 data. The dimensionless depth of the water level has been determined from the measures of the ppt placed at the bottom of the
Figure 3. Variation with the dimensionless depth, z/d, of the sleeve friction resistance, fs, of the pore pressure generated during cone penetration, u2, together with the pore pressure measurements (circles and triangles) and of corrected cone tip resistance, qt.

model; for the test in unsaturated conditions, its value, $z/d_{w,UNSAT}$, is equal to 18.7 and is drawn in bold hatched line (Figure 3).

The ppts and tensiometers monitoring data fit quite well the u_2 measured during penetration, showing a hydrostatic distribution of pore pressures in the positive range of values in both experiments (SAT and UNSAT) and a less than hydrostatic distribution in the unsaturated area (UNSAT model), highlighting that the process of lowering the water table led to a hydraulic equilibrium of pore pressure in the saturated soil area also for the unsaturated test. On the other hand, distributions of q_t and f_s show significant differences between the two tests, i.e. higher cone tip resistance and sleeve friction in the area where desaturation occurred, where the suction effect is clearly tangible. It should be noticed that, since the cone tip and sleeve friction resistances vary with the relevant overburden stress for the same material, the CPT data plotted in Figure 3 require a stress normalization for a proper interpretation and comparison of resistance profiles.

4 STRESS NORMALIZATION

Stress conditions are significantly different in the two tests. The change in the water table depth, in fact, leads to a variation of the saturation level and produces suction states in the partially saturated soil in the UNSAT experiment and subsequent effects on the test results. At least two independent stress state variables should be considered for an accurate description of the relevant soil behaviour (i.e. Morgenstern, 1979; Fredlund et al., 2012); however, it is also well known that the most commonly used CPT charts and correlations are based on a single-valued effective stress approach. To show the implications of adopting a single-valued effective stress approach, the Bishop's effective stress equation (1959) for unsaturated soils has been here used, such as:

$$\sigma' = (\sigma - u_a) + S_r(u_a - u_w) \tag{2}$$

with $(\sigma - u_a)$ being the net stress, S_r the degree of saturation and $(u_a - u_w)$ the matric suction. For such test interpretation, it is therefore required the knowledge of the distribution of S_r and of $(u_a - u_w)$, typically not readily available in traditional engineering applications. Two different assumptions have been thus made here, with a first simplified case (UNSAT,1) considering a hydrostatic distribution of pore pressure above the groundwater line and a constant degree of saturation equal to 0.5, while a second case (UNSAT,2) aims at representing the experimental conditions closely, with a matric suction distribution determined on the base of tensiometer measurements and a variable degree of saturation, provided by the water retention curve obtained from physical soil properties through the procedure suggested in Aubertin et al. (2003). For both cases, the calculated values of total stress, σ_v, and effective stress,

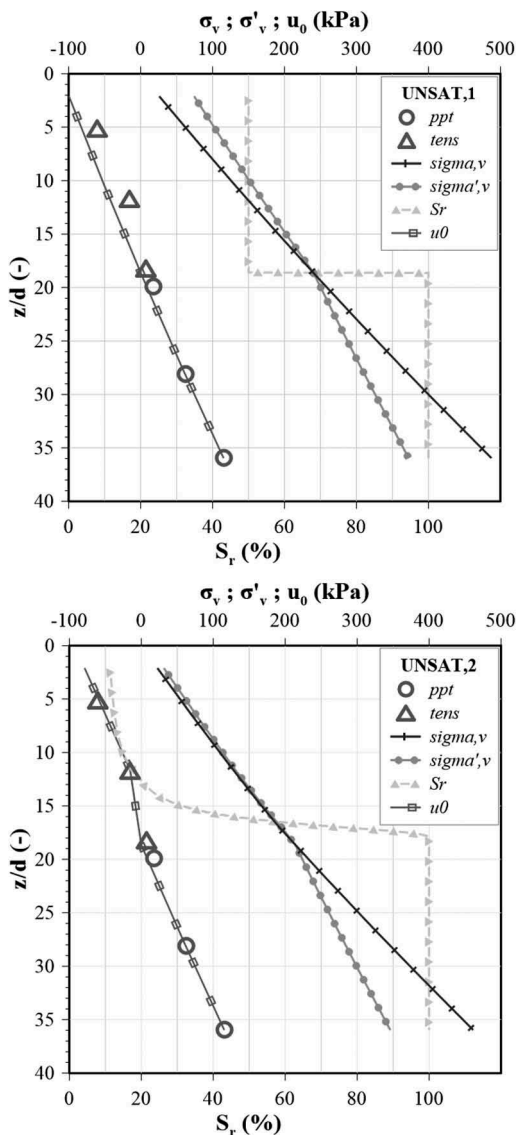
σ'_v, the pore pressure, u_0, and the degree of saturation are plotted with dimensionless depth in Figure 4. Considering a constant 0.5 value of the degree of saturation (UNSAT,1), a noticeable increase in the effective stress distribution is produced. Instead, due to the significant percentage of sand in the tested material, the degree of saturation tends to rapidly reduce with the increase of matric suction (absolute) values, evidencing in case UNSAT,2, a limited impact on the effective stress as calculated with equation (2). It is now possible to try to determine general trends in the soil response to CPT advancement.


Figure 4. Calculated values of total, σ_v, and effective, σ'_v, stresses acting on vertical direction, pore pressure, u_0, and degree of saturation, S_r, are plotted with dimensionless depth, z/d, under a simplified assumption (UNSAT,1 top graph) and based on tensiometer data (UNSAT,2 bottom graph).

According to Robertson's (2009) very popular unified approach, the normalized cone resistance, Q_{tn}, and the Soil Behavior Type index, I_{cn}, are calculated using a stress exponent, n, that varies with soil type and stress level. Specifically:

$$Q_{tn} = \left(\frac{q_t - \sigma_v}{p_{a2}}\right)\left(\frac{p_a}{\sigma'_v}\right)^n \qquad (3)$$

$$I_{cn} = \left[(3.47 - logQ_{tn})^2 + (logF + 1.22)^2\right]^{0.5} \qquad (4)$$

$$n = 0.381(I_{cn}) + 0.05\left(\frac{\sigma'_v}{P_a}\right) - 0.15 \qquad (5)$$

$$F = f_s/[(q_t - \sigma_v)] \qquad (6)$$

where p_a and p_{a2} are reference pressures in the same units of q_c, σ_v and σ'_v, while F is the normalized friction ratio. Results obtained from the present CPT tests performed before (SAT) and after (UNSAT) the water table lowering are plotted in Figure 5, in terms of Q_{tn} and I_{cn}, considering both the simplified (UNSAT,1) and the more accurate (UNSAT,2) assumptions for the calculation of stress conditions (see Figure 4). Considering the test conducted in fully saturated conditions (SAT), values of Q_{tn} and I_{cn} tend to be relatively constant with depth and typical of sandy materials, in good agreement with Robertson's approach.
Figure 5. Variation with the dimensionless depth, z/d, of the normalized cone resistance, Q_{tn}, and the Soil Behavior Type index, I_{cn}, calculated using the stress exponent, n.

However, for the test performed after the water table lowering, significant variations can be found in the values of Q_{tn} when comparing the advancement in the saturated versus the unsaturated zones. For dimensionless depths lower than $z/d_{w,UNSAT}$ (18.7), none of the two assumptions on the effective stress and saturation degree provide uniform Q_{tn} profiles, despite the material is essentially the same in the two experiments, showing higher normalized cone resistances in the unsaturated with respect to the saturated zone. Indeed, below the water table, the assumption based on monitoring data (UNSAT,2) tends to produce similar values to the test performed in fully saturated conditions, rather than for the case of a simplified assumption (UNSAT,1). Analogous observations can be done for the I_{cn} data, always within the range of sandy materials (1.31 – 2.05), but with substantial differences between the saturated and the unsaturated zones.

Hence, adopting a single-valued effective stress approach for stress normalization to interpret the CPT data in the unsaturated zone appears to be not fully reliable.

5 CONCLUSIONS

Results from small-scale laboratory tests, which included CPT execution with pore pressure and suction measurements in a centrifuge environment, have been presented herein. The experiments described are referred to a soil mixture, made of mainly coarse-grained particles with a limited fine fraction, tested under different saturation conditions. In fact, the only variation in the two presented cases was related to their water table depth, either at almost the ground surface or at a lower level, obtained through a dewatering process. Monitoring sensors, pore pressure transducers and tensiometers, located along the model depth, played an essential role in determining the soil suction distribution above the water table and in identifying the hydraulic equilibrium reached at the end of the outflow phase. Data measured during cone penetration tests (f_s, q_t and u_2), before and after the dewatering process, show only limited differences in the saturated zones, further reduced by adopting the stress normalization of Robertson's unified approach.

On the other side, when comparing cone penetration data measured in the unsaturated versus the saturated zones, substantial differences in the selected stress-normalized results (Q_{tn} and I_{cn}), regardless of the assumption on suction and saturation degree profiles above the water table, can be detected. Therefore, from the data presented herein, it would appear that the effect of partial saturation on cone tip resistance provided by the matric suction is not duly taken into account by simply applying a stress normalization by the Bishop's equation for unsaturated soils. In other terms, it seems that the combined use of a single effective stress variable (as typically assumed when more specific information on

unsaturated soil behavior is lacking) with the standard CPT charts and correlations cannot produce a similarly reliable data interpretation. Additional investigations, including the use of other materials, are clearly required to better define such critical issue.

ABSTRACT: The Offshore Wind Industry's rapid expansion across the globe requires geotechnical modelling of sites that are often characterized by layers of silty sand and silt mixtures. The CPTU is the main *in situ* offshore investigation tool for defining the ground conditions and for establishing facility position and soil parameters for foundation design, but no simple and robust methodologies exist for characterizing transitional soils. This paper presents some results of CPTUs carried out in a large calibration chamber and in a centrifuge aimed at contributing to the development of guidelines for planning, specification, execution, and interpretation of CPTUs in transitional soils.

1 INTRODUCTION

After the installation of the first Offshore Wind Farm in Denmark in 1991, the Offshore Wind Industry (OWI) has been increasing exponentially in Europe and recently also in new markets such as the US East Coast and the Asia-Pacific Countries.

Soil modelling and spatial mapping for the design and installation of foundations for offshore wind turbines is generally based on the combined and staged use of seismic surveys, piezocone penetration testing (CPTU) and boreholes with soil sampling. However, in many regions where the OWI is expanding, layers of transitional soils, i.e. neither clean sand nor clay,

are unexpectedly encountered and not predicted by the CPTU interpretation. This is mainly due to the lack of robust methodologies for characterizing silty sand and silt mixtures based on CPTU, as existing correlations between CPTU parameters and classification and engineering properties have been developed for sand and clay. Consequently, the cost and risk of developing offshore wind farms in these regions are high.

The goal of the CSi – CPTU in silty soils – Joint Industry Project is ultimately to develop guidelines for set-up, execution and interpretation of CPTUs in silty soils, see Augustesen et al. (2022). This goal is pursued by a combination of research activities including

in situ testing, numerical modelling and using a significant number of CPTUs, carried out in a large calibration chamber and in a geotechnical centrifuge at the ISMGEO laboratory (Italy, Baldi et al. 1982, Baldi et al. 1986).

With the main aim of highlighting the impact of fines content on soil strength and stiffness, the tests are carried out on a clean sand and on the sands mixed with non-plastic fines to obtain 15% and 30% fines content (grain size < 0.063 mm). Some of the preliminary results of the calibration chamber and centrifuge tests are presented in this paper, together with a brief description of the testing apparatuses and procedures.

2 TESTING SOIL AND PROGRAM

2.1 *Ticino Sand and Ticino Filler*

The sand and silty sand used for the experimentation are Ticino Sand (TS) and Ticino Filler (TF). TS is a clean silica sand used extensively in the past for calibration chamber, centrifuge and laboratory tests (Baldi et al. 1982, 1986, Fioravante 2000, Jamiolkowski et al. 2003, Fioravante & Giretti 2016). The batch used for the CSi project is named TS11, which is a natural, coarse to medium clean sand, with principal components of quartz (36% by weight), feldspar (40%), mica (11%). TF is the natural flour obtained by sieving the coarser fraction of Ticino sand and has similar mineralogical composition (21% quartz, 47% feldspar, 16% mica).

Optical microscope analysis evidenced that in both materials quartz is mainly present in subangular, equidimensional grains, feldspars are in both round and prismatic form, while micas are in lamellae. A diffractometric study shows that the mineralogical composition of the two materials is compatible with dominant origin from metamorphic rocks. Stereo microscope observations denote a type of transport that is relatively low in energy and of short duration, compatible with poorly worked sand.

Grain size distribution of TS11 and TF is shown in Figure 1. Table 1 lists the main index properties.

In this paper the preliminary results of tests carried out on clean TS11 and on a mix of TS11 and TF characterized by 15% FC (MIX15%) are discussed, see Figure 1 and Table 1. The minimum and maximum void ratios reported in Table 1 were measured according to the method proposed by Knudsen et al. (2020), validated for silty sand with FC as high as 14%.

2.2 *Test program and procedure*

Tables 2 and 3 provide the main characteristics of the calibration chamber (CC) and centrifuge (CCC) models discussed in this paper. The values of void ratio e, relative density D_R and dry unit weight γ_d refer to the end of consolidation. The test layout is sketched in Figure 2. All the models were normally consolidated.

The tests on clean TS11 were meant to assess if CC and CCC cone penetration tests were comparable with each other and with previous studies carried out using TS and the same facilities. In addition, they were aimed at validating the use of the centrifuge as a calibration tool of CPTUs in sandy soils. Indeed, centrifuge CPTUs have the advantage, with respect to calibration chamber tests, of giving a q_c-profile over a wide range of vertical stress, rather than a single q_c value associated to the specific level of the applied stress of a single sample. This is under the condition that the effects of rigid boundaries and scale effects are minimised. In addition, CCC models are smaller and a test requires few days compared to about two weeks for a CC test. If validated, CCC CPTUs can be extensively used to explore the effect of variable density, fine content, stress level, overconsolidation ratio on the penetration resistance.

2.2.1 *The ISMGEO calibration chamber*

The calibration chamber specimens are 1.4 m high and 1.2 m in diameter. The CC is a flexible-wall chamber and it can impose four boundary conditions (BC):

- BC1: constant vertical and horizontal stresses, σ_v = const and σ_h = const;
- BC2: zero vertical and horizontal strains, $\Delta\varepsilon_v = \Delta\varepsilon_h = 0$;
- BC3: constant vertical stress and zero horizontal strain, σ_v = const and $\Delta\varepsilon_h = 0$;
- BC4: constant horizontal stress and zero vertical strain, σ_h = const and $\Delta\varepsilon_v = 0$.

Two cells enclose the specimen. This allows obtaining a zero average lateral strain boundary condition by keeping the pressure in the outer cell equal to the pressure, developed by the specimen, in the inner cell. Vertical and horizontal stresses can be applied independently in a controlled manner to the boundaries of the sample. Vertical stresses are applied to the specimen through a piston (positioned at the bottom of the chamber) raised by pressured water and the horizontal stresses are applied by the pressure of water surrounding the specimen.

Table 1. Grain size and index properties of testing soils.

		TS11	TF	MIX15%

11		53		0.7	15.85	V2

* V1 = 20 mm/s, V2 = 100 mm/s

The CC specimens are enclosed at the sides and base by a membrane, sealed at the top around an aluminium plate, which confines the specimen and transfers the thrust of the chamber piston from the specimen to a top lid. A 120 mm diameter hole is present in the centre of the lid; by changing the sealing hollow bush it is possible to press devices of different sizes into the specimen.

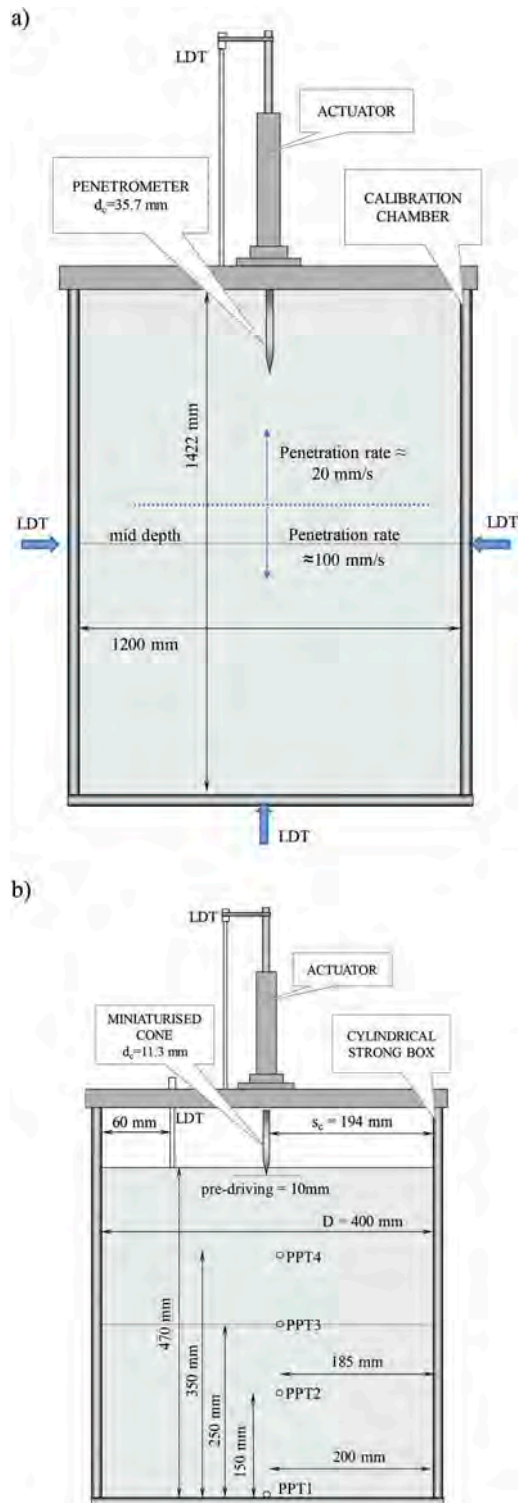
The loading frame, which counteracts the vertical load transferred to the lid during the compression of the specimen, also holds the hydro-mechanical press which pushes the test devices into the chamber during penetration tests. A hollow jack mounted inside the loading frame is used to counteract the vertical load; it is automatically controlled by a closed loop system, which equalizes the compression force in real time and allows to keep the lid position fixed and independent


Figure 2. CC (a) and CCC (b) models.

from the frame deformations. Thus the specimen deformation can be monitored by measuring the chamber piston displacement.

The penetration probes used during the tests is a standard piezocone 35.7 mm in diameter, with a total area of 10 cm^2 and an apex angle of 60°. Two load cells measure the tip resistance and the lateral friction, independently; a pressure transducer measures the pore water pressure behind the tip (u$_2$).

The CC specimens were reconstituted in 15 strata using the undercompaction method (Ladd, 1978), Hereafter, they were saturated through an upwards flow of deaerated water and then by application of a back pressure. Reaching a Skempton B-value equal or larger than 0.95, the specimens were consolidated by applying the target vertical and horizontal stresses. To allow for comparison with the centrifuge tests, during which a rigid strong box houses the models and prevents the development of horizontal strains, the BC3 condition was adopted in the CC. In consequence, horizontal effective stresses imposed in CC were calibrated during the consolidation step to avoid radial deformations. A standard rate (V1 = 20 mm/s) was adopted in the upper part of the specimen and the maximum velocity possible for the loading system (V2 = 100 mm/s) in the lower part, see Figure 2a.

2.2.2 The ISMGEO geotechnical centrifuge

The ISMGEO geotechnical centrifuge is a beam centrifuge made up of a symmetrical rotating arm with a diameter of 6 m, a height of 2 m, a width of 1 m, and a nominal radius of about 2.2 m to the model base (Baldi et al.1988, Fioravante et al. 2021). The miniaturised piezocone used for the tests has a diameter d$_c$ = 11.3 mm, an apex angle of 60° and a sleeve friction of 11 mm in diameter and 37 mm in length. One load cell measures the cone resistance and another one measures the cone resistance plus the shaft friction, up to forces of 9.8 kN. A pressure transducer is installed behind the tip for interstitial pressure measurements (u$_2$).

The centrifuge specimens are 470 mm high and 400 mm in diameter and were reconstituted at 1g using the undercompaction method within a rigid strong box. They were saturated under vacuum using deaerated water and subjected in flight to an acceleration field of 63 g imposed at mid depth (geometrical scaling factor N = 63). The scaling factor and the angular velocity adopted allowed to obtain a vertical stress of about 50 kPa at a depth of 120 mm from ground surface (which is the depth at which the cone resistance q$_c$ is no more affected by top boundary effects) and of 200 kPa at a distance of 150 mm from the container bottom (depth beyond which q$_c$ can be affected by the rigid bottom boundary); 50 kPa and 200 kPa are the vertical effective stresses imposed in the calibration chamber (tests N. 1 and 2 in Table 2).

The CCC boundary conditions are: D/d$_c$ = 35, where D is the internal diameter of the container and s$_c$/d$_c$ = 17, where s$_c$ is the distance between the CPT and the side wall. These values are sufficiently large to minimise any scale effects on the results (Bolton et al. 1999). The ratio of the cone diameter to the mean particle size is d$_c$/D$_{50}$ ≈ 25 for TS11 and d$_c$/D$_{50}$ ≈ 30 for MIX15%. CCC models were instrumented with pore pressure transducers (PPT in Figure 2), located at the base to monitor the water table and at three relevant depths of penetration, at a distance of one cone diameter from the penetration axis.

For each test condition two penetration rates were adopted; a standard rate V1 = 20 mm/s and a higher rate V2 = 100 mm/s (both velocities properly scaled).

3 TEST RESULTS

3.1 CPTUs in clean TS11

The results of the tests discussed in this section are shown in Figure 3 and were obtained from soil models of clean TS11 reconstituted at a relative density D$_R$ slightly lower than 50%. In Figure 3 the corrected cone resistance q$_t$ is plotted as a function of the vertical effective stress σ'$_v$. The tests are numbered according to Tables 2 and 3. The black and white squares represent the representative q$_t$ measured in the CC specimens (Tests 1 and 2). For each CC test, two q$_t$ values are plotted: one is the average value measured in the upper half of the model, with the probe penetrating at the standard rate V1; the second value refers to the faster rate V2 adopted in the lower half of the model. The black and grey lines in Figure 3 are the q$_t$ profiles measured in the CCC (Tests 3 and 4). The vertical effective stresses in the centrifuge models are computed referring to: i) the average soil unit weight at the end of the in-flight consolidation, ii) the depth of the water table (estimated from PPT measurements) and iii) the acceleration field distortion. Figure 3 also shows the q$_t$ profile (dashed line) estimated using the equation of Jamiolkowsi et al. (2003). This allows to express the cone resistance as function of the vertical effective stress and relative density, using correlation coefficients calibrated by the Authors for Ticino sand and accounting for the saturation effects. It is worth noting that the correlation was calibrated on the base of CC tests carried out using the same apparatus employed for the present experimentation. For the centrifuge tests, the u$_2$ profiles, compared with the hydrostatic lines derived from the PPT measures, are given in Figure 4.

The centrifuge test results show that the soil models were rather homogeneous and the tests are repeatable, as the two q$_t$ profiles are almost superimposed. The penetration was, as expected, drained for both penetration rates, see Figure 4. A very good agreement between CC and CCC results can also be observed, see Figure 3. In addition, the measured cone resistance is very well described by the correlation proposed by Jamiolkowski et al. (2003). This is considered an important result, as it demonstrates that CC and CCC give comparable CPT results, which are also consistent with previous studies carried out using TS and the same facilities; these data
Figure 3. Centrifuge (solid lines) and Calibration Chamber (squares) CPTUs on TS11 - cone resistance q_t.
Figure 4. Centrifuge CPTUs on TS11 – PPT measures, hydrostatic line, pore pressure u_2.

are used as benchmark for the following testing stages and, in the first instance, used to evaluate the effect of 15% FC on the cone resistance, for the same relative density and stress state.

3.2 *CPTUs in MIX15%*

Two centrifuge tests (9 and 11 in Table 3) on MIX15% were carried out using the same test conditions as those of tests 3 and 4, i.e. similar relative density (about 50%), stress range and penetration rate. Test 9 was carried out using the standard rate V1; test 11 was

run at V2. Figures 5 and 6 show the results. Inspecting the u_2 profiles (Figure 6), the penetration appears to be practically drained irrespective of the penetration rate, similar to the results on TS11.

However, as to the effect of FC on the penetration resistance (Figure 5), MIX15% had a penetration resistance about 40% lower than TS11, even though the void ratio is higher and the relative density is lower for TS11 compared to MIX15% (see Table 3). It's worth noting that drained and undrained triaxial tests on reconstituted samples indicate a shearing resistance angle at critical state of 36° and 35° for TS11 and MIX15%, respectively. On the other hand, the two materials proved to have different volumetric behavior during shearing. The results of 4 drained triaxial tests carried out on medium dense TS11 and MIX15% samples are shown in Figure 7, in the void ratio e – mean effective stress p' and in the stress deviator q – p' plane. All the samples were reconstituted in strata at medium density (similar to the CC and CCC specimens, see Table 2 and 3) and were K_0-consolidated under a vertical stress of 50 and 200 kPa. While MIX15% manifested a contractive behavior, TS11 dilated.

In general, the cone penetration resistance q_t of an uncemented and unaged soil depends on the material properties and the state of the soil (stress level and density). The state of the soil governs the direction of volumetric strains, (dilation or contraction) during shearing, which, in turns, controls the stress increment around the tip. Consequently, a dilative soil will develop a larger stress increment around the tip and will oppose larger resistance to penetration than a contractive material, as observed for TS11 and MIX15%.
Figure 5. Centrifuge CPTUs on MIX15% - cone resistance q_t.
Figure 6. Centrifuge CPTUs on MIX15% – PPT measures, hydrostatic line, pore pressure u_2.

4 CONCLUSIONS

A very good agreement between results of CC and CCC CPTUs in clean TS11 was observed and the measured cone resistance is very well described by the correlation proposed by Jamiolkowski et al. (2003).

The sand mixed with none plastic silt experiences a drop of cone resistance in the centrifuge, which cannot be attributed to effect of partial drainage during penetration, as the measured u_2 profile is straight and coincident with the hydrostatic line and no excess pore pressures developed neither at the standard penetration rate nor during the faster penetration.

The drop of cone resistance is attributed to contractive behaviour of the silty sand at the test density and stress in contrast with the dilative behaviour of the clean sand.

The centrifuge has proved to be a reliable CPT calibration tool in clean sand, alternative to the calibration chamber, with the advantage of providing a continuous cone penetration resistance profile over a wide range of stress level in significantly less time. If a good agreement between centrifuge and calibration chamber results will be gained also for the MIX15%, the centrifuge alone will be employed in a further stage of experimentation, during which 10 additional calibration CPTUs will be carried out on a mix of TS11 and TF characterized by 30% FC (MIX30%). Samples will be reconstituted varying soil density and overconsolidation ratio and will be tested varying the penetration rate. The calibration CPTUs and the complementary laboratory tests will be interpreted in the frame of CSi project with the final goal of contributing to
Figure 7. Drained triaxial tests on TS11 and MIX15%: a) e-p' plane; b) q- p' plane.

the development of acknowledged, simple and robust guidelines for specification, execution and interpretation of CPTUs in silty soils/silt mixtures.

Comparison between coefficients of consolidation from CPTu and laboratory tests for Guaratiba's soft soil, Rio de Janeiro, Brazil

M.M. Freire, M.E.S. Marques & M.C. Tassi
Military Institute of Engineering, Rio de Janeiro, Brazil

L.A. Berbert
Prodec Consultoria, Rio de Janeiro, Brazil

ABSTRACT: This paper presents a discussion about vertical (c_v) and horizontal (c_h) coefficients of consolidation of Guaratiba's very soft clay, located at the lowlands of the West Zone of Rio de Janeiro city, Brazil. Due to the thickness of the deposit, high compressibility of the clay, and low undrained strength, the settlement stabilization, even with vertical drains, are known to take of about 30 months to occur at these lowlands. Thus it is essential to know c_v, c_h and c_h/c_v relationship in order to predict when settlement stabilization will occur. The variability of c_v and c_h values is very high, probably due to the wide range of organic matter, sand lenses and the sand content throughout the soft soil deposit. The aim of the paper is to compare these values of coefficients of consolidation obtained from the dissipation tests and from the consolidation tests and to discuss an approach to determine them for design considering their variability.

1 INTRODUCTION

Vertical (c_v) and horizontal (c_h) coefficients of consolidation are used to predict settlement evolution with time, and are essential for the design of embankments over soft soils, mainly when vertical drains are used.

Coefficients of consolidation are estimated from dissipation tests, carried out at a prestabilished depth of CPTu, from CRS and incremental consolidation tests, consolidation on triaxial tests and from field monitoring. They are related to permeability (k), which is a parameter that, for soils, has a range of values on the order of about 10^6 m/s. This parameter depends on several factors as: diameter, distribution, shape, texture and mineral composition of particles; flow and fluid type; soil structure; water content; void ratio and temperature.

Thus, it does not come as a surprise that the values from field monitoring, field tests and laboratory are different, due to:

- The boundary conditions are very different in the field, where lateral deformations exist, and in the laboratory consolidation test, where the deformation is unidirectional;
- The occurrence of sand lenses in the field, reducing the stabilization time, a fact that is not reproduced in the laboratory;
- Secondary consolidation takes place in the field and is disregarded in the analysis of field data.

Permeability ratio (k_h/k_v) is used for the estimative of c_h or c_v, but regardless of the type of test, for very soft, very organic soils, there is a wide range of consolidation coefficient values obtained for these deposits.

This paper presents a discussion about coefficients of consolidation values from dissipation tests and consolidation tests carried out at a very soft organic clay deposit of Rio de Janeiro city.

2 SITE DESCRIPTION

The site is located at Guaratiba, a neighborhood area of increasing population density in the city of Rio de Janeiro, Brazil (Figure 1), limited on one side by the coastal massifs and on the other side by the ocean.

The area of the site is 1.5 km² and the thickness of the soft soil in the deposit reaches 13.5 m. The water table is coincident with ground level, and the site is under water at the rainy season.

The geotechnical investigation consisted of 98 boreholes with Standard Penetration Test carried out in order to map clay thickness. After that, 15 geotechnical investigation clusters (see Figure 2) were implemented: 15 CPTu with 41 pore-pressure dissipation tests, 15 undisturbed Shelby samples, 40 oedometer consolidation tests, field vane tests, characterization and mineralogy tests.
Figure 1. Site localization.

Some geotechnical characteristics of the clay are: natural water content values vary from 50% to 150%; the plasticity index is between 62% and 103%; initial void index vary from 1.51 to 3.65; organic matter content from 1.74% to 13.3% and the undrained strength is in the range of 9 to 36 kPa. The compression ratio, $C_c/(1+e_0)$, vary from 0.27 to 0.51, preconsolidation pressure from 23 to 50 kPa and OCR values from 1.07 to 3.34. All those characteristics indicate a very compressible clay.

From macro-drainage projects in this region, conducted by the city of Rio de Janeiro, the embankments must level up to 3m in order to avoid floods. The work schedule of embankment construction over soft soils city is directly related to vertical (c_v) and horizontal consolidation (c_h) values, which are in the order of 2-3 x 10^{-8} m²/s at the West Zone of Rio de Janeiro, under normally consolidated stresses.
Figure 2. Geotechnical investigation clusters.

3 LABORATORY AND CPTU TESTS RESULTS

The main tests used to determine the coefficient of consolidation are laboratory consolidation test

and dissipation field tests carried out with a CPTu.

From dissipation tests, c_h values can be obtained from Equation 1, proposed by Houlsby and Teh (1988):

$$c_h = \left(\frac{T_h \, x \, R^2 \, x \, \sqrt{Ir}}{t} \right) \qquad (1)$$

where:
T_h – Time Factor;
R – Piezocone Radius;
Ir – Rigidity Index (G/S_u);
G – Shear modulus
S_u – Undrained strength
t – Dissipation Time/Period.

In order to obtain c_v values from c_h values of CPTu tests, it is necessary to obtain the permeability ratio (k_h/k_v) as follow.

$$c_h = \left(\frac{k_h}{k_v} \right) c_v \qquad (2)$$

Conventional and special oedometer tests were carried out on Sarapuí organic soft clay, located at Guanabara Bay, 60 km from Guaratiba (Coutinho, 1976; Lacerda et al., 1977, 1995). These tests were carried with radial drainage in order to obtain c_h. The c_h/c_v relationship obtained was between 1.0 and 2.0 at normally consolidated range, which is typical for very soft clays, as shown in Table 1, for worldwide deposits. Thus, the permeability ratio used for design in engineering practice for the soft clay deposits of Rio de Janeiro City has been 1.5.

Table 1. Ranges of possible field values of permeability ratio of soft clay deposits (Jamiolkowski et al. 1985).

Nature of clay	K_h/k_v
No macrofabric, or only slightly developed macrofabric, essentially homogeneous deposits	1.0 to 1.5
From fairly well to well developed macrofabric, e.g. sedimentary clays with discontinuous lenses and layers of more permeable material	2.0a4.0
Varved clays and other deposits comtaining embedded and more or less continuous permeable layers	3.0 to 15.0

In order to obtain laboratory c_h of Guaratiba, from consolidation tests, the samples were rotated 90º from its original in situ position. Using this procedure, c_v values were obtained, as shown in the schema of Figure 3, from 10 HS samples and c_h from 10 VS samples, using square root of time method proposed by Taylor, as shown in Table 2.
Figure 3. Sampling details.

Since the effective stress at the top of the clay deposit was very low, consolidation tests loading began at 3.0 kPa, with load increment ratio equal to one ($\Delta\sigma/\sigma = 1$), and at vertical effective stress of 100 and 200 kPa the samples were at the normally consolidated range. From average values, c_h/c_v was in the order of 1.2 for Guaratiba clay (Berbert, 2016). Thus, it was possible to estimate from $c_h = 1.2\ c_v$, the values of c_h for another set of 20 consolidation tests carried out on HS samples.

Table 2. C_h and c_v from consolidation tests at normally consolidated range.

* Kh/kv assumed=1

From CPTu dissipation tests, the c_h at normally consolidated range was obtained from Equation 3 (Jamiolkowski et al. 1985):

$$c_h(nc) = \left(\frac{C_r}{C_c}\right)c_h(oc) \tag{3}$$

where $c_h(oc)$ at overconsolidated range was obtained from equation (1) and C_r/C_c was 0.15. Table 3 shows results of c_h values from both tests.

Table 3. The c_h values from consolidation tests and CPTu tests at normally consolidated range.

* CPTu values at normally consolidated range
** not considered

Sample Z1-04 at 5m had a high c_v value. A possible cause of this high value is the fact that this sample had the lowest initial void index, natural moisture and organic matter value.

4 DISCUSSION

Guaratiba clay is a little less compressible than most clays from the western region of Rio de Janeiro City
Figure 4. C_v and c_h values from consolidation tests at normally consolidated range.
Figure 5. C_h values from consolidation tests and dissipation tests at normally consolidated range.

and also less plastic. However, the values of c_v and c_h of Guaratiba clay are inside the range of the c_v values obtained for western region Rio de Janeiro clays for the normally consolidated range: 10^{-9}m²/s to 2×10^{-7} m²/s for Recreio and Barra da Tijuca clays (Almeida and Marques, 2013). From consolidation tests, it is not possible to obtain a specific range for c_v or c_h, but the majority of data shows higher c_h, at a certain depth as shown in Figure 4.

Figure 5 shows c_h results from CPTu compared with laboratory consolidation tests. It seems that CPTu values are higher than laboratory tests, which

could be attributed to sample disturbance, since sampling those very compressible clays is very difficult.

Almeida and Marques (2013) showed that the great variability of c_h values is not uncommon for Rio de Janeiro clays, and the difference between c_v values from laboratory data and field instrumentation can be as high as 10.

5 CONCLUSIONS

This paper showed the comparison between c_v and c_h values at normally consolidated range from special

consolidation tests and CPTu tests. These parameters are important to obtain settlement prediction with time, thus essential for deadlines of earthworks.

The c_h values from CPTu tests and from consolidation tests (HS and VS samples) are inside the wide range of magnitude of values of Rio de Janeiro clays.

However, the variation of values makes it difficult to adopt a c_h value for design. In this case, which c_h or c_v is recommended for the practice? Average values does not seem adequate, since it could underestimate the deadlines of the work. It is suggested to choose a value that meets most cases, considering that the work schedule could be adjusted depending on field monitoring.

Therefore, together with field and laboratory tests, field instrumentation is necessary to monitor the work.

ABSTRACT: As geotechnical research and design codes rely increasingly on probabilistic approaches, site characterization should also be conducted in the light of the explicit quantification of the uncertainty and spatial variability in soil properties. This paper provides a practical case-study application of spatial variability analysis of piezocone data obtained at a test site in the Lagoon surrounding the historic city of Venice, in North-Eastern Italy, where unusually dense and regularly spaced CPT test data were available. Empirical semivariograms are calculated for cone resistance, sleeve friction, and porewater pressure, along with the soil behavior classification index obtained from these measurements at a set of reference measurement depths. A number of theoretical semivariogram models are fitted comparatively and best-fit models are selected based on objective criteria and subjective judgment. Characteristic semivariogram parameters, providing information on correlation distance and small-scale variability, are retrieved. Modeling options are explained and results are analyzed and assessed critically.

1 INTRODUCTION

The definition of subsoil properties for engineering purposes is a difficult task due to the indetermination in geotechnical data which is employed in the characterization process. Such indetermination can be ascribed to both the soils and the investigators. Soils are natural materials, which are formed and continuously modified by complex geological processes, as discussed in detail by Hight & Leroueil (2003). The variety and complexity of such processes result in physical heterogeneity and, consequently, in the spatial and temporal variability of quantitative parameters. In any type of real-world geotechnical problem, moreover, it is impossible to obtain exhaustive values of data at every desired point because of practical and economical constraints. The testing methods by which such data are obtained are always imperfect and non-repeatable to some degree. Moreover, if measured parameters require transformation for use in geotechnical analyses and design, they are to serve as inputs to transformation models which, whether theoretical, empirical or experimental, are invariably incapable of perfectly replicating the complexity of the physical world. A steadily increasing bulk of research and experience, not to mention the uncertainty-based

character of evolutionary design codes based on limit-state design and reliability analysis, attest to the relevance of indetermination in geotechnical data and models, and of the importance of considering its effects on characterization and design.

In the technical literature, the terms variability and uncertainty are often employed interchangeably. Here, variability is defined as an observable manifestation of heterogeneity of one or more physical parameters and/or processes, while uncertainty pertains to the modeller's state of knowledge and strategy, and reflects the decision to recognize and address the observed variability in a qualitative or quantitative manner. Inherent soil variability describes the variation of properties from one spatial location to another within a soil mass. Such variability is parameterized quantitatively by aleatory uncertainty. Epistemic uncertainty, on the contrary, stems from the investigator's invariably limited information, imperfect measurement and modelling capabilities.

In investigating the spatial variability of a geotechnical property, both aleatory and epistemic uncertainties are addressed, as both contribute to the uncertainty which is modelled, processed, and reported. The aim of this paper is to provide a practical case-study of characterization of spatial variability of

the mechanical properties of soils as parameterized by piezocone data from a site located near the historical city of Venice, in North-Eastern Italy. Spatial variability analysis is performed through the calculation of empirical semivariograms and the subsequent fitting of theoretical semivariogram models.

2 TEST SITE DESCRIPTION

The Venetian lagoon is underlain by about 800 m of Quaternary deposits which originated from alternate phases of continental and marine sedimentation associated to marine regressions and transgressions occurred over the last 2 million years. Over the last forty years, the upper 100 m sediments of the Venetian lagoon have been thoroughly investigated, in relation to the regional land subsidence (e.g. Ricceri & Butterfield, 1974) as well as the foundation design of the submersible gates intended to protect the historical city of Venice against recurrent flooding (e.g. Simonini et al., 2007). These sediments have proven to be highly heterogeneous and stratified in a continuous alternation of slightly overconsolidated and predominantly silty sediments, ranging from medium-fine sands (SP-SM) with sub-angular grains to silts (ML) and very silty clays (CL). Coarse sediments are predominantly composed of silicates and carbonates, whilst silts and silty clays, which originated from mechanical degradation of sands, display a content of clay minerals (illite with minor quantities of chlorite, kaolinite and smectite) never exceeding 20% in weight. Generally, cohesive soils are slightly overconsolidated due to aging or oxidation.

