The predictive approach proposed to estimate t_{50}, and therefore c_h, from measured cone dissipation tests was similar to the one described by Krage et al. (2015). The polynomial function was fitted to each dissipation test using truncated data sets from 40 to 70% dissipation. The optimal fitting equation was then derived to estimate t_{50} for each set of partial dissipation data, which was then used to estimate c_h ($c_{h,est}$). For data set truncated at dissipation degree less than 50%, a point simulating equilibrium pore pressure in a very long time ($t=100,000s$; $u_2=u_0$) was added to obtain a polynomial equation with a realistic dissipation like shape. An example is provided in Figure 6, where the fitted equation for test CPTu_13m truncated at 40% of dissipation is shown. The polynomial equation fits well the dissipation field data up to 40% dissipation but diverges after, as expected, since the data for dissipation higher than 40% was not used to derive the polynomial equation. Despite this, $c_{h,est}$ was 3.21E^{-7}m^2/s, representing a difference of only 22% when compared to the reference value.

Figure 6. Application of the polynomial fitting method for tests CPTu_13m truncated at 40% of dissipation.

The percentage error ratio for $c_{h,est}$ was calculated as the numerical difference between predicted and reference c_h ($c_{h,ref}$), normalized by $c_{h,ref}$; and expressed as percent, $[(c_{h,est} - c_{h,ref})/ c_{h,ref}]$. The $c_{h,ref}$ is the one obtained from the complete available data interpreted using the reference method. Figure 7 shows the percentage error ratio against truncated data sets at different degrees of dissipation.

Figure 7. Percentage error ratio against truncated data sets from 40 to 70% dissipation for tests CPTu_10m and CPTu_13m.

The percentage error ratio to $c_{h,ref}$ is less than 25% in all cases and less than 20% in most cases, even with only 40% dissipation of excess pore pressure. It is worth recalling that the I_r value has a direct effect on the estimated absolute value of c_h (e.g. Keaveny & Mitchell 1986, Houlsby & Wroth 1991, Robertson et al. 1992, Schnaid et al. 1997, Mayne, 2001) and the uncertainty in selecting an appropriate I_r value exceeds the uncertainty in predicting t_{50} results once dissipation test exceeds 40%. The method seems to have potential to reduce the required time in field to estimate c_h, although further validation is required.

6 CONCLUSIONS

This paper presents an alternative method for t_{50} computation by fitting the piezocone pore pressure dissipation curve with a polynomial equation. Explicit recommendations are given for the fitting technique, including using the first and second derivates to calculate t_{50}. The proposed method has the advantage of being independent of the equilibrium pore pressure measurement and requiring less engineering judgement. Furthermore, the proposed method seems to provide c_h estimates within 25% accuracy from incomplete dissipation test halted after only 40% dissipation (in respect to the c_h using a complete dissipation test and reference method).

Determination of fine-grained soil parameters using an automated system

ABSTRACT: Performing numerical analysis successfully depends on several factors. One of the most important factors is determining the constitutive model parameters correctly. It is often the case that these parameters are determined based on limited soil data. Using in-situ tests for determining these parameters has several advantages such as minimal disturbance of the soil and lower cost compared to laboratory tests. However, it is not possible to determine soil parameters directly from in-situ tests results. Thus, empirical correlations are required for interpreting soil parameters. Generally, several correlations exist for the same parameter, which will lead to calculating several values for the same parameter. An ongoing research project focuses on formulating an automated parameter determination (APD) framework that uses a graph-based approach to identify constitutive model parameters based on in-situ tests. This is achieved by using two spreadsheets as an input, one for parameters and the other for equations (correlations used to calculate parameters). Based on these two spreadsheets, the system generates paths between the parameters and calculates the value(s) for each individual parameter. So far, the research project focused on determining the parameters for coarse-grained soil based on cone penetration test (CPT) results. Due to the fact that the system was set up in a modular and adaptable way, it is possible to expand the system to accommodate more soil types and in-situ tests. It is the aim of the research project to increase the reliability of the parameters values (required to perform numerical analysis) determined from in-situ tests. This paper focuses on expanding the current framework to determine parameters for fine-grained soil. By using the two spreadsheets as an input, the system successfully calculates the value(s) for fine-grained parameters. Further validation, dealing with several values for each parameter, determining the accuracy of derived parameters and expanding the system to accommodate other in-situ tests and types of soils are part of ongoing research.

1 INTRODUCTION

There are several reasons that make the use of numerical analysis preferable compared to the traditional methods. One of the main advantages is the level of detail that can be obtained in several geotechnical engineering problems such as soil-structure interaction Brinkgreve (2019). Several factors influence the success of the numerical analysis. One of the most important factors is determining the constitutive model parameters properly. The main challenge in determining these parameters is the limited available soil data. It is often the case that these parameters need to be defined based on experimental tests (e.g., triaxial and oedometer tests) which are not always available in all projects.

On the other hand there are in-situ investigations, where the cone penetration test (CPT) is one of the most popular in-situ tests as it is quick and often used in soil profiling and estimating soil parameters. Moreover, CPT has other advantages such as minimal

disturbance of the soil and lower cost compared to laboratory tests. The main disadvantage of the interpretation of in-situ tests is that parameters cannot be determined directly from the results of the tests as the laboratory tests. However, a number of empirical relationships exist that link soil parameters to in-situ tests results, it is often the case that several relationships exist to determine the same parameter, which lead to a wide range of values for the parameter of interest. The reason for this variation is mainly related to the fact that these relationships are not applicable for all situations (e.g., specific soil types). In literature, several guides exist dealing with the interpretation of CPT such as Kulhawy & Mayne (1990), Lunne, Robertson, & Powell (1997), Mayne (2014) and Robertson (2015).

An ongoing research project focuses on creating an automated parameter determination (APD) system to determine constitutive model parameters based on in-situ tests. The framework relies on a graph-based approach that uses some of the characteristics of graph

theory. The project aims to create a transparent and an adaptable parameters determination framework. Transparency is achieved by illustrating how the available information is used to compute parameters and adaptability is achieved by allowing the users of the system to incorporate their knowledge and experience into the system. Van Berkom et al. (2022) illustrated the determination of parameters for coarse-grained soils based on CPT data. This paper extends the framework presented in Van Berkom et al. (2022) by including parameters for fine-grained soils.

The 2nd section briefly describes the APD framework, while the 3rd section presents selected empirical relationships used to determine parameters for fine-grained soils. In the 4th section, the output of the APD for a simple example is illustrated. In the final section the conclusions of this study are summarized.

2 AUTOMATED PARAMETER DETERMINATION (APD) FRAMEWORK

2.1 *Framework*

The framework consists of several modules that are connected together. A schematic representation of the modules is shown in Figure 1. CPT raw data, in Geotechnical Exchange Format (GEF) are imported to the first module (GEF Reader). Afterwards the CPT measurements (cone resistance q_c, sleeve friction f_s & porewater pressure readings u_2) are passed to the second module (CPT layer interpretation). The second module determines the SBT based on Robertson (2010) modified non-normalized SBT chart and stratifies the CPT profile into several layers sharing the same SBT. For each layer, the average of the CPT measurements (q_c, f_s & u_2) within this layer is computed. The averaged CPT measurements are used by module 3 (Layer state), to determine the state of all layers (overconsolidation ratio OCR and coefficient of earth pressure K_0). The output of modules 2 and 3 is transferred to module 4, where the parameters are connected with the equations (correlations) and the parameters of interest are calculated. In the final module, parameters calculated in module 4 are converted to constitutive model parameters. The system is built in the programming language Python.

Figure 1. Schematic representation of the parameter determination modules.

The paper focuses on the output of module 4 at a specific depth. The layering process is not considered (modules 2 and 3) in this contribution. Moreover, the paper only presents the determination of fine-grained soil parameters (output of module 4) without the transition to constitutive model parameters (module 5).