A representative test site of such heterogeneous and stratified subsoil was located outside Treporti, a historical fishermen's village on the Cavallino coast line facing the North Eastern lagoon. At this site an extensive research program was recently carried out by the Italian Universities of Padova, Bologna and l'Aquila, with the aim of better understanding the behavior of such heterogeneous sediments. The research program, consisting of a detailed geotechnical characterization through in-situ tests, continuous-coring boreholes and high-quality laboratory tests, also included the construction and the subsequent gradual removal of a full-scale, 6.5 m high and 40 m in diameter, vertical-walled cylindrical test bank, in conjunction with a very detailed monitoring system of subsoil strains and pore water pressures (Tonni & Gottardi, 2011, 2019).

The extensive experimental program carried out in Treporti included no. 24 piezocone tests. The campaign was conducted in four phases, in relation to the different loading conditions associated to the presence of the bank. Figure 1 shows a plan of the area together with the location of CPTU tests.

The 'first phase' of the in-situ testing campaign, including no. 7 piezocone tests located throughout the selected area, was intended to give an initial description of the test site subsoil, with specific

Figure 1. Treporti CPTU test site.

reference to the detection of the most compressible soil layers.

A very detailed 'second phase' testing program was then performed just on the subsoil beneath the test bank to be built. All the second phase tests, numbered from 11 to 20, were located within a - 45 m diameter circular area. They were lined up along three diameters, splitting the circular area in three 120° identical slices, and placed on two concentric circumferences, inner (D=30 m) and outer (D=45 m) with respect to the loading bank (D=40 m). All tests were pushed as deep as possible, depending on the maximum available thrust, typically to about 42 m.

In addition to the main investigation program, two further testing phases were carried out. Immediately after the loading bank construction, the 'third phase' was performed from top of the bank, whereas a final 'fourth-phase' testing campaign was launched after the loading bank removal. The aim was to examine the stress-history effect on the soil mechanical properties along a number of verticals already investigated in both the pre-bank and post-bank construction phases (Tonni & Gottardi, 2009).

Due to the importance of ensuring the quality of the dataset in terms of homogeneity of loading conditions, only testing data from the first and second phases were used in this analysis. Typical piezocone log profiles of Venetian subsoil are reported in Figure 2, showing the corrected cone resistance q_t and the pore pressure u of CPTU tests located along the W-E cross section. Profiles of CPTU 6 and CPTU 14, located approximately 7-8 m north from the selected alignment, are superimposed on the same plot.

The figure clearly shows the high stratification and marked horizontal spatial variability of stratigraphy, which are typical features of Venetian lagoon subsoil. Indeed, while piezocone log profiles provide immediate evidence of a well-defined, 6-7 m thick top layer of silty sand, the underlying, dense alternation of thin layers of sandy and clayey silts is significantly variable from one location to another. The continuous

horizontal variation of the soil stratigraphy is particularly evident in the pore pressure logs, where u rarely follows up the hydrostatic level, often falls below it, but never develops high Δu values, typical of pure normally consolidated or slightly overconsolidated clays. A potentially more compressible fine-grained unit, which is mainly composed of silts, can be detected in the CPTU profiles from 7-8 m to 20 m depth. However, the thickness of such silty unit is clearly not constant throughout the whole test site area, as it is often interbedded with a clean sand layer of variable thickness. Soil heterogeneity and high degree of interbedding make the analysis of field data rather difficult.
Figure 2. Typical soil profile of Venetian subsoil at Treporti site.

3 SPATIAL VARIABILITY ANALYSIS

3.1 *Spatial correlation analysis of CPTU data*

Spatial variability can be investigated quantitatively using several approaches. Semivariogram-based modeling ranks among the most widely used due to its close relationship with geostatistical kriging interpolation. Semivariogram-based modeling accommodates weakly (but not necessarily strongly) stationary data sets, i.e., data presenting spatial trends, provided that spatial correlation depends on measurement spacing but is independent of specific measurement location. The empirical absolute semivariogram of a dataset is computed as

$$\gamma(h) = \frac{1}{2N(h)} \sum_{(i,j)|h_{ij}=h} (\xi_i - \xi_j)^2 \qquad (1)$$

where $N(h)$ is the number of data pairs sampled at locations separated by a spatial distance h (hereinafter referred to as lag distance), ξ_i and ξ_j are the data values at the ith and j^{th} locations, respectively.

Calculating empirical semivariance by Eq. (1) for different lag distances allows quantification of the magnitude and variation of spatial correlation with lag distance. Small $\gamma(h)$ values are representative of high spatial correlation, while high $\gamma(h)$ values attest for low correlation.

The quantitative parameterization of spatial correlation given by the empirical semivariogram includes both aleatory uncertainty (given by the measurable scatter in the parameters of interest) and epistemic uncertainty (comprising measurement error and inherent variability at sub-measurement interval scale). The analysis was performed in a pseudo-3D approach, which means estimating the spatial variability only in the horizontal planes at nominal analysis depth, ranging from 1m to 40m below ground surface at 1-meter intervals. This approach requires the availability of an exceptional database in terms of the number of CPTu verticals at different distances from each other, within the area to be analysed.

In practice, the calculation of empirical semivariograms relies on the establishment of a lag tolerance, both on distance (by accepting data pairs which separation distance is acceptably close to the nominal lag distance) and direction (by allowing a preset degree of deviation from the nominal direction between two sampled locations). The reason for the acceptance of such tolerances (which should not be too large in order to avoid the introduction of excessive distortion and bias) lies in the opportunity to have a greater number of pairs, which results in a more statistically reliable semivariogram structure. In order to identify an optimum lag interval (in terms of regularity and accuracy of empirical semivariance values), a parametric analysis on Δh was carried out. In particular, empirical semivariograms with lag intervals of 5 m, 10 m and 15 m were calculated at each analysis depth and for all three CPTU test parameters; namely: tip resistance q_t, sleeve friction f_s, and induced pore pressure u_2. In all cases, the distance tolerance $\tilde{h}$ was set equal to one half the lag interval Δh (Isaaks & Srivastava 1990), i.e. =2.5 m, 5 m and 7.5 m, respectively. Thus, all data points are considered at least once, with no redundancies at any lag distance value. An intermediate lag interval of Δh=10 m (with an associated lag tolerance $\tilde{h}$=5 m) was deemed to be the most suitable, since it is small enough to preserve the inherent variability of semivariance while providing a clearer structure of spatial correlation than smaller lag intervals.

Example empirical semivariograms, pertaining to q_t at analysis depth of 27 m and calculated for the three different values of lag spacing, are shown in Figure 3. In the plots, for each estimated semivariance value (black points), the corresponding number of contributing data pairs is indicated. is the calculation sample numerosity makes it possible to assess the reliability of each semivariance value (with larger $N(h)$ ensuring lower statistical uncertainty in calculated semivariance).

3.2 *Modelling of empirical spatial variability*

The fitting of suitable semivariogram models to empirical semivariograms is a fundamental step in the quantitative modelling of soil spatial variability
Figure 3. Empirical semivariogram of q_t at 27 m depth, for different values of lag interval and lag tolerance.

using geostatistical approaches.,.Numerous semivariogram models are available in the literature (e.g., Isaaks & Srivastava 1990). Among the most widely used models are the *spherical*, *exponential*, and *Gaussian* models, characterized by the following equations, respectively:

$$(S) \gamma(h) = \begin{cases} C\left[1.5\frac{h}{a} - 0.5\left(\frac{h}{a}\right)^3\right] + C_0 & |h| \leq a \\ C + C_0 & |h| > a \end{cases}$$

(2)

$$(E) \gamma(h) = C\left[1 - exp\left(-\frac{3h}{a}\right)\right] + C_0 \qquad (3)$$

$$(G) \gamma(h) = C\left[1 - exp\left(-\frac{3h^2}{a^2}\right)\right] + C_0 \qquad (4)$$

where C_0 is the semivariogram nugget, $C + C_0$ is the sill (i.e., the maximum value of semivariance), and a is the range (i.e., the lag distance at which semivariance attains the sill value).

The *spherical model* displays a linear behavior at short lag distances; subsequently, it flattens and reaches the sill at a. The *exponential model* and the *Gaussian model* instead approach their sill value asymptotically. For these models, the range a is defined as the lag distance at which the semivariogram value attains 95% of the sill value. Like the spherical model, the *exponential model* is linear at very small lag distances but reaches the sill value more gradually. The *Gaussian model*, instead, shows a parabolic behaviour near the origin, and is characterized by an inflection point.

The three models served as candidates in the analysis of spatial correlation of CPTU parameters within the Treporti site. The choice of the semivariogram model reflects the user's assessment regarding

the structure (model), magnitude (sill), spatial extent (range), and level of epistemic uncertainty (measurement uncertainty and small-scale variability), respectively, of spatial correlation. Such an assessment is based on a combination of objective approaches (provided by the possible use of regression techniques) and subjective belief (e.g., manual fitting, critical assessment of results of regression).

The quantification of the semivariogram nugget is not a univocal procedure. Operationally, the assignment of a semivariogram nugget should rely on the user's "backward extrapolation" of a best-fit semivariogram model to zero-lag distance. In practice, this procedure provides reliable results only if reliable empirical semivariance values are available for small lag distances. This is arguably not the case with the Treporti data sets. Consequently, in order to provide a consistent and conservative criterion for estimating semivariogram nuggets, it is necessary to resort to existing knowledge regarding the phenomena contributing to the nugget effect. The piezocone test is known to have one of the lowest total measurement errors among in-situ test in current practice (Uzielli 2008). CPTU measurement error represents a combination of several sources of variability and cannot generally be evaluated in routine geotechnical analysis. It is thus necessary, in most, to refer to literature approaches and values of measurement uncertainty. The latter is most often parameterized by the coefficient of variation of measurement uncertainty (COV_m). Based on the above, nuggets were tentatively calculated as:

$$C_0 = \frac{1}{2} COV_m^2(\xi) \cdot \xi_N^2 \qquad (5)$$

in which

$$\xi_N = m(\xi) + 3 \cdot s(\xi) \qquad (6)$$

is a "characteristic" conservative estimate of the CPTU parameter ξ of interest. Comprehensive tables of measurement uncertainty parameters for laboratory and in-situ testing are available in Uzielli (2008). Kulhawy & Trautmann (1996) reported COV_m of measurement uncertainty for q_c and f_s in CPTU testing as $COV_m(q_c)=0.07$ and $COV_m(f_s)=0.12$. Gauer et al. (2002) estimated the COV_m of measurement uncertainty for u_2 at $COV_m(u_2)=0.07$. The corrected cone tip resistance q_t is not measured directly but is obtained from q_c and u_2 by the model given in corrected cone tip resistance model. Assuming that q_c and u_2 are independent and statistically uncorrelated parameters, the COV_m of measurement uncertainty of q_t can be approximated using the following additive model:

$$COV_m(q_t) = \sqrt{COV_m^2(q_c) + COV_m^2(u_2)} \qquad (7)$$

The standard deviation of measurement uncertainty can be expressed by inverting the definition of the coefficient of variation:

$$\sigma_m(\xi) = E(\xi) \cdot COV_m(\xi) \qquad (8)$$

Assigning a constant value to a coefficient of variation implies the acceptance of the fact that the standard deviation varies proportionally with the expected value of the parameter. As q_c, f_s and u_2 generally increase with overburden stress (i.e., with depth) in homogeneous soil layers, measurements at greater depths are assumed to be less precise and accurate than measurements taken at shallow depths. This hypothesis is consistent with piezocone practice, as deeper measurements potentially suffer from the undesirable effects of inclination, elastic compression of rods, filter obstruction, etc. Such effects hinder the accuracy and precision of testing results, ultimately increasing measurement uncertainty. The characteristic value in ξ_N was taken as the arithmetic mean $m(\xi)$ of an extended data sample (comprising measurements pertaining to the depth interval defined by the nominal analysis depth ± a depth tolerance, established at 0.10 m to account for possible measurement offsets) increased by 3 sample standard deviations $s(\xi)$ of the same data sample.

Fitting of semivariogram models was performed on empirical semivariograms for each parameter and for each analysis depth, for a total of 120 fitting operations. With the exception of the assignment of semivariogram nuggets as previously described, the fitting procedure was carried out manually, with no implementation of numerical optimization techniques. It is well known that manual semivariogram fitting is preferable over automatized fitting (e.g. Isaaks & Srivastava 1990; Journel & Huijbregts 1978). With the aim of obtaining the best possible adjustment to the empirical data, the three models were tested comparatively: semivariogram model parameters a, C_0 and C were varied subjectively, and the goodness-of-fit of the resulting semivariance values was assessed qualitatively. In the latter process, a greater weight was awarded to the adherence of theoretical models to empirical values at small lag distances, which result in a greater number of data pairs and are thus more reliable than those pertaining to large lag distances.

Despite the typical lack of complete regularity and noted in most of the calculated empirical semivariograms, the overall qualitative assessment of the goodness-of-fit fit of semivariogram models was at least satisfactory. For illustrative purposes, best-fit cases of spherical, exponential and Gaussian models are shown in Figure 4. These cases refer to q_t at depth 32 m, u_2 at depth 29 m and f_s at depth 27 m.

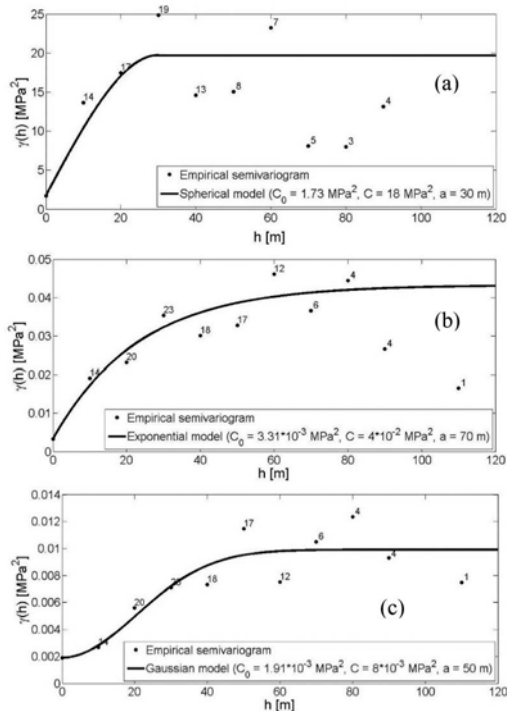
Figure 5 illustrates instead numerical tables with, for each analysis depth, the best-fit semivariogram model (S: spherical; G: Gaussian; E: exponential), best-fit semivariogram parameters (range a; nugget C_0; sill C_0+C) and relative nugget $C_0/(C_0+C)$, for q_t, f_s and u_2.


Figure 4. Semivariogram models fitting to the empirical semivariograms of q_t at 32 m (a), of u_2 at 29 m and of f_s at 27 m.

A number of observations can be drawn regarding the best-fit semivariogram models and their respective parameters. The most frequent best-fit model was found to be the spherical model. Concerning the range a, neither a relationship between the values relative to q_t and f_s at each analysis depth, nor a particular depthwise trend is identified for either parameter. CPTU parameters q_t and f_s show instead a quite strong correlation regarding the nugget term C_0. More specifically, a positive statistical correlation (quantitatively parameterized by a linear correlation coefficient 0.7) between the C_0 values of q_t and those of f_s was noted. For these two parameters, C_0 shows a proportional increase with depth. This is at least partly a consequence of the calculation method adopted for C_0, which partially relies on the definition of a characteristic value which is related to second-moment sample statistics. As both q_t and f_s tend to increase with depth due to in-situ stress effects, it may be expected that increasing sample statistics would induce the above noted correlation. Comparative examination of the relative nugget values showed that the contribution of measurement error and small-scale variation to spatial variability is more relevant (approximately by one order of magnitude) for f_s than for q_t and u_2. This observation is consistent with the well-known fact that sleeve friction

measurements are affected by a larger measurement uncertainty.

4 CONCLUSIONS

This paper has illustrated the background concepts and operational details of the analysis of spatial correlation of CPTU parameters measured at the Treporti site through semivariogram-based modelling. Despite the particularly high stratigraphic complexity of the site, the inspection of output characteristic parameters of best-fit semivariogram models provided interesting qualitative and quantitative correspondences with well-established knowledge regarding the degree of spatial correlation and the magnitude of measurement uncertainty in cone resistance, sleeve friction, and pore pressure measurements.

Aside from their inherent utility in describing spatial correlation structures, the analyses performed herein could serve as inputs to two categories of analyses aimed at non-deterministic geotechnical site characterization; namely: geostatistical kriging and random field modelling. In the first case, semivariogram model parameters serve as direct inputs to geostatistical kriging methods, specifically in the calibration of coefficients in the linear kriging interpolation methods. In the second case, model parameters can be used to estimate scales of fluctuation, which are necessary for the definition of random fields. Both approaches are cost-efficient means in providing estimates of soil properties at unsampled locations and to parameterize the associated uncertainty for seamless inclusion in rapidly developing statistical and probabilistic geotechnical methods.

ABSTRACT: True determination of soil parameters for thin clay layers in sand or silts from CPTU measurements is challenging. Cone resistance in thin layers is influenced by the surrounding layers resulting in unrepresentative measurements. Measurements should be corrected for this effect prior to interpretation of parameters. Such correction requires accurate information about the thickness of the thin layer. Previous studies have shown that the pore pressure parameter of the CPTU may not properly identify the layer interfaces for thin clay layers in sand. In this study a "cone resistance rate of change" parameter is suggested for thin-layer interface detection. Results from recently performed physical experiments at NTNU as well as from prior studies are used to evaluate the ability of this parameter to detect thin layers of clay in sand. The parameter appears to detect layer interfaces with good accuracy, even for layers with thickness as thin as the cone diameter. The results suggest that the approach may estimate layer thickness quite well and aid towards efficient correction of cone resistance to achieve more realistic soil parameters for thin clay layers in sand.

1 INTRODUCTION

The near-continuous measurements of CPTU parameters cone resistance (q_c, q_t), pore pressure (u_2) and skin friction (f_s) provide great details of the subsurface. The combined response of these parameters can be used for characterization of materials for thick homogenous sediments. Close to layer interfaces and in thin layers the measurements may be significantly influenced by multiple materials simultaneously. Accurate characterization and interpretation of geotechnical parameters of thin layers requires correction of these effects, which in turn depends on the layer thicknesses. It is therefore important to obtain detailed information of the layer interfaces. The u_2 parameter may not provide accurate measurement of the thickness of such thin clay layers (Hird et al. 2003, van der Linden et al. 2018, Hammer et al. *in press*).

This study assesses the possibility of detecting layer interfaces from cone resistance measurements based on its rate of change. Layering between different combinations of sand and clay layers are assessed from physical experiments. There are complex relations between the mechanical properties of different materials and the measured cone resistance. However, the

evaluations in the current study relies exclusively on the cone resistance measurements and soil type (i.e., sand or clay), rather than the geotechnical parameters of the soils.

2 TRANSITION AND THIN-LAYER EFFECTS

Values of the cone resistance that only reflect a single, homogenous material is labeled the *characteristic* cone resistance of the material. Close to a layer interface between different materials, the measured cone resistance may deviate from the characteristic cone resistance. This is due to factors such as the cone geometry and difference in stiffness and strength between the materials. The distances of transition effects in the materials are labeled sensing- and developing distance, as illustrated in Figure 1 (a).

In a thin layer, where the layer thickness is less than the sum of the sensing- and developing distance of the thin layer, the extreme value will not equal the characteristic cone resistance, known as *thin-layer effects*. An example of this is illustrated in Figure 1 (b). The characteristic cone resistance in thin layers can be estimated through correction factor, K_H (Youd & Idriss 2001):
Figure 1. Illustration of transition- and thin-layer effects for (a) a two-layered composition and (b) a three-layered composition.

$$q_{thin} = K_H \cdot q_{extreme} \qquad (1)$$

Values of K_H is less than or equal 1 in thin weak layers, e.g., Figure 1(b). For the opposite case, in thin strong layers, values are greater or equal 1. Factors of K_H are proposed for thin sand layers in clay (i.e., thin strong layers) based on field data and experiments. It is however a lack of proposed correction factors for thin weak layers.

The proposed correction factors are typically dependent on the thin layer thickness compared to the cone diameter (H/d_c) and the contrast between the characteristic cone resistance of the thin layer and the surrounding layers (i.e., $q_{thin}/q_{surrounding}$). More advanced methods of thin layer corrections have been proposed, most noticeably the inverse filtering procedure (Boulanger & DeJong 2018).

3 CONE RESISTANCE RATE OF CHANGE

The cone resistance is in this study presented against the depth of the cone tip (z) normalized on the cone diameter (d_c):

$$z_N = \frac{z}{d_c} \qquad (2)$$

The depth is furthermore referenced to the depth of a layer interface (z_{int}):

$$z_{N;int} = \frac{z - z_{int}}{d_c} \qquad (3)$$

The subscript of the cone resistance measurement type is omitted in this study. I.e., the symbol q is used rather than q_c or q_t. The latter is the corrected cone resistance for pore pressure due to unequal area effects. Each measurement of q can be labeled with and index

i, i.e., q_i. These values have a corresponding measurement depth z_i, where values of depth are increasing with increasing indices.

Assuming a constant characteristic cone resistance for each layer, such as for the examples in Figure 1, the derivate of the measured cone resistance is expected to reflect the transition effects. The derivative can be expressed as the change of measured cone resistance over the distance between measurements. The derivative of q becomes:

$$\left(\frac{\Delta q}{\Delta z_N}\right)_i = \frac{q_{i+1} - q_i}{z_{i+1} - z_i} \cdot d_c \qquad (4)$$

The unit of this parameter is given in units of stress, e.g., MPa.

Hammer et al. (in press) proposed a normalized parameter of cone resistance rate of change, q', defined as $\Delta q/\Delta z_N$ divided by the average cone resistance between the two depths:

$$\begin{aligned} q'_i &= \left(\frac{\Delta q}{\Delta z_N}\right)_i \cdot \frac{1}{0.5 \cdot (q_{i+1} + q_i)} \\ &= \frac{q_{i+1} - q_i}{z_{i+1} - z_i} \cdot \frac{2 \cdot d_c}{q_{i+1} + q_i} \end{aligned} \qquad (5)$$

An advantage of normalizing the derivative of the average measurement is an increased emphasize on transition effects in weak materials. This parameter showed promise for detecting interfaces for thin clay layers.

The procedure of Boulanger & DeJong (2018) consisted of three main components, where the first two corrects measurements of cone resistance for thin layer effects. The last component attempts to correct for transition effects. Profiles corrected for thin-layer effects are evaluated based on the rate of change to identify and approximate sharp transition (i.e., interfaces). The resistance rate of change was defined as:

$$m_i = \ln\left(\frac{q_{i+1}}{q_i}\right) \cdot \frac{d_c}{z_{i+1} - z_i} \qquad (6)$$

Interfaces was in the study determined primarily based on whether the values of m (calculated from cone resistance profiles corrected for thin-layer effects) were greater than 0.1.

Both q' and m are parameters describing the relative change in cone resistance over normalized distances (Δz_N). The two parameters are compared for various relations of q_{i+1}/q_i over one cone diameter distance ($\Delta z_N = 1$) in Figure 2. The parameter m is for this situation represented with f_1 while f_2 represents q'. Two additional relationships are added for comparison, f_3 and f_4, these represent $\Delta q/\Delta z_N$ normalized on q_i and q_{i+1} respectively. From this it is evident that there is

a negligible difference between q' and m for small relative changes, q_{i+1}/q_i. Due to the numerical advantages of computing the function f_1 rather than f_2, the parameter m is used in this study for the cone resistance rate of change. Each measurement of m_i is assigned to the average depth between z_i and z_{i+1}. Note that if the distances between measurements are approximately constant, this only results in a change the reference depth.
Figure 2. Different measurements of cone resistance rate of change.

The advantages of the cone resistance rate of change m compared to the derivative $\Delta q/\Delta z_N$ is highlighted through an example of one of the physical experiments from de Lange (2018). Figure 3 presents values of q together with calculated values of m and $\Delta q/\Delta z_N$. The soil sample has thin alternating clay and sand layers of $H=3.2d_c$ between two sand layers. Three measurements of the same sample were performed with the sample exposed to a surcharge load of 25, 50 and 200 kPa.

The two primary advantages of m compared to $\Delta q/\Delta z_N$ are firstly the apparent independency on the stress level, as observed from the figure. Secondly, values of m appear to reach extreme values at constant distances to the layer interfaces. The second advantage will be explored in chapter 5.

4 DATA FROM PHYSICAL EXPERIMENTS

4.1 Experiments

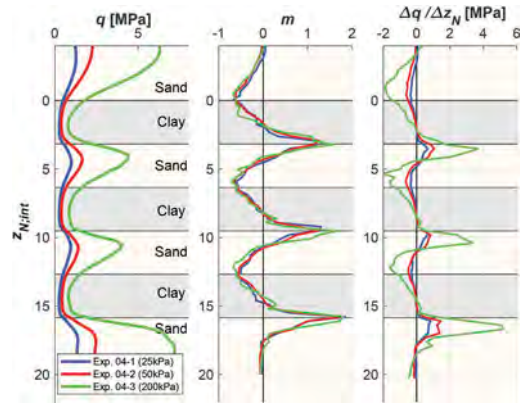
The normalized cone resistance rate of change was applied to measurements from physical experiments on layered sand and clay. The aim to determine its ability to detect layer interfaces as well as characterize thin-layer- and transition effects. Results of recent experiments performed at NTNU are evaluated together with multiple studies from literature. A list of all references of the experiments evaluated in this study is presented in Table 1.


Figure 3. Example of values of m compared to $\Delta q/\Delta z_N$. Measurements from de Lange (2018), containing multiple thin clay and sand layers of thicknesses of $H=3.2d_c$. between sand layers. The names of the series indicate the applied surcharge.

The physical experiments are performed on constructed samples of layered sands and clays in chambers. Preparation methods and material properties of sands and clays vary between the different experiments. In general, the sands in the created samples are described as clean, uniform, and homogenous. Clay layers are also homogenous and primarily described as soft. The relations between the material properties and the measured cone resistance are not evaluated in this study.

The CPT probes used in all experiments have 60° apex while the cone diameters are varying from 1 to 3.6 cm. The diameter size (rounded in millimeters) of the different experiments are shown in Table 1.

The results of Hammer (2020) and Skrede (2021) are corrected for unequal area effects, however, the differences in thin clay layers were found to be neglectable. The measurements from literature are primarily not corrected for unequal area effect.

4.2 Results from chamber tests at NTNU

The problem of thin clay layers in sand has been studied through large scale physical experiments in a CPTU chamber at NTNU (Norwegian University of Science and Technology) in Trondheim during the last two years. Samples were constructed in a chamber of 1.2 m diameter and 1 to 2.2 m height. Multiple cases of varying thin-layer thickness were tested at varied stress states. Details on the experiments and results are presented in the MSc theses Hammer (2020) and Skrede (2021). A combined six sample cases were constructed and tested in the two studies, named E1 - E6.

4.3 Results from literature

Multiple studies have been performed on physical experiments of cone penetration in layered sand and/or clays. The experiments that are found to be relevant for this study are summarized in Table 1. The cone resistance measurements of these studies were digitized from figures in a detailed manner. Depth measurements were converted to the normalized depth of the cone tip below a layer interface ($z_{N;int}$). The measurements from literature were interpolated at $0.3d_c$ intervals since the actual intervals between measurements are unknown. For a standard cone with area 10 cm^2 this corresponds to measurements each 1 cm.

5 RESULTS

5.1 Sand

The profiles of two experiments with dense over loose sand from Tehrani et al. (2017) are presented in Figure 4 (top). Minimum values of m coincide with the layer interface with values of -0.2 and -0.3. The study defined sensing lengths of $5.1d_c$ for both experiments, reflecting approximately the distance from where m changes sign to the layer interface. Developing distances were defined as $2.2d_c$ and $2.4d_c$, respectively.

Figure 4 (bottom) show the opposite layering, i.e., loose sand over dense sand. The maximum values of m for the two experiments were 0.5, these values occur at a distance $1-2d_c$ prior to the layer boundary. Sensing distances were described as 2.8 d_c and 3 d_c, respectively, while developing distances were 3.8 d_c and 3.9 d_c.

5.2 Clay

Transition effects between clay layers was evaluated in the study of Wang (2019). Results of experiments with stiff clay over soft clay are presented in the top of Figure 5. Values of m decrease only from a distance of about $1d_c$ prior to the layer interface. The transition towards the characteristic cone resistance of the soft clay layer (i.e., the developing length) appear to be over about $4-6d_c$.

Results of experiments with soft over stiff clay are shown in Figure 5 (bottom). Sensing distance is for this layering case about $1d_c$ as well, while the developing distance appear to be about $2d_c$.
Figure 4. Q and m profiles for layered sand, experiments of Tehrani et al. (2017). Top: dense over loose sand. Bottom: Loose over dense sand.
Figure 5. Q and m profiles for layered clay, experiments from Wang (2019). Top: stiff over soft clay. Bottom: soft over stiff clay.

5.3 Sand and clay

Various studies have included experiments on thick layers of sand and clay. These include van der Berg (1994), Teh et al. (2010), Młynarek et al. (2012), van der Linden et al. (2018) and Skrede (2021). Four of these are presented in Figure 6 for a thick sand layer over clay. Three of the q-profiles are increasing until $2-3d_c$ distance to the interface due to the proximity to the top surface of the sample. This causes greater uncertainty in the interpretation of sensing distance. An approximation of the sensing distance may be $2-3d_c$ for these three

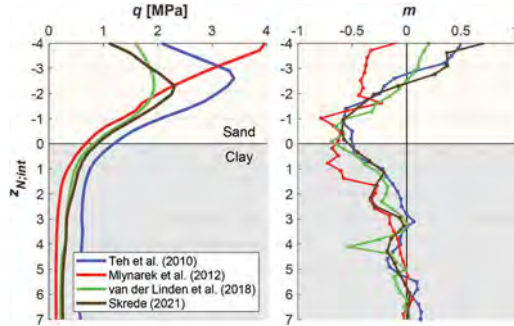
measurements and 5-6d_c for Młynarek et al. (2012). Extreme values of the m-profiles were between -0.8 and -0.6, reached within 1d_c of the actual layer boundary.


Figure 6. *Q* and *m* profiles for two-layered samples of sand over clay from multiple studies.

The opposite layering is presented in Figure 7. Similar to the two-layered clay in section 5.2, the clay layers exhibit a very short sensing distance of about 1d_c. The contrast (i.e., ratio) between the characteristic cone resistance of the bottom sand layer and the clay layer varies from 25 to 100. The developing distance displayed in the sand layer appear to be approximately 3d_c. Extreme values of the m-profiles vary from 2.6 to 4.4 and occur at the layer interface.
Figure 7. *Q* and *m* profiles for two-layered sand and clay from multiple studies. Top: sand over clay. Bottom: clay over sand.

5.4 *Thin clay layer in sand*

Measurements from NTNU experiments E2 (Hammer 2020) and E5 (Skrede 2021) of thin clay layers with thickness 0.56-2.2d_c are presented in Figure 8. The characteristic cone resistance of the sand layers were about 10 times that of the clay layer. The m-profiles for the three different layer thicknesses primarily have extreme values for the top transition of between -0.6 and -0.5. These occur very close to the clay layer interface. Extreme values of m for the bottom transition occur 0-1 d_c below the bottom interface. The extreme values decrease with

decreasing layer thickness. Sensing and developing distances in the sand can be approximated to 2-3d_c and 2d_c, respectively.

5.5 *Multiple thin sand and clay layers*

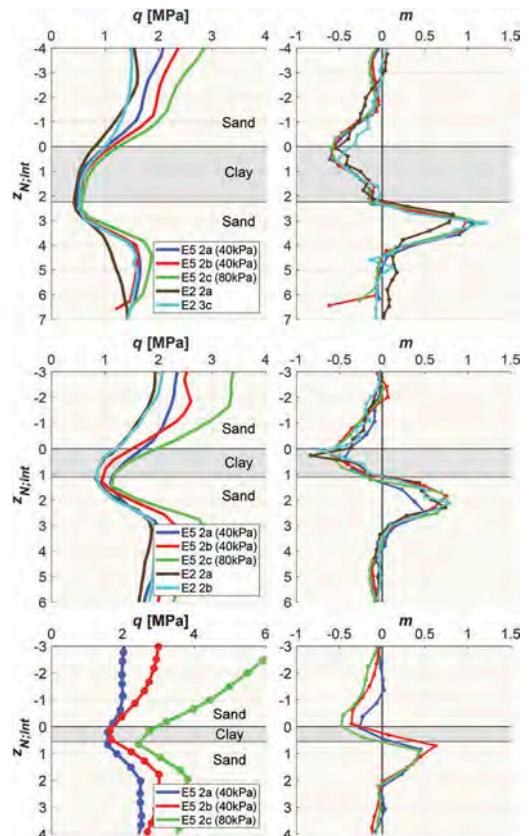
Numerous experiments on samples with multiple thin sand and clay layers of equal thickness is presented in the study of de Lange (2018). Here, three of these are presented. The first is the "exploratory test 4" presented in Figure 3 with thicknesses 3.2d_c. Figure 9 and Figure 10 present respectively "soil model 02" with layer thicknesses 1.6d_c and "soil model 08" with layer thicknesses 0.8d_c. Both the experiment with thicknesses 3.2d_c and 1.6d_c reaches extreme values of m very close to or at the interfaces. Extreme values of m prior to clay layers and sand layers are respectively about -0.6 and 1-1.8. For the sample with layer thicknesses 0.8d_c the values of m are significantly lower than the other two experiments. However, the shape of the m-profile is largely the same and extreme values of m correspond to interfaces fairly well.


Figure 8. *Q* and *m* profiles for thin clay layers in sand. Experiments from Hammer (2020) and Skrede (2021). Top: H= H=2.2d_c. Middle: H=1.1d_c. Bottom: H=0.56 d_c (each measurement point is marked with dots).

Figure 11. Illustration of the expected thin-layer effects in (a) a thin clay layer embedded in sand and (b) a thin sand layer embedded in clay. Black lines are the characteristic cone resistance.

6 DISCUSSION

6.1 *Sensing and developing lengths*

It is evident from the experiments that the sensing and developing distances of sand and clay are significantly different. While penetration in sands exhibit an almost equal sensing- and developing distances, there are large differences in clays. In clays, the sensing distance appear to typically be about one cone diameter in front of the cone tip, while the developing distance are up to six times the amount. This difference is considered to be key in understanding the thin-layer effects acting in sand and clays. Figure 11 illustrates the expected thin-layer effects in (a) a thin clay layer in sand and (b) a thin sand layer in clay due to the difference in sensing and developing distances.

6.2 *Layer interface detection*

Based on the studied experiments, layer interfaces between sand and clay may be interpreted based on representative extreme values of m. The top interface of clay layers can be approximated at a depth with an extreme value of m less than -0.4. For layers with small contrast in characteristic cone resistance, such as the two-layered sand/ or clay, a value of about -0.2 can indicate a layer interface. A bottom interface of a clay layer may be interpreted at the depth where the parameter m reaches an extreme positive value of at least 0.5.

7 CONCLUSIONS

A cone resistance rate of change parameter shows promising possibilities to detect layer interfaces between sand and clays. The parameter additionally yields useful information on transition effects. It allows for efficient interpretation of layer boundaries and may even detect layers as thin as the cone diameter. The use of the parameter for interface detection depends on a significant contrast in characteristic cone resistance between layers. Testing on field data is needed to look deeper into the possibilities and the limitations for this method of layer interface detection in naturally formed deposits.

Recalculation of in-situ CPTu in intermediate soils using G-PFEM

ABSTRACT: Piezocone penetration in intermediate soils is often associated with partially drained behaviour which has to be taken into account when interpretating the results. As part of the research project PITS, the effect of partial drainage on in-situ testing in postglacial silty deposits in Austria is investigated by means of in-situ testing campaigns, laboratory testing and numerical simulations. The present work presents a numerical recalculation of in-situ CPTu, carried out with different penetration velocities in a silty soil layer at the test site Rhesi near lake Constance, using the application G-PFEM. The results agree reasonably well with the in-situ measurements considering the given heterogeneity of the soil layer and suggest that partial drainage occurs during the penetration process.

1 INTRODUCTION

The interpretation of piezocone testing (CPTu) in intermediate soils is a challenging task considering the fact that standard testing with a penetration velocity, v, of 2 cm/s often takes place under partially drained conditions. This has been shown, e.g. by Paniagua *et al.* (2013) on the basis of small-scale experiments where local drainage around the cone tip was observed. Therefore, specific approaches have been developed to quantify partial drainage at normalized penetration velocities (Randolph and Hope, 2004; Schnaid *et al.*, 2020) and to account for this effects when deriving parameters, such as the coefficient of consolidation (DeJong and Randolph, 2012), from CPTu data.

The research project PITS, initiated at TU Graz in cooperation with the Federal Chamber of Architects and Chartered Engineering Consultants, aims to improve the characterization of postglacial silty deposits in Austria by means of in-situ testing addressing, inter alia, the effect of partial drainage.

The present work focusses on the numerical recalculation of CPTu tests carried out in a silty layer, where partially drained behaviour is observed, with penetration velocities of 0.5 and 2 cm/s. First, the in-situ testing campaign and the numerical model are outlined. Then, the results of the recalculations are presented and discussed highlighting the partially drained behaviour during penetration.

2 IN-SITU TESTING CAMPAIGN

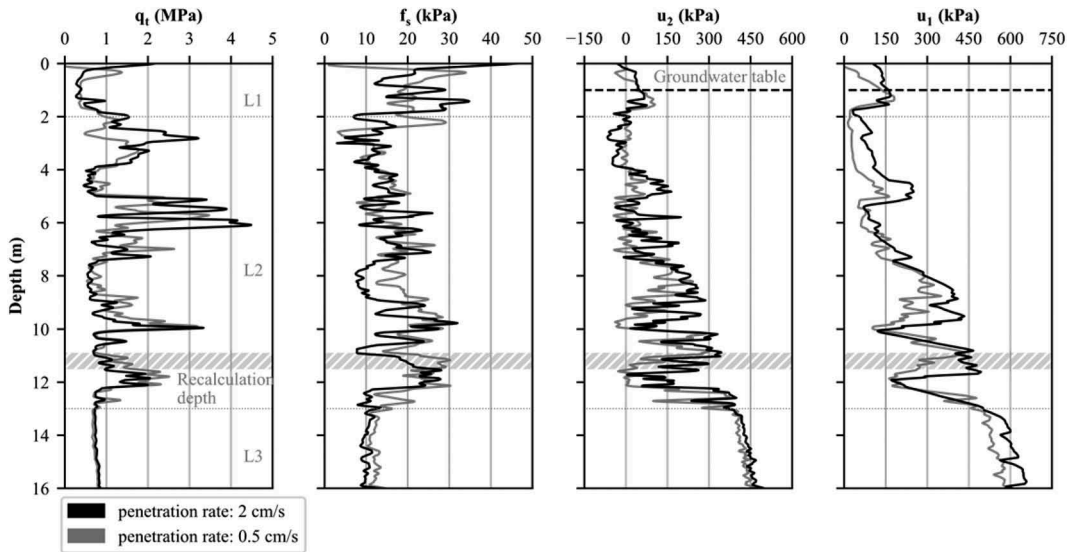
As part of the ongoing research project PITS a comprehensive in-situ testing campaign was carried out at test site Rhesi, located in the forelands of the river Rhine near lake Constance in Austria. CPTu tests with different penetration velocities of 0.1, 0.5, 2 and 10 cm/s were carried out along with dissipation tests at different depths using u_1 and u_2 probes. Additionally, soil samples were recovered for laboratory testing and seismic flat dilatometer tests (SDMT) were performed. Figure 1 shows the obtained profiles of q_t, f_s, u_1 and u_2 over depth for the penetration velocities of 0.5 and 2 cm/s. For the following numerical study, layer L2, characterized by sand-silt alterations, is of main interest and a 0.5 m thick sublayer located at a depth of around 11.3 to 11.8 m is selected for recalculation. According to EN ISO 14688-1, the sublayer is classified as sa' cl' Si. Overall, the in-situ results show a clear scatter due to the sand-silt alterations. However, the calculated mean and median values of q_t, f_s, u_1 and u_2 are in good agreement for the considered sublayer. A shear wave velocity of around 170 m/s was measured at the considered depth and a friction angle of 30° results from direct shear testing.


Figure 1. In-situ measurements (q_t, f_s, u_1, u_2) over depth at test site Rhesi; depth used for the numerical recalculation marked at 11.5 m below the ground surface.

3 NUMERICAL MODEL

The numerical simulation of cone penetration testing is a challenging task involving large displacements and deformations of the soil around the penetrometer, nonlinear material behaviour and frictional contact between the ideally rigid cone and the deformable soil. Advanced numerical methods have already been successfully applied to model cone penetration (Ciantia *et al.*, 2016; Ceccato *et al.*, 2016; Sheng *et al.*, 2009; Yuan *et al.*, 2019). For the present work, the application G-PFEM (Carbonell *et al.*, 2022), an implementation of the Particle Finite Element Method (PFEM) developed for modelling large deformation problems in geotechnics within the framework Kratos (Dadvand *et al.*, 2010), is used.

3.1 *G-PFEM*

In the PFEM, a given boundary value problem is solved performing frequent remeshing of critical regions of the integration domain which is treated as a cloud of particles carrying all information. At the beginning of a time step, particles/nodes may be added or removed in certain regions. Subsequently, the boundaries of the domain are defined and the mesh is created which is used for solving the computation step by means of the Finite Element Method (FEM). Finally, an updated cloud of nodes/particles is obtained at the end of the time step (Oñate *et al.*, 2011). Large deformations of the domain can be treated efficiently as excessive mesh distortion is avoided, however, at the cost of increased computational effort. A stabilized, mixed formulation of the quasi-static linear momentum and mass balance

equations in an Updated Lagrangian manner is used in connection with low equal order approximations (linear triangular elements) of the displacement and pore pressure fields. Additionally, the determinant of the deformation gradient is introduced as a nodal variable (Monforte *et al.*, 2017b). Constraints due to frictional contact between cone and soil, according to a Coulomb friction law, are enforced using a penalty method. Also, no water flow normal to the contact interface is allowed as the rigid body is impervious. The interested reader is referred to Monforte *et al.* (2017a) and Carbonell *et al.* (2022) for a more detailed outline of the application G-PFEM.

For the present study, the Clay and Sand Model (CASM), a non-associated elastoplastic model proposed by Yu (1998), is used allowing for a flexible definition of the yield surface geometry by means of the model parameters r and n. For particular combinations of r and n the surfaces of the Original Cam Clay model (OCCM) and the Modified Cam Clay model (MCCM) may be obtained as shown in Figure 2. Adapted to finite strains according to Monforte *et al.* (2015), the model features the hyperelastic model by Houlsby (1985) with the modified swelling index κ^* and the shear modulus G. Coupling of volumetric and deviatoric response is not considered, thus, the parameter α equals zero. The classical critical state hardening rule is adopted according to which the preconsolidation pressure evolves with plastic volumetric strain depending on κ^* and the modified compression index λ^*. The implemented version of the CASM and its extension for structured material as well as the FD_MILAN model have already been used in connection with G-PFEM for modelling cone penetration (Hauser

and Schweiger, 2021; Monforte *et al.*, 2021; Oliynyk *et al.*, 2021).

3.2 *CPTu model*

The penetration process is modelled in 2D as an axisymmetric problem consisting of a rectangular, deformable soil domain (measuring 2.2 m in height and 1 m in width) and a rigid cone with 15 cm² base area and a tip angle of 60°. Overburden pressure is applied on top of the domain while the lateral and lower boundaries are fixed in normal direction (see Figure 3). Initially, the probe is already inserted in the soil and the downwards movement of the rigid body starts from there. A constant initial stress field is applied assuming weightless soil and the stationary values of q_t, f_s, u_1 and u_2 are reached after an initial transient phase of roughly 10 radii of penetration. The initial mesh, the contact stiffness and the criteria for mesh refinement were chosen based on previous studies (Hauser and Schweiger, 2021).
Figure 2. CASM yield surfaces for different combinations of r and n in the q-p' space normalized with respect to respective preconsolidation pressure p'$_0$.
Figure 3. Axisymmetric model and refined mesh during penetration.

4 RESULTS OF THE RECALCULATION

The recalculation was performed for a 0.5 m thick sublayer at an average depth of 11.55 m leading to the constant initial stress field defined through σ'_v = 128 kPa, σ'_h = 64 kPa and u_0 = 110 kPa with K_0 being 0.5. For this study, the yield surface of the CASM is assumed to be a MCC ellipse (r = 2, n = 1.5) since no experimental evidence for an alternative, more suitable choice of r and n is available. This results in an associated flow rule which influences the pore pressure development. However, the effect of a non-associated flow rule is not addressed in this study. The overconsolidation ratio (OCR) is equal to 1. G_0 is calculated from V_s for a density of 1.83 g/cm³ and a ratio G_0/G = 5 is used to estimate the shear modulus at working strains, G, of 10600 kPa. Marchetti and Monaco (2018) suggest a similar value of around 4.2 for G_0/G for a clayey silt at a site in Italy. Assuming uncoupled volumetric and deviatoric behaviour in the hyperelastic model (α = 0), κ^* is determined in such a way that a Poission's ratio of 0.2 is obtained for the initial mean stress and the given G. Eventually, λ^* is defined through the ratio λ^*/κ^* = 4. The parameter set, as summarized in Table 1, yields an undrained shear strength of 39 kPa which is obtained from a numerically simulated triaxial compression test for the given initial stress state. A contact friction angle of 9° at the interface between penetrometer and soil is used which proved to be a reasonable assumption in previous studies (Hauser *et al*, in press).

Table 1. Material parameters for the numerical recalculation of a silty layer at a depth of 11.55 m at test site Rhesi.

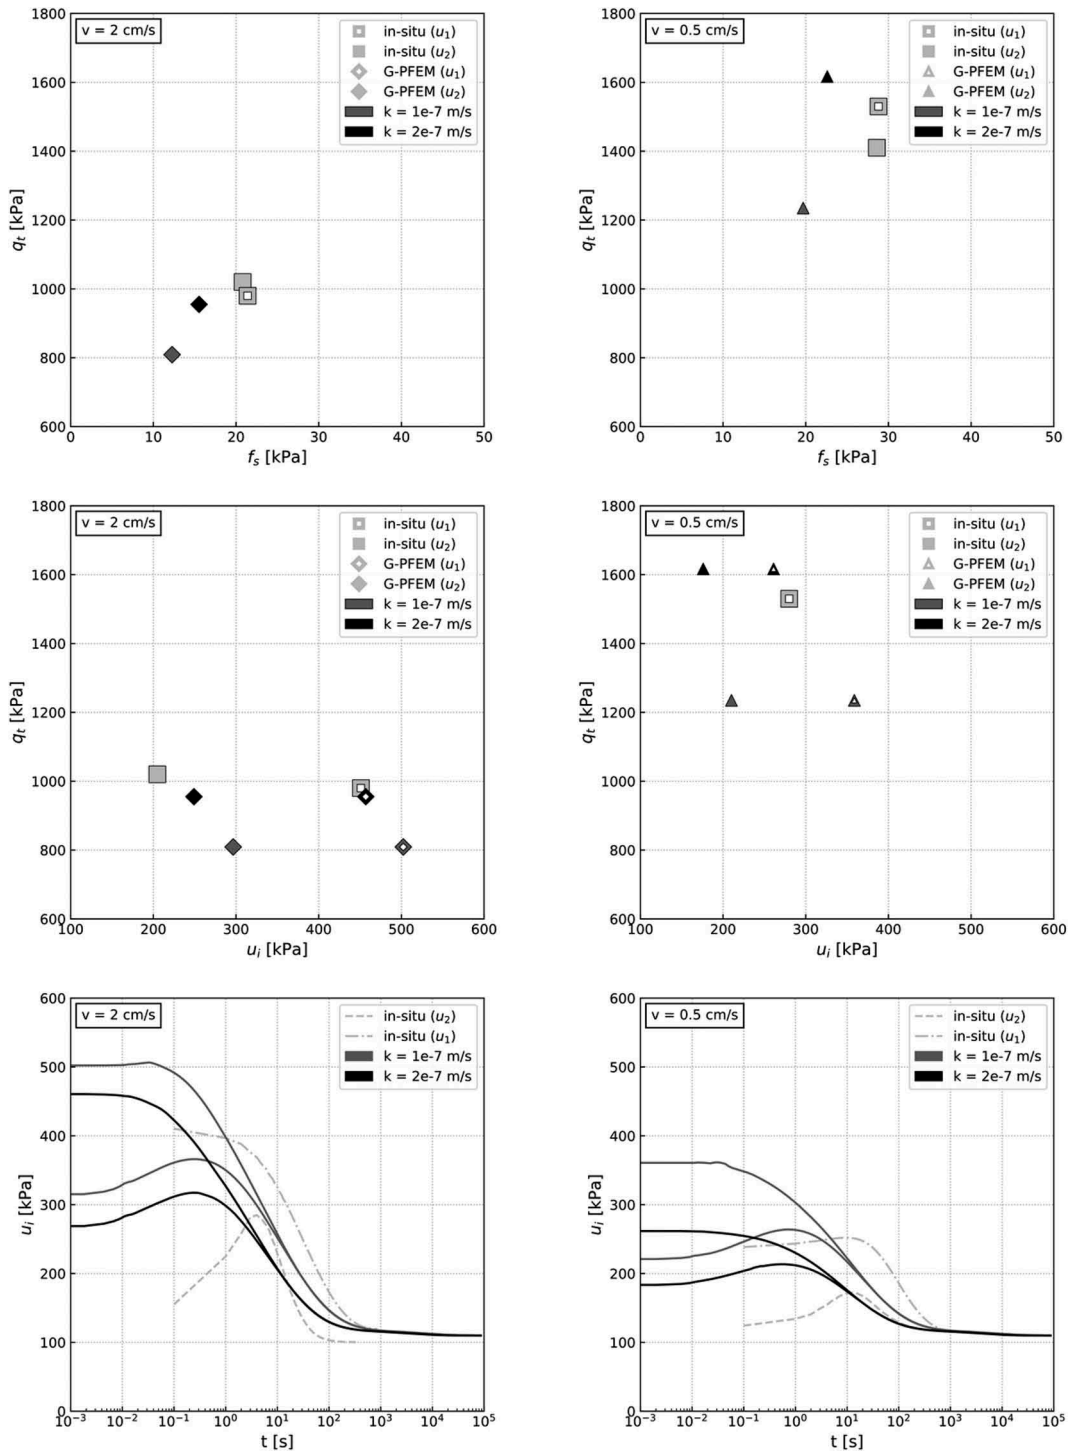
γ [kN/m³]	φ [°]	r [-]	n [-]	OCR [-]
0	30	2	1.5	1
κ^* [-]	G [kPa]	α [-]	λ^* [-]	K_0 [-]
0.0061	10600	0	0.0244	0.5
Figure 4. Results of the recalculation of q_t, f_s, u_2 over normalized depth compared to the in-situ tests executed for v = 2 cm/s with a u_1 und u_2 piezocone, respectively.


Figure 5. Comparison of in-situ measurements (square markers and dashed lines) and numerical recalculations for penetration velocities of 0.5 and 2 cm/s as well as permeabilities of $1*10^{-7}$ and $2*10^{-7}$ m/s in terms of q_t, f_s, u_1, u_2 and pore pressure dissipation curves. Note that the in-situ u_2 pressure for v = 0.5 cm/s is not available for comparison.
Figure 6. Tip resistance Q_t and excess pore pressures Δu_1 and Δu_2 normalized with respect to the undrained tip resistance $Q_{t,ref}$ and the undrained excess pore pressures $\Delta u_{1,ref}$ and $\Delta u_{2,\,ref}$, respectively over the penetration velocity v normalized by the permeability k (Sheng et al., 2014).

Recalculations were carried out for the penetration velocities of 0.5 and 2 cm/s as well as for isotropic permeabilities equal to $1*10^{-7}$ and $2*10^{-7}$ m/s. The results are presented in Figure 5 comparing the in-situ and the recalculated q_t, f_s, u_1, u_2 along with the pore pressure dissipation curves. Thereby, the numerical results for q_t, f_s, u_1, u_2 are obtained from the penetration curves as the average between 16 and 17 radii of penetration (see Figure 4) while the in-situ values represent the average over the considered 0.5 m thick sublayer. As expected, the lower permeability k = $1*10^{-7}$ m/s leads to more "undrained like" behaviour, resulting in lower q_t, f_s and higher u_1, u_2 as well as longer dissipation times, compared with the higher permeability k = $2*10^{-7}$ m/s. However, better agreement between the in-situ results and the recalculations, in terms of q_t, f_s, u_1, u_2, is reached for k = $2*10^{-7}$ m/s as both penetration velocities match the in-situ results reasonably well. Numerically, the dissipation curves at the u_1 und u_2 position tend to coincide after around 10 to 12 s which is not the case for the in-situ measurements. For k = $1*10^{-7}$ m/s, the recalculated dissipation curves lie between the in-situ ones, however, the initial pore pressure is significantly higher.

For k = $2*10^{-7}$ m/s, the dissipation time and the initial pore pressures are reduced suggesting better agreement with the in-situ measurements in terms of initial pore pressure. Additional calculations with permeabilities of $1*10^{-1°}$ m/s and $1*10°$ m/s were performed in order to obtain fully undrained and fully drained references cases.

5 DISCUSSION

The recalculations employing the higher permeability of $2*10^{-7}$ m/s appear to match the in-situ q_t, f_s u_1 and u_2 best for the two considered penetration velocities. In case of faster penetration (2 cm/s) the numerical response is slightly more "undrained like" compared to the in-situ measurements while the response is rather on the drained side for slower penetration (0.5 cm/s). The difference between the in-situ and the recalculated dissipation curves is more pronounced as the pore pressure at the u_1 position decays significantly faster compared to the in-situ measurement. However, considering the heterogeneity of the layer and the fact that the in-situ curves for u_1 and u_2 originate from two different tests, carried out in close proximity and at roughly the same depth with the u_1 and u_2 probe, respectively, the overall behaviour, especially the non-monotonic decrease of the u_2 pressure, is properly reproduced by the numerical model. Also, anisotropic permeability was not considered in the present numerical study.

The recalculated CPTu quantities appear to be sensitive to the considered range of penetration

velocities and permeabilities suggesting partially drained behaviour. Figure 6 shows the tip resistance Q_t and the excess pore pressures Δu_1 and Δu_2 normalized with respect to the undrained reference $Q_{t,ref}$, $\Delta u_{1,ref}$ and $\Delta u_{2,ref}$, respectively, plotted against the penetration velocity normalized by the permeability (Sheng *et al.*, 2014). Therefore, the undrained calculation for v = 2 cm/s and k = $1*10^{-1\circ}$ m/s is used as reference case. Compared to the undrained reference, the tip resistance increases by a factor of 3 for v = 0.5 cm/s and k = $2*10^{-7}$ m/s and by a factor of more than 5 for the drained case. Similarly, Δu_1 decreases by a factor of up to 2.8 and Δu_2 by a factor of up to 5 with respect to the maximum undrained pressure suggesting that the shape of the pore pressure bulb changes with drainage condition. Also, the recalculated tests lie within the proposed range for partial drainage, i.e., $2*10^1 < v/k < 2*10^6$ (Sheng *et al.*, 2014).

6 CONCLUSION

The numerical recalculation of in-situ CPTu, performed in a silty postglacial deposit in Austria, confirmed that partial drainage governs the penetration process as the obtained q_t, f_s, u_1 and u_2 are highly sensitive to the considered range of penetration velocities and soil permeabilities. Overall, the numerical results match the in-situ measurements reasonably well for the considered 0.5 m thick sublayer, which is, to a certain degree, heterogeneous due to the presence of alternating thin layers of sand and silt. Hence, the dissipation behaviour could not be reproduced as accurately as q_t, f_s, u_1 and u_2 resulting in faster dissipation of pore pressure at the u_1 position compared to the in-situ results. Nevertheless, the study demonstrates that the application G-PFEM is capable of modelling cone penetration under partially drained conditions in a realistic way.

ABSTRACT: The T-bar is a full-flow CPT with a larger probe surface area compared with the conventional CPT probe. The tip has the shape either of a ball or as an upside-down T, a so-called T-bar. The term 'full-flow' comes from the assumption that the earth 'flows' around the tip, which is a realistic assumption for soils with extremely low undrained shear strength. This paper presents a case study where a large number of T-bar tests have been performed in a nearshore organic clay with high water content and very low undrained shear strength. The test site is located in Stockholm, Sweden, where planned land reclamation and capping of contaminated top soils are challenging from a stability perspective due to the low strength of the soil. T-bar tests were thus performed to characterise the shear strength profile of the soil in detail, especially at shallow depths where sampling was difficult and the shear strength values were under 5 kPa. A N-factor relating the net cone resistance (q_{net}) and the undrained shear strength of the soil (c_u) was evaluated based on T-bar measured parameters and direct simple shear tests and undrained triaxial tests on samples taken at greater depths. This allowed to estimate shear strength profiles with depth. For all tests, both the penetration and extraction cone resistance were measured, and a good correlation was obtained between this ratio and the soil sensitivity measured in the laboratory. In addition, the sensitivity was correlated to the organic content of the clay. These correlations were found to be OCR-dependent. Further, cyclic tests were performed, and their results were correlated with the remoulded shear strength values. This facilitated mapping of the soil conditions across the site.

1 INTRODUCTION

Conventional CPT tests have long been used in all types of soil to interpret strength characteristics. In extremely soft clays the penetration resistance is however very small, and hence full-flow penetration tests was developed during the late 1990s, mainly for offshore applications (Stewart & Randolph, 1994; Randolph, 2004). The full-flow probe has the shape of a ball or a upside-down 'T' in order to increase its probe area and hence the penetration resistance.

The probe area is normally enlarged 10 times compared to conventional CPT tests. As the full-flow probe is mounted on conventional CPT probe, only replacing the tip, the probe area is 10 times larger than the drilling rod. This gives several advantages in extremely soft soils:

– The penetration resistance is 10 times higher, i.e. the meaurement uncertianties originating from the load cell decrease

– The correction of overburden stress and pore pressure measurements are one tenth, i.e. they are almost negligable
– The resistance can be measured during penetration and extraction, giving additional data on soil type and behaviour

This paper presents a case study where full-flow CPT tests have been performed nearshore as part of a land reclamation project. An old industrial area, located in the northeastern part of central Stockholm, is undergoing residential development. Highly contaminated soils are also planned to be capped, i.e. a fill layer is placed on the seabed to minimize dispersion of contamination. The soil consists of extremely soft organic clay and gyttja, and hence the filling is challenging from a stability persective. The full-flow CPT tests were performed to obtain high-quality detailed strength properties, especially in the upper part of the soil. In addition, the area had local variation due to earlier unknown works such as dredging, and hence mapping of the nearshore area

was important. The full-flow CPT tests was shown to be an excellent method to quickly map the area, as a complement to sampling and laboratory testing.

2 BACKGROUND

2.1 Previous work on full-flow CPT tests

The full-flow CPT tests have been used during the last 20 years for field applications (e.g., Yafrate *et al.*, 2009; Peuchen & Terwindt, 2016; Nakamura *et al.*, 2009; Boylan *et al.*, 2011; Schaeffers & Weemees, 2012), as well as in laboratory tests including centrifuge tests (Almeida *et al.*, 2011; Levacher *et al.*, 2016; Sahdi *et al.*, 2014). In addition, the full-flow test has been analysed theoretically by e.g. Randolph & Andersen (2006) and Zhu et al. (2020).

In Sweden, a research project on sensitive clays on land was performed around 10 years ago (Larsson *et al.*, 2014; Åhnberg & Larsson, 2012). The purpose was to investigate cyclic strength degradation of highly sensitive and quick clays.

Randolph (2004), DeJong *et al.* (2010) and Lunne *et al.* (2011) provide excellent all-inclusive description of the method.

2.2 Correction of tip resistance

Similar as for the conventional CPT test, the measured tip resistance is corrected by overburden stress and measured pore pressure. This corrected tip resistance (q_{net}) is calculated by Eq. 1 (DeJong *et al.*, 2010):

$$q_{net} = q_c - [p_o - u_2(1 - a)]\frac{A_s}{A_P} \qquad (1)$$

where q_c = measured tip resistance; p_0 = total vertical overburden stress; u_2 = measured pore pressure, a = area ratio, A_s = area of rod; and A_p = tip area. This equation assumes that the soil 'flows' around the probe and applies a vertical stress on the upper surface. As the ratio $A_s/A_p \approx 0.1$, the effect of overburden stress and pore pressure is one tenth of that for conventional CPT tests. It is thus often negligible.

2.3 Evaluation of shear strength

The undrained shear strength (c_u) is calculated as:

$$c_u = \frac{q_{net}}{N_{Tbar}} \qquad (2)$$

Usually, site specific calibrations are recommended, however, the N_{Tbar} factor normally is found to be around 10-13 (Lunne *et al.*, 2011; DeJong

Figure 1. The Iskymeter (top left), column penetration test (top right) and T-bar used in this study (bottom). The T-bar was Ø40 mm and width 250 mm (tip area 10,000 mm^2). The drilling rod is Ø36 mm (area ~1,000 mm^2) Sources: Kallstenius (1961), Massarsch (2014), Geotech (2019).

et al., 2010). It is found to be dependent on soil type, sensitivity and rate of strain softening.

According to theoretical studies by Randolph & Andersen (2006) the N_{Tbar} is in the range 11-13, not noticeably dependent on strength anisotropy if the average strength is used. For cyclic tests, i.e. several cycles of penetration and extraction over an interval, a remoulded strength can be interpreted with a N_{Tbar} varying between 10.5-15.

Larsson *et al.* (2014) studied 13 different Swedish soils and found that N_{Tbar} was highly dependent on the soil's plasticity, in particular its liquid limit. A range between ~7 for low-plastic soils to ~16 for high-plastic soils were found.

2.4 Comparison with similar tests

Although the shape of the T-bar probe is unique, there are two other penetration tests which are remarkably similar. The 'Iskymeter' was developed by the Swedish Geotechnical Institute during the 1930s for soft clays. The Iskymeter consists of two foldable wings which are folded during penetration and unfolded when extracted where the extraction resistance is measured. Calibration of shear strength was done by comparing extraction resistance, fall cone test and in situ vane tests, and a N-factor of around 10-15 was found, dependent on both sensitivity and organic content (Kallstenius, 1961).

The Iskymeter is no longer in use but was supposedly the origin for the column penetration tests which is used as a quality control of dry deep mixing columns. For this application, a N-factor of 10 is used (Axelsson, 2001), but this has undergone surprisingly little research.

Photographs of the Iskymeter, the column penetration and T-bar probe are shown in Figure 1. Notably, the Iskymeter, the standard dimension column penetration test and the full-flow CPT have equal probe areas, i.e. 10,000 cm^2. The N-factor for interpretation of shear strength is also similar.

2.5 Extraction ratio

The extraction ratio for full-flow CPT tests, i.e. ratio between penetration (q_{in}) and extraction (q_{out}) resistance is often used to interpret the soil's sensitivity. For low sensitive soils, the ratio is typically 0.6-0.8 decreasing to around 0.3 for highly sensitive soils (DeJong *et al.*, 2010).

3 SITE AND METHODS

3.1 Soil profile

Figure 2 shows a typical soil profile in one of the boreholes with a water depth of ~18 m. The sediments consist of clayey gyttja from seabed down to appr. 10 m depth. From around 10 m the soil is categorised as clay. As the organic content and water content decreases with depth, the density increases.

The plastic limit is normally not determined in Swedish engineering practice. Instead, only the liquid limit is used for empirical correlations, including silt and organic content. Figure 3 shows values of liquid limits vs. organic content from tests on the soil profile shown in Figure 1. This correlation allows a simple mapping of soil type only by liquid limit values.

3.2 Execution of the field work

The nearshore area had limited water depths, and all tests and sampling were done using a pontoon with supporting legs as a stable working platform. A total of around 30 T-bar tests were performed in an area of around 400x500 m. However, only a few is presented herein due to limited space. Around half was done with data acquisition also during extraction, and a few was performed with cyclic tests.

All T-bar tests were performed with the drilling rod within a casing to prevent excess deflection of the rod. Divers attached the T-bar probe under the casing, and also noted the time of penetration into seabed.

Sampling was done using the standard Swedish piston sampler (50 mm and 60 mm diameter).

3.3 Laboratory tests

A total of around 40 samples were retrieved. Routine analyses, i.e. bulk density, natural water content, liquid limit and intact and remoulded shear strength with fall cone (FC) tests were performed on all samples.

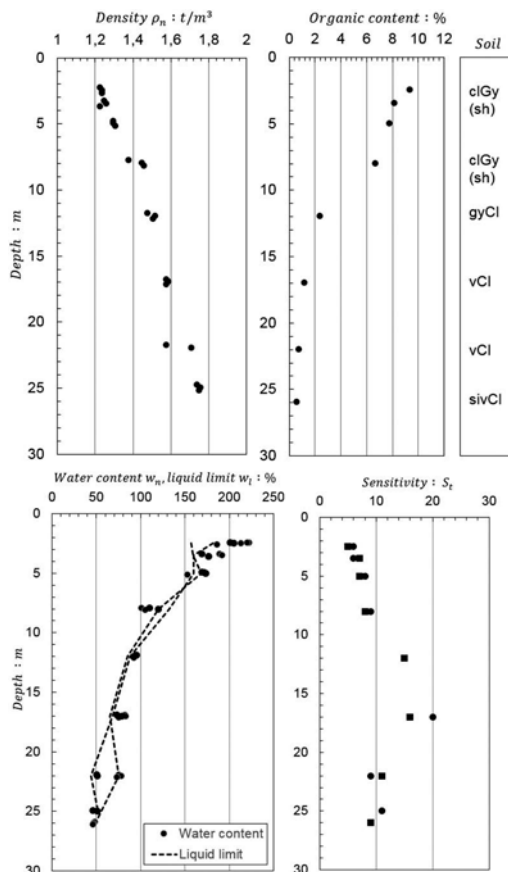

Figure 2. Typical soil profile (water depth ~18 m). cl = clay, gy = gyttja, sh = shales, v = varved, si = silt. Soil classification according to EN ISO 14688-1 and -2.

Figure 3. Liquid limit vs. organic content on samples from borehole shown in Figure 1.

On selected samples, CRS oedometer, direct simple shear (DSS) and triaxial compression and extension tests were performed.
Figure 4. Liquid limit vs. sensitivity on all samples.

4 RESULTS

4.1 Evaluation of undrained shear strength

The strength anisotropy is larger for silty clay than organic clay and gyttja. It was thus decided to calibrate the N_{Tbar} against the undrained direct simple shear strength (c_u^{DSS}). This eliminates any anisotropy effects in the penetration tests as it is done in a stratigraphy of both organic and silty clay (example in Figure 2). Interpreting the c_u^{DSS} is also normal practice for conventional CPT tests in Sweden.

Trials of correlating q_{net} with strengths from FC and DSS tests were done using several soil parameters, however, the N_{Tbar} was found to be best expressed as a function of the liquid limit. Notably, the liquid limit reflects the type of soil, its organic content and sensitivity (Figure 3 and 4). The following expression was evaluated:

$$N_{Tbar} \approx 5 + 10 \times w_L \qquad (3)$$

w_L is here given in decimal form. A typical example of a strength profile with depth is shown in Figure 5. Here, Equations 1–3 gives strength values similar to FC and DSS tests. The figure also shows c_u^{DSS} calculated by empirical correlations with preconsolidation stress from CRS oedometer tests and c_u^{DSS} (Hov et al., 2021). Figure 5 also shows results from triaxial tests at shallow depths, although these were not used for intepretation of the T-bar tests.

As seen in the figure, the strengths are extremely low just below the seabed, in practice zero at seabed, but increasing with around 1.2 kPa/m. By correlating the T-bar tests with laboratory data on greater depths, it is thought that a strength extrapolation towards the seabed is realistic. The T-bar tests seemed to confirm this. Obviously, strengths evaluations from full-flow tests are more certain than conventional CPT test due to the larger tip resistance, thus reducing the measurement uncertainties.

For normal ranges of liquid limits for inorganic clays, i.e. liquid limits around 40-80%, the N_{Tbar} varies between ~10 and ~13. These values are similar to those found by Larsson et al. (2014), Nakamura et al. (2009), Randolph & Andersen (2006) and others.

For higher values of liquid limits, i.e. organic clays and gyttja, the N_{Tbar} is up to ~20 according to Equation 3. This is in the same range as reported for tests in peat (e.g., Long & Boylan, 2012; Boylan et al., 2011).

4.2 Evaluation of sensitivty

The extraction resistance was measured for several of the T-bar tests. An example is given in Figure 6 where both the extraction (q_{out}) and penetration (q_{in}) resistance is shown. The q_{out} is consistently lower than q_{in}, as expected, due to the remoulding occuring around the probe.

Figure 7 plots all extraction ratios (q_{out}/q_{in}) vs. sensitivity values from laboratory FC tests where T-bar tests and sampling were done in the same location. The ratios varies between 0.45 and 0.9, decreasing with increasing sensitivity. This is in the same range as reported by e.g. DeJong et al. (2010) for low sensitive soils.

There is a clear correlation between the two variables, despite the relative small variation in sensitivity. This relationship is also seen in e.g. Yafrate et al. (2009). The correlation is however OCR-dependent (the OCR in the OC area is around 1.2–3).

4.3 Evaluation of remoulded shear strength

Cycles were performed in an attempt to correlate the penetration resistance with the remoulded strength measured in the laboratory (using FC tests). Cycles over 1 m intervals are shown in Figure 6, and a detailed resistance plot of the upper cycle is shown in Figure 8. This cycle was perfomed in clayey gyttja with a water content of 150–200%. A clear decrease in both penetration and extraction resistance is seen for each cycle.

Figure 9 plots the average penetration resistance (q_{in}) for each cycle vs. number of cycles. It seems that after 5-7 cycles, the decrease in resistance seems to level off. This is similar to the findings from e.g. Yafrate et al. (2009).

The measured remoulded undrained shear strength in the laboratory was 1.1 kPa. The N-factor in the clayey gyttja was thus evaluated to:

$$N_{Tbar,rem} \approx 35 \qquad (4)$$

It should be noted that cycles were performed in a very limited number of locations, so the dependency of plasticity, sensitivity or OCR has not been evaluated.
Figure 5. Typical example of evaluated strength by Eqs. 1-3 plotted together with results from laboratory tests. Strength "Emp.corr" is based on empirical correlations with the preconsolidation stress σ'_c from CRS oedometer tests; $c_u^{DSS} \approx (0.125 + 0.205 \times w_L) \times \sigma'_c$ for OCR=1,0-1,3 (Hov *et al.*, 2021).

5 DISCUSSION

The T-bar tests were shown to be very useful for this type of project. The two main benefits were: a) detailed analyses of undrained shear strength in the upper part of the deposit, i.e. for strengths which in practice increases from zero, and b) a rough mapping of soil conditions by analysing the extraction ratio.

The very low strengths are difficult to measure with conventional CPT probes due to the large measurement uncertainty. In addition, sampling of such low strength sediments is very difficult, and in practice impossible with the Swedish piston sampler as it is dependent on soil resistance when coring (the coring is done by rotation of the drilling rods, but the outer part of the sampler is kept still using the soil resistance).

The use of T-bar tests showed that the strength increases almost linearly from zero at seabed. This was valuable information for stability evaluation of

Figure 6. Typical example of penetration and extraction resistance in one T-bar test. Two sets of cycles were performed during penetration.
Figure 7. Values of sensitivity from laboratory tests (fall cone) and evaluation extraction ratio (example given in Figure 6).

the planned capping of the contaminated areas and filling for land reclamation.

The rough mapping of soil conditions was possible using the correlations between extraction ratio, sensitivity, liquid limit and organic content.
Figure 8. Example of cyclic test (upper cycle shown in Figure 6). Shear strength evaluated using N = 35. Negative strength is shown for extraction to make the figure more readable.
Figure 9. Measured strength using N=35 and remoulded strength from FC tests for cycle shown in Figures 7 and 8.

6 CONCLUSIONS

This paper presents a nearshore case study where a large number of T-bar tests have been performed.

The sediments consisted of organic clay and gyttja. The following conclusions are drawn:

– The T-bar test is a useful testing equipment for soils with extremely low shear strengths,
– The N-factor was evaluated to vary between ~10 and ~20,
– The N-factor increases with increasing plasticity (i.e. liquid limit),
– A good correlation was obtained between the extraction ratio and sensitivity,
– A N-factor of around 35 was found for cyclic tests to evaluate the remoulded shear strength.

Bayesian supervised learning of 2D subsurface soil stratigraphy using limited cone penetration tests with consideration of uncertainty

Yue Hu
Department of Civil and Environmental Engineering, National University of Singapore, Singapore

Yu Wang
Department of Architecture and Civil Engineering, City University of Hong Kong, Hong Kong, China

ABSTRACT: Cone penetration tests (CPT) have been widely used for soil stratification in geotechnical site investigation for decades. However, due to time and budget limits, the layout of CPT sounding at a specific project site is often sparse, leading to significant interpolation uncertainty in the development of subsurface soil 2D cross-section, particularly at locations without CPT measurements. Such development is often combined with empirical classification criteria, which further introduce model uncertainty to soil stratification. These uncertainties may pose great risks to the geotechnical engineering practice. A Bayesian supervised learning method is presented in this paper for probabilistic soil stratification in a 2D cross-section using limited CPT. The proposed method can not only automatically stratify soils in a 2D cross-section from limited CPT soundings, but also can properly quantify the associated uncertainties. Complete 2D CPT data cross-section is firstly learned from limited number of 1D CPT profiles using Bayesian supervised learning. The associated interpolation uncertainty is modelled numerically using non-parametric random field simulation based on the results of Bayesian supervised learning. Parametric autocorrelation function of CPT data along either vertical or horizontal direction is not needed. A probabilistic model is also developed to account for the model uncertainty of an empirical soil behavior type classification chart. The interpolation uncertainty and soil classification model uncertainty are then evaluated simultaneously in a Monte Carlo simulation framework. A simulated data example is used for illustration. The results suggest that the proposed method performs well.

1 INTRODUCTION

Subsurface soil stratification is an indispensable element in geotechnical engineering as required for geotechnical designs and analyses. However, due to time and budget limits, the layout of site investigation points is often sparse, leading to significant challenge and uncertainty in the development of 2D subsurface soil stratigraphy which is frequently adopted in geotechnical analysis. In engineering practice, such development is often combined with an empirical soil classification system, which inevitably introduce additional model uncertainty to soil stratification. These uncertainties may pose great risks to the geotechnical designs, analyses, and construction process (e.g., Clayton 2001; Mayne 2007). It is therefore necessary to properly evaluate the uncertainties associated with 2D subsurface soil stratification.

Cone penetration tests (CPT) have been widely used for soil stratification in geotechnical site investigation. It can be used to classify subsurface soils, identify stratification, and quantify associated uncertainty in a single sounding (e.g., Robertson 1990;

Wang et al. 2013). When interpreting 2D vertical soil cross-section using CPT, interpolation between adjacent CPT profiles or stratigraphy should be performed. However, direct 2D interpolation using conventional geostatistical methods is difficult because of the limitation of CPT soundings number and the spatially varying soil layer boundaries which render the soil properties in the 2D cross-section highly non-stationary (e.g., Wang et al. 2019). In this case, it is even more challenging to reasonably tackle the interpolation uncertainty quantification associated with the 2D subsurface stratigraphy. On the other hand, CPT-based soil classification relies on empirical soil classification charts to transform the continuous CPT measurements to discrete soil behavior type (SBT). Note that these charts rely on a series of deterministic SBT classification boundaries which are developed from site investigation data globally. These classification charts might not provide consistent results at a specific site and introduce model uncertainty when used locally (e.g., Boulanger & Idriss 2014; Maurer et al. 2019). How to incorporate the model uncertainty of SBT classification

boundaries in the CPT-based 2D soil stratification remains unsolved.

To address the abovementioned challenges, a Bayesian supervised learning method is proposed to interpret 2D subsurface soil stratigraphy from limited CPT with explicit evaluation of both interpolation uncertainty and SBT chart model uncertainty. The proposed framework is introduced in the following section and then illustrated using a simulated example.

2 THE PROPOSED METHOD

The proposed framework is based on a Monte Carlo simulation (MCS) and comprises of three components. First, SBT index I_c of CPT data is firstly interpolated in the concerned 2D cross-section from limited CPT using a Bayesian supervised learning algorithm in a non-parametric manner. The interpolation uncertainty is quantified automatically during learning process and then modelled by I_c random field simulation based on the learning outcome. Second, a probabilistic SBT chart is developed by adapting an empirical chart to consider the model uncertainty using which random samples of SBT chart with random classification boundaries are drawn. Third, each random field sample of I_c is matched with a random sample of SBT chart to produce a Monte Carlo sample of SBT cross-section with soil stratigraphy. Statistical analysis is then performed on the generated Monte Carlo samples. Both uncertainties are evaluated simultaneously under MCS. The three components are introduced in the following three subsections, respectively.

2.1 Bayesian supervised learning with random field simulation

The full I_c data variability in the concerned 2D cross-section are learned from the profiles of limited CPT. In the context of the Bayesian supervised learning, 2D data matrix $\mathbf{F}$ (e.g., I_c data matrix of a 2D cross-section), which is spatially varying along coordinates x_1 and x_2 (e.g., depth direction and horizontal direction), has a dimension of $N_{x_1} \times N_{x_2}$. Mathematically, $\mathbf{F}$ is expressed as a weighted summation of a series of orthonormal 2D basis functions (e.g., Zhao et al. 2018; Hu et al. 2020; Wang et al. 2020&2021):

$$\mathbf{F} = \sum_{t=1}^{N_{x_1} \times N_{x_2}} \mathbf{B}_t^{2D} \omega_t^{2D} \qquad (1)$$

in which $\mathbf{B}_t^{2D}$ is the t-th 2D basis function, while ω_t^{2D} is the weight coefficients of $\mathbf{B}_t^{2D}$. Discrete wavelet transform may be selected to construct $\mathbf{B}_t^{2D}$ (e.g., Donoho et al. 2006). Note that for compressible images (e.g., spatially correlated CPT data cross-section), most ω_t^{2D} have negligibly small values

except for a limited number of non-trivial ones. Therefore, the $\mathbf{F}$ may be reconstructed approximately if those non-trivial weight coefficients can be identified and estimated using sparse measurements $\mathbf{Y}$ (e.g., CPT profiles data at limited locations), which is a sub-matrix of $\mathbf{F}$ with a dimension of $M_{x_1} \times M_{x_2}$ ($M_{x_1} \ll N_{x_1}$, $M_{x_2} \ll N_{x_2}$). The relation between $\mathbf{Y}$ and ω_t^{2D} is expressed as:

$$\mathbf{Y} = \sum_{t=1}^{N_{x_1} \times N_{x_2}} \mathbf{A}_t^{2D} \omega_t^{2D} \qquad (2)$$

in which $\mathbf{A}_t^{2D}$ is the sub-matrix of $\mathbf{B}_t^{2D}$ with a dimension of $M_{x_1} \times M_{x_2}$. $\mathbf{A}_t^{2D}$ just reflects the measured elements in $\mathbf{B}_t^{2D}$. Equation 2 enables those non-trivial coefficients to be learned through maximum likelihood estimation under a Bayesian framework (e.g., Tipping 2001). The learned weight coefficient vector is denoted as $\hat{\boldsymbol{\omega}}^{2D}$. After derivation, it is found that the posterior distribution of $\hat{\boldsymbol{\omega}}^{2D}$ given measurement data follows a multivariate Student's t distribution, with the mean vector and covariance matrix expressed as (e.g., Zhao et al. 2018; Hu et al. 2020):

$$\mu_{\hat{\omega}^{2D}} = \mathbf{H} V_{\text{tr}} = (\mathbf{J} + \mathbf{D})^{-1} V_{\text{tr}}$$
$$\mathbf{COV}_{\hat{\omega}^{2D}} = \frac{d_n \mathbf{H}}{c_n - 1} = \frac{d_n (\mathbf{J} + \mathbf{D})^{-1}}{c_n - 1} \qquad (3)$$

in which $\mathbf{J}$ is a matrix with element $J_{t,s} = tr[\mathbf{A}_t^{2D}(\mathbf{A}_s^{2D})^{\text{T}}]$, $(t, s = 1, 2, \ldots, N_{x_1} \times N_{x_2})$. "$tr$" represents trace operation in linear algebra. $\mathbf{D}$ is a diagonal matrix with diagonal elements $D_{t,t} = \alpha_t$ ($t = 1, 2, \ldots, N_{x_1} \times N_{x_2}$) in which α_t are non-negative parameters to be determined by a maximum likelihood algorithm (e.g., Tipping, 2001). V_{tr} is a $N_{x_1} \times N_{x_2}$ vector with element $V_{\text{tr}}(t) = tr[\mathbf{Y}(\mathbf{A}_t^{2D})^{\text{T}}]$. $c_n = M_{x_1} \times M_{x_2}/2 + c$; $d_n = d + (\|\mathbf{Y}\|_2^2 - \mu_{\hat{\omega}^{2D}}^{\text{T}} \mathbf{H}^{-1} \mu_{\hat{\omega}^{2D}})/2$. c and d are non-negative small constants to achieve an uninformative prior in the Bayesian formulation. Due to the compressibility of $\mathbf{F}$, only those N_a ($N_a \ll N_{x_1} \times N_{x_2}$) non-trivial coefficients need to be estimated, and the rest are zeroed out. Therefore, in Equation 3, the $\mu_{\hat{\omega}^{2D}}$ is reduced to an $N_a \times 1$ vector and $\mathbf{COV}_{\hat{\omega}^{2D}}$ is reduced to an $N_a \times N_a$ matrix for simplicity.