Table 1. SBT zones according to Robertson (2010).

Zone	Soil Behaviour Type (SBT)
1	Sensitive fine-grained
2	Clays – organic soil
3	Clays: clay to silty clay
4	Silt mixtures: clayey silt & silty clay
5	Sand mixtures: silty sand to sandy silt
6	Sands: clean sands to silty sands
7	Dense sand to gravelly sand
8	Stiff sand to clayey sand (overconsolidated)
9	Stiff fine-grained (overconsolidated)

2.2 *SBT interpretation*

Robertson (2010) modified non-normalized SBT chart is used to classify the CPT profile. This SBT chart is based on dimensionless cone resistance, (q_c/p_a), where p_a is the atmospheric pressure and friction ratio (R_f in percent, $R_f = f_s/q_c$ 100%). The chart consists of 9 different zones, each corresponding to a different soil behaviour type (Table 1). At each depth, q_c and R_f are used to access the chart and determine the SBT for this depth. As a result, this module is used to distinguish between fine and coarse-grained soils.

2.3 *Graph-based approach*

The graph-based approach used in APD is described in detail in Van Berkom et al. (2022) and illustrated in Figure 2. The idea is to create links between source parameters (CPT raw data) via intermediate parameters to destination parameters (final soil or model parameters). Based on a given set of correlations, the system will create all the paths (chains of correlations) that provide the link from the source parameters all the way to the destination parameters and the system will calculate the destination parameter values from the input values of the source parameters (CPT data).

In the APD framework, the terms 'correlation', 'formula', 'equation', 'rule of thumb' is replaced by the term 'method'. This general term is used as parameters could be determined based on several ways (e.g., tables and charts) (Van Berkom et al. (2022)). The system must link the methods and parameters that share a relationship. As an example, a method to compute the coefficient of earth pressure at rest according to Jaky (1944) is defined as follows, $K_0 = 1 - \sin(\phi')$, where K_0 is the coefficient of earth pressure at rest and ϕ', is the effective internal friction angle of the soil. The system must identify

the input and output for this method (the output is K_0 and the input is ϕ'). Consequently, links connecting these parameters should be generated.

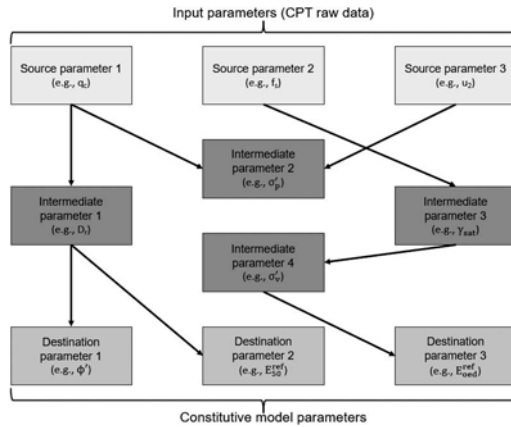

Figure 2. Graph-based approach implemented in APD.

2.4 *Generating the graph*

As shown in the previous subsection, the relationships between methods and parameters are defined by the output and input(s) of different methods. The parameters and methods are considered as external inputs to the system. The system requires two input files: methods and parameters. Users of the system may extend the standard database of methods and parameters provided with the system. The system connects the methods and parameters together, and computes the intermediate and destination parameters. Two different spreadsheets in comma-separate values (CSV) format corresponding to parameters and methods are used to generate the graph.

Each of the two CSV files has special properties. The methods CSV file requires the following properties, *method_to*, *formula*, *parameters_in*, *parameters_out*, *validity* and *reference*. Each of these unique properties need to be provided by the user in a CSV file. Taking the coefficient of earth pressure at rest method presented in the previous subsection as an example, *method_to* would present the name of the method, in this case it might be *method_to_K0*. In the field of *formula*, the equation should be defined, $1 - \sin(\phi')$. *Parameters_in* implicitly states the input for this method, ϕ'. Similar to *parameters_in*, the output of the method is stated in the field of *parameters_out*, K_0. The validity field specifies the applicability of different methods. Some methods are applicable for all types of soils, other methods are only valid for coarse-grained soils and others are only suitable for fine-grained soils. As shown in Table 1, the SBT is based on Robertson (2010) modified non-normalized SBT chart. In that sense, the validity is defined in terms of SBT. If the

method is only valid for silt, the validity would be SBT(4). Regarding the method of coefficient of earth pressure at rest, the validity would be SBT(1234567). The reference field is an optional argument, where the user could state the author of the method (e.g., Jaky_1944).

The parameters CSV file requires the following properties, *symbol*, *value*, *unit*, *constraints*, and *description*. All of the parameters that have been used in the methods CSV files (in the fields of *formula*, *parameters_in* and *parameters_out*) must be defined in the parameters CSV file. The notation of the parameter (which was used in the methods CSV file) is stated in the *symbol* field (e.g., u for porewater pressure). In case the user wants to fix a value for a parameter (e.g., unit weight of water), the *value* field is used for this purpose. The *unit* field is an optional argument where the user could specify the unit of the parameter. It is highly recommended to provide the unit for all parameters to avoid unit conversion mistakes (e.g., using q_c in MPa in a method that requires q_c in kPa). Lower and upper bounds could be applied to parameters through the *constraints* field. Any computed value lower than the lower bound or higher than the upper bound would be discarded for the given parameter. The *description* field is an optional argument, where the user could define the parameter (e.g., OCR is the overconsolidation ratio).

By formulating the two CSV files (methods and parameters) as described, the system imports the two files and forms links between the methods and parameters (*parameters_in* & *parameters_out*) that are related together. The output of this procedure is a graph showing the links between all the defined parameters and methods. Moreover, the computed values for different parameters are shown on the graph. The current version of APD contains more than 100 methods.

3 SELECTED CPT FINE-GRAINED SOIL CORRELATIONS

A standard validated database for methods and parameters has been compiled and is continuously updated and improved. However, users are responsible for validating the outcome of the system, even if they used the provided standard database. Users still need to apply their geotechnical experience and knowledge to the outcome. Nevertheless with limited geoetechnical knowledge, the system should result in reasonable values for different parameters. In this section, some methods for different fine-grained soil parameters are presented. These methods and parameters are used to generate the graph in the following section.

3.1 *Unit weight*

The calculation of the total unit weight (γ_t) is required to compute the total and effective vertical

stress, that are important in many correlations between CPT results and soil parameters. The selected correlations for estimating the unit weight in the APD system are:

- $\gamma_t = \gamma_w[0.27[\log R_f] + 0.36[\log(q_t/p_a)] + 1.236]$ (1)

by Robertson & Cabal (2010), where γ_w is the unit weight of water and q_t is the corrected cone resistance (defined as $q_t = q_c + (1 - a) \times u_2$, where a is the cone tip net area ratio).

- $\gamma_t = 19 - 4.12\left[\dfrac{\log(\frac{5}{q_t})}{\log(\frac{30}{R_f})}\right]$ (2)

by Lengkeek, de Greef, & Joosten (2018).

- $\gamma_t = 26 - \dfrac{14}{1 + [0.5 \log f_s + 1]^2}$ (3)

by Mayne (2014).

3.2 Stress history

The stress history is often represented by the overconsolidation ratio ($OCR = \frac{\sigma'_p}{\sigma'_v}$, where σ'_p is the preconsolidation stress and σ'_v is the effective vertical stress). The selected correlations for estimating OCR in the APD system are:

- $OCR = \dfrac{\sigma'_p}{\sigma'_v} = \dfrac{0.33(q_t - \sigma_v)^{m'}}{\sigma'_v}$ (4)

by Mayne et al. (2009), where σ_v is the total vertical stress and m' is the yield stress exponent that increases with fines content and decreases with mean grain size. Mayne (2017) proposed determining m' from CPT material index I_c as follows:

- $m' = 1 - \dfrac{0.28}{1 + (\frac{8I_c}{2.65})^{25}}$, where I_c is determined by an

iterative process Robertson (2009) based on normalized cone parameter (Q_{tn}) with variable stress exponent (n) that varies with I_c).