Given the learning results in Equation 3, random samples of $\hat{\omega}^{2D}$ can be generated through eigen decomposition (e.g., Hu et al. 2019; Hu and Wang 2020):

$$\hat{\omega}^{2D} = \mu_{\hat{\omega}^{2D}} + \sum_{i=1}^{N_a} \mathbf{U}_i \sqrt{\lambda_{\hat{\omega}_i^{2D}}} Z_i \qquad (4)$$

in which U_i is the i-th eigen-vector of the covariance matrix $\mathbf{COV}_{\hat{\omega}^{2D}}$; $\lambda_{\hat{\omega}_i^{2D}}$ is the i-th eigenvalue of $\mathbf{COV}_{\hat{\omega}^{2D}}$; Z_i is a set of independently and identically distributed standard Gaussian random variables. Using Equation 4, random vectors $\hat{\omega}^{2D}$ can be generated readily through realizations of Z_i. After that, extensive RFS of the approximated 2D data $\hat{\mathbf{F}}$ (e.g., I_c data 2D cross-section) are subsequently reconstructed by substituting the random vectors $\hat{\omega}^{2D}$ into Equation 1 as below:

$$\hat{\mathbf{F}} = \sum_{t=1}^{N_a} \mathbf{B}_t^{2D} \hat{\omega}_t^{2D} \qquad (5)$$

Each generated 2D RFS indicates a possible outcome of Bayesian supervised learning. The ensemble directly reflects the interpolation uncertainty.

2.2 *Probabilistic SBT chart*

The empirical I_c – based SBT chart summarized in Table 1 was developed from a global soil database compiling CPT data obtained predominately within limited depths (e.g., Robertson 1990; Robertson & Wride 1998). It is expected that the SBT chart might not provide accurate classification and introduce model uncertainty when used locally at a specific project site. In other words, those empirical I_c classification boundaries (e.g., see Table 1) can vary from site to site (e.g., Boulanger & Idriss 2014; Maurer et al. 2019). To consider the model uncertainty, a probabilistic I_c – based SBT classification chart is developed. The five SBT classification boundaries (i.e., 1.31, 2.05, 2.6, 2.95, 3.6) listed in Table 1 are denoted as B1 to B5 and modelled as five Gaussian random variables, respectively. The mean values of B1 to B5 are taken as their original values, as summarized in the second column of Table 2. According to literature (e.g., Boulanger & Idriss 2014; Maurer et al. 2019) on I_c data variability, a set of standard deviation (SD) values for B1 to B5 is suggested in this study, as summarized in the third column of Table 2. SD of B1, B2 and B5 are taken as 0.1, while the SD of B3 and B4 are taken as 0.05. The probabilistic SBT chart allows for the varying nature of I_c – based classification criteria at different local sites. Extensive random samples of classification boundaries can be generated by repetitively sampling B1 to B5, leading to random samples of SBT chart. Each random sample is a possible state of the uncertain SBT classification chart and will randomly match with one RFS of I_c data cross-section for classification and stratification purposes.

2.3 *Statistical analysis of Monte Carlo simulation*

By pairing 2D I_c RFS with a random sample of SBT chart, each point in that 2D cross-section can be mapped, leading to a 2D SBT cross-section. After repeating the process N_B times with different combination of 2D I_c data RFS and SBT chart random samples, N_B 2D SBT cross-sections are generated. Each SBT cross-sections serves as a possible state of subsurface soil stratigraphy given limited CPT. Statistical analysis is then performed for those N_B SBT cross-sections. The probability of soil at a given point (x_1, x_2) being mapped to a specific SBT, e.g., SBT=t (t=2, 3, $\cdots$, 7), can be calculated as (e.g., Hu and Wang 2020):

$$p\left(\mathrm{SBT}_{x_1,x_2} = t\right) = \frac{N_{x_1,x_2}^t}{N_B} \times 100\% \qquad (6)$$

in which N_{x_1,x_2}^t is the number of SBT values at point (x_1, x_2) that equal to t. Equation 6 quantitatively measures how likely the soil at a point (x_1, x_2) is classified as any one of the six SBT. The SBT with the highest probability is taken as the most likely SBT at the point (x_1, x_2). Similarly, the most likely SBT cross-section is obtained. In addition, the classification uncertainty is quantified by the SD of SBT samples at a given point. The higher the SD, the higher the uncertainty. Similarly, an SD cross-section can be calculated which reflects the pattern of uncertain region in the 2D cross-section. The SD cross-section directly assesses the reliability of soil stratigraphy.

3 ILLUSTRATIVE EXAMPLE

To illustrate the proposed framework, a simulated geological cross-section example is provided in this section. As shown in the Figure 1a, a 2D vertical cross-section is simulated. Four soil types exist in this cross-section, i.e., clay, silt mixtures, sand mixtures and sand, which correspond to SBT values of 3 to 6, respectively. Spatial variability of I_c data in each soil layer is generated using assumed random field model. The random field parameters used (e.g., mean μ_{Ic}, standard deviation σ_{Ic}, correlation lengths along horizontal direction λ_h and vertical direction λ_v) are summarized in Table 3. An exponential correlation structure is adopted in this simulation. The simulated 2D I_c data cross-section is shown by colormap in the Figure 1b. The I_c data cross-section is a 128×256 matrix with resolution of 0.1m for both directions. It is regarded as a geological setting at a specific site. Note that the complete I_c data cross-section is usually not available in engineering practice. This example is just for illustration and validation purposes. Suppose that six (i.e., M=6) CPT soundings are conducted within the cross-section, as denoted by black dash lines (e.g., M1-M6) in Figure 1. I_c data profiles of M1-M6 are shown in Figure 2. These six 1D I_c data

profiles are used as input to interpret the soil stratigraphy under the proposed framework.

After constructing the **Y** matrix in Equation 2 from data profiles of M1-M6, the Bayesian supervised learning is implemented. Then N_B=500 2D RFSs of I_c data are generated from the learning results. Four examples of I_c cross-section are shown by colormap in Figure 3. Each plot in Figure 3 is a possible interpolation of I_c data in this 2D cross-section from six CPT soundings. No parametric correlation structure is needed for the learning process. Next, N_B=500 random SBT classification charts are generated from the probabilistic SBT classification boundary model. Note that a Gaussian random variable ranges from negative infinity to positive infinity. To mitigate the overlapping problem, the Gaussian probability density functions (PDF) for B1-B5 are truncated respectively to a range of mean ± three standard deviation, as summarized in the fourth column of Table 2.

By randomly pairing a RFS of I_c data cross-section with one random sample of SBT chart, a Monte Carlo sample of 2D SBT cross-section is obtained. After repeating this procedure 500 times, N_B=500 SBT cross-sections are obtained. Four examples of SBT cross-sections are shown in Figures 4a-4d. These four 2D SBT cross-sections correspond respectively to the four RFS of 2D I_c data shown in Figure 3 mapped with random sample of SBT charts shown above each subplot of Figure 4. Note that each of these SBT cross-section indicates a possible soil stratigraphy.
Using N_B=500 Monte Carlo samples of 2D SBT cross-section, statistical analysis is performed using Equation 6. The most likely SBT cross-section is shown in the Figure 5a. In the most likely SBT cross-section, four SBT (i.e., SBT3-6) are presented, which is consistent with the underlying true stratigraphy. The original soil zone boundaries are shown by black solid lines for comparison. Note that the most likely SBT cross-section is generally comparable to the underlying true one, although the soil zone boundaries are not perfectly learned due to interpolation uncertainty and model uncertainty in SBT chart. The uncertainties can be evaluated simultaneously through SD of N_B=500 SBT cross-sections, as shown in Figure 5b. It is found that the bright areas with high uncertainty are generally consistent with the underlying true boundaries (i.e., the black solid lines). The results in Figure 5b suggest that the underlying true soil zone boundaries can be approximated based on the SD of N_B SBT cross-sections. The proposed framework performs reasonably well in the interpretation of 2D soil stratigraphy and uncertainty quantification, given only six CPT soundings.

Figure 1. Simulated geological cross-section (a) and I_c data (b) in a 2D cross-section.

Figure 2. I_c profiles of six CPT soundings.

Table 1. I_c – based SBT classification chart (after Robertson 1998).

Range of SBT index I_c	SBT ID	SBT description
I_c <1.31	7	Gravelly sand to dense sand
$1.31 < I_c < 2.05$	6	Sands: clean sand to silty sand
$2.05 < I_c < 2.60$	5	Sand mixtures: silty sand to sandy silt
$2.60 < I_c < 2.95$	4	Silt mixtures: clayey silt to silty clay
$2.95 < I_c < 3.60$	3	Clays: silty clay to clay
I_c >3.60	2	Organic soil: peats

Table 2. Probabilistic model of the I_c – based SBT classification boundaries.

Boundaries	Mean	SD	Range
B1	1.31	0.1	[1.01, 1.61]
B2	2.05	0.1	[1.75, 2.35]
B3	2.6	0.05	[2.45, 2.75]
B4	2.95	0.05	[2.8, 3.1]
B5	3.6	0.1	[3.3, 3.9]

4 EFFECT OF SOUNDING NUMBER

To investigates the effect of CPT soundings number M on the proposed framework, an additional scenario with M=25 CPT soundings is discussed. Those 25 CPT are performed with equal space in the 2D cross-section of illustrative example (i.e., see Figure 1). Following the same procedures as described above, N_B=500 Monte Carlo samples of 2D SBT cross-section are obtained. The most likely SBT cross-section in this scenario is shown in Figure 6a. The approximated soil stratigraphy in this scenario becomes more accurate. The quantified uncertainty also shrinks significantly, as shown in the Figure 6b. Those thin bright area with high uncertainty is in good agreement with boundary locations. The proposed method is data-driven and features fine scale spatial variability to the interpolation result when M increases.

5 CONCLUSIONS

A novel Monte Carlo simulation (MCS) – based framework was proposed in this paper for interpreting soil stratigraphy in a 2D cross-section from

Table 3. Random field parameters for the simulated 2D I_c cross-section.

Layer	μ_{Ic}	σ_{Ic}	λ_h (m)	λ_v (m)
Layer1	3.2	0.1	15	1
Layer2	2.8	0.07	30	2
Layer3	2.3	0.1	20	1.5
Layer4	1.5	0.1	25	1.8

limited cone penetration tests (CPT) with consideration of uncertainty. Complete CPT data cross-section was learned from limited CPT soundings via Bayesian supervised learning. The associated interpolation uncertainty was modelled by non-parametric random field simulation based on the learned results. A probabilistic soil behavior type (SBT) chart was developed for incorporating the model uncertainty in the empirical chart. The interpolation uncertainty of I_c data and model uncertainty in SBT chart were considered simultaneously under MCS. Key equations and detailed implementation procedures were provided. Numerical example was illustrated and showed that the proposed method performed reasonably well. Sensitivity study suggested that the proposed method was data-driven. As the number of CPT soundings increased, the most likely SBT cross-section became accurate and associated interpolation uncertainty reduced significantly.

Estimation of constrained modulus from CPT measurements in case of Holocene sands

Zsombor Illés, István Kádár, Gábor Nagy, András Mahler & László Nagy
Budapest University of Technology and Economics, Budapest, Hungary

ABSTRACT: In case of major projects there are numerous measurements which provide a sufficient set of data to determine characteristic values based on statistical methods. In the current paper Cone Penetration Test (CPT), oedometer and Flat Dilatometer Test (DMT) results are analyzed. Constrained or oedometric modulus is one of the most important deformation parameters, which has a key role in settlement estimation. There are various recommendations to derive E_{oed} from CPT tip resistance values. Three of these recommendations are compared with the results of the oedometer tests and the correlation used in case of DMT measurements.

Keywords: Constrained modulus, CPT, Tip-resistance, DMT, Normally-consolidated layers

1 INTRODUCTION

1.1 *Measurements and methods*

Several Cone Penetration Tests were conducted at a site in South-Central Hungary near the Danube. The probes penetrated until the depth of 20 - 40 meters. Altogether 32 CPTs were analyzed, penetrating at least to the depth of 25 – 26 m, until the bottom of Holocene layers; clay, sand, and gravel. Below that, over-consolidated late Miocene (Pannon) layers were found.

Different methods are evaluated for estimating constrained modulus from cone penetration resistance of the CPT measurements in the article. These three methods are the following: Sanglerat (1972), Lunne and Christoffersen (1983) and Eslaamizaad and Robertson (1996).

Furthermore, laboratory soil identification and oedometric tests were also carried out. In addition, there is a possibility to compare Cone Penetration and Flat Dilatometer Test (DMT) results.

1.2 *Geology and stratigraphy of the site*

The project site is located in South-Central Hungary. It used to be the flood plain of the river Danube until the construction of a dike system. During the previous phases of the industrial compound's construction, the extracted soil was placed on the current site as a backfill. The fill material consists of fine sands, less often silty sands, mostly grey-yellow silty clay and lean clay, and medium sands. The landfill includes construction waste as well. Its thickness varies between 3.5-5.5 m.

Alluvial deposits are generated during periods of high-water level when a predominantly suspended fine matter settles to the surface of the floodplain. It is composed of lean clay mixed with firm-stiff organic matter, and its thickness is approximately 0.7 m.

As described by Kádár and Nagy (2018), below the alluvial deposit, there is eolian sand (transported by wind). The rounded particles are in the size range of silt and fine sands; the layer has a thickness of 5.0 m. It is followed by fluvial sand containing fine, medium, coarse and gravelly sands over a thickness of 5.3 m. It abruptly turns into gravelly sands and gravel; it forms a 10.0 m thick gravel terrace. Both the in-situ measurements, CPT and DMT, and the oedometric compressions, are evaluated up to the base of the gravelly sand layer. In this study, the eolian and fluvial sands are treated as one layer.

2 SOIL CLASSIFICATION AND LABORATORY MEASUREMENTS

2.1 *Evaluation of CPT measurements*

The CPT measurements were conducted according to MSZ EN ISO 22476-1:2013.

The CPT-based soil behavior of the layers; landfill, lean clay, silty sand and gravelly sand are presented in Figure 1. A CPT-based normalized soil behavior chart was suggested by Robertson (1990) and updated by Robertson (2009). The parameters used are summarized in Robertson (2016).

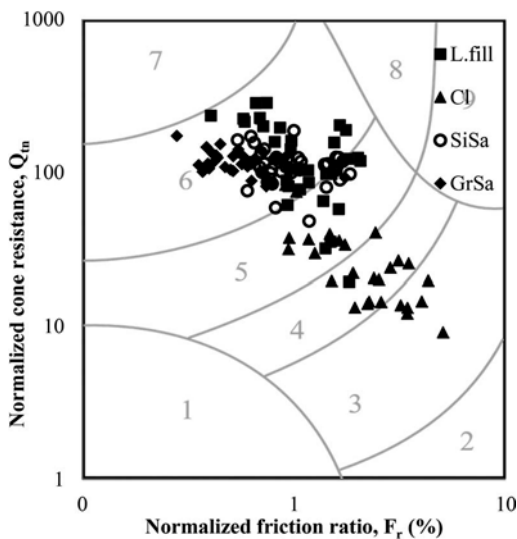
The stratification of the area was defined according to traditional geotechnical soil identifications and CPT measurements. The layers appearing at the CPT logs are presented in Figure 1. One dot is one layer in one CPT. According to normalized cone resistance (Q_{tn}) and normalized friction ratio (F_r), the top layer, landfill, is classified as silty sand and sand. The lean clay is regarded as clay, silty clay and sandy silt. This layer is not present in all the CPTs. The layers of eolian and fluvial sands (Kádár and Nagy, 2018) are classified as silty sand and sand, while the last normally consolidated layer is sand. The four layers are not overconsolidated as they more or less fall in the diagonal of the diagram.


Figure 1. Classification of the layers according to Robertson (2009).

Each layers' parameters obtained by CPT are summarized in Tables 1-4, tip resistance (q_c), skin friction (f_s) and friction ratio (R_f). To each of the three parameters, minimum, maximum, average, standard deviation and coefficient of variation are defined.

Table 1. CPT parameters of the landfill.

Parameter	q_c [MPa]	f_s [MPa]	R_f [%]
No. of samples	33	33	33
Average	10.08	102.30	1.38
Min	2.11	36.58	0.28

Std.	3.47	71.21	0.38
Co.V.	0.20	0.42	0.37

Table 4. CPT parameters of the gravelly sand.

Parameter	q_c [MPa]	f_s [MPa]	R_f [%]
No. of samples	33	33	33
Average	23.64	126.19	0.67
Min	16.76	68.75	0.27
Max	30.86	234.51	2.99
Std.	3.23	34.66	0.49
Co.V.	0.14	0.27	0.73

The landfill and the lean clay CPT parameters have a higher coefficient of variation than the sandy layers.

2.2 *Evaluation of DMT measurements*

On the test site 11 DMT soundings penetrated to different depth. The flat dilatometer was developed in the 1980s by Silvano Marchetti. Shear strength parameters of the soils such as undrained shear strength (c_u). and friction angle (φ). can be derived. One of the most helpful information that DMT measurements can derive is related to the soil layers' stress history. Overconsolidation ratio (OCR), and coefficient of lateral earth pressure (K_0) can be determined in the case of sands, in which sampling would be difficult (Marchetti et al. 2001).

In this paper. constrained modulus is estimated by DMT measurements, which is the key parameter for settlement calculation.

Two corrected readings $(p_0$ and $p_1)$ are obtained by the flat dilatometer, from these, material index (I_D), horizontal stress index (K_D), and dilatometer

modulus (E_D) are calculated. Vertical drained constrained modulus M_{DMT} can be determined according to Eq. (1) (Marchetti, 1980) as:

$$M_{DMT} = E_D \cdot R_M(K_D . I_D) \qquad (1)$$

where R_M is a correction primarily depending on the stress history (K_D).

2.3 Oedometer tests

To test the stress-strain relationship and the consolidation parameters of each layer oedometer tests were carried out according to MSZE CEN ISO/TS 17892-5:2010 standard. Undisturbed samples were tested with 0-100-200-400-600 kPa, it was a usual practice to load, unload and reload the samples; a common load path was 0-2-23-45-100-2-100-200-400 kPa.

A linear assumption was used between each load step according to Eq. (2).

$$E_{oed} = \frac{\Delta\sigma_{ef}}{\Delta\varepsilon} = \frac{\Delta\sigma_{2.ef} - \Delta\sigma_{1.ef}}{\varepsilon_2 - \varepsilon_1} \qquad (2)$$
Figure 2. Different layers oedometric modulus and the depth of the samples.

The results of the oedometric tests and the depth from where the samples were extracted are presented in Figure 2. the modulus is related to the stress state as well as the depth.

In the case of the silty sand layer, the following correlation can be derived between the depth and oedometric modulus:

$$E_{oed} = 3.64 \cdot z - 18.42 \qquad (3)$$

While in case of the gravelly sand layer, a different correlation can be made:

$$E_{oed} = 3.43 \cdot z - 38.14 \qquad (4)$$

The linear correlations (Eq. 2.-3.) describe the connection between depth and oedometric modulus well.

3 METHODS USED TO DERIVE THE CONSTRAINED MODULUS

3.1 Sanglerat method

The Cone Penetration Testing (CPT) sounding was developed in the Netherlands in the 1930s. It was used to investigate the layers' penetration resistance for pile foundation design. A key parameter for settlement calculation is the restrained modulus (M). Buisman (1940) proposed the following correlation between the tip resistance and oedometric modulus in case of cohesionless soils (sands):

$$M = 1.5 \cdot q_c \qquad (5)$$

1.5 multiplier in Eq. (5) was replaced to α_m by Sanglerat (1972):

$$M = \alpha_m \cdot q_c \qquad (6)$$

The values for the coefficient in the case of cohesive soils were also defined and presented by Sanglerat (1972), later synthesized by Kumala Sari et al. (2017). According to Figure 1. the landfill is classified as "silts of low plasticity", although it is very heterogenic, and a high percentage of construction waste can be found in it. According to Figure 1. and laboratory identification tests, the lean clay layer is considered a "clay of low plasticity", while the last two layers of silty sand gravelly sand are regarded as "sands".

3.2 Lunne and Christophersen method

Most correlations between CPT results and the drained constrained modulus (M) refer to the tangent modulus, as found from oedometer tests. The reference value of M is typically based on the effective vertical stress σ'_{v0} (Lunne et al. 1997).

Lunne and Christoffersen (1983) reviewed the available (at that time) calibration chamber test results and made the following recommendations to estimate M in case of normally consolidated uncemented silica sands:

$$M = 4 \cdot q_c \qquad \text{for } q_c < 10 \; MPa \qquad (7)$$

$$M = 2 \cdot q_c + 20 \; (MPa) \; \text{for } 10 < q_c < 50 \; MPa \quad (8)$$

$$M = 120 \; MPa \qquad \text{for } q_c > 50 \; MPa \qquad (9)$$

They also included overconsolidated sands in their studies and made rough estimates for them as well.

3.3 Eslaamizaad and Robertson method

Based on the assessment of extensive calibration tests on quartz sand (Baldi et al. 1986; Fioravante et al. 1991). Eslaamizaad and Robertson (1996) proposed an alternative method to estimate M from CPT data.

The method presents a correlation incorporating normalized cone resistance and normalized vertical effective stress in the form of:

$$M = k_M \cdot p_a \left(\frac{\sigma'_{v0}}{P_a} \right)^n \qquad (10)$$

where:

n: stress exponent equal to 0.200 for normally consolidated sands. and 0.128 for overconsolidated sands.

p_a: atmospheric pressure. in the same units as σ'_{v0}, M and q_c.

k_M: is a dimensionless modulus number which can be determined using Figure 3. based on normalized cone penetration resistance (q_c/P_a) and estimated overconsolidation ratio (OCR).
Figure 3. Consolidation modulus number of sand as a function of cone resistance and OCR (Eslaamizaad and Robertson, 1996).

The k_M functions of different OCRs' are estimated by digitalizing the figure in Lunne et al. (1997). The estimated functions are the following:

$$NC = 61.66 \cdot \left(\frac{q_c}{p_a} \right)^{0.4634} \qquad (11)$$

$$OCR \; 2 = 510.45 + 252.69 \ln \left(\frac{q_c}{p_a} \right) \qquad (12)$$

$$OCR \; 4 = 558.56 + 172.06 \ln \left(\frac{q_c}{p_a} \right) \qquad (13)$$

$$OCR \; 6 = 396.68 + 164.20 \ln \left(\frac{q_c}{p_a} \right) \qquad (14)$$

$$OCR \; 8 = 163.71 + 182.77 \ln \left(\frac{q_c}{p_a} \right) \qquad (15)$$

$$OCR \; 10 = 142.53 + 172.72 \ln \left(\frac{q_c}{p_a} \right) \qquad (16)$$

The method has the advantage that prior knowledge of relative density is not required (Lunne et al. 1997). When Eslaamizaad and Robertson (1996) compared the estimated values against the ones measured in the calibration chamber, they were between 75% and 125%. Later the M values are provided for each layer in Figure 5; the ones estimated according to Eslaamizaad and Robertson (1996) are divided by 1.25.

4 EVALUATION OF THE RESULTS

4.1 Vertical soil profile

The 32 CPTs average. minimum and maximum tip resistance (q_c) are presented in a vertical profile (Figure 4). The average cone resistance (q_c) was used for the calculation of restrained modulus (M) by Sanglerat (1972), Lunne and Christoffersen (1983) and Eslaamizaad and Robertson (1996) methods.

There are lower and upper limits for cohesive soils (landfill and lean clay). The eodometric moduli of each layer measured on undisturbed samples in the laboratory are also shown in Figure 4. Eodometric (E_{oed}) and constrained (M) modulus are the same mechanical parameters. If it was measured in the laboratory, the E_{oed} abbreviation is used, while if it is estimated from field measurements, CPT and DMT, M is allocated.

The layers' thickness in Figure 4. is just the average of the 32 CPTs. It happens that sometimes an oedometric or DMT test falls below or above the assigned stratum.

Figure 4. Soil strata with CPT values, estimated constrained (M), measured oedometric (E_{oed}) moduli.

method (Figure 4. Table 5.). However, the results of the oedometric test vary with depth, Figure 2. Eq. 2-3.

Table 5. Constrained modulus of silty sand and gravelly sand.

| Parameter	Silty sand		Gravelly sand	
	E_{oed}	$M_{Sang.}$	E_{oed}	$M_{Sang.}$
No. of samples	33	102	6	85
Average	15.59	25.56	33.03	33.48
Min	5.30	15.78	26.31	25.99
Max	38.46	33.64	40.63	46.08
Std.	7.44	3.44	6.26	4.71
Co.V.	0.48	0.13	0.19	0.14

In lower two strata the DMT measurements result in a higher constrained modulus (Figure 4.) as the methods proposed by Lunne and Christoffersen (1983) and Eslaamizaad and Robertson (1996).

4.2 Different soil layers

The estimated constrained moduli by different methods for each layer are summarized in Figure 5. From the applied methods Lunne and Christoffersen (1983) and Eslaamizaad and Robertson (1996) were calibrated against tests of silica sand, their capability to estimate soil parameters in cohesive soils is questionable. It is assumed that DMT measurements give a better prediction of constrained modulus as CPT measurements (Marchetti, 2015) for two main reasons: (i) blades cause penetration distortions lower than axy-cylindrical probes, (ii) modulus by a mini load test relates better to a modulus than a penetration resistance.

This is supported by many case studies such as the Sunshine Skyway Bridge in Florida (Schmertmann, 1998), where the constrained modulus from back calculation was closes by the DMT measurements. It is also common to use the DMTs as a calibration for CPT sounding, Jacksonville Power Plant reported by Schmertmann (1998) and a project in Bucharest (Poenaru et al., 2021).

The correlation between CPT and DMT data was analyzed in the top layer of the silty-sand, regarded as eolian sand, Figure 6.

Only 4 DMT and CPT test results for a single sub-layer, 47 measurement pairs are analyzed. The CPT data is averaged to be compared with a DMT measurement. R^2 value greater than 0.7 indicates that the linear correlation describes the investigated parameters with sufficient accuracy. The following equation is on the border of the criteria, where: q_c and the constant is in MPa, so as the obtained M_{DMT} result.

$$M_{DMT} = 5.87 \cdot q_c + 92 \qquad (17)$$

In the upper two strata (landfill and lean clay) the oedometric moduli measured in the laboratory seem to agree with the minimum value estimated by Sanglerat (1972). In the top layer. constrained modulus derived from DMT measurements are way higher. than the results of other methods. The local inhomogeneity is probably also playing a part in the extreme DMT results. The scatter of the measurements is not really concerning as no foundation will be built in landfill. The moduli estimated by DMT measurements in lean clay spread between the other methods based on CPT. In the lower two strata of silty sand and gravelly sand, the results of oedometer tests distribute around the values estimated by the Sanglerat (1972)

Figure 5. Constrained modulus of the layers (landfill. lean clay. silty sand and gravelly sand).
Figure 6. Correlation between q_c and M_{DMT} for Eolian sand layer.

5 CONCLUSIONS

According to Table 5. the constrained moduli estimated by the Sanglerat (1972) method correlates well with the measured ones in the laboratory by oedometer.

The calculated oedometric modulus values have a linear correlation with depth (Figure 2. and Eq. 3–4.).

The dilatometer disturbs the soil less than the CPT, so more realistic constrained modulus can be estimated, which is way higher than the results of investigated correlations (Eslaamizaad and Robertson, 1996; Lunne and Christoffersen, 1983) Figure 4-5.

A simple linear connection (Eq. 17) is derived between the cone resistance of CPT and the constrained modulus estimated by DMT in case of the upper eolian layer of silty sand (Figure 6). It corresponds to the mean value, in case of design the characteristic value must be used.

ABSTRACT: The u_2 complex pore water pressure dissipation tests made in NC-LOC sandy soils at the Bolivian test site were evaluated with the variants of a mathematically precise, automatic method in the function of the testing time. The identified c became near constant and its error became small after a so called minimum testing time $t_{min} < t_{50}$ depending on the variant. The traditional t_{50} method failed in some cases since the tests were with types I, II, III, V and t_{50} varied from 4s to a value being larger than 15 min (not measured).

1 INTRODUCTION

The pore water pressure dissipation tests of B.E.S.T were started to be evaluated by using the well-known t_{50} method and some suggested methods.

The complex dissipation tests were made in NC-LOC sandy soils, the t_{50} varied from 4s to an unknown value being longer that 15 min (in tests with $t_{max} < t_{50}$), therefore, the t_{50} method failed in some cases.

By using the suggested methods, the evaluation was made in the function of the testing time for all tests. The c identified from truncated tests became near constant with t after a minimum testing time $t_{min < t_{50}}$.

2 MATERIALS AND METHODS

2.1 The tests

The B.E.S.T. site is about 40 m wide and 100 m long. The geotechnical conditions of the site have been investigated using conventional in-situ and laboratory methods at each single pile location (Figure 1). The following in-situ tests have been performed: SPT, SCPTU (with dissipation tests), SDMT, PMT, SASW and REMI geophysical tests. Each borehole and field test is identified with the letter of its designated test pile.
Figure 1. Dissipation test locations.

2.2 Geology and soil profile

he city of Santa Cruz de la Sierra lies in the southern part of the Amazonas. The geology of the area is characterized by a Paleozoic (250 million years old) sedimentary basin.

The soils of interest are quaternary. The main agent is the Piray River and its tributaries, which past meandering over the area has resulted in a sedimentation-erosion-sedimentation process and a geological profile dominated by fine to medium sands with intermittent layers of clay or clayey sand. Due to the compressible soils, even light buildings need to be supported on piles.

The groundwater table at the site is situated seasonally between the ground surface and about 0.5 m depth.

Sandy/plastic soils had negative/positive excess pore water pressure during penetration and dissipation, which indicates the soil types. The upper about 10 to 20 m part of the profile consists of LOC clays, silts, sands, in various combination and thickness.

In the pore water pressure profile (Figure 2) four plastic layers 1 to 4 with positive excess pore water pressure were isolated between the following depths: 2.5 to 5.0 m; 11 to 15 m; 15 to 17 m; below 22 m, resp. Sand-silt is found among the plastic layers.

The measured u_2 dissipation curves (Figures 2 to 3) were with types I, II, III, V, (Sully et al, 1999). The t_{50} varied between 4 s and $t_{50} > 15$ min. A crust was likely found in layer 1, indicated by the larger t_{50} values (Figure 2.).
Figure 2. Dissipation tests in plastic soil layers 1 to 4.

2.3 The evaluation methods

The one-point model fitting (Teh-Houlsby, 1988; Lunne at al. 1992) requires time of t_{50} and I_r which is difficult to assess (Mayne, 2007).

The one-point model fitting (at t_{50} cannot handle more than one initial condition (if $t_{50} < 50$ s, and if the dissipation is starting from less than u_0 values). The reliability of the identified c is not tested.

The suggested evaluation methods imply (i) an automatic and mathematically precise non-linear inverse problem solution, (ii) some initial condition identification methods which can be used in partly drained penetration, (iii) some reliability testing.

The methods are depending on r_1 but its value can be taken into account using a model law, resulted from the derived time factor T (see App,).

The newer methods ("fast" and "slow") are based on the mathematically precise Least Squares fitting of a new consolidation model, with different initial condition identification.

In the "slow" method, the first 1..200 terms of the analytical solution (large numerical work) are used, with some pre-elaborated, parametric shape functions. In the "fast" method, the first few (1..k) terms are used (small numerical work) for both the monotonic ($k = 1$) and the non-monotonic (1..k >1) time variation of the pore water pressure.

The c values were identified at testing times t = 0,3 min; t = 0,5 min; t = 5 min besides at t = t_{max}. Since only one case (test 24) was a "real time" evaluation in the sense, that the evaluation was made after each measured data sampled generally in every second, the results of this work are approximate. It can also be noted that the LS merit function related to the slow method has several minima, the fast method has a unique distinct minimum for $k = 1$, can be quasi-degenerated, with large error for $k = 3$ (see Figure 4).

3 RESULTS

3.1 *Evaluation using maximum testing time*

According to the results (Table 3), the c values identified with the various methods as earlier (Imre et al, 2018). The fast methods gave larger c by about a factor of 1.5 than the slow methods. The one-point $t50$ method gave smaller c by generally about factor of 10 to 30 depending on Ir. The fast $k = 1$ method usually gave distinct solution, a worse fit, a faster decay, and thus a higher c value than the slow method.

3.2 *Evaluation of truncated tests, monotonic data*

According to the results (see Figures 5 to 7, Tables 4 to 6), the c - t functions generally decreased for the fast method, and was generally constant for the slow method. The identified c became generally about constant at a minimum testing time t_{min} except in one case (test 21). The $t_{min} < t_{50}$ was met for the slow method in every case, the t_{min} was shorter or longer than the t_{50} time for the fast methods. The fast $k = 3$ method gave better fit but too large parameter error.

3.3 *Evaluation of truncated tests with complex data*

According to the results shown in Figures 8 to 10, Tables 7 - 8, at the initial – non– monotonic – part of the tests, the parameter error was high and c changed. The identified c became about constant and the error dropped at a minimum testing time t_{min}.

Figure 8. Complex dissipation curves, measured and fitted data. (a) Test 23, layer 2 at A3. (b) Test 9, layer 4 at B2.
Figure 9. Complex dissipation tests. Test 34, layer 1, D2, t_{50} = 500 [s]. (a) Function c-t. (b) Coefficient of variation $C_v(c)$-t.

The $t_{min} < t_{50}$ was met for the slow method and the fast $k = 1$ method in general.

The tests 9 and 10 – made on a more plastic soil layer, being shorter than t_{50} –, and test 36 – made in sand with fully negative excess pore water pressure – were successfully evaluated with similar results.

4 DISCUSSION

4.1 *The effect of filter position*

The c - t function was determined for the monotonic dissipation tests of the Bothkennar soft clay measured after undrained penetration, in filter positions E to A with the fast $k = 1$ method (Imre et al, 2010). The c - t function was about constant in fps E, in filter position D it became about constant at a minimum testing time t_{min} ~30 min which was less than t_{50} ~90 min (Figure 11, Table A-1).

In the present study, after partly drained penetration, in fps u_2 (~fps D and C), the t_{min} was the smallest and less than t_{50} in every case for the slow method only. For the fast methods, t_{min} was less than t_{50} in about half of the cases. The minimum testing time t_{min} can be assessed precisely from real-time evaluation. Further research is suggested on this.

4.2 *Complex dissipation of LOC soils*

According to Figure 3, in the same layers both monotonic, non-monotonic curves occurred. Type I and II curves are commonly understood results from normally consolidated (NC) and lightly over-consolidated (LOC) clays, type III to V are attributed to heavily over-consolidated (HOC) soils.

Some recent studies (Lim, 2019, Figure 11) revealed that „Extremely fine mesh around the cone penetrometer made possible to study dissipation curves from very closely spaced stress points. It is found that type I, II and III curves are all possible outcomes from NC and LOC soils."

4.3 *Initial condition and space domain*

The suggested methods are based on r_1, valid after undrained penetration. The one-point t_{50} method gave smaller c by about factor of 10 to 30 than the suggested methods. The difference can probably be attributed to the due to undrained value $r_1 = 37 r_0$.

The c identified can be modified for other r_1 using the model law (see the App.) but no values are available to r_1 valid in (partly) drained penetration. Further research on is needed (Osman, 2021).

5 SUMMARY, CONCLUSION

5.1 *The evaluation results*

In the present study, the complex dissipation curves of B.E.S.T. test site, measured in filter position u_2, were evaluated in the function of the testing time t.

(1) The c identified with the various methods (t_{50} and the newer) using the long test data ($t = t_{max}$) showed similar pattern as in previous research. Some complex or short tests were impossible to be evaluated with the t_{50} method.

(2) Truncated tests ($t < t_{max}$), were evaluated with the newer methods with various elapsed time values. Generally (with one exception), at a minimum testing time t_{min}, the identified c became about constant, the error of c became as small as in the long tests. The t_{min} was always smaller than t_{50} for the slow method, and sometimes for the fast methods even in the case of the complex shaped, short tests.

5.2 *Summary, conclusions*

The c was identified with various methods only in a few elapsed times. It became generally constant after a minimum testing time t_{min}, which was always smaller than t_{50} for the slow method but only in half of the cases for the fast methods with various k.

It follows that - by evaluating in real time with the fast methods -, the c can be determined theoretically earlier than $t_{50.}$ More than one method is suggested to be used for the evaluation since the solution of the fast $.k$=1 method is unique only. The slow method is suggested to be applied for the evaluation only in a few elapsed times, due to the large numerical work.

Previous research indicates that t_{min} can be the shortest in filter position u_3 (Imre et al 2010) due to the one-dimensional state. Further research is suggested on the real time evaluation, on the t_{min} in various filter positions and on partly drained penetration (to assess initial and boundary condition).

APPENDIX - SUGGESTED MODEL/MODEL LAW

Consolidation model

The system of differential equations, new boundary conditions, for pore water pressure u for displacement v and the suggested time factor T (Imre et al 2010):

$$E_{oed} \frac{\partial}{\partial r} \frac{1}{r} \frac{\partial}{\partial r}(r\,v) - \frac{\partial u}{\partial r} = 0 \qquad (1)$$

$$-\frac{k}{\gamma_v} \frac{1}{r} \frac{\partial}{\partial r}\left(r\frac{\partial u}{\partial r}\right) + \frac{\partial}{\partial t} \frac{1}{r} \frac{\partial}{\partial r}(r\,v) = 0 \qquad (2)$$

$$u(t,r)|_{r=r_1} = 0,\; \frac{\partial u(t,r)}{\partial r}\Big|_{r=r_1} = 0 \qquad (3)$$

$$v(t,r)\,|_{r=r_1} \equiv v\,0, >\, 0, v(t,r)\,|_{r=r_1} \equiv 0 \qquad (4)$$

$$T = \frac{ct}{(r_1 - r_0)^2} \qquad (5)$$

where v is displacement, r is space coordinate, t is time. k is permeability, γv is unit weight of water, E_{oed} is oedometric modulus, J_n and Y_n are Bessel functions, c is coefficient of consolidation, the λ_i, μ_i and C_i ($i=1..k$) depend on the space domain (r_0 and r_1) and the initial condition, T time factor.

The value of r_1 and initial condition can be determined by the strain path theory using the rigidity index I_r, the OCR, friction angle and rate of penetration (Figure A-1, Baligh 1986).

Model law

In this section the use of the model law is presented on some examples, regarding the evaluation of the monotonic data of Bothkennar clay (fast model, first term solution, $k=1$).

If the evaluation is made assuming $r_1 = 37r_0$ – valid in filter position E but using data of various filter positions, – then from the identified c, the "correct" value of r_1 can be back-calculated with the "c formula":

$$r_{1,2} = \sqrt{\frac{c_2}{c_1}}(r_{1,1} - r_0) + r_0 \qquad (6)$$

According to the results (Table A-1), the back-computed r_1 values varies from $37r_0$ to 17 r_0 as the sensor positions changes from E to A. As a comparison, the value of r_1 with the strain path prediction of Baligh 1986 varies from 22-$23r_0$ to $37r_0$.

The r_1 can be computed on the basis of the measured dissipation times with the "t formula":

$$r_{1,2} = \sqrt{\frac{t_2}{t_1}}(r_{1,1} - r_0) + r_0. \qquad (7)$$

using the r_1 value valid for filter position E. According to the results (Table A-1), the back-computed r_1 values vary from $37r_0$ to $18r_0$ as the sensor positions changes from E to A.

Table A-1. The r_1 from identified c and measured t_{50} values.

M. Karlsson & J. Dijkstra
Department of Architecture and Civil Engineering, Chalmers University of Technology, Sweden

ABSTRACT: This paper presents the results from numerical simulations of CPTu penetration in a natural clay combining the SCLAY1S constitutive model with a large deformation Finite Element framework including a coupled deformation and porewater pressure formulation. The hierarchical model formulation of SCLAY1S captures many features of a natural sensitive clay, such as the evolving anisotropic strength-stiffness response, as well as the degradation of the initial bonding. A sensitivity analysis is performed varying the overconsolidation ratio (QCR), bonding and anisotropy, also the hydraulic conductivity (hence, c_v) of the clay. The findings indicate that some soil properties (the c_v and OCR) impact both the normalised cone resistance Q_t and the generation of excess porewater pressures. In contrast the sensitivity S_t of soft soils primarily affects Q_t. In the current work it seems that the effects of the inherent and stress induced (from CPT penetration) anisotropy is not detected using these normalised plots.

1   INTRODUCTION

The cone penetration test is a widely used method to perform geotechnical site investigation, by continuous measuring of the cone resistance, the sleeve friction, and in case of the piezocone (CPTu) the generated excess porewater pressures, during the penetration into a soil. This allows the mapping of a deposit to be performed in a time-effective manner with a high resolution (Lunne et al. 1997). Further soil characterisation can be performed using classification systems based on statistical correlations of normalised CPTu results against borehole data, see e.g. Robertson (2016) and Schneider et al. (2008). Due to the continuous measurement of the soil response, the CPTu is a great tool to detect differences in the response between and within soil layers by relying on a contrast in hydro-mechanical properties, e.g a change in hydraulic conductivity, overconsolidation ratio or sensitivity (brittleness).