- $OCR = 0.33 \times Q_{tn}$ (5)

by Kulhawy & Mayne (1990) and Robertson (2009), where:

$-\ Q_{tn} = \dfrac{q_t - \sigma_v}{p_a}/(\frac{p_a}{\sigma'_v})^n$, where p_a is in the same units as q_t and σ_v

$-\ n = 0.381(I_c) + 0.05(\dfrac{\sigma'_v}{p_a}) - 0.15 \leq 1.0$

$-\ I_c = \sqrt{(3.47 - \log Q_{tn})^2 + (\log F_r + 1.22)^2}$

3.3 Strength parameters

The following correlation is used to determine the effective friction angle (ϕ') in the APD system:

$\phi' = 29.5 B_q^{0.121}(0.256 + 0.336 B_q + \log(Q_t))$ (6)

by Mayne et al. (2009), where B_q is the normalized porewater pressure ($B_q = (u_2 - u_0)/(q_t - \sigma_v)$) and Q_t is the normalized cone resistance ($Q_t = \frac{q_t - \sigma_v}{\sigma'_v}$). The valid range for this correlation is $0.1 \leq B_q \leq 1.0$ and $20 \leq \phi' \leq 45$.

3.4 Stiffness parameters

The 1-D constrained tangent modulus, M is used to estimate settlements. The following correlation is used to determine the constrained modulus in the APD system:

$M = \alpha_M(q_t - \sigma_v)$ (7)

Robertson (2009) suggested an approach based on I_c to determine α_M as follows:

- When $I_c > 2.2$:
  $\alpha_M = Q_{tn}$ (if $Q_{tn} < 14$)
  $\alpha_M = 14$ (if $Q_{tn} > 14$)

- When $I_c < 2.2$:
  $\alpha_M = 0.03[10^{(0.55I_c + 1.68)}]$

4 DETERMINING FINE-GRAINED SOIL PARAMETERS

In this section, an example of the output of the system is presented. The methods CSV file used for this example, contains the correlations presented in the previous section, as well as other formulas used to compute some intermediate parameters (e.g., methods to calculate q_t, B_q, R_f, Q_t). The parameters CSV file includes all the parameters defined in the methods CSV file.

The system imported a CPT GEF file and determined the SBT at each depth. The interpreted SBT at

each depth is shown in Figure 3. For generating the graph, a CPT measurement at a depth of 10 m ($z = 10$ m) was chosen (Figure 3). This measurement has the following properties, $q_c = 1015.5\ kPa, f_s = 31.5\ kPa$ and $u_2 = 351.6\ kPa$. The ground water level (GWL) is located at 6 m below the ground level. The cone tip net area ratio is provided in the CPT GEF file as 0.85 ($a = 0.85$).
The unit weight of water (gamma_w) is defined as $10\ kN/m^3$. The atmospheric pressure (p_a) corresponds to $100\ kPa$. The interpreted SBT is 3, therefore, the soil type at this depth is clay (according to Table 1). The generated graph is shown in Figure 4.

The graph consists of green and blue nodes. The green nodes correspond to parameters, while the blue nodes correspond to methods. The arrows between different nodes, show the link between different entities (parameters and methods) within the system. The arrows have a defined direction (going from a parameter to a method or from a method to a parameter).

Focusing on the unit weight of the soil (gamma_sat located at the lower left corner in Figure 4), it is clear that three methods contribute to gamma_sat. The methods correspond to the three correlations presented in the previous section, where method_to_gamma_sat_1 is Equation 1, method_to_gamma_sat_2 is Equation 2 and method_to_gamma_sat_3 is Equation 3. Three values were computed respectively as, 17.33, 16.25 and 17.09 kN/m^3. Moving to OCR (located at the lower right corner in Figure 4), two methods contribute to OCR, where method_-to_OCR_1 corresponds to Equation (4) and method_to_OCR_2 corresponds to Equation (5). Two values were computed respectively as 2.14 and 2.18. The friction angle (phip located at the lower part in Figure 4) is obtained by only one method (method_to_phip) corresponding to Equation (6). The friction angle was computed as 30.99. Similar to the friction angle, the constrained modulus (M_CPT located at the right-hand side of the graph in Figure 4) is obtained by only one method (method_to_MCPT) corresponding to Equation 7. The constrained modulus was computed as 5903 kPa.

As discussed in Equation 4, I_c, Q_{tn} and n are determined through an iterative process. This iterative process requires the knowledge of the total and effective vertical stress. As a result, an initial

Figure 3. Interpreted SBT at each depth.

Figure 4. An example of a graph.

estimate for the unit weight is required to compute these parameters. In that sense, Equation 1 is used to compute an initial value for the unit weight, which in turn, is used to calculate the total stress (sigma_tot in Figure 4), effective stress, I_c, Q_{tn} and n. Consequently, it might be noticed from Figure 4 that Q_{tn} and I_c (located at the top right corner in 4) are used directly as source parameters because they were calculated in a previous step internally before the graph was generated. Therefore, Equations 2 and 3 are only used to compute gamma_sat for comparison purposes and they do not influence the calculation of the total and effective stress. As the system is formulated in an adaptable way, the user can decide which correlation for the unit weight to be used for the initial estimate for the total, effective stress and for the calculation of I_c, Q_{tn} and n.

5 CONCLUSIONS

This paper is an extension to the automated parameter determination system presented in Van Berkom et al. (2022). The previous section presented proof of concept where a graph-based approach was used to calculate parameters for fine-grained soil. The presented system is transparent, flexible, and adaptable where the users can incorporate their experience and knowledge into the system by extending the standard database of methods and parameters provided with the system. The research project aims to increase the confidence in the parameters values (required to perform numerical analysis) determined from in-situ tests.

Figure 4 presented a simple example where a limited number of methods were used. In case of using several methods, this will lead to a scatter for the computed parameters. Dealing with this scatter and determining which approach is more suitable for choosing a specific value from the range of the computed values is part of an ongoing research. In addition, other SBT charts (e.g., Robertson (2009)) normalized SBTn chart and Robertson (2016) SBT chart) are added to the system. Moreover, the compiled correlations database is continuously validated, updated and the output of different correlations is compared to laboratory tests results whenever they are available. Correlations for calculating typical fine-grained soil parameters (e.g., plasticity index, PI, liquid limit, LL, compression index, C_c and swelling index, C_s) were also added to the database. Furthermore, the connection between soil parameters and constitutive model parameters is to be established. The database includes several correlations between soil parameters and Plaxis Hardening Soil model with small-strain stiffness (HSsmall) (Benz (2007)). This is one of the main aspects of the research project as it will allow the transition from the CPT measurements to constitutive model parameters that could be used directly for numerical analysis.

Undrained shear strength of clays from piezocone tests: A database approach

P.W. Mayne
Georgia Institute of Technology, Atlanta, GA, USA

J. Peuchen
Fugro, Nootdorp, The Netherlands

ABSTRACT: Deriving undrained shear strength of clays from piezocone tests (CPTU) suits the use of a database approach, particularly because good correlations are expected on the basis of theoretical correspondence. Benefits of a database approach include a minimal environmental footprint and field schedule shortening, primarily because of reduced borehole sampling and laboratory testing focused on verification rather than development of comprehensive site-specific data sets. This paper expands on the classic expression $s_u = q_{net}/N_{kt}$ where s_u is a reference undrained shear strength obtained by laboratory testing, q_{net} is the net cone resistance and N_{kt} is a cone bearing factor that is noted to decrease with increasing values of CPTU pore pressure ratio B_q. The database includes CPTU results and high-quality laboratory triaxial compression tests from 70 different clay deposits, of which 8 represent new case studies. The clays are allocated to 5 main categories: (a) soft-firm offshore; (b) soft-firm onshore; (c) soft sensitive; (d) stiff overconsolidated intact; and (e) stiff fissured clays. Organic clays and cemented clays are excluded.

1 INTRODUCTION

When a geotechnical exploration discovers that clay forms all or a portion of the subsurface environment, the magnitude of the undrained shear strength (s_u) parameter is generally sought for input into calculation models involving ground stability, particularly related to shallow foundations, pilings, and slopes. Undrained shear strength can also be important for transitional soils and sands, where combinations of geometry and loading rate can lead to undrained soil response.

Undrained shear strength is not a unique property of clays but affected by many variables, including mode of shearing, rate of loading, shear direction, initial stress state, failure criterion and other factors (Mayne 2008). This paper expands on the most common expression $s_u = q_{net}/N_{kt}$ where s_u is a reference undrained shear strength, q_{net} is net cone resistance and N_{kt} is a cone bearing factor according to classical bearing capacity theory. Values of N_{kt} can be obtained from analytical, theoretical, or numerical solutions, such as those based on limit plasticity, cavity expansion, finite elements, and strain path method. Well over 50 solutions are available for N_{kt} (e.g., Lunne, et al. 1997; Yu & Mitchell 1998; Colreavy 2016; Agaiby 2018).

Here, an empirical database approach is considered for N_{kt}. The database approach uses data from high quality piezocone penetration test (CPTU) results matched at the same elevations as high quality samples subjected to laboratory testing.

2 DATABASE PARAMETERS

2.1 *Triaxial compression tests*

The reference undrained shear strength was defined as a triaxial compression mode, designated s_{uc}:

- Derived value (Eurocode 7) of s_{uc} from laboratory tests on Class 1 samples (ISO 22475-1:2006);
- Anisotropically-consolidated undrained triaxial compression tests (CAUC or CK$_0$UC) according to ISO 17892-9:2018 or equivalent; Note for fissured clays, often only CIUC tests were available;
- Recompression to the estimated in-situ stress conditions, using conventional back pressures for specimen re-saturation;
- $s_{uc} = \frac{1}{2}(\sigma_1-\sigma_3)_{max}$ defined as failure criterion or $(\sigma_{1'}/\sigma_{3'})_{max}$ as failure criterion when $(\sigma_1-\sigma_3)$ provides no distinct maximum (Ladd & DeGroot 2003; Lade 2016), where $\sigma_{1'}$ and $\sigma_{3'}$ are the effective principal stresses.

2.2 Piezocone penetration tests

For the CPTU (ISO 22476-1:2012), three separate measurements are obtained: (a) corrected cone resistance, q_t; (b) sleeve friction, f_s; and (c) pore pressure, u_2. These measurements are acquired at depth intervals of between 10 mm and 50 mm during a constant vertical push rate of 20 mm/s.

For each elevation, values of q_{net} and pore pressure ratio B_q were derived:

- $q_{net} = q_t - \sigma_{vo}$, where σ_{vo} = total vertical overburden stress;
- $B_q = \Delta u_2/q_{net}$, where $\Delta u_2 = u_2 - u_0$ and u_0 = hydrostatic pressure.

Of further note, f_s can be used to provide an evaluation of the soil unit weight (γ) needed in the calculation of σ_{vo} (Mayne et al. 2010a, 2010b; Mayne & Peuchen 2012). Consequently, all three readings (q_t, f_s, u_2) are utilized in the assessment of s_{uc} of clays.

3 TRIAXIAL - PIEZOCONE DATABASE

A total of 62 natural clays that were subjected to CAUC lab testing (n = 407) provided the initial basis for this study (Mayne 2014). The majority of clays were deposited in a marine environment, although a few were lacustrine or alluvial or deltaic in origin. A few sensitive clays were originally formed as sediments in salt-water and later exposed to leaching by freshwater.

The clay sites were classified into 5 separate groups (Mayne & Peuchen 2018), including: (a) 17 offshore clays that were normally-consolidated (NC) to lightly-overconsolidated (LOC); (b) 29 onshore clays that were also NC - LOC, (c) 6 soft sensitive clays; (d) 5 intact overconsolidated clays (OC); and (e) 5 fissured OC clays.

From the database approach, the trend of the relationship for evaluating N_{kt} is presented in Figure 1

Figure 1. Trend of N_{kt} with B_q (Mayne & Peuchen 2018).

and expressed by Equation 1 (Mayne & Peuchen 2018) for values of $B_q > -0.1$:

$$N_{kt} = 10.5 - 4.6 \cdot \ln_e \left(B_q + 0.1\right) \qquad (1)$$

Comments are as follows:

- An advantage of this approach over many other solutions for N_{kt} is that the CPTU provides all the necessary input;
- The methodology covers a wide range of clays showing $B_q > -0.1$, including soft to firm to stiff clays which vary from sensitive to insensitive, and intact to fissured;
- The approach does not apply to organic or cemented clays.

Since the initial database findings, a number of new case studies have become available that permit a validation of Equation 1. Herein, triaxial and CPTU data from 8 clays from Europe, Asia, and North America are presented. Three sites are from offshore locations and five clays are onshore deposits.

4 NEW CASE STUDIES

4.1 Luva, Norwegian sea

Luva is an offshore gas reserve located in 1300 water depth of the Norwegian sea. The site consists of very soft plastic clays having sensitivities in the range of 2 to 5. Index testing indicates a natural water content w_n ≈ 65 % to 75 %, liquid limit w_L ≈ 70 %, plastic limit w_P ≈ 29 %, and plasticity index I_p ≈ 41 % (Lunne et al. 2014). Series of consolidation tests indicate that the site has not been mechanically overconsolidated, showing yield stress ratios (YSR = σ_p'/σ_{vo}') in the general range of 1.2 to 1.7, primarily due to ageing.

Figure 2 shows q_t and u_2 with depth below the seafloor, pore pressure ratio B_q, and derived profile of s_{uc} from the N_{kt} relationship. In the last graph, the CPTU results are shown in comparison with 42 CAUC triaxial tests with good agreement.

4.2 Sipoo, Finland

Sipoo is located about 30 km north of Helsinki. The site consists of a homogeneous soft clay deposit between 2 and 9 m depth and water table near the surface (DiBuò et al. 2019). Index tests on the clay include: w_n = 101 ± 12 %, w_L = 79 ± 10 %, w_P = 30 ± 1 %, I_p = 50 ± 9 %, and clay fraction CF = 79 ± 11 %. Laboratory CRS consolidation tests give a mean YSR = 1.76 and sensitivity by laboratory fall cone ranges from 15 to 44 with a mean S_t = 25 ± 8.

Results from a representative CPTU at Sipoo are shown in Figure 3. The CPTU-evaluated profiles of s_{uc} compare well with the four laboratory CAUC test values on high-quality samples taken from the site.
Figure 2. Profiles in clay at offshore Luva site, Norwegian Sea (data from Lunne et al. 2014).

Figure 3. Profiles at Sipoo soft clay test site, Finland (data from DiBuò et al. 2019).

Figure 4. Profiles in soft clay at Saga, Japan (data from Hossain & Chai 2014).

4.3 Saga, Japan

The Saga TB site is located at the south of Japan next to the Ariake Sea. The upper 4 to 5 m is comprised of sandy silty clay while the underlying 12 m is a silty clay. Groundwater is encountered at a depth of 0.6 m.