Another approach to establish the relation between soil properties and CPTu response is to use numerical modelling where a prescribed change of a model parameter of a given constitutive model leads to a change in CPTu response. This approach is becoming increasingly more attainable with the ongoing developments for numerical analyses. Three modelling aspects that are necessary for accurate simulation of CPTu penetration are (i) the capability of the Finite Element (FE) code to deal with large deformations (ii) the adequate coupling of deformations and the generation/dissipation of excess porewater pressures (iii) a constitutive model that incorporates the complex features of natural soils.

A number of numerical methods able to simulate the kinematics of CPTu penetration in FE have been reported, among others the Arbitrary Lagrangian Eulerian method (Berg et al. 1996, Walker & Yu 2006), Material Point Method (Ceccato et al. 2016), Geotechnical Particle Finite Element Method (Hauser & Schweiger 2021, Monforte et al. 2021), and remeshing procedures (Hu & Randolph 1998, Orazalin & Whittle 2018, Mahmoodzadeh et al. 2014). In some cases the effects of CPT penetration are captured in an Updated Lagrangian framework (Yi et al. 2012, Konkol & Bałachowski 2018, Mahmoodzadeh et al. 2014).

Some of the studies (Ceccato et al. 2016, Monforte et al. 2021, Yi et al. 2012, Konkol & Bałachowski 2018, Mahmoodzadeh et al. 2014, Orazalin & Whittle 2018) also incorporates a coupled stress formulation enabling the study of partial drainage during penetration. Constitutive models able to describe advanced soil features such as brittleness (Monforte et al. 2021) and anisotropy (Hauser & Schweiger 2021, Orazalin & Whittle 2018) has also been incorporated to simulate CPTu penetration.

This paper builds upon those previous studies by implementing SCLAY1S in a fully coupled Eulerian Finite Element (FE) framework. Subsequently, the relation between the CPTu response and different soil properties is investigated. The model parameters varied, include the hydraulic conductivity (k), the sensitivity of the soil (S_t), the fabric anisotropy and the overconsolidation ratio (OCR).

2 NUMERICAL MODEL

Natural features of soft clay, such as breakage of initial bonding and fabric anisotropy, are captured by the SCLAY1S constitutive model (Koskinen et al. 2002) and (Karstunen et al. 2005). The elasto-plastic model originates from the Modified Cam Clay (MCC) constitutive model (Roscoe & Burland 1968), in addition to the volumetric hardening of MCC, SCLAY1S also incorporates rotational hardening and gradual degradation of bonding due to plastic strains in the soil. In short, the evolution of the initial anisotropy and degradation of strength is controlled by volumetric plastic strains and deviatoric plastic strains in the hardening law. The model is hiearchical, i.e. an appropriate choice of model parameters leads to the (de-) activation of the model features that capture (evolution of) anisotropy and destructuration. Hence, in its simplest form the model formulation becomes identical to MCC.

For the current work, the SCLAY1S model was implemented in the Tochnog Professional (Roddeman 2021) finite element framework that is able to handle large deformations by using an Eulerian description with a fixed mesh, where the solution fields for the stress, material velocity and other state variables of the calculation are advected through the domain. Penetration of the CPTu into the soil is performed with the moving boundary method proposed by Dijkstra et al. (2011). Initially, the cone is considered to be outside of the calculation domain, i.e. above the soil surface, and the desired stress state and other state variables required for the model are prescribed to establish the initial state in the model. The numerical penetration is then performed by defining a geometric entity representing the CPTu and prescribing the penetration velocity v to all nodes in this geometry while simultaneously expanding the geometry downwards with the same penetration velocity.

The axisymmetric nature of the problem is exploited using a 2D simplification where the horizontal soil movement and groundwater flow is prevented perpendicular to the axis of symmetry. The geometry and boundary conditions of the numerical model are presented in Figure 1. The initial stress state is prescribed by the vertical effective stress (σ_v'), initial porewater pressure (u_0) and the initial earth pressure coefficient (K_0). Horizontal movement is prevented at the far right boundary while keeping the porewater pressure constant to u_0, hence

allowing for groundwater flow across the boundary. At the bottom boundary, vertical groundwater flow and soil movement is prevented. The top boundary of the domain is modelled with a prescribed vertical load that is in equilibrium with the total vertical stress (σ_v) and is equal to the sum of σ_v' and the initial porewater pressure u_0. The increase in stress due to the weight of the soil in the domain is set to be zero to create a uniform soil domain.
Figure 1. Boundary conditions and mesh in the region close to the penetrating CPTu.

All simulations presented in the study were performed using a 60 cone with a diameter (d) of 0.036 m corresponding to a radius (r) of 0.018 m. The height of the domain h was set to two times the penetration depth and the width w was set to $40r$, to prevent numerical disturbance related to boundary effects. A structured quadrilateral mesh (see Figure 1) was required in the location of the penetrating cone to ensure geometrical compatibility between the mesh and the penetrating cone that is prescribed with a geometry entity. Quadrilateral elements were used in a region extending 5 cone radii (r) from the axis of symmetry. The rest of the domain is filled with unstructured triangular elements. In total, the model contains 1789 quadrilateral elements and 3579 triangular, both with first order shape functions. All simulations in this paper were performed with a penetration rate v of 0.02 m/s down to a final penetration depth of $20d$. The porewater pressure presented in this study was extracted from a position right above the cone shoulder corresponding to the u_2 position. The cone resistance q_c was calculated from the total force needed to push the inclined cone tip downwards divided by the area of the cone. The net

cone resistance q_{net} was calculated by subtracting the initial vertical stress σ_{v0} from the cone resistance q_c.

Table 1. Model parameters used to investigate the effect of drainage conditions on the CPTu response.

Symbol	Parameter	Value
$\sigma_v{}'$	Vertical effective stress [kPa]	109
u_0	Initial porewater pressure [kPa]	70
$K0$	Initial earth pressure coefficient [-]	0.61
OCR	Overconsolidation ratio [-]	1.02

ω	Rate of rotation [-]	0
ω_d	Rate of rotation due to deviator strain [-]	0

3 VARIATION OF HYDRAULIC CONDUCTIVITY

Initially, the effect of the drainage conditions on the CPTu response was studied using a MCC model formulation, by varying the hydraulic conductivity k in the range $5.5 \cdot 10^{-3}$ m/s and $1.1 \cdot 10^{-8}$ m/s. An isotropic hydraulic conductivity was used in all performed simulations. All the model parameters used in the numerical study are presented in Table 1 and are based on those derived for kaolin clay, as used for the numerical studies of the CPTu in Mahmoodzadeh et al. (2014). The normalised penetration velocity V is used to define the current drainage conditions for quasi-static penetration problems, as it enables the comparison between various test conditions. V is defined as:

$$V = \frac{vd}{c_v} \tag{1}$$

where v is the penetration rate, d is the diameter of the CPT cone and c_v is the vertical consolidation coefficient of the soil.

$$c_v = \frac{k_v(1 + e_0)\sigma'_{v0}}{\lambda \gamma_w} \tag{2}$$

The normalised penetration velocity helps to correct for experimental scaling conditions by linking the penetration velocity and size of the object and soil

volume (drainage lengths) to the properties of the soil such as the vertical effective stress σ'_{v0}, initial void ratio e_0, stiffness λ and the hydraulic conductivity (via the vertical consolidation coefficient c_v).

DeJong & Randolph (2012) proposed a backbone curve of both the net cone resistance and excess porewater pressure normalised with the corresponding undrained value based on the result from seven different studies investigating the change in response for the CPTu under different drainage conditions and confining stress p. Mahmoodzadeh & Randolph (2014) also proposed a backbone curve based on a series of centrifuge test of CPTu penetration in kaolin clay. The net cone resistances are normalised with the results from the undrained penetration simulation and are presented in Figure 2. Whereas, the results for the normalised excess porewater pressure are presented in Figure 3. Both figures also show the two proposed backbone curves.

The transition of the simulated net cone resistance from the undrained to the intermediate and drained state are in good agreement with both backbone curves. The relative magnitude of the net cone resistance in the drained state, however, is considerably larger when compared to the proposed backbone curves. As this study is with equal strength in the soil as in the element near the interface, the contact between the CPTu and the soil can be considered rough. Monforte et al. (2021) performed an additional sensitivity study on the impact of the interface roughness on the CPTu simulations. The normalised net cone resistance for the rough interface ($\phi = 19$) increased with about 40 % from the smooth interface (included in Figure 2). In contrast, the normalised excess porewater pressure response is not greatly affected by the interface formulation. Looking at Figure 2 the results from this study fit in between the smooth and the rough interface response reported by Monforte et al. (2021).

The normalised excess porewater pressure from this study is slightly shifted compared to the other studies (Figure 3). This is due to the presence of some numerically locked-in porewater pressures in a single element near the cone shoulder, i.e. at the u_2 position and is most prominent for very low hydraulic conductivities corresponding to a practically undrained state with normalised penetration velocities above 50. The porewater pressure presented herein, are unsmoothed and taken from the u_2 position and is considered to be accurate when looking at the relative change in response between the analyses in the sensitivity study.

4 CPTU IN SOFT CLAYS

The numerical investigation into the impact of soil properties on the CPTu penetration in soft (sensitive) clays was performed starting from a normally consolidated and isotropic reference state without
Figure 2. Normalised cone resistance over normalised penetration rate. Comparison between results from this study and Mahmoodzadeh & Randolph (2014) and DeJong & Randolph (2012). Results from Monforte et al. (2021) is included to indicate the effect of interface properties on the CPTu response.

Figure 3. Normalised excess porewater pressure over normalised penetration rate. Comparison between results from this study and Mahmoodzadeh & Randolph (2014) and DeJong & Randolph (2012). Results from Monforte et al. (2021) is included to indicate the effect of interface properties on the CPTu response.

Table 2. Parameters used for investigation of the CPTu response in soft clays.

Symbol	Parameter	Value
OCR	Overconsolidation ratio [-]	1.2, 1,5, 1,8
χ_0	Initial amount of bonding [-]	2, 5, 10, 20, 50
a	Rate of destructuration [-]	6

α_0	Initial anisotropy [-]	0.352
ω	Rate of rotation [-]	10
ω_d	Rate of rotation due to deviator strain [-]	0.374

initial bonding, using a normalised penetration velocity of $V = 200$ for the CPTu. First, the impact of OCR on the soil response was investigated by increasing the OCR in three increments from 1.02 to 1.8. The brittleness of the soil was also investigated by varying the SCLAY1S state parameter for destructuration χ_0 between 0 (no initial structure) and 50 (clay with a high sensitivity). Although this parameter is closely related to the sensitivity of the soil it should not be considered to be similar. Finally, the impact of fabric anisotropy on the

CPTu response was studied by introducing an initially inclined yield surface, that evolves with deviatoric and volumetric strains, in the model formulation. Table 2 presents the range of the SCLAY1S parameters used. The rate parameters and anisotropy α_0 are assumed based on Gras et al. (2017) for natural clays, whilst keeping the original parameters from the kaolin clay. This ensures consistency of model parameters between simulations. Although this approach captures the soft soil features found in natural clays, the dataset does not represent a natural clay deposit.

Robertson (1990) proposed a classification system based on the normalised cone resistance Q_t and pore pressure ratio B_q, where

$$Q_t = \frac{q_{net}}{\sigma'_{v0}} \tag{3}$$

$$B_q = \frac{\Delta u}{q_{net}} \tag{4}$$

The Q_t is the relation between the net cone resistance from the CPTu measurements and the initial effective vertical stress. B_q is the excess porewater

pressure divided by the net cone resistance. This classification system is shown in Figure 4 with the results from the present numerical study. The arrows that annotate the data points correspond to each model parameter and are showing the direction of the normalised CPT response when the parameter is increased in the numerical analysis. Distinct trends for each parameter are clearly identified and are in good agreement with trends proposed by Robertson (1990), for both S_t and OCR.

The numerical results are also presented in the classification chart (Figure 5) originally proposed by Schneider et al. (2008), which is based on Q_t and the excess porewater pressure (Δu) normalised with the initial vertical effective stress (σ'_{v0}). The impact of changing S_t, OCR and c_v indicates clear trends that are in good agreement with the response suggested by Schneider et al. (2008). The effect of fabric anisotropy α only shows limited impact on the results. The results only slightly changed, due to the lower Q_t and excess porewater pressures when compared to the isotropic model results.

Figure 5. The effect on CPTu response from changing consolidation coefficient c_v; overconsolidation ratio OCR; sensitivity S_t and considering fabric anisotropy α in the charaterisation chart for CPTu proposed by Schneider et al. (2008).

5 CONCLUSIONS

This paper presents the results from a series of CPTu simulations using a large deformation Finite Element framework in which partial consolidation during penetration is considered by linking the material deformations to the coupled response of porewater flow. An Eulerian framework, in which the mesh is fixed and the soil is able to move independently of the mesh, has been used, to avoid mesh distortions from large deformations associated with the CPTu penetration. The SCLAY1S model is implemented for these analyses, as it captures the evolving anisotropic strength-stiffness response, as well as the degradation of the initial bonding present in natural sensitive clays.

In the first part of the paper the effect of different drainage conditions is quantified and the overall trend compares well with prior work. Further studies need, however, to be conducted to improve the accuracy of the calculated porewater pressures at the shoulder of the CPTu. Extending the study to also include the response on the friction sleeve of the CPTu could further expand the conclusions of this study.

The impact of features that are fundamental to soft soils, i.e. hydraulic conductivity, OCR, sensitiv-

Figure 4. The effect on CPTu response from changing the consolidation coefficient c_v; overconsolidation ratio OCR; sensitivity S_t and considering fabric anisotropy α in the characterisation chart for CPTu proposed by Robertson (1990).

ity and anisotropy, on the CPTu response have been investigated in a hierarchical manner. The following can be concluded after integrating the results in the CPTu classification charts:

- Increasing the hydraulic conductivity leads to an increase in normalised penetration resistance while the normalised excess porewater pressure is decreasing.
- Increasing the OCR is associated with an increase in both the normalised cone resistance and the normalised excess porewater pressure.
- Increasing S_t leads to a considerable decrease in the normalised cone resistance while leaving the normalised excess porewater pressure nearly unaffected
- The simulated CPTu response is practically unaffected by soil anisotropy.

The conclusions of this study are in good agreement with suggestions from Robertson (1990) and Schneider et al. (2008) for the anticipated response from a change in c_v, OCR and S_t. Hence, the results of this study contribute to the interpretation of the widely used classification charts, by linking it to the fundamental features of natural soils.

The extensive empirical evidence used to establish the relation between CPT and soil characteristics is in good agreement with the numerical results, increasing the confidence in the ability to accurately simulate penetration into soft soils with the proposed numerical method. Finally, the numerical simulations should be validated further against in-situ CPTu data.

ABSTRACT: This paper presents a practical approach for developing a site-specific CPT-based method for monotonic undrained shear strength (s_u) in sands and transitional soils, using results of laboratory undrained tri-axial compression (CU) tests on reconstituted and undisturbed specimens as reference. The methodology includes use of net cone resistance values normalised to vertical effective stress, a procedure for pairing of CPT data with CU test results, and definition of a practical failure criterion for deriving s_u from CU test data. The presented approach is particularly useful for application in offshore wind, where the economics of wind farm development favour performing only a single cone penetration test (CPT) per wind turbine location. This setting drives development of CPT-based methods for key geotechnical parameters for foundation design.

1 INTRODUCTION

The characterisation of undrained behaviour of sands and transitional soils (e.g. silty sands, low plasticity silts) is important for large foundations subject to significant short-duration loading and cyclic loading. Therefore, undrained shear strength (s_u) of sands and transitional soils is an important geotechnical parameter that can be used (i) as direct input in calculation models for fully undrained modelling, and (ii) for defining a reference for normalisation of cyclic soil parameter values.

This study presents a practical framework for developing a site-specific CPT-based method for s_u in sands and transitional soils, using results of laboratory undrained triaxial compression (CU) tests on reconstituted and undisturbed specimens as reference. The methodology includes use of (1) net cone resistance values (q_n, defined as $q_n = q_c + (1-a)u_2 - \sigma_v$, where q_c is cone resistance, α is net area ratio, u_2 is pore pressure at the cylindrical extension above the base of the cone and σ_v is vertical total stress) normalised to vertical effective stress (σ'_v), (2) a procedure for pairing of CPT data with CU test results, and (3) definition of a practical failure criterion for deriving s_u from CU test data.

The approach outlined in this paper is particularly useful for application in offshore wind, where the economics of wind farm development can dictate performing only a single cone penetration test (CPT) per wind turbine location. This setting drives development of CPT-based methods for key geotechnical parameters for foundation design.

This paper includes an example of the site-specific approach, using input data taken from two wind farm sites offshore Netherlands, namely the Hollandse Kust (west) site and the Hollandse Kust (noord) site (Figure 1, HKW and HKN respectively). The input data are in the public domain, as per the European INSPIRE (2018) directive for spatial information.

2 DATABASE

2.1 Geological setting

The HKW site and the HKN site are located in the southern North Sea. Water depths are typically between 15 m and 34 m relative to LAT.

The sites comprise Quaternary deposits with a predominantly sandy sedimentary profile with occasional clay layers associated with internal channelling (RVO, 2019; RVO, 2020). Sands are mainly fine and medium with occasional coarse size in some of the soil units. The sites have been subject to evolution throughout the Pleistocene and the Holocene. Sediments and processes from these time periods dominate the geological framework. Geological formations present at the two sites within the top 50 m below seafloor include (from older to younger) Yarmouth Roads, Eem, Naaldwijk and Southern Bight. These geological formations show no evidence of cementation. Figure 2 illustrates a microscopic photograph of a typical sand sample from the HKW site.

Figure 1. Locations of HKW and HKN sites.

Figure 2. Microscopic photograph of a typical unwashed sand sample from the HKW site.

2.2 CPT data

The available CPT data were acquired according to ISO (2014). The data are available in digital tabular format and include piezocone CPTs and seismic piezocone CPTs performed in both non-drilling mode (direct push from seafloor) and drilling mode (vessel drilling, downhole push) deployment.

2.3 CU data

The database includes results of CU tests performed according to ISO 17892-9:2018, using reconstituted specimens, prepared by moist reconstitution, and undisturbed specimens. Reconstituted specimens were prepared based on estimated in situ density. Other specimen density considerations are described below (section titled 'data pairing'). It is generally

recognised that reconstituted specimens may give lower shear strength than undisturbed specimens (Hoeg et al., 2000).

The specimens were recompressed to the estimated in situ stress conditions, using conventional back pressures for specimen saturation. No pre-cycling was applied. Recompression conditions were either isotropic or anisotropic, depending on the estimated in situ stress state ($K_0 = 1$ for isotropic stress state and $K_0 \neq 1$ for anisotropic stress state, where K_0 is coefficient of earth pressure at rest).

Database screening was applied, considering soil type and laboratory specimen homogeneity. Soil type was assessed based on sample description, review of particle size distribution and Atterberg limits. Particularly for undisturbed test specimens of transitional soil, specimens containing interbedded or non-uniform material, distinct strata/layer changes or gravel were excluded from further analysis because they can adversely affect undisturbed sample quality and test processing results for a premise of a homogeneous laboratory test specimen.

The screened database includes laboratory results from 33 CU tests on reconstituted soil specimens (26 in sand and 7 in transitional soil) and 5 CU tests on undisturbed soil specimens in transitional soil. The specimen test depths ranged from 2 m to 38 m below seafloor. Table 1 presents classification parameters for the database used. Figure 3 presents results of two typical triaxial tests from the database, one in sand and one in transitional soil.

Table 1. Classification parameters.

Parameter	Sand	Transitional soil
D_r (%)	55-110	35-85
FC (%)	1-8	20-80
CC (%)	-	3-24
C_u (-)	1.5-3.8	5.3-80
D_{50} (mm)	0.17-0.35	0.02-0.15
quartz content (%)	85-100	84-95
particle shape	subangular to well rounded	subangular to rounded

Notes: Transitional soil = (very) silty sand, clayey sand, low plasticity (clayey, sandy) silt; D_r = relative density; FC = fines content; CC = clay content; C_u = coefficient of uniformity; D_{50} = particle diameter where 50 % of the dry mass of soil has a smaller particle diameter

It is generally inconsistent and impractical to use peak deviator stress as a criterion for deriving s_u for dense dilative soils such as many of the ones in the database used for this study. In dilative specimens, large negative pore pressures develop until the end of the test (to about 20 % axial strain; see blue line in bottom plot of Figure 3) or until cavitation occurs.
Figure 3. Example of typical triaxial test results from the database (applied back pressures: CIUcBE11 – Sand: 1291 kPa; CAUcBE09 – Transitional soil: 687 kPa).

Cavitation depends on the back pressure applied to the triaxial test specimen. Sufficiently high back pressure should be applied to test specimens that are expected to exhibit dilative behaviour while shearing. It should be noted that large negative pore pressures can be sustained in a laboratory setting with controlled application of (high) back pressure, but are typically not observed during cone penetration. All tests of the database had a back pressure which was at least equal to the hydrostatic pressure at the depth point of each test specimen.

Common criteria were reviewed for deriving s_u from the CU data, i.e. peak deviator stress, peak stress ratio, peak pore pressure, zero excess pore pressure and limiting strain (refer to Brandon et al. (2006) for background information on the various criteria for interpretation of s_u). Peak stress ratio was selected as the most practically useful and most consistent criterion across the database. Therefore, this paper defines s_u at $(\sigma'_1/\sigma'_3)_{max}$, where σ'_1 and σ'_3 are the effective principal stresses.

2.4 Data pairing

Pairing of CPT data (q_n) with CU test results considered the following:

– Laboratory test data were considered as primary, because of single data points versus CPT profiling data;

– Selection of CPT values for comparison with the laboratory data from reconstituted soil specimens focused on estimation of an equivalent in situ relative density D_r of the reconstituted soil specimen based on (1) specimen density and (2) estimated values for minimum and maximum (index) dry densities:

$$D_r = (e_{max} - e)/(e_{max} - e_{min}) \qquad (1)$$

where e_{max} is maximum index void ratio, e_{min} is minimum index void ratio and e is specimen void ratio. Selection of values for e_{min} and e_{max} included assessment of laboratory test results per soil unit, per soil type and site-wide;

– Final selection of D_r involved some engineering judgement, particularly for transitional soil specimens, since the estimation of D_r inevitably involves significant uncertainty, which increases with increase of percentage fines. The uncertainty in the selected values for e_{min} and e_{max} should also be noted, particularly since there are various test methods commonly used in the industry that can give significant differences, especially for the maximum (index) dry density (Lunne et al., 2019). The equivalent value of q_n was then back-calculated based on the following equation by Kulhawy & Mayne (1990):

$$q_n = 350 \cdot D_r^2 \cdot P_a^{0.5} \cdot \sigma'^{0.5}_v - \sigma_v \qquad (2)$$

where P_a is atmospheric pressure;

– Selection of CPT values for comparison with the laboratory data from undisturbed soil specimens focused on CPT-borehole proximity, use of CPT data showing the lower q_n values and relatively high values of soil behaviour type index I_c, thereby accounting for the expected bias in selection of the laboratory test specimens, and allowance for small (< 1 m) depth offsets between nearby CPT and sample borehole locations.

3 CPT-BASED METHOD

The approach to estimate continuous profiles of s_u involved analysis of the relationship between derived values of s_u and q_n, normalised to effective vertical stress σ'_v. This led to a bi-linear relationship that is presented in Figure 4 and Equation 3:

$$\frac{s_u}{\sigma'_v} = \begin{cases} 0.0096 \cdot \frac{q_n}{\sigma'_v} - 0.4823, \text{for } \frac{q_n}{\sigma'_v} \geq 124 \\ 0.703 \qquad\qquad\quad , \text{for } \frac{q_n}{\sigma'_v} < 124 \end{cases} \qquad (3)$$
Figure 4. Undrained shear strength derived from in CU tests on sand and transitional soil as a function of net cone resistance.

Comments on Equation 3 are as follows:

- A best fit relationship based on linear least squares regression was considered for values of $q_n/\sigma'_v \gtrsim 124$ based on paired sets of data in sand ($n = 26$, $R^2 = 0.87$, S.E. = 0.59);
- A constant value of s_u/σ'_v for values of $q_n/\sigma'_v < 124$ considering a mean value for s_u/σ'_v within this range, the wide scatter and the absence of a significant trend ($R^2 = 0.38$) between s_u and q_n in transitional soil;
- The method is robust and allows for development of continuous profiles of s_u in sand and transitional soil based solely on input from CPT data, though it is noted that for transitional soil engineering judgement has been applied;
- CPT parameter uncertainty for strongly layered soil will be higher than for uniform soil (Peuchen and Terwindt, 2015). Note also that CPT results are influenced by uncertainty related to undrained, partially drained or drained conditions during cone penetration, particularly in transitional soil with drainage conditions influenced by factors such as soil constituents and (post-)depositional settings. Any of these conditions may apply (DeJong and Randolph, 2012);
- The method covers medium dense to very dense normally consolidated to slightly overconsolidated silty to clean sands and sandy silts;
- Derived values of s_u in sand correspond to values for cone factor N_{kt} ranging between 85 and 176 for the range $q_n/\sigma'_v \geq 60$, which represents more than 95 % of the q_n/σ'_v values in sand across the wind farm sites;
- Derived values of s_u in transitional soil correspond to values for cone factor N_{kt} ranging between 28 and 107 for the range $20 \leq q_n/\sigma'_v \leq 75$, which represents more than

95 % of the q_n/σ'_v values in transitional soil across the wind farm sites;
- Derived values of s_u are in good agreement with the scatter of derived values presented in Andersen (2015).

4 DISCUSSION AND CONCLUSIONS

The method, in combination with an equivalent method for clays, enables derivation of continuous s_u profiles at any CPT location within a given site. This is particularly useful for offshore wind farm developments where one or multiple CPTs are performed per wind turbine location without availability of location-specific laboratory data. Soil behaviour type (i.e. sand, transitional soil or clay behaviour) can be distinguished directly from CPT with application of general or site-specific limits of soil behaviour type indices such as I_c or I_B (Robertson, 2016). Figure 5 presents an example profile from the HKW site.

Equation 3 can be applied with appropriate modifications to produce design profiles of characteristic values of s_u for use in foundation design calculations. To this purpose, the modifications would need to consider at least the following (ISSMGE, 2021):

- Calculation model and its specified principles;
- Limit state and mobilised zone of ground;
- Loading regime and field drainage conditions;
- Transformation uncertainty of derived values to characteristic values;
- Statistical evaluation accounting for statistical fitting uncertainties within the given dataset.

For the horizontal portion of the bi-linear relationship (i.e. the cut-off value for $q_n/\sigma'_v < 124$, see Equation 3), the following particular considerations also apply for selection of characteristic values:

- A probable low value for s_u/σ'_v should be used for slightly overconsolidated soil that would be in the order of magnitude for conventional clays;
- Allowance should be made for *overestimation* of s_u derived from undisturbed transitional soil specimens due to sample disturbance and subsequent reduction of water content during reconsolidation that can lead to soil phase transformation from contractive to dilative (Andersen, 2015).

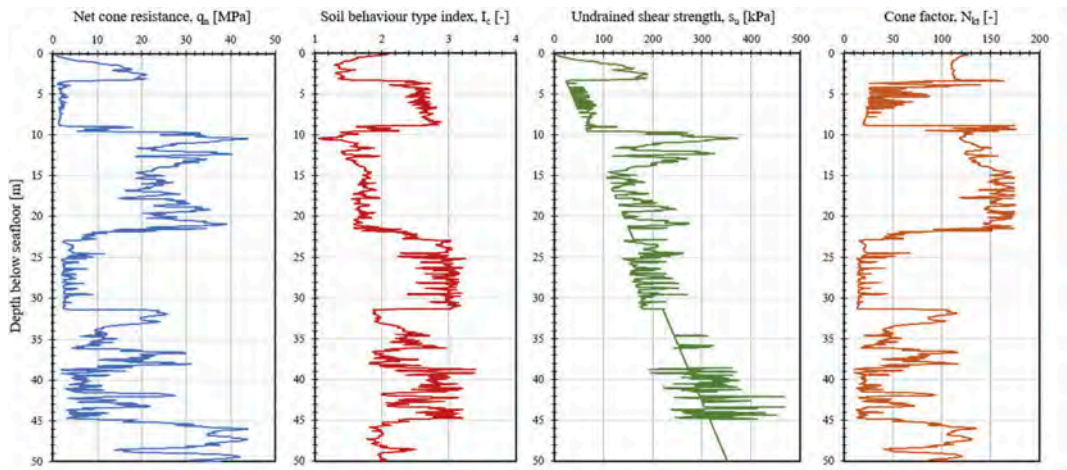
The method appears robust for two particular sites at the North Sea. The two sites include multiple geological units and multiple soil types; further optimisation should be feasible by differentiation on the basis of geological unit and soil type. Soil type differentiation can consider CPT-based soil behaviour type indices, with confirmation by index sample data that can easily be acquired in an offshore laboratory, such as particle size distribution and particle shape by image analysis (ISO, 2006). Further differentiation may also allow wider application of CPT-based methods.


Figure 5. Example profile of s_u from the HKW site comprising three soil types (i.e. sand, transitional soil and clay). Supplementary profiles of q_n, I_c and N_{kt} are also displayed. Soil type is distinguished based on I_c ($I_c < 2.05$: Sand, $2.05 < I_c < 2.6$: Transitional soil, $I_c > 2.6$: Clay). Note that in clay a CPT-based correlation, similar to Equation 3, was used.

Various advanced regression algorithms can be trialled in order for the optimum results to be obtained in terms of statistical evaluation of datasets, including opportunities for potentially making better use of the data by means of automated advanced data analytics such as machine learning and big data.

Comparison of frozen soil strength characteristics by cone penetration and triaxial compression testing

Daniil Lagosha
Lomonosov Moscow State University, Russian Federation

Ivan Sokolov & Nikolay Volkov
Fugro, Russian Federation

ABSTRACT: The paper provides comparison of field and laboratory tests of permafrost soil. Electrical resistivity and temperature piezocone penetration tests (RTCPTu) were carried out in the area of sporadic distribution of permafrost. RTCPTu detected islands of permafrost at depth more than 10 meters. Based on this information, undisturbed samples of warm permafrost soils with massive cryogenic structure and thick ice lenses (up to 10 cm) were collected using CPT equipment with a direct push soil sampler (MOSTAP) mounted instead of cone. The samples were kept in frozen condition and transported to the soil lab, where physical properties and triaxial compression tests were carried out. The CPT results included the characteristics of long-term frozen soil strength such as σ_c – the long-term cone resistance and σ_n – the net long-term cone resistance. The results of triaxial tests provided the characteristics of peak strength: σ_1 – the maximum vertical stress and σ_1-σ_3 – deviator stress at failure. The frozen soil samples were cleared from ice lenses since it is not possible to test them with thick ice lenses. The results of CPT and triaxial testing showed fairly similar values, when the cone measured resistance in frozen soil with massive cryogenic structure. When the cone was located near ice lenses, the net long-term cone resistance appeared to be much lower compared to deviator stress. This observation is in line with conventional theory on physics of ice which states that ice has near-zero long-term strength. The obtained results clearly show the value and advantage of CPT in permafrost (in-situ testing) compared with triaxial compression testing (laboratory). The properties of frozen soil in-situ may significantly differ from properties of frozen soil in a sample. This must be considered for designing civil structures on permafrost.

1 INTRODUCTION

Conventional geotechnical drilling and sampling of permafrost is a challenging problem due its vulnerability. Frozen soils with high ice content at a temperature near freezing point may be easily disturbed due to frictional heating, drilling fluid, ice brittleness and other factors. CPT on permafrost is a maturing technology which has been successfully applied recently. A great benefit would be to use CPT equipment together with direct push soil sampling which is commonly used for non-frozen soils. This combination of CPT and frozen soil sampling was successfully tested in the city of Novy Urengoy, West Siberia, Russia in 2019.

The site is located in Novy Urengoy, Russia. The soils of the site were investigated on a depth of more than 25 m using field and laboratory tests. Retrospectively the site is located in the northern part of the West Siberian plain in the river basin, where accumulation of lake-alluvial sediments took

place. The surface relief is flat due to urban construction. Site soils are represented by clays (from sandy to silty) and sands, rarely peat. In some areas, there are permafrost soils from a depth of 9-15 meters.

The roof of permafrost soils is marked at different depths under the structures on this site. Moreover, there is the complete absence of frozen rocks on some parts of the site. So, there are uneven settlements of structures, which lead to theirs deformation and formation of cracks in them, causing the emergency condition of structures.

The site was located in the basements of two residential buildings (Figures 1, 2). The height of the basements is less than 2 meters. There are many continuous sewer and heating pipes inside, complicating the tests. Thus, site conditions did not permit the using of a heavy vehicle-based cone penetration unit or other commonly used field methods using large-sized equipment.
Figure 1. Map location area – Novy Urengoy, Russia.

Figure 2. Site view.

2 FIELD TESTS OF PERMAFROST - CPT

2.1 *CPT performing*

To perform cone penetration tests (CPT) with measuring of conductivity, temperature and pore pressure RTCPTu, a special small-sized unit with a nominal penetration force of 150 kN was used (Figure 3).

CPT was carried out in two modes: continuous (a constant rate-controlled penetration) and "with stabilization" of the cone (similar to "dissipation" test but rods are kept clamped). The second mode when q_c is measured is also called stress relaxation test, which carried out in a frost layer of the soil to investigate the relaxation behaviour of permafrost.

The stress relaxation test allows to obtain the soil strength parameters similar to those of the continuous type test, but instead of the values of first type test, stabilized second type test values of the cone and at the friction sleeve resistance (q_{cs}, MPa and f_{ss}, MPa) are obtained. Based on the results of the stress relaxation test, it is calculated the long-term strength of the soil under the cone (σ_c, MPa) and on the friction sleeve (σ_s, MPa). In moving of a cone, the soil is loaded by a value more than the instantaneous strength. When a cone stops moving, it is fixed and the stress relaxation is recorded. The values are recorded until the readout parameters stabilize.

Correlation of the listed parameters for frozen soils is as follows:

- for the cone resistance: $q_{cv} > q_{cs} > \sigma_c$ is always observed, and $q_{cv} = q_{cs}$ (0 sec) at the same CPT point and at the same depth;

Figure 3. Map location area – Novy Urengoy, Russia.

- for the friction sleeve resistance: can be $f_{sv} \approx \approx< f_{ss}$ and $f_{sv} > f_{ss}$, but f_{sv} and f_{ss} are always more than σ_s.

Cone penetration tests in velocity mode were executed at 2 cm/s for maximum depths up to 30 m, including tests in cone stabilization mode. They were performed to a depth of 25 m below the ground surface. Temperature and stress relaxation measurements were mostly made at the depth of permafrost spreading: from 7-9 m to 25 m with intervals of 1 m at 9-11 m and 2-5 m at 11-25 m. Frozen soil temperature measurements confirmed the presence of frozen soils at the site. The tests were carried out in July-August 2019. Measured temperatures in the frozen soils ranged from -0.9 to -0.1°C.

2.2 *MOSTAP soil sampling*

Soil sampling was performed with a MOSTAP direct push soil sampler (Robertson, 2014) from the CPT unit. A total of 13 soil sampling points were executed on the site. Sampling was carried out very close to the CPT points, at a distance of 1-2 m, for reliable correlation of the results of testing and sampling and minimal influence of soil variability factor. In total, 146 samples were taken, of which 110 of them were unfrozen and 36 of them were frozen (Figure 4). It is worth to emphasize that the sampling of frozen soils using the MOSTAP technology was carried out for the first time.

In this paper, frozen clay was considered as the object of researching. It was chosen due to the fact that it was the cause of uneven sedimentation at the site. It was also of scientific interest to research the strength characteristics of the frozen soil areas with thick ice lenses.

Considering frozen soil layer was investigated well by both sampling and cone penetration testing. The temperature of the investigated soil varies from -0.3 to -0.11°C. It is deposited from a depth of 10 m. Sampling was carried out at a depth of

10-15 m. 11 samples were taken. Within this layer, 16 points of CPT were executed in the velocity mode and 45 stress relaxation tests in the stabilization mode of the cone. Out of this number of tests, values for analysis were selected from 8 points. All the CPT points with stress relaxation tests were located very close to the frozen soil sampling points - at a distance of 1-2 m.

Figure 4. Part of investigated frozen soil, sampled by MOSTAP.

3 LABORATORY TESTS OF PERMAFROST – TRIAXIAL COMPRESSION TESTING

3.1 *Specimens preparing*

Various characteristics of the composition and properties of investigated soils were determined in the field laboratory. According to their results, the soil can be characterized as frozen clay from silty to sandy, with ice from well-bonded, no excess ice to thick ice inclusions, non-saline, from very stiff to soft.

To determine the strength characteristics of the investigated soil by triaxial test, specimens were made of selected samples of frozen clay. Soil samples with a massive cryogenic structure were tested in a triaxial compression apparatus to ensure that the homogeneity condition of the specimen was met.

Specimen preparation for the test was carried out in a special room with the maintenance of negative temperature (cryogenic chamber). The specimens cut from the frozen samples had a cylinder shape with a height (h) to diameter (d) ratio of 2:1 (70 mm: 35 mm) (Figure 5).

3.2 *Performing tests and theirs results*

The chamber and the counter-pressure system of the triaxial apparatus chamber supplying the fluid to the stamps, and the holes in the stamps were filled with a special liquid with a negative freezing temperature by raising the pressure in the counter-pressure system with complete displacement of air bubbles. The triaxial tests were executed in the consolidated-undrained mode without pore pressure measurements. The investigated soil was in the frozen state, so it was not possible to measure pore pressure.

In this case to determine the strength of the soil in full stresses, it was measured by the peak of the stress deviator. The specimen is broken by applying a vertical loading with the pressure in the chamber

Figure 5. Example of a test soil specimen in cross-section and longitudinal section.

previously reached and the drainage blocked. Kinematic test mode was used: vertical loading is applied with a given constant rate of deformation of the specimen. The rate of specimen loading was 0.02 mm/minute.

Soil temperature during triaxial tests is -1°C. This is the highest subzero temperature that can be maintained in the apparatus to keep specimens in frozen state. In the natural soil conditions, their temperature is close to the freezing start temperature and to zero - from -0.3 to -0.1°C, which is technically extremely difficult to assign in the device today. The tests lasted from 11 to 21 hours. The consolidation time of the samples was 4 hours. The confining stress in the triaxial device was within 280-300 kPa.

Of the executed five tests, it can be highlighted two "paired" tests, i.e. performed on specimens taken from one sampling point and one depth interval, and one "unpaired" test. Therefore, all specimens were aged for 1 day and tested under identical consolidation and loading conditions, so the "paired" tests could be compared to each other.

Figures 6 and 7 show the results of triaxial tests. Specimens No. 2-5 exhibited a brittle behaviour,

specimen No. 1 exhibited a ductile behaviour (Figure 7). "Paired" specimens No. 1 and No. 2, No. 3 and No. 4 showed quite close peak strength to each other: 697 and 679 kPa; 989 and 935 kPa, respectively. The results are repeatable and confirm the validity of the testing procedure.

Figure 6. The graph of deviator stress dependence on vertical axial deformation.

It should be noted that fracturing time of specimens No. 1 and No. 2 was quite close - 15 and 13 hours, respectively. At the same time, specimens No. 3 and No. 4 had two times more different fracturing times - 7 and 16 hours. However, in both cases the values of stress peak deviator in "paired" specimens are quite close.

The vertical stresses σ_1 and deviators at fracture of specimens $\sigma_1 - \sigma_3$ obviously have the same patterns. The values of σ_1 and $\sigma_1 - \sigma_3$ range from 0.96 to 1.28 MPa and from 0.68 to 0.94 MPa, respectively.

Figure 7. A frozen soil sample after the triaxial test and its failure character.

4 COMPARISON CPT AND TRIAXIAL TESTS RESULTS

4.1 *Mechanism of tests*

The triaxial tests simulated natural soil conditions similar to the stress relaxation tests performed by cone penetration testing.

The mechanism of these tests is quite similar. In the triaxial compression device, the stamp transmits vertical stress to the specimen, and the fluid filling the chamber space makes all-round pressure on the specimen, allowing the stress-strain state of the tested soil in the natural conditions to be remake as much as possible (Figure 8b).

When executing the stress relaxation test by CPT, the cone is penetrated directly into the soil to the depth of the investigation, stopping at that depth. As a result, the soil mass makes all-round compression of the investigated soil layer from all sides, and the cone, similarly to the stamp in the triaxial apparatus, assigns vertical stress at a constant rate of deformation. In addition, CPT is sensitive to transient zones of the soil mass (changes in soil type) and soil variability, such as ice lenses, due to the influence zone of the cone (Figure 8a).
Figure 8. Mechanism of the main stresses in the test method of: a) CPT and zone of influence of the cone; b) triaxial compression.

The principle of the major stresses in both test methods is similar, but it is necessary to consider factors that will reflect the difference between the results obtained by them. These factors are:

- ground temperature;
- geometric shape of the stamp/cone;
- soil variability;
- stress-strain state of the soil.

As a result of the performed tests and their processing the following strength characteristics were obtained:

- by CPT method:
- cone resistance q_c;
- long-term cone resistance σ_c;
- net long-term cone resistance σ_n;
- by triaxial compression method:
- vertical stress at specimen failure σ_1;
- stress deviator at specimen failure (peak soil strength) $\sigma_1 - \sigma_3$.

The cone resistance of the soil q_c in this paper is taken equal to the corrected cone resistance values

$$q_t = q_c - (1 - a)u_2 \qquad (1)$$

where a - base area coefficient of the cone,
   u_2 - pore pressure (Lunne et al., 1997),
   i.e. pore pressure in frozen soils is not considered. Consequently, $q_t = q_c$.
From the values of q_c obtained from direct measurements, it was obtained the values of the long-term cone resistance σ_c. For this purpose, it was used the method of calculating this parameter based on the dynamometric method of Vyalov (1986).

This method of measuring stress relaxation helps in evaluating the long-term strength of the soils which serve as the basement of the structure. Processing application of stress relaxation curves obtained in the field tests with the help of the described equation makes it possible to obtain values of long-term strength of soil at a given depth. The validity of application of this equation is confirmed by researches of Vyalov (1986), Volkov and Sokolov (2018; 2019; 2020).

4.2   Comparison of the results

Based on the obtained values of the long-term cone resistance σ_c, the values of the net long-term cone resistance of the soil σ_n were obtained by:

$$\sigma_n = \sigma_c - \sigma_{vo} \qquad (2)$$

where σ_{vo} - overburden stress (Lunne et al., 1997).
To compare the results of the strength characteristics investigation of the investigated soil, the values of σ_c and σ_1 and as well σ_n and $\sigma_1 - \sigma_3$ were taken and their dependence on the depth of the investigation was plotted (Figures 9, 10).

As a result of the analysis it should be paid attention to the following:

1. The pattern of σ_1 and $\sigma_1 - \sigma_3$ values growth with depth is clearly traced, similar to the pattern of the long-term cone resistance of the soil.
2. The values of σ_c obtained at the depth of investigated soils vary from 0.25 to 1.15 MPa. It should be noted the increase of long-term cone resistance of the soil with increasing the depth of investigation.

Figure 9. The graph of long-term cone resistance and vertical stress at triaxial test failure of specimen dependence on depth.

Figure 10. The graph of net long-term cone resistance and stress deviator at triaxial test failure of specimen dependence on depth.

3. The values of σ_n change from 30 to 920 kPa. A higher net long-term cone resistance with increasing depth is also noted.
4. Minimum values of σ_n (30 kPa) are close to zero. This indicates the presence of ice lenses in the zone of cone influence. Such frozen soils are characterized by low bearing capacity during long-term loading application.
5. The maximum values of σ_n (0.56-0.92 MPa) and σ_c (0.82-1.15 MPa) obtained by CPT correlate well with stress deviatiors (0.7-1.0 MPa) and vertical stress (0.96-1.3 MPa) in failure of specimens tested by triaxial compression. These values were observed in frozen soils with massive cryogenic

structure, which was confirmed by sampling. In addition, frozen soil samples were tested in the triaxial apparatus with exactly this cryogenic structure to meet the condition of sample homogeneity.

6. The temperature of the triaxial tests is -1℃. This is the highest subzero temperature that can be maintained for high-temperature frozen specimens in triaxial testing. In the natural soil conditions, their temperature is close to the freezing start temperature and to zero - from -0.3 to -0.1℃, which is technically extremely difficult to create in the device today. As it is known, when the temperature of frozen soil decreases, its strength increases. Perhaps that is why the values of the results of triaxial tests are correlated with the maximum values of CPT.

Thus, the results of cone penetration and triaxial testing show fairly similar results in the case of a massive cryogenic structure of soil. Determining the strength in frozen soil with lensed cryogenic structure is currently a important question. There is not yet a consistent method for such determination. In this case, CPT revealed that in frozen high-temperature ice-rich clays, the long-term strength over time when the load is applied will tend to small values, close to zero.

ABSTRACT: The paper presents the results of a recent study on the application of CPTU on soft sensitive Finnish clays. An extensive field and laboratory investigation program was carried out, including 9 test sites of which 5 were studied in more detail. In each of the test sites, a minimum of 4 CPTU soundings, 2-3 field vane test with a new type of down hole vane, sampling with a newly developed large diameter tube sampler and an extensive laboratory investigation program were carried out. Transformation models were developed to estimate the undrained shear strength, preconsolidation stress, and constrained modulus for the over consolidated region. In addition, new information about anisotropy of Finnish clays were obtained. In general, the CPTU tests proved to be very reliable with very good repeatability. However, the measurement of sleeve friction proved to be somewhat problematic for the very soft and sensitive clays studied.

1 INTRODUCTION

Until 2010, the use of CPTU had not gained wide popularity in Finland. Attempts made in the 90's to assess the undrained shear strength of Finnish soft clays with the CPTU had not been very successful mainly due to accuracy problems related to the low undrained shear strength (s_u)values for both the CPTU and the field vane tests used as reference. As the problems with the field vane test became clearer (Mansikkamäki, 2015), a need to find better solutions became obvious.

Based on this background Research Centre Terra at Tampere University started together with the Finnish Transport Agency a comprehensive study to establish reliable correlations to estimate s_u and preconsolidation stress (σ'_p) of soft clays, and to promote the use of CPTU in Finland. To achieve these goals, an extensive field and laboratory investigation program was carried out at 9 test sites. This paper gives an overview of the project, describing the test sites, field, and laboratory work executed, and the correlations and other results found during the study.

2 TESTING PROGRAMME

The CPTU tests included tests with two different probes, i.e., a sensitive cone and a high-capacity cone with a maximum cone resistance of 7.5 MPa and 75 MPa respectively. Both cone types have a standard 60° apex tip, with a cross-sectional area (A_c) of 10 cm^2 and a sleeve area (A_s) of 150 cm^2. The filter element for measuring the pore-water pressure is located at the shoulder, above the cone tip (u_2).

In addition, seismic and resistivity modules were used. A minimum of 4 soundings were performed at each site. In addition to CPTU tests, field vane tests were carried out with a new type of down hole vane, characterized by measuring system and torque motor located right above the vane, to overcome problems related to rod friction (Selänpää et al. 2018). Comparative test with standard type of up-hole devices were carried out at some of the sites.

To ensure high quality undisturbed samples for the laboratory tests, a new sampler was developed (Di Buò et al. 2019). The sample resembles the SGI type of Laval sampler, with a cutting wire and possibility to feed air/water to avoid suction during withdrawing.
Figure 1. Index properties and undrained shear strength for Paimio (upper figure) and Sipoo (lower figure) test sites.

The sample is though somewhat smaller is size, having an internal diameter of 131 mm. Another difference is that the samples are stored in the sampling tubes that can be pressurized to keep the in-situ stress conditions.

The laboratory tests included classification tests, CRS oedometer tests, triaxial compression and extension tests and direct simple shear (DSS) tests. All tests have been conducted in accordance with appropriate standards when available.

3 TEST SITES

Field and laboratory investigations have been carried out altogether in 9 different sites, i.e., in Perniö, Masku, Paimio, Sipoo, Lempäälä, Murro, Kotka, Joensuu and Pohja. The five foremost have been the main testing sites in calibration of cone factors and are presented here in more detail.

The Perniö test site is located on the southwestern coast of Finland, about 140 km west of the city of Helsinki. The soil stratigraphy of the deposit includes a 1–1.5 m thick dry crust underlain by 8–9 m thick, soft clay layer; silt and stiff sandy layers can be found at a greater depth. The groundwater table is located at 1 m depth.

The Masku test site is located at the southwestern coast of Finland, near the city of Turku. The soil stratigraphy includes a 1.5 m thick weathered clay crust, followed by an 8 m thick, soft clay layer. The groundwater table is located at 1.2 m depth.

The Paimio test site is also located close to the city of Turku. The stratigraphy consists of a 2 m thick clay crust overlaying an 8 m thick, soft clay layer. The groundwater table is located at 0.8 m depth.

The Sipoo site is situated 30 km north of the city of Helsinki. The deposit consists of a homogeneous soft clay layer between 2 and 9 m depth and a - 2 m thick dry crust layer. The groundwater table is located at 1 m depth.

The Lempäälä test site is located close to the city of Tampere. The soil stratigraphy consists of a 1–1.5 m thick dry crust layer, followed by 1–1.5 m of organic soil underlain by a soft sensitive low-plastic clay layer. The groundwater table is located at 0.6 m depth.

All sites are characterized by low s_u values and high water content (w), usually above the liquid limit (LL). The clays are thus very sensitive and their remolded shear strength values obtained by the fall cone test are generally below 0.5 kPa for Perniö, Paimio and Lempäälä sites, and close to unity for Sipoo and Masku sites.

The index properties and the intact (black) and remolded (white) undrained shear strength obtained from the fall cone test, of the clays for Paimio representing highest sensitivity (S_t) and Sipoo representing lowest S_t are presented in Figure 1. Typically for

the clays with lower plasticity index *PI*, the *w* is much higher than the *LL*, resulting in high liquidity index (*LI*), which correlates strongly with S_t.

4 QUALITY OF DATA

In general, the repeatability of the CPTU tests was found very good. As an example, the coefficient of variation (*COV*) values for corrected cone tip resistances and pore pressure measurements varied between 0.026 – 0.060 and 0.023 – 0.106 respectively between different sites (Knuuti & Länsivaara 2019 a, b). However, for the sleeve friction measurements, the resolution was too low for the very soft sensitive clay sites, in which the measured values generally were below 5 kPa (*COV* values in the range 0.15 -0.30). In Figure 2 results from four tests carried out using the sensitive cone and one with the high-capacity cone are presented from Paimio test site. As can be seen, the four corrected tip resistance measurements are very similar, while the one using the high-capacity cone is giving somewhat lower values. This observation was generally made in all test sites. It should be noted that the high-capacity cone had not been calibrated especially to low values. The too low resolution is clearly visible on the sleeve friction graph.

While the pore pressure measurements for the two types of cones were performed with same kind on transducers having the same accuracy, the minor differences that can be seen between the different pore pressure measurements are related to the preparation works and actual measurements, not to the equipment.

The new down-hole field vane device showed better consistency and repeatability than traditional up-hole devices. The *COV* values for the down hole field vane test varied in between 0.04 and 0.23 between different sites, with an average of 0.14 for 88 tests. When the tests are performed with care, and casing is used for the up-hole device, the two methods gave very similar results for intact clay, although there was a slight tendency to higher values for the down-hole devise. However, for the remolded undrained shear strength the down-hole device clearly yielded lower values, closer to values obtained with the fall-cone.

The quality of the undisturbed soil samples was mainly evaluated based on the criteria proposed by Lunne et al. (1997). Accordingly, sample quality is classified as "very good to excellent", "good to fair", "poor", and "very poor". In Figure 3 the sample quality found for CRS oedometer tests are presented as change of void ratio versus depth. The same sampler types are indicated by equal marker shapes while different shades are used for the various sites. As can be seen, most of the samples fall into categories "very good to excellent" and "good to fair". The poor results for the TUT sampler at Lempäälä site is explained by it being the first site where the new sampler was tested, and all procedures were not in order at the beginning. However, as the procedures were optimized mostly "very good to excellent" quality samples were obtained. Results from laboratory test obtained from samples classified as poor or very poor have not been used in the calibrations. As reported by Di Buò et al. (2019), the sample quality did not suffer from a storage time of two years.

Figure 2. CPTU results from Paimio test site. Results from four sensitive cone measurements are presented with solid lines, while the results from one high-capacity cone measurement are given by a black dotted line.

Figure 3. Sample quality according to the Lunne criteria (1997), 1 – very good to excellent, 2 – good to fair, 3 – poor, 4 -very poor.

5 TRANSFORMATION MODELS

5.1 Evaluation based on SCE-CSSM

Di Buò et al. (2020) and Di Buò (2020) studied the possibilities of the hybrid spherical cavity expansion – critical state soil mechanics (SCE-CSSM) framework by Mayne (1991) and Chen and Mayne (1994), and the modified SCE-CSSM solution (Agaiby 2018) for the determination of σ'_p /OCR. It can be concluded that for low sensitivity (St) clays both solutions gave a relatively good match, but as St increased the modified solutions preformed much better. Another general finding of the study is that the friction angel values needed in the solutions can be seen more as curve fitting values rather than true values. To get good correlation to laboratory based σ'_p values, the used friction angle values needed to be clearly higher than those observed in the laboratory.

Based on the above theoretical framework Di Buò et al. (2020) and Di Buò (2020) proposed simplified transformation models based on average operational values, calibrated those based on the entire data, and finally suggested five equations for evaluating σ'_p in Finnish clays. Out of those five the following two are herein suggested as the primary transformation models:

$$\sigma'_p = 0.28(q_t - \sigma_{vo}) \qquad (1)$$

$$\sigma'_p = 0.39(u_2 - u_o) \qquad (2)$$

The outcome of Eq. (1) and (2) are presented in Figure 4 in comparison to CRS oedometer based σ'_p values for Paimio and Sipoo test sites.
It could further be noted, that for Equation (1), the low sensitivity clays indicated generally a lower multiplier than 0.28, while for high sensitivity clays a higher multiplier were generally found. All clays had an OCR generally below 2.

5.2 Evaluation based on index properties

After discussing varies theories Selänpää (2021) studied the influence of index properties and pore pressure ratio (B_q) to the cone factors. The main goal was to determine the best practical transformation models for determination of undrained shear strength. Cone factors were determined in relation to different shearing modes (tests) for undrained (triaxial) compression ($s_{u\ comp}$), undrained (triaxial) extension ($s_{u\ ext}$), direct simple shear (DSS) (test) ($s_{u\ DSS}$), measured field vane ($s_{u\ FVmeas}$) and corrected field vane ($s_{u\ FVcorr}$) undrained shear strength. Field vane measurements were corrected as a function of liquid limit according to Helenelund (1977). In general, it can be concluded that best correlations were found for $s_{u\ comp}$ as the triaxial compression test revealed to be the most reliable test with lowest scatter. For the $s_{u\ FVcorr}$ Selänpää suggested that the N_{kt} and $N_{\Delta u}$ cone factors would depend on PI and the N_{ke} cone factor on Bq. The two previous proposed $s_{u\ FV\ corr}$ equations are as follows:

$$s_{u\ FV\ corr} = \frac{(q_t - \sigma_{vo})}{0.126 \cdot PI + 11.793} \qquad (3)$$

Figure 4. Values of σ'_p evaluated using Equations (1) and (2) in comparison to CRS test results.

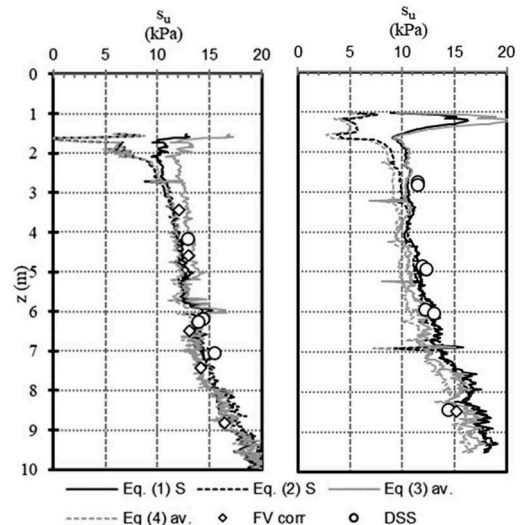

Figure 5. Values of s_u evaluated using Equations (3) and (4) and (1) and (2) applying the SHANSEP approach in comparison to field vane and DSS test results for Paimio (left) and Sipoo (right) test sites.

$$s_{u\,FV\,corr} = \frac{(u_2 - u_o)}{0.064 \cdot PI + 10.279} \quad (4)$$

In Figure 5 the results of Equations (3) and (4) are compared with $s_{u\,FVcorr}$ and $s_{u\,DSS}$ data for Paimio and Sipoo test sites using average PI values. To compare the different approaches by Di Buò (2020) and Selänpää (2021), values determined using Equations (1) and (2) applying the SHANSEP to estimate s_u is applied. Accordingly, s_u can be determined from:

$$s_u = S \cdot \sigma'_{vo} \cdot OCR^m \quad (5)$$

For the parameters S and m values reported by D'Ignazio et al. (2016) with S = 0.244 and m = 0.763, are used.

For the Sipoo test site, only one good quality field vane test was achieved, so the comparison is primarily to DSS test results. As can be seen from Figure 5, all equations performed quite well for the Paimio site. For the Sipoo test sites, the estimation is also good, although some minor underprediction might be indicated by the $s_{u\,DSS}$ values in the upper part.

6 SOME OTHER FINDINGS

6.1 *SBT charts*

For all test sites the soil behaviour type (SBT) was evaluated based on the normalized SBT charts by Robertson (1990). A general finding was that although the clays were in general sensitive, the classification charts indicated them with very few exceptions as clays, rather than sensitive clays. For the chart based on the normalized friction ratio this can at least partly be explained by the low accuracy of the sleeve friction measurements as discussed before. However, neither the chart based on the normalized porewater ratio succeeded in identifying the sensitive clay layer while the values in

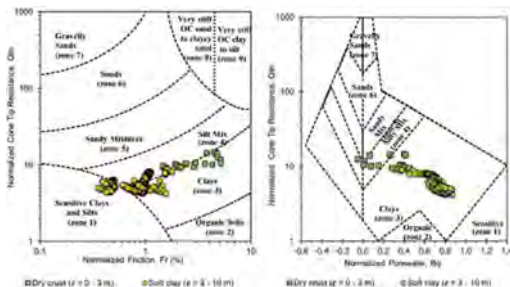

Figure 6. Soil behavior type (SBT) according to Robertson (1990) for the sensitive Paimio clay (Di Buò, 2020).

practise never plotted on the zone for sensitive clays. The SBT charts for Paimio site, with a high sensitivity of the clay (S_t = 60...100%) is presented in Figure 6 (Di Buò, 2020).

6.2 *Anisotropy of su*

The anisotropy of s_u for Finnish clays was studied systematically for the first time. The anisotropy ratios were determined by comparing the peak undrained strength values of respective tests corresponding to the different shear modes, irrespective of the shear strain values (Selänpää 2021). The ratio $s_{u\,ext}/s_{u\,comp}$ varied between 0.52-0.70, with a slight tendency to increase with plasticity and/or water content. The average value for the ratio is 0.615. Similarly, the ratio $s_{u\,DSS}/s_{u\,comp}$ varied between 0.56-0.72, with a slight tendency to increase with water content. The average value for the ratio is 0.64. What is notable is the very small difference between $s_{u\,ext}$ and $s_{u\,DSS}$ values.

6.3 *Constrained modulus for OC region*

Di Buò et al. (2018) and Di Buò (2020) evaluated different approaches to determine the constrained modulus M_0 for the overconsolidated region. As the value for M_0 is quite sensitive to sample quality, the correlations generally showed a rather high scatter. However, a simple approach relying on the relatively accurate determination of σ'_p proved to provide a pragmatic solution giving consistent values. The σ'_p for high quality samples of soft Finnish clays is reached approximately at a vertical strain of 4%. Therefore, the value of M_0 can be evaluated by firstly using transformation models as in Equations (1) and (2) to evaluate the σ'_p, and then divide the σ'_p value with 0.04 to obtain the M_0. As example such an approach for the pore pressure based Equation (2) yielded a COV value of 0.21 between CRS and CPTU based M_0 values.

6.4 *Additional modules*

In all test sites investigations were also conducted using two additional modules connected directly behind the cone, namely the seismic (S) and resistivity (R) modules. In general, two tests were performed for each site using both modules, showing good repeatability.

The shear wave velocity values varied between 40-110 m/s. The measured electrical conductivity values ranged from about 50 up to 300 mS/m, correlating highly with pore water salinity.

7 CONCLUSIONS AND FUTURE DEVELOPMENTS

In the FINCONE project the application of CPTU was studied for soft sensitive Finnish clays. Comprehensive testing, including high quality sampling, extensive laboratory program and down hole field

vane in addition to the CPTU was performed altogether on 9 test sites, of which 5 were studied in more detail. Based on the achieved database transformation models were developed to evaluate σ'_p, s_u and M_0. Moreover, information about the anisotropy of Finnish clays were achieved for the first time. In addition, shear wave velocity and resistivity data were obtained from the S- and R-modules of the used CPTU equipment.

The CPTU data proved to be very reliable with good repeatability. However, the sleeve friction measurements suffered from too low resolution for the very low values. Some doubts were also raised about their accuracy. The resulting transformation models proved to work well for studied soft clays. It should though be noted that the clays are rather similar in nature, with low OCR and generally high water and clay content.

In the future, the aim is to broaden the range of studied soils to silty soils and fine sands and develop further transformation models for them. In addition, CPTU based soil characterization as well as determination of deformation properties for the normally consolidated will be studied. Some early results of the former are also presented in this conference (Farhadi et al. 2022).

CPT-based unit weight estimation extended to soft organic clays and peat: An update

H.J. Lengkeek
Delft University of Technology, Delft, The Netherlands
Witteveen+Bos, Deventer, The Netherlands

R.B.J. Brinkgreve
Delft University of Technology, Delft, The Netherlands
Bentley Systems, Delft, The Netherlands

ABSTRACT: Various CPT-based correlations exist for the unit weight of natural soils. One such correlation includes organic soils Lengkeek et al. (2018). This correlation is presented as a framework where the coefficients can be optimized and is based on predominantly Class 2 CPT records. This publication uses an expanded database which includes additional pairs of predominantly Class 1 CPT records selected from Holocene deposits in the Netherlands, on mineral clays, organic clays and peats. This results in a more extensive database and an improved CPT-based unit weight correlation for the whole range of soil types, which is proposed to replace the existing correlation. In addition, a specific unit weight correlation for peats is presented.

1 INTRODUCTION

1.1 Automated processing of CPTs

Cone penetration testing (CPT) has become increasingly popular as the preferred in-situ test method as it can be used for soil classification, estimation of geotechnical parameters and use in empirical methods. With the increase of automated processed CPT data in engineering (Brinkgreve, 2019), it is critical to have an accurate estimation of soil unit weight as this is the first and most important step in geotechnical parameter determination. This is particularly relevant for organic soils which are often not included in existing CPT-based parameter determination methods.

1.2 Organic soils

Organic soils are formed during the decomposition of dead organic substances i.e., remnants of plants and animals. This process takes place in different ways, mainly through bacterial activity, intensified by oxygen and temperature. Another type of sediment with a highly variable organic content are the floodplain sediments, which are deposited when streams at high water overflowed natural embankments. The peat areas and deposits of organic soils occur to a large extent in the northern parts of the world.

To date, most published research on CPT application is on mineral soils. Existing CPT-based correlations for mineral clays do not capture the behavior of soft organic clays and peats well compared to other soils. The properties of peats have been investigated and extensively published, i.e. Den Haan and Kruse (2007), (Mesri and Ajlouni, 2007). However, limited attention has been devoted to the whole range of slightly organic clay to peat, and how this relates to CPT measurements. These organic soft soils are frequently present within the Holocene deposits in the Netherlands and in other deltaic areas worldwide. Organic soft soils are characterized by a low unit weight and high compressibility. Organic soft soils can be identified by a high organic content and high CPT friction ratio. In contrast to other soft soils, the strength is not necessarily low.

1.3 Aim of this publication

By combining soil properties obtained from laboratory testing with CPT results, layer-, site- or region-specific correlations can be obtained between CPT measurement data and geotechnical properties of the soil. When automating the interpretation of CPTs, it is preferable to have a direct and reliable relation between the measurements and the soil unit weight. With a more reliable in-situ derived estimation of unit weight, the effect of human interference is limited to a minimum. Moreover, because many soil properties (and thus the applicable correlations) depend on the stress level, it is paramount to have an indication of the stress profile over the depth. For this purpose, the use of lookup tables such as those found in textbooks is not preferable. The aim of this publication is twofold:

- To validate and improve the CPT-based unit weight correlation (Lengkeek et al., 2018) for the whole range of soils.
- To present additional insight in relations between index properties and CPT measurements for organic soils.

1.4 *Research approach and databases*

The 2018 database includes the sample unit weight and Class 2 CPTs (ISO22476-1, 2012) of Holocene and Pleistocene sedimentary deposits in the Netherlands. This database is used for the initial unit weight correlation and includes all soil types, however mainly mineral soils.

The 2021 database follows from soil investigations from various dike reinforcement projects across the Netherlands. This database includes classification laboratory tests and Class 1 CPTUs of mainly Holocene organic clays and peats. The CPT data is taken from the same depth as the samples, with a maximum allowable distance between borehole and CPT of 1 meter. These soil investigations are performed in the period 2010-2020.

Figure 1. Overview of 57 CPT-borehole pair locations in the Netherlands.

The Dutch Water Authorities requires that all new soil investigations be performed according to a dedicated protocol for dikes, summarized in a standardized STOWA Excel sheet (www.helpdesk water.nl). The CPTs are standardized in GEF format. These standardized formats are very useful and efficient to set up a comprehensive database. An overview of the locations and number of CPT-borehole pairs is presented in Figure 1. The total number of undisturbed samples is 464, the number of CPT pairs is 233 of which 211 include the unit weight, 136 include organic content and 109 include specific gravity. The data of this research is available in the Delft University of Technology repository and published in Lengkeek (2022).

2 UNIT WEIGHT CORRELATION

2.1 *Soil type categories*

The selected classification method for organic fine-grained soils is based on the FHWA system. Sand (coarse grained soils) are classified based on the sample identification description. The FHWA classification system, based on organic content measured by the Loss on ignition (N), consists of the following soil categories:

- mineral fine-grained soils: $N \leq 3\%$.
- mineral fine-grained soils with organic matter: $3 < N \leq 15\%$.
- organic fine-grained soils: $15 < N \leq 30\%$.
- peats: $N > 30\%$.

The classification results for the 2021 database with organic soils are presented in Table 1. The names of the soil categories in the graphs are shortened for practical reasons. For samples where the organic content is unknown, the classification is based on the unit weight; Peat: $\gamma_{sat} \leq 12$, Organic clay: $12 < \gamma_{sat} \leq 14$, Clay with organic matter: $14 < \gamma_{sat} \leq 17$, Clay, mineral: $\gamma_{sat} > 17$, all in kN/m³.

Table 1. Classification results for organic soil types: average organic content, range of unit weight and specific gravity per soil type in the 2021 database.

Results:	N_{mean}	γ_{sat}	G_s
Soil type	(%)	(kN/m³)	(-)
Peat	79	10.1 - 13.1	1.4 - 2.0
Organic Clay	22	11.6 - 14.0	1.9 - 2.4
Clay (org.matter)	8	12.4 - 19.2	2.3 - 2.7
Clay (mineral)	2	15.6 - 20.0	2.6 - 2.7

2.2 *Updated CPT-based unit weight correlation*

The updated CPT-based unit weight correlation is based on the combined database. The 2018 database mainly consists of mineral soils whereas the 2021 database mainly consists of organic soils. The combined database allows for a validation and improvement of the correlation for unit weight. The CPT-based unit weight correlation of Lengkeek et al. (2018) is shown in Equation (1). The correlation is

based on the corrected cone resistance q_t and friction ratio R_f, which are both normalized by a reference value. The reference unit weight, here 19.5 kN/m³, is the value when q_t equals $q_{t,ref}$. The updated variables based on the combined database of 427 pairs are presented in Table 2.

$$\gamma_{sat} = \gamma_{sat,ref} - \beta \cdot \frac{\log\left(\frac{q_{t,ref}}{q_t}\right)}{\log\left(\frac{R_{f,ref}}{R_f}\right)} \quad (1)$$

Herein:

$\gamma_{sat,ref}$ is the reference unit weight at which the cone resistance is constant regardless of R_f.

$q_{t,ref}$ is the reference cone resistance at which the unit weight is constant regardless of friction ratio.

$R_{f,ref}$ is the reference friction ratio at which the apex of all lines of equal unit weight is located.

β is the fit factor, which is a measure for the inclination of the equal unit weight contours.

Table 2. Updated parameters for unit weight correlation.

Parameter	Value	Unit
$\gamma_{sat,ref}$	19.5	kN/m³
$q_{t,ref}$	9.0	MPa
$R_{f,ref}$	20	%
β	2.87	

Figure 2 presents all measured data per soil type combined with the lines of equal unit weight [10, 21] kN/m³. The results are plotted on the SBT template of Robertson (2010). From this figure it can be concluded that the lines of equal unit weight are well aligned with the orientation of SBT zone boundaries. Coarse grained soils, SBT=5 and higher correspond to a unit weight of 18 to 21 kN/m³. The variation in unit weight for fine soils is much larger.

Figure 3 shows the measured unit weight versus the predicted unit weight using the improved correlation. The points are subdivided in the database categories [Peat; Organic Clay; Clay with organic matter; Mineral Clay; Sand]. These database categories are based on the laboratory classification. From this graph it can be seen that the trend follows the 1:1 line very well. The scatter is larger for lower unit weights and organic soils; however, for peats the results are close to 10 kN/m³, which is also the minimum value as applied.

Figure 4 presents an example of a CPT with clay, peat and sand layers, including the unit weight according to Equation 1. The unit weight from the laboratory tests are respectively 12.6 to 15.0 kN/m³ in the upper 2m clay, 10.3 kN/m³ for the peat layer and 19.5 kN/m³ for the underlain sand layer.

The performance of the improved correlation can be expressed in statistical parameters such as the coefficient of determination (R^2) and the standard deviation

on regression (S_y) and the slope of the trendline through the origin [x=measured, y=predicted]. The comparison with other existing correlations Mayne (2014), (Robertson and Cabal, 2010, Lengkeek et al., 2018) is presented in Table 3. The R^2 and S_y comply to Ordinary Least Squares (OLS) regression with free intercept. The slope complies to regression through the origin and is a measure for the bias of the trend in Figure 3. From this comparison it can be concluded that the new correlation performs better for all statistical parameters. The 2018 correlation results in slightly different values which validates the use it.

Figure 2. Unit weight measurements and lines of equal unit weight of the improved correlation, presented on top of Robertson (2010) SBT template.

Figure 3. Measured versus predicted unit weight based on the improved correlation.

Table 3. Comparison of statistical results of multiple correlations for the whole range of soils.

| Method	R^2	S_y	OLS slope [y:x]	slope through origin [y:x]
Improved correlation Lengkeek (2022)	0.80	1.32	0.84	1.00
Lengkeek (2018)	0.79	1.33	0.80	1.00
Robertson & Cabal (2010)	0.25	1.46	0.26	1.06
Mayne (2014)	0.12	1.68	0.20	1.03

3 CPT-BASED CORRELATIONS FOR ORGANIC SOILS

3.1 Introduction

The pairwise established database of classification test results and CPT measurements allows for comparison of properties of organic soils and additional insight in relations. In this section three graphs with organic content and index properties are presented as well as three graphs with CPT-based correlations.

For each graph the results and the confidence intervals are plotted in the graphs and the statistical parameters are shown in the title. The subcategories are indicated in the legend. The regression is applied to all samples as one group and not per soil type.

Correlations for each soil category would result in a lower coefficient of determination and limit any reliable correlation to an average value and standard deviation per soil type.

3.2 Correlations with organic content

Figure 5 presents the organic content versus the water content and was first published by Mitchell and Soga (2005). This correlation provides a first estimate of the organic content for any soil which is expected to be organic. The data shows an increase of organic content with water content up to N=90 which is considered as a physical upper bound. The bi-linear fit performs better than the correlation by Mitchell and Soga (2005), which is based on less data.

Figure 6 presents the specific gravity versus the organic content. The results confirm the empirical relation as published by Den Haan and Kruse (2007). Once the organic content is known, the specific gravity and ultimately the unit weight can be estimated.

Figure 5. Organic content versus natural water content, for organic to mineral soils. Best bi-linear fit: $N = \min[90\%, 0.239\, w_{nat} - 7.08]$ with standard deviation Sy=7.53.

Figure 7 presents the unit weight versus the organic content. This figure is the basis for the secondary criteria for classification of organic soils based on the unit weight. The variation is more than that for the specific gravity correlation as the unit weight is not just a unique soil property but also a state parameter depending on the preloading and stress level.
Figure 6. Specific gravity versus organic content, for organic to mineral soils. The standard error on regression (Sy) is 0.082 and coefficient of determination (R^2) is 0.97.

Figure 7. Saturated unit weight versus organic content, for organic to mineral soils. The best power function fit is: $\gamma_{sat} = 20.8N^{-0.153}$ with standard deviation Sa=1.48 (for $y=a \cdot x^b$).

3.3 *CPT-based correlations*

Figure 8 presents the unit weight of soils that are classified as peat and the correlation is shown in Equation (2). This figure illustrates a linear relation where the range is [10, 12] kN/m³, the R^2 is moderate and the S_y=0.265 kN/m³. This correlation is only applicable with prior knowledge of the soil type and cannot be used for organic clays. The accuracy is however better than Equation (1).

$$\gamma_{sat;peat} = 0.000685 \cdot q_t + 10.1 \qquad (2)$$

Where $\gamma_{sat,peat}$ is the saturated unit weight of peat in (kN/m³) and q_t is the corrected cone resistance in (kN/m²).

Figure 9 presents the specific gravity versus the friction ratio. Figure 10 presents the organic content versus the friction ratio. Both correlations confirm that the unique soil properties are reasonably correlated with the friction ratio with a high R². However, the large variation S_y makes these correlations less useful in practice.

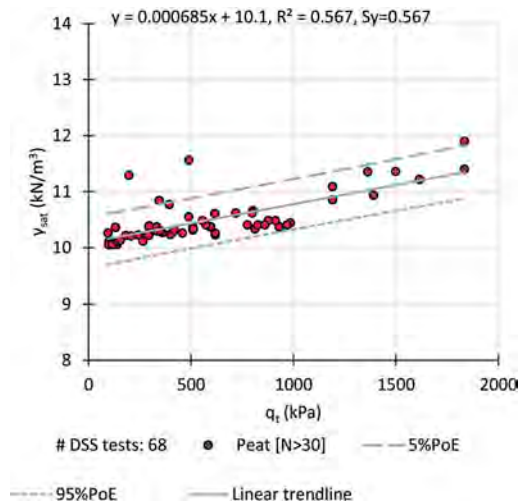

Figure 8. Saturated unit weight versus CPT corrected cone resistance, for soils classified as peat.

Figure 9. Specific gravity versus CPT friction ratio, for organic to mineral soils. The subcategories are indicated in the legend. The best linear fit is: $G_s = -0.147R_f + 2.88$ with standard deviation Sy=0.227.
507

Figure 10. Organic content versus CPT friction ratio, for organic to mineral soils. The subcategories are indicated in the legend. The best linear fit is: $N = 10.5R_f - 17.6$ with standard deviation Sy=17.0.

4 CONCLUSIONS AND RECOMMENDATIONS

The pairwise established database of classification test results and CPT measurements provides valuable insight into the properties of organic soils as well as new and updated correlations.

The existing unit weight correlation is validated and improved by the extension of the 2018 database with organic soils resulting in 427 pairs. The statistical parameters of the improved CPT-based unit weight correlation are compared with existing correlations and show better performance. The advantage of the improved correlation shown in equation 1 is that it can be applied for organic soils and mineral sedimentary soils. This is useful for SBT classifications which include stress correction. Specifically, for soils which are classified as peat, equation 2 can be used with even higher accuracy.

The 2021 database confirms existing relations between the organic content and other index parameters. Furthermore, the organic content and specific gravity can be correlated to the CPT friction ratio. Both correlations confirm that the unique soil properties are reasonably correlated with the friction ratio.

The correlations allow for establishing prior estimates where no laboratory tests are available. The disadvantage of this approach is that it increases inherent variation along the trend and the possibility that site specific units are biased to the trendline.

The confidence interval and standard deviation are provided to account for such bias. For final estimates of soil parameters, it is recommended to combine these correlations with sampling and testing of site-specific geological units.

In general, it is highly recommended to perform CPTs adjacent to boreholes, select pairs of high-quality laboratory tests according to a standardized protocol (STOWA). This will allow for new or improved correlations which will improve prior estimates.

ABSTRACT: An updated CPT-based classification system of organic clays and peat is proposed based on an extensive pairwise established database of classification tests and CPT measurements. This new classification system is proposed to supplement the existing dimensionless q_t/p_a-Rf-chart of Robertson (2010). The Robertson (2010) dimensionless classification system is selected for refinement because it appears to perform better than normalized systems for peats with very low stresses (<20 kPa). A combination with Robertson (2009 and 2016) is possible in cases where a stress normalization cut-off is used.

1 INTRODUCTION

1.1 *Application of CPTs in dike projects*

To successfully plan, design and construct a geotechnical project, various types of investigative techniques to obtain sufficient geotechnical information are required. Geotechnical field investigations generally comprise boreholes with sampling and in-situ cone penetration tests, performed with a friction cone penetrometer (CPT) or with a piezocone penetrometer (CPTU).

The use of CPTs in the design of dikes in the Netherlands has increased over the years. On a typical dike project, CPTs are performed typically every 100m along the center line and supplemented with 3 CPTs and 1 borehole along a cross section every 200m. The number of CPTs is typically 5 times greater than the number of boreholes. This is due to the relative costs and the increased possibilities associated with the use of CPTs.

1.2 *CPTs in organic soils*

Cone penetration testing has become increasingly popular as the preferred in-situ test method as it can be used for soil classification, estimation of geotechnical parameters and use in empirical methods. The initial soil texture-based classifications were based on direct measurement of cone resistance (q_c) and sleeve friction (f_s) e.g. Begemann (1965). The current CPT-based classification systems are based on behavior characteristics and are often referred to as

a Soil Behavior Type (SBT) classification. These classification systems include pore pressure measurements from CPTU tests and the shear wave velocity from SCPT tests, e.g. Robertson (2016). Examples of CPT based empirical methods can be found in the Eurocode (EN1997-1, 2005, EN1997-2, 2007), where the cone resistance is used for the estimation of soil strength. In addition, there is a wide range of publications on CPT based estimation of geotechnical parameters. A comprehensive overview can be found in Kulhawy and Mayne (1990), (Lunne et al., 2002, Mayne, 2014).

To date, most published research in the field of CPT application is on mineral soils. Existing CPT-based correlations for mineral clays do not properly capture the behavior of organic clays and peats compared to other soils. The properties of peats have been investigated and extensively published, i.e., Den Haan (1997), (Mesri and Ajlouni, 2007). However, limited attention has been devoted to the whole range of slightly organic clay to peat, and how this relates to CPT measurements. These organic soils are frequently present within the Holocene deposits in the Netherlands and in other deltaic areas worldwide. Organic soils are characterized by a low unit weight and high compressibility. Organic soils can be identified by a high organic content and high CPT friction ratio. In contrast to other soft soils, the shear strength is not necessarily low.

1.3 *Aim of this publication*

The aim of this publication is to improve the applicability of CPTs for organic soils. To achieve

this, results from soil investigations from dike reinforcement projects across the Netherlands have been collected. CPTs and boreholes that were performed in proximity of each other have been selected. The laboratory tests results and CPT measurements were taken at the same level, paired, and processed into a regional database. In this paper an improvement for CPT based classification systems for organic soils is proposed.

1.4 Research approach and databases

This research combines an existing database (Lengkeek et al., 2018) and a new compiled database for organic soil properties, referred to as the 2021 database. The 2018 database includes the sample unit weight and Class 2 CPTs of Holocene and Pleistocene sedimentary deposits in the Netherlands. An overview of the locations and number of CPT-borehole pairs is presented in Figure 1.

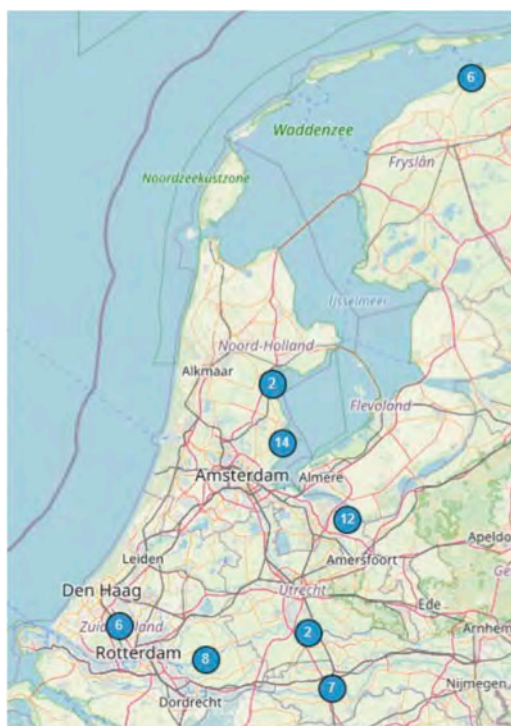

Figure 1. Overview of 57 CPT-borehole pair locations in the Netherlands.