Figure 4 shows profiles from a representative CPTU at the site (Hossain & Chai 2014). Nine consolidation tests on this clay indicated a mean

YSR = 1.83. Mean values of laboratory index parameters include: $w_n = 107 \pm 20$ %, $w_L = 88 \pm 20$ %, $w_P = 38 \pm 4$ %, and $I_p = 54 \pm 13$ %.

Using the aforementioned consolidation data and normalized undrained strength ratios from triaxial compression tests on Saga clay reported by Samang and Miura (2005), a profile of undrained shear strength was developed using the SHANSEP method (Ladd & DeGroot 2003). Figure 4 shows the comparison of the laboratory reference profile of s_{uc} in very good agreement with the CPTU derived values.

4.4 Tiller-Flotten, Norway

Tiller-Flotten near Trondheim, Norway serves as the experimental grounds involving quick clay research (L'Heureux et al. 2019). Groundwater is subjected to drawdown so that the hydrostatic pressure is considerably lower than normal.

Figure 5 shows a representative piezocone sounding (Mayne et al. 2019). The uppermost 2.5 m of soil is interpreted as a dry/desiccated layer of stiff overconsolidated sandy clay. Beneath this crust, throughout the sounding depths up to 30 m lies a soft fine-grained soil. The clay is extremely sensitive to quick from approximately 7.5 m below the surface (sensitivity > 100). In the quick clay zone below 7 m depth, typical index parameters are $w_n = 45$ %, $w_L = 35$ %, $w_P = 20$ %, and $I_p = 15$ %, with CF ≈ 45 %.

Figure 5 shows very good agreement from the CPTU-derived s_{uc} values with those obtained from 7 benchmark CAUC series on high-quality block samples.

Figure 5. Profiles in highly sensitive clay at Tiller-Flotten research site, Norway (data from L'Heureux et al. 2019).

4.5 Sainte-Monique, Canada

Locat et al. (2015) detail the results of ground investigations for a major landslide involving firm to stiff sensitive nearly normally-consolidated plastic grey silty clay. The site is located some 130 km northeast of Montreal near the Nicolette River. Index tests show $56 \leq w_n \leq 77$%, $53 \leq w_L \leq 65$ %, $28 \leq I_P \leq 40$%, 72 < CF

< 85%, and liquidity index $1.1 \leq LI \leq 1.4$. Sensitivities derived from fall cone indicate $39 \leq S_t \leq 55$. Laboratory consolidation tests gave YSR between 0.9 and 1.2.

Figure 6 shows the piezocone profile in an undisturbed area outside of the limits of the landslide. The high value of B_q gives a low value of N_{kt} which in turn compares well with two CAUC and three CIUC triaxial tests performed on undisturbed samples.

Figure 6. Profiles in sensitive clay at Sainte Monique, Quebec (data from Locat et al. 2015).

Figure 7. Profiles in soft plastic clay at Liwan offshore site, South China Sea (data from Palix et al. 2013).

4.6 Liwan, South China Sea

A deepwater geotechnical investigation was performed at the Liwan 3-1 offshore site in the Pearl River Mouth Basin of the South China Sea involving geophysics, sampling, piezocones, T-bars, vane, dissipation tests, and advanced laboratory testing (Palix et al. 2013). The site is underlain by soft highly-plastic clays. Liquid limits decrease from 130 % at seafloor to 80 % at 10 m below seafloor, with corresponding I_p going from 85 % to 50 % over the same depth interval. Clay fractions range between 25 to 50 %. Natural water contents vary from over 200 % at seafloor to about 90 % at 20 m depth. Measurements of calcium carbonate content range from 6 % to 25 %.

Figure 7 shows a piezocone profile and the corresponding and reasonable profiles of s_{uc} from the representative CPTU sounding and 6 CAUC triaxial tests.

4.7 Martin's Point Bridge, United States

A field case study with CPTU soundings in natural overconsolidated intact clays of the Presumpscot Formation is presented using data from Martin's Point Bridge, near Portland, Maine (Hardison & Landon 2015). The general stratification of the site (Figure 8) consists of a shallow organic silt layer underlain by stiff OC Presumpscot clay that extends from depths to 2 to 14 m and overlies glacial outwash sand and bedrock.

Shelby tube samples of the clay were collected at the site from different elevations and tested for index properties, consolidation parameters, and triaxial strength characteristics. The results of laboratory index testing on the clay gave an average unit weight $\gamma = 16.5$ kN/m^3, natural water contents $w_n \approx 30$ to 40 %, liquid limits in the range of $20 \leq w_L \leq 45$ %, and plasticity indices (I_p) between 10 and 20 %. Sensitivities derived from field vane and fall cone were generally in the range of 2 to 9.

The groundwater table is located at a depth of 2 m. The stress history profile was determined by a series of 13 constant-rate-of-strain (CRS) consolidation tests that showed YSRs decreasing from 11 at 2 m depth to YSR = 3 at 14 m depth.

A total of 15 CAUC triaxial tests were performed, including both recompression and SHANSEP type methods (Ladd & DeGroot 2003). The derived profile of s_{uc} from the CPTU is presented in Figure 8 with values increasing from about 35 to 100 kPa in the deposit and shown to be in reasonably good agreement with the triaxial series.

Figure 8. Profiles in firm OC clay at Martin's Point Bridge, Maine (data from Hardison & Landon 2015).

4.8 Offshore Denmark

This case study considers the Danish sector of the North Sea. The site has a water depth of about 45 m and includes about 3 m of Holocene sands which are underlain by hard Pleistocene age clays of the Doggerbank formation. Laboratory index tests on the clay indicate mean values: $w_n = 34$ %, $w_L = 49$ %, $I_p = 27$ % and $\gamma = 19.4$ kN/m^3. Calcium

carbonate contents average 19 % for the clay. Consolidation tests indicate the clay to be overconsolidated with YSR decreasing from about 9 to 4 in the depth interval from 3 to 15 m below the seafloor.

Figure 9 shows low B_q values averaging 0.08, the N_{kt}-B_q algorithm gave a high mean value of $N_{kt} = 21$ for the clay and the corresponding profile of s_{uc} compares reasonably with the values from only two CAUC tests on undisturbed samples from the site.

Figure 9. Profiles in stiff fissured OC Doggerbank clay at Danish offshore site.

5 CONCLUSIONS

The empirical methodology considers cone bearing factor ($N_{kt} = q_{net}/s_{uc}$) as a function of pore pressure ratio ($B_q = \Delta u_2/q_{net}$). The underlying database includes statistical analyses of 407 CAUC triaxial tests performed on 62 different clay deposits that were also field tested by CPTU.

The general trend shows N_{kt} varying from as high as 30+ for stiff fissured overconsolidated clays to low values of around 6 for soft sensitive and quick clay deposits. Generally, N_{kt} decreases with B_q.

Eight new case studies are presented showing the reasonableness and reliability of the earlier-derived methodology for assessing undrained strength of clays from piezocone penetration tests. Triaxial compression tests (CAUC, CK_0UC, and occasionally CIUC) on high-quality undisturbed samples were used as the benchmark reference tests. The final tally for the database now includes CPTU data from 70 clay sites with a total of 497 triaxial compression tests that provide the benchmark values of s_{uc}.

ABSTRACT: Using two sets of analytical solutions for CPTU in clays, a suite of theoretically-consistent geoparameters is shown to be in good agreement with independent laboratory and field test results obtained on sensitive Presumpscot clay in Portland, Maine, USA. Fall cone tests indicate a mean sensitivity of $S_t \approx$ 37. Values of undrained rigidity index (I_R), undrained shear strength (s_u), and yield stress ratio (YSR) are provided by a modified spherical cavity expansion-critical state hybrid model while an effective stress limit plasticity solution is utilized to assess the effective friction angle of the sensitive clay at both peak strength [Φ' at q_{max}] and also at maximum obliquity [Φ' at $(\sigma_1'/\sigma_3')_{max}$]. A CPTU screening method that uses three simplified equations for YSR helps to identify that the clay is sensitive.