The 2021 database includes soil investigations from various dike reinforcement projects across the Netherlands. The 2021 database includes classification laboratory tests and Class 1 CPTs of Holocene organic clays and peats. The CPT data is taken from the same level as the samples, with a maximum allowable distance between borehole and CPT of 1 meter. These soil investigations were performed in the period 2010-2020. Recently, the Dutch Water Authorities required that all new soil investigations be performed according to a dedicated protocol for dikes, summarized in a standardized STOWA Excel sheet (www.help deskwater.nl). The CPTs are standardized in GEF format. These standardized formats are very useful and efficient to set up a comprehensive database. The data of this research is available in the Delft University of Technology repository and published in Lengkeek (2022).

2 CLASSIFICATION OF ORGANIC SOILS

2.1 Laboratory classification

Existing classification systems are based on geomorphology, topography, chemical properties, botanical origin, genetic processes, or physical characteristics. From a geotechnical engineering perspective, the physical characterization is the most relevant. Several classification systems for organic soils are used in various countries and are based on similar grounds. In many cases, a certain degree of humification Von Post (1922) is used for the classification of peat, together with the normal geotechnical parameters, such as water content, Atterberg limits, organic content, bulk density etc. Understanding the stratification and properties in a soil profile is made easier if the geological history and the environmental conditions at deposition of the sediments are known.

Examples of classifications for geotechnical engineering can be found in Landva et al. (1983), (NEN5104, 1989, Huang et al., 2009, ISO14688-1, 2017, ISO14688-2, 2017, Von Post, 1922). Both the term 'organic content' and 'ash content' are used to identify organic soils. The classification systems differ, in particular for organic content in the range [20,50] %, where peats and organic clays overlap.

2.2 CPT-based classification methods

CPT-based classification methods provide two-dimensional charts for soil type classification based on the CPT measurements. These charts were developed through direct correlation between the CPT data and the corresponding soil type determined from adjacent borings. The initial soil texture-based classifications were based on direct measurement of cone resistance and sleeve friction (Begemann, 1965, Schmertmann, 1978).

Robertson et al. (1986) developed a non-normalized soil behavior-based classification, initially with 12 zones. In Robertson (2010) this is updated to 9 zones based on dimensionless cone parameters (q_t/p_a, R_f) and the non-normalized SBT-index I_{SBT}. Robertson (1990) presented the normalized soil behavior classification for 9 zones based on the linear normalized cone parameters (Q_{t1}, F_r, B_q). The soil behavior type index I_{c1} is added to this in Robertson and Wride (1998). In (Robertson, 2009,

Zhang et al., 2002) the classification system SBTn is adjusted with a variable stress exponent n and non-linear normalized cone resistance Q_{tn} and nonlinear SBT-index I_{cn}.

Since 1990, more CPT soil behavior-type charts have been developed including (Been and Jefferies, 1993, Eslami and Fellenius, 1997, Schneider et al., 2008). In Robertson (2016) a modified SBT classification system is presented with 7 zones and charts based on Q_{tn} versus the small-strain rigidity index I_G and versus the normalized pore pressure U_2. Furthermore, a new hyperbolic shaped modified SBT-index I_B is introduced.

Existing CPT based classifications generally relate to mineral soils which are present worldwide. The major disadvantage of existing CPT based classification methods is that the classification of organic soils is inaccurate. In many cases a peat layer is classified as clay (SBT=3) instead of organic material (SBT=2). Furthermore, it does not distinguish between peats and organic clays. Engineering of dike projects in the Netherlands, where peat is often present, is therefore mostly based on local experience or the non-stress normalized q_t/p_a-Rf chart of Robertson (2010). CPTUs are generally performed; however, the pore pressure classification charts are not used due to the presence of gas in organic soils, which causes a reduced and unreliable pore pressure response.

2.3 *Organic soil type categories*

The 2021 database includes classification tests according to different standards and systems (NEN, EN, ISO).The organic content is measured for most samples. The fine grained soils are classified according to one system: FHWA (Huang et al., 2009). The FHWA classification system is based on the organic content measured by the loss on ignition (N) and consists of the following soil categories:

– mineral fine-grained soils: N≤3%.
– mineral fine-grained soils with organic matter: 3<N≤15%.
– organic fine-grained soils: 15<N≤30%.
– peats: N>30%.

For samples where the organic content is unknown, the classification is based on the unit weight; Peat: $\gamma_{sat} \leq 12$, Org.Clay: $12 < \gamma_{sat} \leq 14$, Clay (org.mat): $14 < \gamma_{sat} \leq 17$, Clay (mineral): $\gamma_{sat} > 17$, all in kN/m³.

3 UPDATED SBT ZONES FOR ORGANIC SOILS

3.1 *Stress normalization*

The samples of the combined database (2018 and 2021) are taken from 0.5 to 15m depth and effective vertical stresses in the range of 5 to 150 kPa. For situations with the presence of peat layers and high-water

tables, stresses are sometimes less than 20 kPa at 10m depth. Therefore, care should be taken with CPT-based classifications that include stress normalization, as illustrated in the following example.

A peat layer below a dike with a high stress level of about 100 kPa is originally classified as SBT=2 (Robertson, 2010) and SBTn=2 (Robertson, 2009), but the same peat layer beside the dike with a low stress of 20 kPa moves up to SBTn=3 and will be classified as clay. This second classification is not correct as the soil type is the same, but only the stress state is different. Consequently, the soil profiling beside the dike can be incorrect, and the wrong parameters will be appointed to this layer. In this example, the normalized cone resistance Q_{tn} is 5 times higher than Q_t. These high stress corrections are not included in the international databases where most of the stresses are typically in the range of 50 to 300 kPa.

Particularly for dike projects there is a second argument not to apply a large stress correction. The peat layers beside the dike are generally over-consolidated by an OCR of 2, due to a combination of water level changes and aging. The same peat layer below the dike, which has been raised periodically, is only slightly over-consolidated. As the cone resistance is related to the preconsolidation stress more than the vertical effective stress, the actual stress correction should be about 2 to reflect the state properties.

The proposed adjustments to the SBT charts, as will be presented in the next paragraphs, are valid for the non-stress normalized SBT chart (Robertson, 2010) and the stress-normalized SBT chart (Robertson, 2009) with the application of the stress normalization cut-off $C_n \leq 2$.

3.2 *Proposed SBT adjustment*

This paragraph presents the adjustment to the SBT classification for organic soils, such as those encountered in deltaic areas in the Netherlands. The results from the combined database are plotted on the (Robertson, 2010) template in Figure 2. The soil categories consist of the categories in Table 1, including one category for sand.

The data coincides to a large extent with SBT zones, which is expected for the mineral soils. A few datapoints coincide with SBT=1 (sensitive soils) and no points coincide with SBT=7, 8 and 9. Soils of SBT=7 can be present in Pleistocene sand deposits and gravelly deposits, which are present along the river Meuse in the South of the Netherlands. Soils of SBT=8 and 9 are not expected in a deltaic area up to 15 m depth.

There are major differences in SBT=2 and 3, where a significant amount of organic soils plot in SBT=3. The performance results based on the existing Robertson (2010) classification of organic fine-grained soils are presented in Table 2. It is concluded that most of the organic soils, including most of the peats, plot in

SBT=3 ($I_c \leq 3.6$). The performance is about the same for I_{cn} based on stress normalization including $C_n \leq 2$. Without the C_n cut-off almost all points plot outside of SBT=2.

Table 1. CPT results of 2018 and 2021 database.

| Soil type	average		range	
	q_t	R_f	q_t	R_f
	(MPa)	(%)	(MPa)	(%)
Peat [N>30]	0.5	7.8	0.1 - 1.8	3.2 - 11.0
Org. Clay [15<N≤30]	0.4	3.8	0.1 - 0.9	1.0 - 9.6
Clay (org.mat) [3<N≤15]	0.6	2.5	0.1 - 2.1	0.6 - 6.5
Clay (mineral) [N≤3]	1.7	2.4	0.2 - 5.1	1.1 - 4.6
Sand	10.2	0.9	2.2 - 33.1	0.4 - 1.9

Figure 2. 2018 and 2021 database results and proposed SBT adjustment for organic soils, presented on top of Robertson (2010) SBT template.

Table 2. Performance results for organic soils based on existing Robertson (2010) SBT classification. Percentage is number of samples per category plotted in a SBT zone.

SBT zone: Soil type	SBT2 (Ic>3.6)	SBT3,4 (Ic≤3.6)
Peat [N>30]	35%	65%
Org. Clay [15<N≤30]	21%	79%
Clay (org.mat) [3<N≤15]	6%	94%
Clay (mineral) [N≤3]	0%	100%

Table 3. Performance results for organic soils based on proposed adjustments to Robertson (2010) SBT classification.

SBT zone: Soil type	SBT=2a	SBT=2b	SBT=2c	SBT=3, 4
Peat [N>30]	**78%**	15%	1%	4%
Org. Clay [15<N≤30]	16%	**42%**	40%	2%
Clay (org.mat) [3<N≤15]	3%	22%	**38%**	37%
Clay (mineral) [N≤3]	0%	11%	3%	**86%**

The proposed adjustment is that SBT=2 and part of SBT=3 are redefined and split up into SBT=2a (Peat), 2b (Organic Clay) and 2c (Mineral Clay, with organic matter). No adjustments are proposed to the boundaries between SBT=3, 4 and higher. This is also not possible as this database does not distinguish between silts and clays due to the lack of Atterberg limits tests. Most of the classified points plot in the correct SBT zone when using the proposed adjustment, although there is still some overlap with the adjacent SBT zones. The selection of the boundaries is determined by maximizing the group of positives and minimizing the number of false positives and false negatives.

In addition, the boundaries are selected to separate over-consolidated organic soils from over-consolidated plastic clays, such as Pot clay (Pleistocene) and Boom clay (Oligocene) encountered in the Netherlands. The maximum cone resistance occasionally measured in peats at high stress levels is about 2 MPa. This results in a rather sharp transition from SBT=2a to SBT=3. The new boundaries are extended to a friction ratio of 20%, which is occasionally measured in peats at low stress levels.

The performance results are presented in Table 3. It is concluded that majority (78%, 86%) of the classified points in SBT=2a, 3, 4 are correct. For SBT=2b and 2c, it is concluded that a significant number of points plot in the adjacent SBT zone but still the largest subgroup (38%, 42%) complies with the proposed SBT zone. The number of false positives outside of the adjacent SBT zones is less than 5%.

The formulation for the new proposed boundaries is shown in Equation (1). The parameter values are shown in Table 4.

$$q_t/p_a = a\left(R_f - R_{f,min}\right)^b \qquad (1)$$

Figure 3 presents a CPT according to the adjusted classification system. From the borehole and samples, the following layers are identified: organic clay from surface, soft clay with organic material

Table 4. Parameter values for boundaries of proposed adjustments to Robertson SBT (2010) and SBTn (2009) classification.

SBT & SBTn boundary: Parameter	SBT=2a	SBT=2b	SBT=2c
a (-)	8.0	5.2	4.7
b (-)	0.50	0.62	0.64
$R_{f,min}$ (%)	5.2	2.3	0.60

(-1.5 m NAP), peat (-2.0 m NAP), sand (-4.3 m NAP). The layers are well captured except that based on the CPT classification an intermediate layer is shown between the peat and sand layer, which is likely a transition effect.

Figure 3. CPT LKMP33 at Eemdijk the Netherlands classified with the proposed system to include soils.

The proposed boundaries are optimized such that they can also be applied as adjustment to (Robertson, 2009, Robertson, 2016), in combination with a stress normalization cut-off equal to $C_n \leq 2$. The parameters in Equation 1 are replaced by Q_{tn} and F_r. These boundaries for organic soils do not apply if there is no stress normalization cut-off applied. The results of the 2021 database are plotted in Figure 4 on top of the combined 2009 and 2016 template. In this figure $C_n=1.7$ is applied in line with recommended practice by (Boulanger and Idriss, 2016). The mineral clays and sands are not included, as not all stresses required for normalization are known. Most

Figure 4. 2021 database results and proposed SBT adjustment for organic soils, presented on top of Robertson (2009 & 2016) SBT template.

points plot in the CC category, contractive clays, although quite some points plot in the CCS, contractive clays sensitive, category which is larger than the SBT=1 (2009) category. A few points plot in the CD category, dilative clays. Those points correspond to the organic soils with high stresses or large over-consolidation.

4 CONCLUSIONS AND RECOMMENDATIONS

This publication presents the challenges in CPT-based classification of organic soils. One of the challenges is that the identification and estimation of unit weight for organic clays and peats from CPT data is often in accurate using existing methods.

The coarse grained and fine-grained soils classified as mineral soils correspond well with existing SBT classifications. The organic soils, classified according to the FHWA method, do not match well with the SBT classification. In the proposed adjustment to Robertson (2010), SBT=2 (Organic soils) and SBT=3 are redefined and split up into SBT=2a (Peat), SBT=2b (Organic Clay) and SBT=2c (Mineral Clay with organic matter). The classification is based on data pairs up to 15 m depths and 150 kPa vertical effective stresses. The new SBT zones can also be applied in the SBTn classifications by Robertson (2009) and (Robertson 2016) in combination with a $C_n=1.7$ as stress normalization cut-off.

In general, it is highly recommended to perform CPTs adjacent to boreholes, select pairs of high-quality laboratory tests according to a standardized protocol (STOWA). The pairwise established 2021 database of classification test results and CPT

measurements provides valuable insight in the properties of organic soils and an improved classification system.

Shear wave velocity – SCPTU correlations for sensitive marine clays

M. Long
School of Civil Engineering, University College Dublin (UCD), Ireland

J.-S. L'Heureux
Norwegian Geotechnical Institute (NGI), Trondheim, Norway

ABSTRACT: The purpose of this paper is to encourage the use of the seismic cone penetrometer (SCPTU) in soil characterisation studies. There has been an increase in use of shear wave velocity (V_s) data in geotechnical engineering. This has been prompted by improvements in measurement and analytical systems. A significant advantage, as is confirmed here, is that V_s can be measured easily and repeatedly by several different techniques in the sensitive marine clays under consideration here. Here the focus is on the derivation of preconsolidation stress (p_c') from V_s. A rational method of determining a V_s/p_c' relationship is outlined with resorting to empirical data analysis. The proposed relationship is shown to work well for Canadian sensitive clay data as has been shown previously for Norwegian and Swedish clays

1 INTRODUCTION

There has been increasing recent use of shear wave velocity (V_s) measurements in geotechnical engineering practice. This has been driven by advances in cost effective and efficient methods of determination of V_s. Traditionally V_s measurements were used for seismic and dynamic analyses. However, they are being increasingly used for site characterisation studies, determination of soil parameters, foundation settlement analyses, assessment of sample disturbance and in the quality control of ground improvement schemes.

This paper focuses on the use of V_s values to provide first order estimates and quality control checking of some geotechnical properties of sensitive marine clays. Unfortunately, it has been shown that different forms of the correlation equations have been developed in different areas. It appears that local correlations are necessary for satisfactory use of the technique as demonstrated for example by L'Heureux and Long (2017), Duan et al. (2019) or Elbeggo et al. (2021). In this paper data for clays in eastern Canada will be examined and compared with similar clays in Norway and southern Sweden. The marine clays of these three countries have similar properties and share a comparable geological depositional environment.

The V_s profiles and basic soil properties in these areas will be studied to investigate any systematic differences and links between the V_s measurements. Focus will be then placed on use of V_s to determine the important preconsolidation stress (p_c') parameter. It is hoped that that this work can lead to a unification of these important practical relationships.

2 V_S MEASUREMENTS

2.1 *Invasive methods*

Geophysical methods can be divided into two categories: invasive and non-invasive. Common invasive methods include down-hole logging, cross-hole logging, suspension logging, seismic dilatometer (SDMT) and the seismic cone penetration test (SCPTU). In Scandinavia and Canada most invasive testing is done with the SCPTU.

A standard CPT is equipped with one or more seismic sensors. The seismic signals are only recorded during pauses in penetration, commonly every 0.5 or 1.0 m. A horizontal beam coupled to the ground surface by the weight of the testing vehicle is the source of the seismic energy. The beam is struck on end with a hammer to generate shear waves. V_s is determined from the travel-time differences along the assumed travel path length for receiver depth.

2.2 *Non-invasive methods*

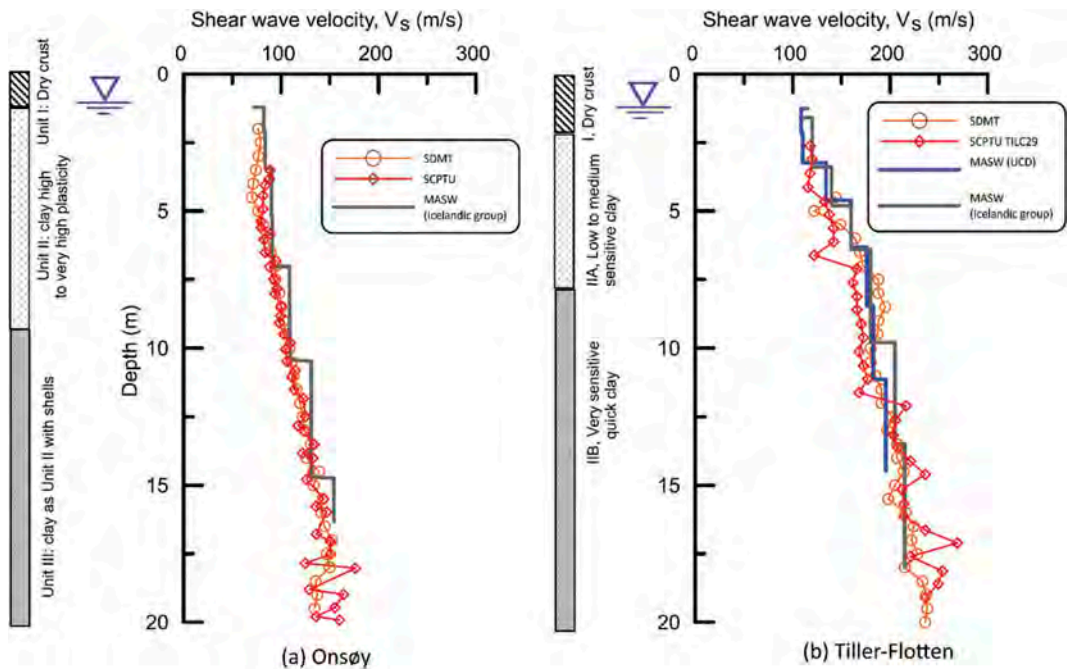
Of available non-invasive geophysical methods, perhaps that most widely used in Scandinavia and Canada is the multichannel analysis of surface waves (MASW) technique. This technique was introduced in the late 1990s by the Kansas Geological Survey (Park et al., 1999). This method utilises the dispersion property of surface waves for the purpose of V_s profiling. Some further details on the use and validation of the MASW technique in Norwegian clays can be found in L'Heureux and Long (2017).


Figure 1. (a) V_s profiles Onsøy site. Data from Gundersen et al. (2019) and Icelandic group MASW from Ólafsdóttir et al. (2019) and (b) Tiller-Flotten. SDMT and SCPTU No TILC29 data from L'Heureux et al. (2019) and MASW from Icelandic Group from Ólafsdóttir et al. (2019).

2.3 *Comparison of V_s measurements using different techniques*

Between 2016 and 2019, NGI and its partners established five National GeoTest Sites (NGTS) in Norway for testing and verifying innovative soil investigation methods and foundation solutions (L'Heureux et al., 2017). Two of the sites at Onsøy and Tiller-Flotten are underlain by soft sensitive marine clays. The soils at Tiller-Flotten can be classified as quick below a depth of about 8 m using laboratory Swedish fall cone data. V_s profiles have been made with several techniques at these two sites, see Figures 1a and 1b.

The profiles from SCPTU, SDMT and MASW at the two sites are very similar. The V_s values at Onsøy are significantly less than those at Tiller-Flotten. The reasons for this will be explored below.

3 V_S PROFILES FROM NORWAY, SOUTHERN SWEDEN AND EASTERN CANADA

Several V_s profiles from a series of selected sites in Norway are shown on Figure 2a. The sites are from several areas of the country including southern Norway, the area around Trondheim and northern Norway. Measurements were made using a variety of techniques as discussed above. In general the V_s profiles are very similar and show V_s increasing approximately linearly with depth from about 125 m/s at the

surface to about 225 m/s at 20 m depth. The Tiller-Flotten data falls within this general trend. An exception to the trend is the data from Onsøy where the values of V_s are significantly lower though they do show a clear tendency for an increase with depth.

A similar set of data from Southern Sweden is shown on Figure 2b. Again all values are very similar but here they are much lower than the Norwegian measurements with V_s increasing from some 50 m/s near ground level to 125 m/s at 20 m depth. In fact the Swedish data is very similar to the Onsøy profile.

A compilation of available Eastern Canadian data is shown on Figure 3. Many of the profiles fall within the bounds of the Southern Sweden sites. An exception is the profile from the Quyon Landslide site and perhaps the City of Ottawa data.

4 COMPARISON OF PROPERTIES OF CLAYS FROM THE THREE COUNTRIES

A summary of the key properties of the clays from the three countries is given on Table 1. For this purpose typical sites have been chosen, namely Göteborg Central Station from Southern Sweden, St. Alban from Eastern Canada as well as the two NGTS sites at Onsøy and Tiller-Flotten from Norway.

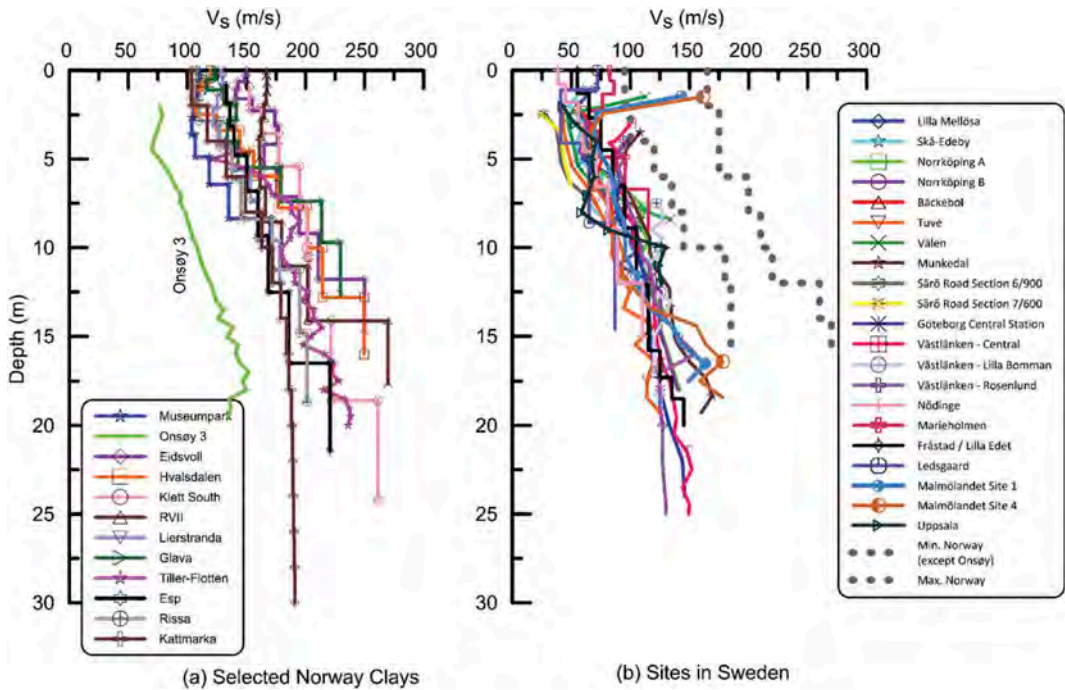
The Tiller-Flotten site (and generally many of the Norwegian sites) are significantly different from the other sites.


Figure 2. (a) V_s profiles for selected Norwegian sites. Data from L'Heureux and Long (2017) and this paper and (b) for Swedish clays from Long et al. (2017) and Long and D'Ignazio (2020).

Figure 3. V_s profiles for Eastern Canadian sensitive clays Data from Bouchard et al. (2017), Lefebvre et al. (1994), Leroueil et al. (2003), Mayne et al. (2019), Fabien-Ouellet et al. (2014), Motazedian et al. (2011), Elbeggo et al. (2021) and Agaiby (2018).

These Norwegian sites have relatively lower water content and plasticity and higher density ($1.7 - 1.9$ Mg/m^3 compared to $1.6 - 1.7$ Mg/m^3) than the Canadian and Swedish sites. Also Tiller-Flotten has very low organic content compared to the other sites. The Onsøy site parameters are much closer to those of the Swedish and Canadian sites. All sites under consideration have similar clay content and stress history.

Table 1. Summary of material properties for the study sites: w = water content, I_p = plasticity index, Org. = organic content OCR = overconsolidation ratio, S_t = fall cone sensitivity. Main references Gundersen et al. (2019), L'Heureux et al. (2019), Wood (2016) and Trak et al. (1980).

| Site	W (%)	Clay (%)	I_p (%)	Org. (%)	OCR	S_t
Onsøy	40-80	50-70	25-50	2.5-4	1.1-2.0	5-8
Tiller-Flotten	30-50	45-70	8-20	Very low	1.5-2.0	up to 350
Göteborg CS	60-90	70-90	27-40	2-5	1.5-2.0	12-30
St. Alban	60-90	45-81	5-30	0.9	2.2	14-22

Figure 4. Normalised V_s profiles (a) by vertical effective stress and (b) preconsolidation stress.

5 NORMALISATION OF V_S VALUES

5.1 Normalisation by vertical effective stress

According to Hight and Leroueil (2003) and Hardin (1978) the controlling factors on V_s are primarily functions of soil density, void ratio, and effective stress, with secondary influences including soil type, age, depositional environment, cementation and stress history. It is logical then to attempt to harmonise the V_s profiles by normalising them with respect to in situ vertical effective stress (σ_{v0}'). Here the normalised parameter V_{sn} is determined from as follows:

$$V_{sn} = \frac{V_s}{\left(\frac{\sigma_{v0}'}{p_a}\right)^n} \qquad (1)$$

Mayne et al. (1998), Robertson (2009) and others have chosen n = 0.25 based mostly on laboratory data on silica sands. Here a value of 0.5 has been chosen. Data from the four selected study sites normalised as above are plotted against depth on Figure 4a. Although the normalisation brings the values from the four study sites closer together there are still significant differences between the values especially those of Tiller-Flotten and St. Alban below about 4 m. The value of n was altered but no improvements in the relationships were observed.

5.2 Normalisation by preconsolidation stress

To take the stress history of the materials into account the measured V_s data have been normalised by the preconsolidation stress (p_c') on Figure 4b. A form of normalisation very similar to that expressed in Equation 3 has been used as follows:

$$V_{s2} = \frac{V_s}{\left(\frac{p_c'}{p_a}\right)^{0.5}} \qquad (2)$$

Unfortunately, as is well known, p_c' can be heavily influenced by sample disturbance effects and by the method used to determine p_c' from the measured oedometer tests data. To deal with the issue of sample disturbance the sites have been chosen where very high quality samples are available. Data from Sherbrooke block or mini-block samples were available for all four sites. The Casagrande (1936) technique was used to determine p_c' at three of the sites with the Janbu (1969) approach being used for the Göteborg Central Station site. No correction has been applied to the p_c' data. The reported values have been used and compared directly to V_s measurements at the same depth.

As can be seen on Figure 4b this form of normalisation was very successful in harmonising the four sets of data. All four profiles are very similar and show an average V_{snp} value of about 100 m/s. Taking this average V_{snp} value the following equation can be obtained to relate V_s and p_c'.

$$p_c' = 0.01 V_s^2 \qquad (3)$$

This form of power equation supports and justifies some previous similar empirical equations that have been developed. These include the general relationship developed by Mayne et al. (1998) as shown on Equation 4, that derived for Norwegian marine clays by L'Heureux and Long (2017) (Equation 5) and by Duan et al. (2019) for Jiangsu clays in China (Equation 6)

$$p_c' = 0.106 V_s^{1.47} \qquad (4)$$

518

Figure 5. Relationship between V_s and p_c' for Eastern Canada clays. Data from Lefebvre et al. (1994), Tavenas and Leroueil (1979), Leroueil et al. (1983b), Landon (2007), Leroueil et al. (1983a), Lo et al. (1976), Bozozuk (1972), Hamouche et al. (1995), Leroueil et al. (2003), Tanaka et al. (2003), Bouchard et al. (2017) and Burnotte et al. (2004).

$$p_c' = 0.00769 V_s^{2.009} \qquad (5)$$

$$p_c' = 0.1097 V_s^{1.3575} \qquad (6)$$

6 V_S-P_C' RELATIONSHIP FOR EASTERN CANADA CLAYS

Available V_s and parallel p_c' data for Eastern Canada clays is shown on Figure 5. This data should be treated with caution as it comes from several sources and it is possible different sampling techniques, testing techniques and methods of deriving p_c' may have been used. The data is shown merely to illustrate the application and usefulness of Equation 5 and suggests further work on this approach is well warranted.

7 CONCLUSIONS

The purpose of this paper was to highlight some advantages in the use of V_s values in soil characterisation studies and to therefore encourage the use of the

SCPTU device. The particular focus here was the derivation of p_c' from V_s data for sensitive marine clays. It was shown that despite V_s profiles for marine clays from different countries being often different, normalisation by p_c' harmonises the different profiles. A rational method, without resorting to empirical correlations, is outline for the derivation of a formula which relates V_s and p_c'. The derived formula is tested successfully on a set of data for Canadian marine clays. More sites should be included in the relationship shown on Figure 4b to study the likely variation in the values determined.

A simplified method to incorporate the benefits of microstructure for cyclic liquefaction analyses using the SCPT

K. Lontzetidis
CMW Geosciences, New Zealand

P.K. Robertson
Gregg Drilling Inc., USA

D.J. Morton
CMW Geosciences, New Zealand

ABSTRACT: Cyclic liquefaction resistance of sand deposits can increase due to microstructure that results from several factors, such as aging and bonding. Available empirical correlations, using either SPT, CPT or shear wave velocity (V_S) data, were derived from cyclic liquefaction case histories that considered very young Holocene-age, essentially normally consolidated, unbonded, silica-based soils that may not apply to soils with significant microstructure. Seismic CPT (SCPT) data can be used to identify soils with significant microstructure, since both aging and bonding tend to increase the small-strain stiffness (reflected in the measured V_S) significantly more than they increase the large-strain strength of a soil (reflected in the CPT penetration resistance). Hence, for a given soil, both age and bonding tend to increase V_S more than the larger-strain cone resistance, all other factors (such as, in situ stress state, density, etc.) being constant. The normalized rigidity index (K_G) has been proposed (Robertson, 2016) as a parameter, that combines V_S and normalized CPT tip resistance (Q_{tn}), to detect and quantify the presence of microstructure. This paper presents and discusses a suggested method to quantify the increased resistance to cyclic liquefaction due to microstructure by utilizing K_G. Results will be presented from older soil deposits in New Zealand well as compare the results with existing correlations that account for "aging".

1 INTRODUCTION

Over the last 40 years, since the first simplified method to assess soil liquefaction potential was proposed by Seed and Idriss (1971), empirical methods have evolved to improve the reliability of predicting liquefaction triggering. Empirical correlations are based on either standard penetration test (SPT), cone penetration test (CPT) or shear wave velocity (Vs) data. The CPT is now the most commonly used in-situ test to evaluate liquefaction potential in liquefaction-prone areas. The main advantages of the CPT are the continuous and repeatable measurements that provide a detailed profile of the soil, as well as major developments in CPT-based liquefaction prediction methods that have occurred over recent years (e.g., Boulanger and Idriss 2014). A limitation of all liquefaction prediction methods is that they have been derived from cyclic liquefaction case histories that consider very young Holocene-age, essentially normally consolidated, unbonded, silica-based soils. Correlation of results from those case histories can therefore be conservative when applied to older or bonded soils. Pleistocene-aged soils (>12,000 years)

are considered to have a low risk of cyclic liquefaction (Youd and Perkins, 1978). Several researchers have worked to quantify the influence of the age on liquefaction potential through laboratory and in-situ testing (e.g., Seed 1979; Troncoso et al. 1988, Arango and Migues 1996; Arango et al. 2000; Robertson et al. 2000; Lewis et al. 2004, Lewis et al. 1999; Hayati and Andrus 2008).

The objective of this paper is to investigate an alternative method to estimate the potential positive effects of either age or bonding of a soil by utilizing the normalized rigidity index (K_G) proposed by Robertson (2016). Seismic CPT (SCPT) data from early to late Pleistocene-age soils in New Zealand (NZ) are used to evaluate the proposed method. The results using the proposed method are compared with another method also utilising seismic CPT data.

2 PREVIOUS STUDIES

Several researchers have established correlations between the age of a soil and the increase in liquefaction resistance (e.g., Seed (1979); Troncoso et. al

(1988); Lewis et al. (1999) Arango et al. (2000) Lewis et al. (2004) Leon et al. (2006) Hayati and Andrus (2008). Results show that there is an increase in liquefaction resistance with increasing soil age.

Andrus et al. (2009) proposed a ratio of the measured to estimated Vs (MEVR) to quantify the increase in resistance to cyclic loading of older soils. Saftner et al. (2015) presented a summary of past relationships, in terms of a Strength Gain Factor K_{DR}, for resistance to cyclic loading and age (Figure 1) and proposed a new relationship to account for geologic age by evaluating data from explosive compaction tests.

Figure 1. Relationship between strength gain factor (K_{DR}) and soil age based on data from explosive compaction tests and previous studies (After Saftner et al. 2015).

One limitation of a correction based on geologic age, it that past liquefaction events can modify the behavior of a soil so that its 'behavior age' is not the same as its geologic age. Hence, a correction based on behavior characteristics may have wider application.

3 MICROSTRUCTURE

Eslaamizaad and Robertson (1996) showed that it is possible to identify soils with significant microstructure (due to age, bonding or unusual mineralogy) using the SCPT based on a link between the ratio of small strain shear modulus (G_o), net cone resistance (q_n) and the normalized cone resistance (Q_{tn}), since both aging and bonding tend to increase the small-strain stiffness (G_o) significantly more than they increase the large-strain strength of a soil (reflected in Q_{tn}). Hence, for a given soil, both age and bonding tend to increase the small-strain shear wave velocity (Vs) more than the larger-strain cone resistance, all other factors (in situ stress state, etc.) being constant.

Robertson (2015) modified slightly the equation proposed by Schneider and Moss (2011) to identify soil microstructure. This was done by extending the link between the CPT and the V_S using the empirical parameter, K_G defined by:

$$K_G = (G_o/q_n) \ (Q_{tn})^{0.75} \qquad (1)$$

where G_o is in same units as q_n, Q_{tn} is dimensionless, and K_G is essentially a normalized rigidity index.

Most of the existing empirical correlations developed for the interpretation of CPT results are predominately based on experience in silica-based soils with little or no microstructure (e.g., Robertson 2009; Mayne 2014). Hence, if soils have $K_G < 330$, the soils are likely young and unbonded (i.e., have little or no microstructure) and can be classified as 'ideal' soils (unstructured) where most traditional CPT-based empirical correlations for liquefaction prediction likely apply. Soils with $K_G > 330$ tend to have significant microstructure, and the higher the value of K_G, the more microstructure is likely present. Hence, if a soil has $K_G > 330$, the soils can be classified as 'structured' soils where traditional generalised CPT-based empirical liquefaction prediction correlations may have less reliability and where local modification may be needed. The influence of increasing microstructure on in situ soil behavior is often gradual, and any separating criteria can be somewhat arbitrary. Data suggests that very young unbonded soils tend to have K_G values closer to 100, whereas soils with some microstructure (e.g., early Pleistocene-age) tend to have K_G values closer to 330. As will be shown later, soils with $K_G < 330$ tend to have little or no microstructure where empirical CPT-based liquefaction prediction correlations tend to provide good estimates of soil behavior.

4 STUDY AREA

4.1 Site description

The Ruakura site comprises an area of approximately 177 ha and is located at the intersection of Silverdale Road and Ruakura Road, in Hamilton, New Zealand. The land use has generally remained unchanged from agricultural practices since at least 1974 (circa). There are a few buildings/structures, which have occupied the land to service the agricultural operations (i.e., sheds, water tanks). The natural topography of the site is typically flat with minor undulations from historic stream channels. The elevation of the site ranges from RL 40.0 m to RL 42.0 m.

4.2 Geology

The published geological map (Edbrooke, 2005, Figure 2) indicates that most of the site is underlain by late Pleistocene-age river deposits of the Hinuera Formation (12,000-27,000yr) consisting of cross-bedded pumice sand, silt, and gravel with interbedded peat

(2Qa). Early to mid-Pleistocene-age river and igneous deposits of the Walton Group (27,000-2,000,000y) extend into the western part of the site and comprise a sequence of ignimbrites and tephra from several sources and fine-grained volcanoclastic alluvium (eQa). The north-eastern part of the site is indicated to be underlain by Holocene-age swamp deposits and peat of the Tauranga Group (0-12,000y), consisting of soft, dark brown to black, organic mud, muddy peat and woody peat with minor overbank sand, silt, and mud swamp deposits (Q1a).

Based on site specific CPT data, the mean I_c values for each geological formation are 1.9 for the Tauranga Group, 1.8 for the Hinuera Formation and 2.7 for the Walton Group.

4.3 Geotechnical investigation

Several phases of geotechnical investigation have been undertaken within the site over recent years. It was recognised that the soils at Ruakura are unlikely to fit the historical liquefaction database used to develop most empirical liquefaction prediction techniques due to:

1. The geologic age of the deposits found in parts of the site are older (Pleistocene-age) than the database (Holocene-age).
2. The Hinuera deposits are composed of unusual mineralogy (pumice) compared to the historical data base (silica-based soils).

The latest investigation included twenty-two (22) SCPTs. Factual data from those tests are presented in various geotechnical reports prepared by CMW. The SCPTs were undertaken to support the liquefaction analysis as well as to check for increased resistance to cyclic liquefaction of soils due to their age.

Figure 2. Geological map of the Ruakura site.

5 CORRELATION BETWEEN THE STRENGTH GAIN FACTOR AND K_G

Andrus et al. (2009) and Hayati and Andrus (2009) suggested a method using MEVR, to account for soil aging on the resistance to cyclic loading (CRR) using CPT and Vs results. Based on laboratory and field cases, they proposed a deposit resistance factor (strength gain factor, K_{DR}) to correct for age using:

$$K_{DR} = 1.08 \text{MEVR} - 0.08 \qquad (2)$$

to correct the cyclic resistance ratio, CRR_K due to the age of the deposit:

$$CRR_K = CRR_{CPT} \times K_{DR} \qquad (3)$$

where CRR_{CPT} is the CPT-based CRR from case histories for young Holocene-age deposits. The measured V_S is computed from in-situ distance and travel time measurements using the SCPT and the estimated V_S can be obtained for sands by the following equation:

$$V_{s1,E} = 62.6 \left(Q_{tn,cs} \right)^{0.231} m/s \qquad (4)$$

where $V_{s1,E}$ is the estimated shear-wave velocity corrected for overburden pressure and $Q_{tn,cs}$ is the normalized clean sand equivalent cone resistance.

Hayati and Andrus (2009) showed that the MEVR approach is based on a reference age of about 23 years for $V_{s1,E}$ which was considered a representative average age for the liquefaction case history database. Many of the liquefaction cases are associated with deposits that have a "behavioral age" (the time since the last critical disturbance or liquefaction event) not more than 100 years. Previous liquefaction (or even ground improvement implementation) is assumed to be a critical disturbance event when the grain-to-grain contacts were damaged and reformed.

A similar approach has been proposed by Robertson (2015) using the Schneider and Moss (2011) empirical parameter K_G following a similar measured to estimated K_G ratio defined by

$$MEK_G = K_{G,M}/K_{G,E} \qquad (5)$$

where $K_{G,M} = K_G$ based on measured values of Vs and qt, and $K_{G,E} = 200$ is the estimated average value for very young (~23 years), unbonded soils. Based on the definition of K_G [Eq. (1)], the MEK_G ratio is insensitive to changes in CPT q_t and $Q_{tn,cs}$ due to aging. Since q_t has been shown to be

relatively insensitive to aging and/or light bonding, it is reasonable to assume that,

$$MEK_G = MEVR^2 \qquad (6)$$

The advantage of using MEK_G is that it does not require the calculation of an estimated Vs, which has an associated uncertainty, especially in soils that are not clean sands. Hence, a similar approach can be applied using MEK_G instead of MEVR and apply Eqs. (2) and (6) to estimate the strength gain factor, K_{DR}.

6 DATA USED TO ESTIMATE SOIL MICROSTRUCTURE

The locations of the most recent twenty-two SCPTs undertaken as part of the project investigation are shown in Figure 3.

At each test location, shear wave velocity (Vs) measurements were undertaken at 1m intervals vertically. The CPT cone resistance data was then averaged over a depth of 0.5m above and below the relevant Vs measurement depth. From the Vs data and soil density (averaged within 1m zone), the maximum shear modulus (G_o) was calculated using the following.

Figure 3. Site plan showing the locations of the SCPTs.

$$G_o = \rho \, (Vs)^2 \qquad (7)$$

where ρ is the soil density in kgr/m^3.

Compiling the CPT data, the net cone resistance (q_n) and the normalized cone resistance (Q_{tn}), were calculated using the following two equations.

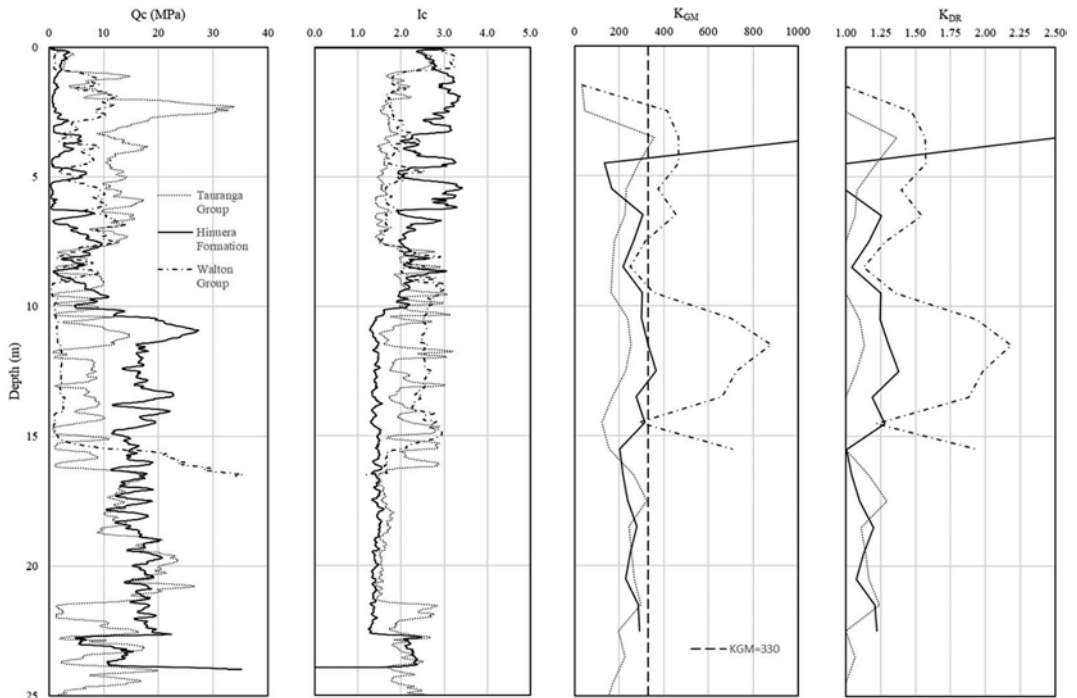

Figure 4. Typical examples of in-situ test results and the calculated values of K_{GM} and K_{DR}.
Figure 5. Comparison of the K_{DR} calculated using MEVR and $K_{G,M}$.

$$q_n = q_t - \sigma_{vo} \qquad (8)$$

$$Q_{tn} = \left(\frac{q_t - \sigma_{vo}}{P_{a2}}\right)\left(\frac{P_a}{\sigma'_{vo}}\right)^n \qquad (9)$$

where q_t is the corrected cone resistance, σ_{vo} the vertical total stress, P_a and P_{a2} are reference pressures (100kPa), σ'_{vo} is the effective vertical stress and n is the stress exponent that varies with I_c (Robertson & Cabal 2015).

Based on the above methodology, a set of small strain shear modulus (G_o), net cone resistance (q_n) and normalized cone resistance (Q_{tn}) data points were calculated at 1m depth intervals. By utilizing equation 1, the measured normalized

rigidity index (K_{GM}) was then calculated. Finally, by combining equations 2, 5 and 6, the strength gain factor (K_{DR}) was calculated using the following equation.

$$K_{DR} = 1.08\sqrt{K_{G,M}/K_{G,E}} - 0.08 \qquad (10)$$

And since $K_{G,E} = 200$ for very young (~23 years), unbonded soils, this is simplified to:

$$K_{DR} = 1.08\sqrt{K_{G,M}/200} - 0.08 \qquad (11)$$

Equation 11 presents the strength gain factor K_{DR}, as a function of the measured normalised rigidity index $K_{G,M}$ without the need to calculate a reference Vs value.

Figure 4 presents the results from three typical SCPTs, one for each geological formation encountered in the area, together with the calculated profiles of measured normalized rigidity index (K_{GM}) and the strength gain factor (K_{DR}). Figure 4 illustrates that the average K_{DR} value increases with the geological age of the soil deposits.

Figure 5 presents a comparison of K_{DR} values calculated by Andrus et al., 2009 using MEVR with those using $K_{G,M}$ as proposed in this study. This shows that the $K_{G,M}$ method estimates a K_{DR} value that is on average 10% lower than that using the MEVR method. It is also noted that at shallow depths, the K_{DR} values calculated from $K_{G,M}$ are higher than those calculated using MEVR, while this trend decreases with depth.

Figure 6 shows the cumulative frequency distribution of K_{DR} from each method ($K_{G,M}$ and MEVR) for

Figure 6. Comparison of the results of the K_{DR}, calculated using the proposed $K_{G,M}$, and MEVR for each of the three geological formations.

each of the three geological formations. The results indicate that the Holocene-age deposits of the Tauranga Group (Q1a), indicate little or no microstructure with 50th percentile $K_{DR}(K_{G,M})$ = 1.0, and K_{DR} (MEVR) = 1.1. The slightly older Hinuera Formation (2Qa) indicates some microstructure with 50th percentile $K_{DR}(K_{G,M})$ = 1.2 and $K_{DR}(MEVR)$ = 1.3. The older Walton Group (eQa), indicates more microstructure with 50th percentile $K_{DR}(K_{G,M})$ = $K_{DR}(MEVR)$ = 1.5. These results plot at the low range of the values presented in Saftner et al. 2015 (Figure 1) for the age of the Hinuera (2Qa) and Walton Group (eQa).

7 CONCLUSIONS

As part of the geotechnical investigation for the Ruakura Development in New Zealand a number of geotechnical investigation campaigns have been undertaken that included 22 SCPTs to support liquefaction analysis and to evaluate the increased resistance of older soils to cyclic loading.

This paper presents an alternate method to quantify the increased resistance to cyclic loading of soils due to microstructure, which can be readily implemented utilising SCPT data.

The results of the strength gain factor K_{DR}, by the proposed method using the normalised rigidity index, compare well with results using the MEVR.

The proposed method returns a rather low increase in resistance to liquefaction compared to other methods (see Figure 1).

Classification of Miocene deposits using CPT data

A. Makra
GR8 GEO, Athens, Greece

H. Kim
DL E&C Co. Ltd, Seoul, South Korea

ABSTRACT: Soil classification based on CPT data is commonly carried out using classification charts which link the type of soil behaviour to the measured tip resistance, sleeve friction and pore water pressure. These charts have been successful in interpreting soil behaviour in young, saturated, uncemented soil deposits but often diverge from observations in samples in older deposits. The geotechnical investigation conducted for the 1915 Çanakkale bridge included 20 offshore boreholes with 18 adjacent CPT soundings conducted downhole that penetrated several meters into Miocene-age sediments. This paper investigates those data sets and proposes a modified chart for the classification of the Miocene deposits accounting for their microstructure. The proposed modification is useful for classifying Miocene deposits in similar geological settings through the performance of CPTs.

1 INTRODUCTION

Cone Penetration Testing (CPT) is a very common in situ sounding tool used to collect geotechnical data at sites. The CPT provides a cost-efficient, fast and reliable method to obtain continuous soil profiles. The basic idea of the test is that a standardized cone is pushed into the ground at a constant penetration rate while the tip resistance, sleeve friction and pore water pressure are measured.

Several methods of soil classification have been developed to correlate CPT data to soil characteristics (Schmertmann 1978, Robertson 1990, 2009, Schneider 2008, Robertson 2016). Unlike the most common soil classification systems [ASTM D2487 (USCS), BSCS BS 5930] that are based on the physical properties of soils such as grain size distribution and plasticity index, CPT classification methods are based on behaviour characteristics and are generally described as Soil Behaviour Type (SBT) classification systems (Robertson 2016).

These CPT based classification charts have proven to be very efficient in predicting soil type in young (Quaternary) soil deposits. However, older soils with significant microstructure often require site specific modifications to the classification charts so that the effect of the microstructure on the CPT data is properly reflected in the SBT classification system (Robertson 2016).

Although the existing CPT database is extensive for younger and softer deposits, fewer data exist for Miocene sediments because the high stiffness and strength of the deposit typically precludes significant CPT penetration. This lack of data has limited the development of a globally accepted approach for interpretation of CPT data in Miocene sediments. However, evolutions in CPT techniques increasingly allow for achieving greater penetration in stiffer soils. An early interpretation of the ground profile in these stiffer soils using CPT based SBT classification systems can be very useful, especially at an early stage of project development.

In the 1915 Çanakkale bridge project area, a significant number of CPT soundings were conducted onshore, nearshore and offshore in combination with geophysical surveys, boreholes and other geotechnical in situ tests (SPT, wireline logging, etc.) and extensive laboratory testing.

In addition to seabed CPTs, the down-hole mode was adopted for offshore CPTs to be able to collect data from relatively stiff and competent materials. In contrast to onshore and seabed CPT testing where the cone is continuously pushed from the surface to refusal, down-hole CPTs are conducted within a borehole with typically 1.5 to 3.0m stroke lengths. Upon completion of the CPT, the portion penetrated by the cone is drilled out and the borehole is continued with either a subsequent CPT test or sampling (Figure 1).

In the 1915 Çanakkale Bridge project, down-hole CPTs were continuously advanced with drill outs to the depth where the material became too stiff for
Figure 1. Procedures for drilling, push sampling and CPT testing (modified after ISSMGE 2005).

Figure 2. CPT Classification Chart from Robertson (2009).
Figure 3. CPT classification chart from Robertson (2016).

CPT testing. Thus, a significant CPT data set of Miocene soils was collected from the site.

The identification of the Miocene deposits was primarily based on the interpretation of the geophysical survey data, which were also confirmed by borehole data. When CPT data associated with the Miocene deposits were interpreted, the classification based on the Robertson (2009, 2016) charts shown on Figures 2 and 3 was inconsistent with the observations and laboratory data obtained from borehole core samples - probably due to the significant microstructure of the Miocene. For instance, the CPT data obtained from Miocene mudstone were expected to fall within Zone 9: Very Stiff Fine Grained and CD: Clay like Dilative based on Robertson (2009, 2016) (Figures 2 and 3, respectively), but many CPT data points plotted outside of Zone 9, displaying a different trend. Thus, site-specific modifications of the chart were required for the Miocene sediments. This paper proposes a modified Robertson classification chart that can be used for the classification of fine grained heavily overconsolidated Miocene mudstones using CPT data based on the data set from the 1915 Çanakkale bridge project.
2 FRAMEWORK

The 1915 Çanakkale bridge is located between Gelibolu in East Thrace and Lapseki on the Biga Peninsula (Troas). The site investigation was conducted by Fugro (Fugro 2018a, b) and consisted of extensive geological, geophysical and geotechnical investigations. CPTs were performed onshore, nearshore and offshore. Although the onshore CPTs penetrated only a few meters into the upper (typically weaker) Miocene layers before experiencing refusal, offshore CPT using down-hole mode allowed for the continuation of testing beyond initial refusal and the collection of data deeper within harder strata. Although down-hole CPTs are discontinuous and require additional care in the execution and processing of the test results, they are an efficient method to collect CPT data in deeper strata or below a very stiff/dense layer where seabed CPTs would have refused. Offshore CPTs using down-hole mode are the main source of CPT data in Miocene units presented in this paper. Boreholes were drilled adjacent to the CPT locations to facilitate the interpretation and integration of the geotechnical data. The boreholes progressed with continuous sampling

in the soil layers and rotary core drilling in the rock and the samples were immediately processed at the site and onboard laboratories to minimize sample disturbance and to expedite data availability. In several of these explorations, after the completion of drilling, P-S wireline logging was conducted (Fugro 2018a).

3 RESULTS AND DISCUSSION

The bedrock of the project site consists of Miocene sedimentary rock of the Çanakkale formation, composed primarily of mudstones and sandstones with few siltstone, marl and limestone layers of limited thickness. The top of the Miocene geologic unit was initially interpreted from geophysical data and then refined locally by borehole and CPT data (Figure 4). The Miocene deposits are of the same origin as the overlying younger (Holocene and Pleistocene) layers, complicating the visual distinction between the stratigraphic units. Thus, the top of Miocene bedrock in the boreholes was identified based on the degree of cementation, structure (bedding, fissures) and strength of the material.

Figure 4. Geophysical and geotechnical cross section, Çanakkale Strait, Offshore, (Fugro 2018a).

CPT data were acquired only in Miocene mudstones with occasional thin sandstone interlayers. The CPT equipment was not able to penetrate through thick sandstone layers. The top of Miocene was characterized by a sudden increase in tip resistance, followed by increases in friction ratio and pore water pressure. Figure 5 presents typical tip, sleeve friction and pore water pressure traces of CPT data in Miocene mudstones. The tip resistance generally ranges between 5MPa and 25MPa and the friction ratio from 1.5 to 6%, with the lower friction ratio (less than 2%) corresponding to the thin sandstone interlayers.

Figure 6 shows CPT data collected from the Miocene deposit plotted on the Robertson (2009, 2016) classification charts. Most of the CPT data are plotted within Zones 4 and 5 of the chart as per Robertson (2009) and TD and CD as per Robertson (2016). However, the Zones 4 and 5 are described as having a mainly drained behaviour and being primarily coarse grained (Zone 4: Silt mixtures, Zone 5: Sand mixtures, refer to Figure 2 and Figure 6a). The TD and CD are described as dilative and mainly transitional material with smaller portion in the clay-like and sand-like range. Note that these descriptions showing the soil behaviour do not properly reflect the expected behaviour of the Miocene deposit.

A small fraction of the data (about 20%) are plotted within Zone 3 which corresponds to clays. CPT data plotted within Zone 3 are mostly located close to the boundary between Quaternary and Miocene deposits where the stiffness of mudstones/clays is low (*i.e.,* less than a few hundred kilopascals).

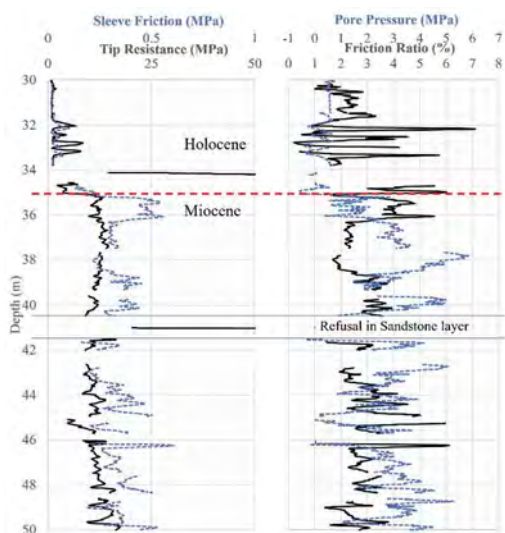

Figure 5. Typical CPT trace of Holocene and Miocene deposits from the European Tower explorations (CPT ID: ET-5).

Laboratory tests performed on mudstone samples showed fines contents exceeding 80% and an average plasticity index (PI) of 45, which is classified as fat clay (CH) per ASTM D2487. Based on the geotechnical descriptions of the boreholes with consolidation and strength tests (uniaxial compressive and UU triaxial strength values), the Miocene mudstones are lightly lithified, fresh, overconsolidated, with strengths ranging from extremely weak (<1MPa) to very weak (1-5MPa) rock per ISRM (2007) recommendations or hard clay (>0.2MPa) per the ASTM soil classification system.

Although the Miocene mudstone is classified as CH per USCS, the CPT classification chart incorrectly suggests that the material displays sandlike behaviour due to its relatively high normalized tip resistance caused by the effects of cementation and aging as well as overconsolidation.

Figure 7 shows a comparison of the CPT data from Holocene clayey deposits with the data from Miocene mudstones in the offshore European side of the Çanakkale bridge project. The CPT data from two deposits show that whilst the normalized friction ratios are similar, the normalized tip resistances are much higher in the Miocene deposits. As shown on Figure 7a, b, the CPT data obtained from Holocene deposits fall within Zone 3 (clay and clay-like contractive), and CC (Clay-like Contractive) and CCS (Clay-like Contractive Sensitive). Although the classification of Miocene deposits using the CPT data were inconsistent with sample descriptions and laboratory tests, the SBT classification using CPT data for the Holocene clayey deposits is consistent with the borehole and laboratory data, both of which indicate the Holocene deposit to be a soft to firm, near-normally consolidated clay.

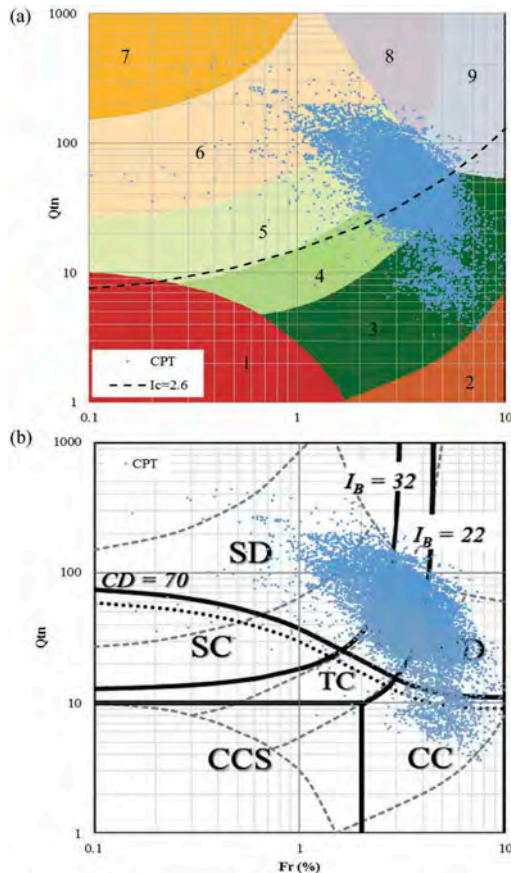

Figure 6. CPT data from the Miocene deposit on (a) Robertson (2009) and (b) Robertson (2016) Classification Charts, (Data obtained from Çanakkale Strait, Offshore European and Anatolian Towers).

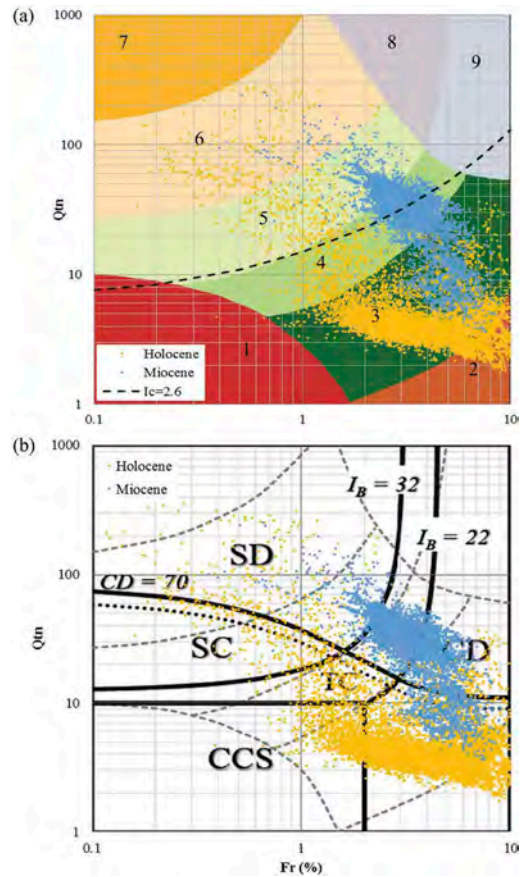

Figure 7. CPT data from Miocene and Holocene deposits on (a) Robertson (2009) and (b) Robertson (2016) Classification Charts, (Data obtained from Çanakkale Strait, Offshore European and Anatolian Towers).

Since Miocene age deposits are expected to have microstructure related to aging and cementation or other post-depositional processes, the microstructure of the sediments around the 1915 Çanakkale bridge was assessed following the recommendations of Robertson (2016) which relate microstructure to the normalized tip resistance (Q_{tn}), the small strain stiffness (G_0) and the net cone tip resistance ($q_n = q_t - \sigma_v$). Robertson (2016) introduces a modified normalized small strain rigidity index K_G^* defined as:

$$K_G^* = \left(\frac{G_0}{q_n}\right)(Q_{tn})^{0.75} \tag{1}$$

Young, uncemented soils tend to have K_G^* values ranging between 100 and 330, while soils with significant microstructure tend to have K_G^* values

exceeding 330 (Robertson 2016). The small strain stiffness of the Miocene deposits was measured using seismic CPT and wireline logging data.

Figure 8 presents the normalized tip resistance (Q_{tn}) versus small-strain rigidity index (I_G) plot for Holocene, Pleistocene and Miocene deposits in the Çanakkale bridge area. The plotted data in the figure are from the European and Anatolian Tower explorations and cover a range of depths between 5 and 50m to represent the various ground units (Holocene, Pleistocene and Miocene) and changes in stiffness. The plot was made using representative small strain stiffness values corresponding to measured shear wave velocities and associated normalized tip resistances taken from the representative value of measured tip resistances within the same sublayer where the shear wave velocity was measured (about 1m above and below the depth where the shear wave velocity was measured).

Based on Figure 8, Holocene soils appear to have little or no microstructure while the Pleistocene and Miocene deposits likely have significant microstructure. Hence, classifying these sediments requires adjustments to the SBT classification systems proposed by Robertson (2009, 2016) to account for microstructure.

Figure 8. Q_{tn} – I_G chart to identify soils with microstructure per Robertson (2016).

The CPT data obtained from the Miocene deposit are characterized by: normalized tip resistances between 25 and 100MPa and normalized friction ratios between 2% and 5% (Figure 6). Thus, a new Zone associated with the Miocene mudstones on the Q_{tn} versus F_r (%) plot is proposed by modifying Robertson (2009) chart. Basically, the modified zone from SBT classification that corresponds to Miocene

mudstones extends Zone 9 into Zones 4 and 5 with a normalized friction ratio of 2% and higher. In addition, the zone also covers small portions of Zones 6 and 8 bounded by F_r (%) of 2% and Q_{tn} of 200. The newly proposed Miocene Zone represents the CPT data collected from the Miocene mudstones at the site.

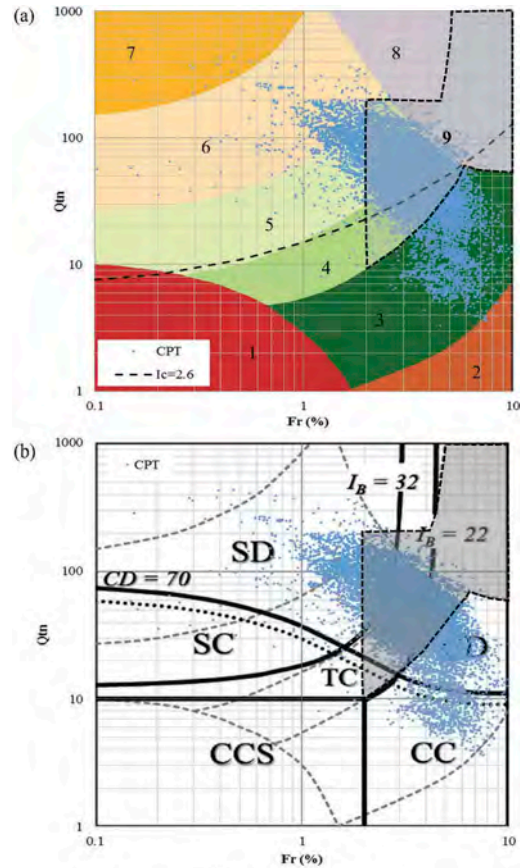

Figure 9. Proposed Modification of the (a) Robertson (2009) and (b) Robertson (2016) Classification Charts for Miocene Deposits.

4 SUMMARY AND CONCLUSION

A Modified Soil Behaviour Type (SBT) classification is proposed to identify Miocene fine-grained deposits on the Q_{tn} versus F_r (%) chart based on the CPT data obtained from the 1915 Çanakkale bridge project. The Miocene deposits were identified through the performance of geophysical surveys, and boreholes drilled adjacent to CPT soundings. The subsurface stratigraphy interpreted from the geophysical survey is in good agreement with borehole data, which enabled delineation of CPT data within

the Miocene deposits. The use of down-hole mode CPT allowed for the collection of significant data set from the Miocene deposits.

While the Robertson charts have proven to be effective for young uncemented soils, modifications appear to be warranted for sediments with significant microstructure.

Within Miocene mudstones, inconsistencies were noted between the soil classification of samples and those interpreted from CPT charts typically where the CPT data plot in zones of the soil classification charts that are described as primarily coarse-grained. Based on a comparison of the CPT data with the cores and samples collected within the Miocene deposit, the materials characterized by friction ratios greater than about 2% that plot within these zones are mostly fine-grained and appear to display mainly undrained responses during cone penetration. For this study, the Robertson (2009) chart has been modified to delineate Miocene deposit with friction ratios greater than 2 percent as fine-grained. Similar modifications are expected to be applicable in similar geological settings where fine-grained intermediate geomaterials are present and are weak enough to permit meaningful penetration by commonly used CPT equipment. The finding from this study should facilitate the classification of similar deposits especially when CPT soundings are performed at an early project stage prior to conducting boreholes.

ABSTRACT: Piezocone dissipation tests are routinely used to estimate the *in situ* coefficient of consolidation (c_h). This is achieved either by extracting a single point of the dissipation curve (usually, the time for 50% dissipation, t_{50}) or by adjusting a theoretical solution to the experimental data. Results from a piezocone investigation carried out in the Holocene clay deposit of Tubarão are reported and interpreted to evaluate the accuracy of existing procedures to estimate c_h. Explicit recommendations on how to curve fit dissipation curves and use the first and second derivates to estimate t_{50} are presented. Validation of the proposed method is provided from field tests reaching up to 75% dissipation. The proposed method does not require accurate measurements of equilibrium pressure and relies less on engineering judgment when compared to reference procedures. Furthermore, the method performed reasonably well with a shorter dissipation time (40% dissipation).

1 INTRODUCTION

The coefficient of consolidation (c_h) can be measured in laboratory from oedometer tests or assessed from *in situ* test results, preferably from piezocone dissipation tests. In the case of piezocone data, evaluation of c_h is based on the variation in pore pressure with time and interpretation rely either on one-dimensional cavity expansion (Vésic, 1972; Torstensson, 1977; Randolph & Wroth, 1979; Burns & Mayne, 1998) or two-dimensional strain path method (Levadoux & Baligh, 1986; Baligh & Levadoux, 1986; Teh & Houlsby, 1991). Both monotonic and dilatory soil response can be modelled in this type of approach, being the Teh & Houlsby method (1991) the standard for monotonic pore pressure dissipation response and the Burns & Mayne method (1998) the alternative for dilatory response.

The procedure for assessing c_h from dissipation tests is based on a series of straightforward recommendations that requires plotting normalized excess pore pressure ($U = (u_t - u_0)/(u_i - u_0)$), against time on a log and/or $\sqrt{t}$ scale, where u_t is the pore pressure at time t and u_0 is the *in situ* equilibrium pore pressure (Lunne et al, 1997). Albeit the procedure is apparently simple to apply, there

are uncertainties in assessing both the initial pore pressure u_i and the equilibrium *in situ* pore pressure u_0. Reliable measurement of the equilibrium *in situ* pore pressure, essential to the interpretation of c_h, is not always straightforward to obtain and requires considerable engineering judgment in many applications. In clays, the pore pressure generated in a piezocone test can be allowed to dissipate to the equilibrium value to assess the *in situ* equilibrium pore pressure but this can take hours and makes the use of the piezocone economically unfeasible for routine engineering applications. In cases such costal and nearshore investigation, tests are affected by tide variations and piezometer measurements have to be interpreted to estimate average equilibirum pressures. In man-made structures such as tailing-retention dams the determination of phreatic surface location is influenced by pond location, anisotropic permeabiity of deposits, boundary flow conditions, permeable layers, among other factors (e.g. Vick, 1983). Furthermore, equilibrium pore pressure will be higher than hydrostatic pressure in the presence of artesian flow or in soil layers undergoing consolidation, and lower than hydrostatic pressure in the presence of donward flow (Robertson & Cabal, 2008).

Due to uncertainties in defining u_0, the time for 50% dissipation of excess pore pressure (t_{50}) may be in error and so is the estimated value of c_h. To partially overcome this problem, a recommendation is made to adjust the complete dissipation curve to obtain the best global value of the horizontal coefficient of consolidation, instead of matching just a single point (usually 50%) of the recorded dissipation (e.g. Lunne et al. 1997). The present paper extends this view by deriving the equation used to curve fitting the measured pore pressure data. Once this is accomplished, the slope of the derivate at the minimum point is zero and corresponds to t_{50}. The time t_{50} can then be used in the interpretation of the value of c_h using standard methods.

A polynomial equation was shown to best-fit the theoretical solutions of Teh & Houlsby (1991) and Burns & Mayne method (1998), and the derivative of the function is easily computed. Since the equilibrium *in situ* pore pressure is no longer required to calculate the percentage of dissipation, one of the uncertainties in deriving c_h is eliminated.

These concepts have been applied to two long duration dissipation tests carried out in the Holocene clay deposit of Tubarão. Results show excellent agreement between the reference and polynomial curve fitting methods in assessing c_h. The polynomial fitting method was shown to provide reasonable estimates of c_h even for lower degree of dissipation.

2 THEORETICAL BACKGROUND

The proposed method was first presented in Mántaras et al. (2014) and consists on curve fitting the field pore pressure measurements to estimate t_{50}. The fitting generates a standard curve that can be useful in interpolating a set of pore pressure values to define a function that is smooth and comes close to the measured data. Once the function is selected and the curve fitting is completed, the function's first derivative is calculated and the minimum point of the function where the slope is zero is identified. In the second derivate this point is zero. These two points (zero slope in the first derivate and zero in the second) correspond to the point of inflection of the normalized dissipation curve and define the theoretical value of t_{50}.

This simple mathematical procedure captures the essence of physical models developed for the interpretation of piezocone dissipation data. Verification, justification, and reasoning is given through mathematical derivation of the solutions proposed by Teh & Houlsby (1991). A polynomial equation is used to curve fit the data, with the actual mathematical expression (degree) defined by the minimum r^2. First and second derivates correspond to the point of inflection of the normalized dissipation curve and define the theoretical value of t_{50}.

Basic arguments introduced by Mántaras et al. (2014) are re-stated here before discussing the applicability of the proposed approach to piezocone dissipation tests. The method's mathematical reasoning was also verified against a theoretical solution for dilatory response (Burns & Mayne, 1998), which is available in Mántaras et al., 2014. As dilatory response is not in the scope of this paper, the derivation is not presented here.

Teh & Houlsby (1991) method: From a theoretical perspective, the strain path method was used to demonstrate that dissipation curves are not unique because the initial pore pressure distribution is highly sensitive to the value of I_r (Baligh, 1985). This prompted the normalization of test data by means of dimensionless time factor T^*, as introduced by Teh & Houlsby (1991):

$$T^* = \frac{c_h t}{r^2 \sqrt{I_r}} \qquad (1)$$

where r is the probe radius, t the dissipation time (normally adopted as t_{50}), I_r the rigidity index (= G/S_u) and G the shear modulus. A constant I_r is used in the solution although in fact the value of the shear modulus depends on the shear strain amplitude, which is shown by strain path calculations to vary in a complex manner around a 60° penetrometer.

Excess pore pressure in the soil generated during penetration of the piezocone can be expressed as a negative function distribution for the probe radial distance, with no excess pore pressure at an infinite distance from the cone face. The rate of decay can be conveniently represented using approximate numerical algorithms, thus offering a means of implementing data on a spreadsheet. Exponential and logarithm equations for matching the data have been proposed by Mayne (2001), Chung (2014) and others (Fig. 1). The logarithm equation proposed by Mayne (2001) to fit the data is:

$$u_2^* \cong (0.85 + 10T^*)^{-0,45} - 0.08 \qquad (2)$$

In a logarithmic time scale, the variable T^* is replaced by $10^{(x-3)}$:

$$u_2^* \cong \left(0.85 + 10 \cdot 10^{(x-3)}\right)^{-0,45} - 0.08 \qquad (3)$$

The derivative of the function with respect to the variable x is expressed as:

$$\frac{du_2^*}{dx} \cong \frac{-4.5}{\left[0.85 + 10^{(x-2)}\right]^{1.45}} \cdot 10^{(x-2)} \cdot \ln(10) \qquad (4)$$

Alternatively, a polynomial expression is used to facilitate the mathematical treatment of the differentiation. Expression (4) could be accurately represented by an xth degree polynomial, providing means of fitting both monotonic and dilatory soil response.

$$u_2^* = a_0 + a_1 x + a_2 x^2 + a_3 x^3 + \ldots \ldots \ldots + a_n x^n \tag{5}$$

The first and the second derivates from equation (5) can be easily obtained:

$$\frac{du_2^*}{dx} = a_1 + 2 \cdot a_2 \cdot x^1 + 3 \cdot a_3 x^2 + 4 \cdot a_4 x^3$$
$$+ \ldots \ldots + n \cdot a_n \cdot x^{(n-1)} \tag{6}$$

$$\frac{ddu_2^*}{ddx} = 2 \cdot a_2 + 6 \cdot a_3 x^1 + 12 \cdot a_4 x^2$$
$$+ \ldots \ldots + n \cdot (n-1) \cdot a_n \cdot x^{(n-2)} \tag{7}$$

Equation 6 represents the slope of pore pressure dissipation in log scale and can be differentiated to obtain the inflection point of the $u_2^* \overline{x} T^*$ curve (Fig. 2).

Figure 1. Teh & Houlsby solution (1991) and approximation with logarithmic equation from Mayne (2001).

Figure 2. 1st and 2nd derivates of Teh & Houlsby (1991) solution.

In the analysis, the program is instructed to graph the curve to check the compatibility of the measured data with the superimposed curve, as well to plot the first and second derivates to calculate t_{50}. The minimum value of the polynomial first derivate corresponds to a time factor $T^*=0.245$ which is the theoretical value calculated by Teh & Houlsby (1991).

It is then concluded that the mathematical approach of adjusting the complete dissipation curve, followed by the determination of t_{50} from the first and second derivates, is the simplest and most consistent way to obtain the best global value of the coefficient of consolidation, c_h.

3 TESTING PROGRAM

The testing program was performed at the Experimental Testing Site located in the delta of Tubarão river in the Southern Coast of Brazil. Comprehensive site investigation comprising seismic piezocone, field vane shear tests, dilatometer tests and standard penetration tests has been carried out to identify soil type and stratigraphy (e.g. Mántaras et al., 2015). Sediments in the upper 20m are predominantly normally consolidated, formed during the last 8000 years in the Holocene period after the most recent glaciation (Odebrecht & Schnaid, 2018; Schnaid & Odebrecht, 2015; Lunne et al. 2014). Below a depth of 6m the clay layer has an average plasticity index (PI) of 55% (Schnaid et al., 2016).

A standard 10cm² piezocone (CPTu) with pore pressure measurement on the shoulder just above the cone face (u_2) was used in the testing program. Tests were carried out according to ASTM D5778 (2012) standards. Figure 3 shows the penetration test results obtained from the piezocone penetration test at the Tubarão Site. The clay layer from 7 to 13m is relatively homogeneous, with occasional lenses of silty sand. After tests measurements show that the water level fluctuates around 1m below the ground surface.

The penetration test was halted at the target depths of 10 and 13m, where the soil is normally consolidated. Up to 1.5h was allowed for pore pressure dissipation to obtain at least 75% of dissipation. Table 1 summarizes the piezocone test program.

4 RESULTS

The normalized field excess pore pressure dissipation curves for the tests CPTu_10m and CPTu_13m are presented in Figure 4. The clay is normally consolidated, exhibiting monotonically decreasing dissipation curves.

The monotonic excess pore pressure dissipations were evaluated by best fitting the complete dissipation curves using the Teh & Houlsby (1991) method. The theoretical fitting provides good matching with the experimental dissipation over the complete pore pressure monotonic decay for both tests, and consequently, the interpreted c_h values are considered as reference
Figure 3. Results from piezocone penetration test at Tuburão Experimental Testing Site: (a) corrected cone tip resistance, q_t (b) pore pressure, u_0 and u_2 and (c) pore pressure parameter, B_q.

Table 1. Test program at the Tubarão clay site

| Dissipation test name	Depth (m)	Test time (s)	Degree of dissipation at end of test $(1 - \Delta u / \Delta u_{max})$
CPTu_10m	10.00	3700	0.78
CPTu_13m	13.00	5470	0.75

Figure 4. Dissipation test at 10 and 13m depth.

for the Tubarão Site. The horizontal coefficient of consolidation evaluated by the model was 7.79E^{-7}m^2/s and 4.10E^{-7}m^2/s for 10m and 13m depth respectively, assuming the rigidity index was 100 (Odebrecht & Schnaid, 2018).

The polynomial fitting method was used to compute t_{50} from tests CPTu_10m and CPTu_13m. First, the measured piezocone pore pressure dissipation data were best fitted with a polynomial equation of 8th degree in the logarithm of time plot. The first and second derivate were then computed to obtain the inflection point, which correspond to t_{50}, as discussed in section 2. Figure 5 illustrates the application of the polynomial fitting method to obtain t_{50} from tests CPTu_10m and CPTu_13m.

The c_h values evaluated from t_{50} extracted from the polynomial method fall within the range of values calculated with the reference method. For the tests performed at 10m depth, c_h was 7.32E^{-7}m^2/s, whereas for the test carried out at 13m, c_h was 4.55E^{-7}m^2/s. This represents a difference of less than ~10% between methods for both tests.

This set of complete dissipation tests shows that the proposed mathematical fit provides estimates of c_h that compares well with values from the existing theoretical solutions, enhancing the confidence in the proposed method. The polynomial fitting method has the advantage of being independent of an accurate measurement of the equilibrium pressure and relying less in engineering judgement in fitting the data with theoretical solutions, which introduces uncertainties in the estimation of c_h.

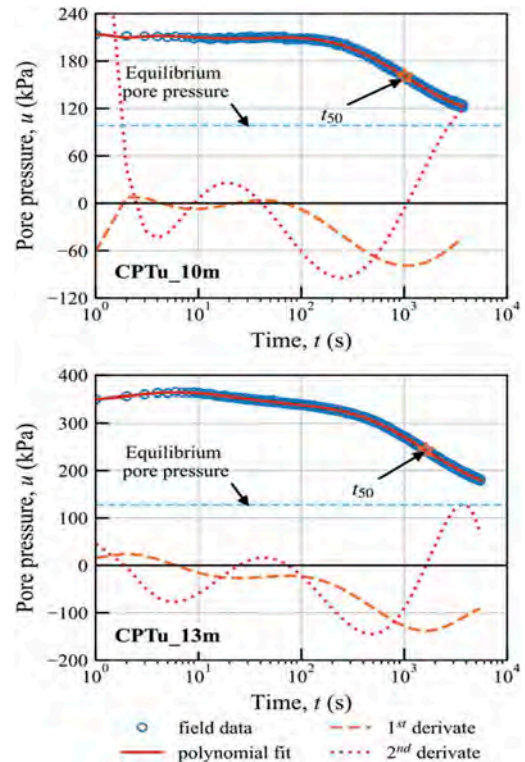

Figure 5. Application of the polynomial fitting method for tests CPTu_10m and CPTu_13m.

5 INCOMPLETE PIEZOCONE DISSIPATION TESTS

Previous interpretation was centered in complete dissipation tests where the degree of dissipation was greater than 75%. It is then necessary and economically convenient to evaluate incomplete CPTu dissipation tests where c_h values are estimated for early degrees of dissipation. Previous researchers have already considered the alternative of interpreting incomplete dissipation test (e.g. Schnaid et al, 1997; Krage et al, 2015), because significant time savings allow for more pore pressure dissipation tests in a site investigation plan.