1 INTRODUCTION

1.1 *Falmouth Bridge, Maine*

A geotechnical investigation for a new bridge along state highway route 26/100 at the northern portion of Portland, Maine, USA was performed by the University of Maine for the Maine Department of Transportation (Hardison & Landon 2015). The site is located to the east of Interstate I-95 and underlain by sensitive clays of the Presumpscot Formation and in close proximity to prior landslides along the Presumpscot River in the community of Westbrook (Devin & Sandford 2000), as shown by Figure 1.

The subsurface exploration for the Portland-Maine bridge included soil test borings, drive sampling, undisturbed sampling, seismic piezocone penetration test (SCPTU) soundings, and various series of laboratory tests (Langlais 2011). A detailed summary of the geotechnical data and results is provided by Hardison & Landon (2015).

1.2 *Interpretation of CPTU in clays*

The interpretation of CPTU in clays often relies on empirical correlations and simple statistical trends, although theoretical formulations also play a role. In this paper, two sets of analytical closed-form solutions are utilized so that a consistent and rational assessment is made for stress history and shear strength, both in terms of effective stress parameters (i.e., friction angle, Φ') and total stress analysis (i.e. undrained shear strength, s_u).

The yield stress, or preconsolidation stress (σ_p') is presented in terms of the normalized yield stress ratio: YSR $= \sigma_p'/\sigma_{vo'}$. Conventionally, results from one-dimensional consolidation tests are taken at various elevations to develop the profile of YSR with depth in clays. Herein, a modified spherical cavity expansion-critical state soil mechanics (SCE-CSSM) hybrid model for CPTU in clays provides three YSR profiles, as well as a measure of undrained rigidity index ($I_R = G/s_u$), where G is the shear modulus.

2 CONE PENETRATION TESTS

2.1 *Piezocone soundings*

The CPTU provides three continuous readings with depth: (a) cone tip resistance, q_t; (b) sleeve friction, f_s; and (c) penetration porewater pressure, u_2. The standard rate of advancement is 20 mm/s, although the use of variable rate CPTU soundings have been revealed

Figure 1. Locations of bridge site and landslide in soft sensitive Presumpscot clay, Portland, Maine, USA.

Figure 2. Profiles of q_t, f_s, u_2, and V_s from SCPTU at Route 26/100 bridge site in Portland, Maine (data from Hardison & Landon 2015).

to provide an effective method to characterize silts, mixed soils, and mine tailings that exhibit partially-drained behavior.

2.2 Seismic piezocone testing

The addition of a set of geophones to the standard penetrometer allows for downhole geophysical testing, most often at the 1-m rod breaks. A horizontal seismic source or autoseis unit is used to generate horizontally-polarized shear waves that are propagated vertically with depth. The profile of shear wave velocity (V_s) is used to obtain the small-strain shear modulus ($G_0 = G_{max}$) via elastic theory:

$$G_{max} = \rho_t \cdot V_s^2 \qquad (1)$$

where $\rho_t = \gamma_t/g_a$ = total soil mass density, γ_t = total soil unit weight, and g_a = acceleration constant.

A representative SCPTU at the Portland-Maine Bridge site showing q_t, f_s, u_2, and V_s in sensitive soft clay is presented in Figure 2.

2.3 CPTU parameters

It is convenient to express the CPTU results as net readings: (1) net cone resistance: $q_{net} = q_t - \sigma_{vo}$; (2) excess porewater pressure: $\Delta u = u_2 - u_0$; and (3) effective cone resistance: $q_E = q_t - u_2$; where σ_{vo} = total vertical overburden stress, u_0 = equilibrium porewater pressure; and $\sigma_{vo}' = \sigma_{vo} - u_0$ = effective overburden stress.

Furthermore, several normalized and dimensionless CPTU parameters can be defined: $Q = q_{net}/\sigma_{vo}'$, $= \Delta u/q_{net}$, $U = \Delta u/\sigma_{vo}'$, and F_r (%) = $100 \cdot f_s/q_{net}$. Note that the first three of these parameters are interrelated via: $U = Q \cdot B_q$.

An update to the normalized Q is now provided with a variable exponent that depends upon soil type, termed Q_{tn}. Details are provided by Robertson (2009) and Robertson & Cabal (2015).
3 GEOPARAMETERS FROM CPTU

The evaluation of soil engineering parameters from CPTU is often addressed using empirical correlations and/or statistical trends derived from prior databases. As a result, some of the obtained values of the geoparameters are inconsistent with each other, or not well-matched well amongst each other, since they are assessed independently.

In this paper, the following geoparameters are assessed theoretically using two analytical solutions: (a) effective stress friction angle (Φ') at both q_{max} and $(\sigma_1'/\sigma_3')_{max}$; (b) rigidity index, I_R; (c) undrained shear strength, s_u; and (d) yield stress ratio $YSR = \sigma_p'/\sigma_{vo}'$. Thus, their values are obtained in a consistent and rational manner. Moreover, independent laboratory reference data on recovered soil samples are shown to be comparable with the CPTU evaluations.

3.1 Index parameters of clay

Laboratory index tests on the sensitive Presumpscot clay at the Portland-Maine site indicated: natural water content, $w_n = 43.6 \pm 7.3\%$, liquid limit: LL = $42.1 \pm 6.9\%$, plasticity index: PI = $17.5 \pm 5.6\%$, liquidity limit: LI = 1.13 ± 0.34; and specific gravity of solids: $G_s = 2.78$. Measured unit weights gave a mean of $\gamma_t = 1.74$ kN/m^3, while natural water contents using G_s and S = 1 indicated a value of around 18.4 kN/m^3.

3.2 Soil behavior type

For soil classification by CPTU, it is common to utilize soil behavior type (SBT) charts. Hardison & Landon (2015) discuss the use of SBT that rely on Q-F and Q-B_q diagrams (Robertson & Cabal 2015). For the CPTU data at Portland-Maine Bridge, the

Q-F charts primarily indicate a zone 3 soil type (clays to silty clays), with an intermingling of zone 1 (sensitive soils), as shown in Figure 3. For the Portland CPTU data, the Q-B_q chart fails to find sensitive clays, as presented in Figure 4.

A SBT chart by Schneider et al. (2012) uses Q and U to identify soil types. This approach seems to better recognize sensitive clays, as shown in Figure 5.

Figure 3. Portland-Maine CPTU data in Q-F soil behavior chart.

Figure 4. Portland-Maine CPTU data in Q-B_q soil behavior chart.

In fact, clay sensitivities (S_t) measured by lab fall cone range from 9 to 268 at the Portland bridge site. Based on the guidelines discussed by Holtz et al. (2011), the clay classifies as medium to highly sensitive below depths of 6 m where $S_t > 8$, as evidenced by Figure 6.

Figure 5. Portland-Maine CPTU data in Q-U soil behavior chart.

Figure 6. Profiles of SBT zone number from Q-F chart and clay sensitivity for Presumpscot clay at Portland-Maine site.

3.3 Screening for sensitive clays by CPTU

In addition to SBT charts for identification of sensitive soils, a simple CPTU screening can be used, as detailed elsewhere (Agaiby & Mayne 2018, 2021; Mayne et al. 2019).

For "regular" clays that are inorganic and insensitive, the following applies:

$$0.60q_E \approx 0.33q_{net} \approx 0.54 \, \Delta u_2 \qquad (2)$$

For sensitive clays, the following hierarchy applies:

$$0.60q_E < 0.33q_{net} < 0.54 \, \Delta u_2 \qquad (3)$$

For the CPTU at Portland-Maine Bridge, Figure 7 shows that the hierarchy from (3) applies, thus identifying sensitive soft clay at depths below 6 m.

Figure 7. CPTU screening hierarchy to identify sensitive clays at Portland-Maine site.

Figure 8. Triaxial stress path for Presumpscot clay at land-slide site in Portland, Maine (data from Devin & Sandford 2000).

3.4 *Friction angle of sensitive Presumpscot clay*

The effective stress friction angle (Φ') is a fundamental property of soil and an important parameter for stability analysis, foundation design, and numerical FEM simulations.

For the landslide investigation near Route 26/100, Devin & Sandford (2000) presented triaxial compression test data on soft sensitive Presumpscot clay. Figure 8 shows CK_0UC triaxial stress paths for a NC specimen, indicating a value of $\Phi'_1 = 30°$ at peak strength, while at later stages of shearing, a value of $\Phi'_2 = 30°$ is obtained at maximum obliquity (M.O.), defined when $(\sigma_{1'}/\sigma_{3'})_{max}$ occurs.

To obtain Φ' in sensitive clays from CPTU, the Norwegian Institute of Technology (NTH, now NTNU) developed an effective stress limit plasticity solution for assessing Φ' in all soil types (Janbu & Senneset 1974; Senneset et al. 1989; Sandven et al 2016). The expression for the case where $c' = 0$ and undrained

penetration ($\beta = 0$) can be expressed:

$$Q = \frac{\tan^2(45° + \phi'/2) \cdot \exp(\pi \cdot \tan\phi') - 1}{1 + 6 \cdot \tan\phi' (1 + \tan\phi') \cdot B_q} \quad (4)$$

Since iteration is required, an approximate inversion to express Φ' directly in terms of CPTU parameters Q and B_q has been devised for the following ranges: $0.05 \leq B_q < 1.0$ and $18° < \Phi' < 45°$ (Mayne 2007):

Figure 9. Profiles of Φ'_1 and Φ'_2 from CPTU using NTH solutions.

$$\Phi' = 29.5° \cdot B_q^{0.121} \cdot [0.256 + 0.336 \times B_q + \log_{10}Q] \quad (5)$$

The value of Φ' corresponding to large strains or maximum obliquity is obtained with this original

555

NTH solution. Figure 9 shows the profile of Φ'_2 with depth and that a value of $\Phi'_2 \approx 33°$.

To obtain the value of Φ'_1 at q_{max}, a modified NTH solution is implemented (Sandven et al. 2016; Ouyang & Mayne 2019). In this case, Q in (4) is replaced with Q' that includes stress history:

$$Q' = Q/YSR^\wedge \qquad (6)$$

where YSR $= \sigma_p'/\sigma_{vo}' =$ yield stress ratio. The exponent Λ can be theoretically calculated as $\wedge = 1 - C_s/C_c$ where $C_c =$ compression index and $C_s =$ swelling or recompression index, however, more often is assigned as a value $\wedge \approx 0.7$ to 0.8 for insensitive clays and $\wedge \approx 0.95$ to 1.0 for sensitive and quick clays (Ouyang & Mayne 2019).

At the Route 26/100 Falmouth Bridge site in Portland, Maine, the trend of YSR with depth from CRS consolidation tests indicates:

$$YSR \approx 5.12 \cdot z^{-0.508} \qquad (7)$$

where z = depth (meters). The CRS results will be presented later in the paper.

Adopting $\wedge = 0.95$ for soft sensitive Presumpscot clay and using Q' from (6) in (5), the profile of Φ'_1 with depth is shown in Figure 9. From depths between 8 to 20 m, the CPTU value more or less agrees with the CK_0UC value $\Phi'_1 = 30°$.

3.5 Rigidity index

The undrained rigidity index is defined as $I_R = G/s_u$ where G = shear modulus and $s_u =$ undrained shear strength. The difficulty here is that the magnitude of G ranges greatly, from a very high value at the nondestructive range at G_{max} to a low value at failure (G_f) corresponding to peak strength.

In many instances, empirical correlations for estimating I_R are used. A UC-Berkeley method developed from triaxial tests on clays by Keaveny & Mitchell (1986) relates I_R with plasticity index (PI) and YSR, for which an approximate expression is available (Mayne 2007).

$$I_{R50} \approx \frac{\exp[(137 - PI)/23]}{1 + \ln_e\left[(YSR + 1)^{3.2}/26 + 1\right]^{0.8}} \qquad (8)$$

which applies when: $10 < PI < 50$ and $YSR < 10$. For the range of PI at Portland-Maine Bridge ($9 < PI < 28$), this indicates an $120 < I_R < 250$.

A UC-Davis approach uses results from SCPTU to obtain a mobilized stress level based value of I_R

at 50% strength. In this case, I_{R50} is obtained from:

$$I_{R50} = \frac{1.81 \cdot G_{max}}{(q_{net})^{0.75}(\sigma_{vo}')^{0.25}} \qquad (9)$$

where G_{max}, q_{net}, and σ_{vo}' are all in same units. At the Portland, Maine site, this approach gives a range: $148 < I_R < 260$.

A spherical cavity expansion - critical state soil mechanics (SCE-CSSM) model for CPTU in sensitive clays provides the direct assessment of I_R (Agaiby & Mayne 2018):

Figure 10. Plot of U-1 versus Q to obtain slope parameter a_q for evaluating rigidity index of Presumpscot clay.

$$I_R = \exp\left[\frac{1.5 + 2.925 \cdot M_{c1} \cdot a_q}{M_{c2} - M_{c1} \cdot a_q}\right] \qquad (10)$$

where $M_c = 6 \cdot \sin\varphi'/(3-\sin\varphi')$ is the frictional parameter in Cambridge q-p' space and a_q is obtained as the slope of (U-1) versus Q. The value of M_{c1} corresponds to Φ'_1 at q_{max} while M_{c2} is associated with Φ'_2 at large strains.

For the Portland site, a slope parameter $a_q = 0.581$ is obtained, as shown in Figure 10. Using the corresponding values of $M_{c1} = 1.20$ and $M_{c2} = 1.33$ gives a calculated $I_R = 266$.

The three approaches for I_R are presented in Figure 11. The upper bounds for the UCB and UCD methods imply that $I_R = 266$ from SCE-CSSM solution is reasonable.
Figure 11. Undrained rigidity index profiles at Portland site.

Figure 12. Profiles of yield stress and undrained shear strength for sensitive Presumpscot clay in Portland, Maine (reference lab data from Hardison & Landon 2015).

3.6 Yield stress ratio at Portland-Maine site

The SCE-CSSM provides three expressions for YSR in clays that are functions of either Q or U, as well as both Q and U (Di Buò, et al. 2019):

$$YSR = 2 \cdot \left[\frac{Q/M_{c1}}{1.95 + 0.667 \cdot \ln_e I_R} \right]^{1/\Lambda} \quad (11)$$

$$YSR = 2 \cdot \left[\frac{U - 1}{0.667 \cdot M_{c2} \cdot \ln_e I_R - 1} \right]^{1/\Lambda} \quad (12)$$

$$YSR = 2 \cdot \left[\frac{Q - (M_{c1}/M_{c2}) \cdot (U - 1)}{1.95 \cdot M_{c1} + (M_{c1}/M_{c2})} \right]^{1/\Lambda} \quad (13)$$

The input parameters of Q and U, together with $M_{c1} = 1.20$, $M_{c2} = 133$, $\Lambda = 0.95$, and $I_R = 266$ are used to generate three profiles of YSR. The associated yield stresses $(\sigma_p{}')$ are consistent and shown to be in good agreement with CRS consolidation tests on undisturbed samples from the site, as seen in Figure 12a.

3.7 Undrained shear strength

For the Portland, Maine site, a series of constant volume direct simple shear (DSS) tests were performed (Langlais 2011). These results can be converted to an equivalent triaxial compression mode (CK_0UC) via a simple relationship that depends on Φ' (Mayne 2008):

$$s_{uDSS}/s_{uc} = 0.65 \quad (14)$$

Alternatively, a SHANSEP type approach can be used where (Hardison & Landon 2015):

$$s_{uc} = S \ YSR^{\wedge} \ \sigma_{vo}{}' \quad (15)$$

where S = 0.33 and $\wedge$ = 0.95. Here, the results of the CRS consolidation tests provide the YSR.

For the CPTU, the undrained shear strength is a triaxial compression mode such that:

$$S_{uc} = q_{net}/N_{kt} \quad (16)$$

where N_{kt} is a cone bearing factor obtained from SCE theory (Vesić 1977):

$$N_{kt} = 4/3 \cdot (\ln_e I_R + 1) + \pi/2 + 1 \quad (17)$$

For a value of $I_R = 266$, the calculated bearing factor is $N_{kt} = 11.35$.

All three evaluations of s_{uc} for soft sensitive clay at Portland are presented in Figure 12b with reasonable agreement shown for all profiles.

4 ADDITIONAL CASE STUDIES

These analytical CPTU solutions have also been successfully applied to a number of other sensitive clays, including Finland (Di Buò, et al. 2019), Norway (D'Ignazio, et al. 2019; Mayne et al. 2019), USA (Mayne & Benoît 2020), and Canada (Agaiby & Mayne 2018; Agaiby et al. 2021).

5 CONCLUSIONS

Two sets of analytical solutions for CPTU in soft sensitive clays are applied to a case study involving the Presumpscot Formation in Portland, Maine. A consistent and theoretical assessment is made for the geoparameters of the clay, including effective stress friction angle (Φ' at q_{max} and Φ' at M.O.), rigidity index (I_R), undrained shear strength (s_{uc}), and yield stress ratio (YSR). The values from these closed-form solutions are in general agreement with results from laboratory testing on undisturbed samples, including CRS-type consolidation tests, triaxial compression tests, and direct simple shear. A simple means for screening to identify sensitive clays from "regular" insensitive and inorganic clays is also presented.

CPTU evaluations in Appalachian Piedmont residual sandy silts

P.W. Mayne
Georgia Institute of Technology, Atlanta, GA, USA

E. Cargill
ConeTec Group, Richmond, VA, USA

ABSTRACT: Results from recent piezocone testing are compared with a statistical set of 22 prior CPTU soundings at the Opelika National Geotechnical Experimentation Site in Alabama. The site is underlain by residua comprised of fine sandy silts of the Appalachian Piedmont geologic province in the eastern USA. The cone resistance and sleeve friction from a 2016 CPTU compare well with the mean values from previous soundings while the porewater pressure readings are similar yet different because of a drop in the groundwater table from 2 m to 10 m over the period of study. Evaluations of the effective friction angle and yield stress from CPTU in residual soils are presented and compared with benchmark values obtained from laboratory triaxial and consolidation test results. Most interestingly, as the soil is intermediate with about 50-50 silt and sand, both undrained and drained penetration give more or less the same results.

1 INTRODUCTION

Since 70% of the Planet Earth is covered by oceans, most soils are formed originally as marine sediment. As a consequence, the majority of geotextbooks and research studies have focused on the interpretation of in-situ and laboratory tests involving water-borne deposits. It is estimated that approximately 5% of soils globally are found to be residual type, formed by the inplace disintegration and weathering of parent bedrock (USDA 2021), thus the evaluation of geoparameters in residua has been less well understood and quantified.

In this paper, results from piezocone penetration tests (CPTU) in residual sandy silts at a national test site in the southeastern USA are presented and interpreted. Of specific interest, the interpretation of effective stress parameters (c' and ϕ') and yield stress profile (σ_p') with depth provide the main focus.

When standard CPT soundings are performed at 20 mm/s, the results are considered *undrained* in clays, whereas in sands the response is taken as *drained* (Lunne et al. 1997). For silts, however, it is unclear whether the data are undrained or drained, or more likely in the regime of *partially-drained* behavior (DeJong, et al. 2012; Holmsgaard et. al. 2016; Blaker et al. 2019).

2 APPALACHIAN PIEDMONT RESIDUUM

The Appalachian Piedmont geologic province extends along the eastern USA ranging from Alabama to New Jersey, as shown in Figure 1. In addition to the surficial extent, the Piedmont lies beneath younger sediments of the Atlantic Coastal Plain deposits. Moreover, the Piedmont serves as an important source of crushed stone, aggregate, and sands from quarries, as well as provides the natural foundation bearing material for buildings, bridges, and highway pavements for major urbanized centers, including Atlanta/GA, Greenville/SC, Columbia/SC, Raleigh/NC, Charlotte/NC, Richmond/VA, Washington/DC, Baltimore/MD, and Philadelphia/PA.

Figure 1. Extent of Appalachian Piedmont in eastern USA.

Primary rock types include gneiss and schist of Precambrian Z-age that were later intruded by granitic rocks of Paleozoic age. Residual soils commonly form as very fine sandy silts (ML, MH) to very silty fine sands (SM) and a dual system (ML-SM) has been used in a modified form of the Unified Soil Classification System.

A generalized profile of the residual and saprolitic soil and rock types is presented in Figure 2. In the
Figure 2. Generalized soil-rock profile in Piedmont geology.

Figure 3. Comparison of mean q_t and f_s profiles from 22 CPTU series (2009 vintage) with 2016 sounding at Opelika test site.

southern Piedmont, saprolitic residuum is called *partially-weathered rock* (PWR) when the standard penetration test (SPT) values exceed 100 blows per foot (bpf), whereas in the northern Piedmont, the term *decomposed rock* is used and defined when SPT values exceed 60 bpf.

2.1 Opelika test site, Alabama

Some three decades ago, six national geotest sites were established with federal funding in the continental USA (Benoît & Lutenegger 2000).

The Opelika test site in Alabama is situated in the Piedmont geology and serves as research grounds for laboratory, in-situ, geophysical, and full-scale foundation studies (Vinson & Brown 1997; Mayne et al. 2000; Mayne & Brown 2003; Anderson et al. 2019). The site

is approximately 150 hectare, owned by the Alabama Dept. of Transportation, and managed by Auburn University.

2.2 CPTU soundings at Opelika NGES

During the period from around 1995 to approximately 2000, many CPTU soundings were conducted at the Opelika NGES by several research groups and commercial testing firms (Mayne & Brown 2003). A statistical summary of some 22 CPTUs at the site are reported by Mayne et al. (2009), as shown by Figure 3. At the time of those series of soundings, the groundwater table was generally found to be around 2 to 3 m deep (Anderson et al. 2019).

In 2016, two new CPTUs were conducted by Cone-Tec Group as part of a new research program on energy piles (Atalay 2019). Results from one of these soundings is superimposed on the q_t and f_s profiles in Figure 3, showing very good overall agreement in these profiles in magnitudes while also displaying some local variations within the residual soil profile due to differential weathering.

Penetration porewater pressures at the shoulder position (u_2) in the Piedmont residuum is often negative below the groundwater table (Finke et al. 2001), as evident in Figure 4. The 2016 CPTU reading is also shown and differs in that the water table was considerably lower ($z_w \approx 10$ m), as detailed by Anderson et al. (2019).

Figure 4. CPTU porewater pressure readings in fine sandy silt at Opelika test site.

2.3 Groundwater effect on CPTU

The depth to groundwater governs the equilibrium porewater pressure (u_0) and may affect the CPTU readings. Of interest here too is that the soils may be either dry, partially- or fully-saturated due to capillarity, since partially saturated soils may occur in the vadose zone between the ground surface and groundwater.

In some reported studies involving groundwater tables and partially saturated soils, the CPTU readings can show differences at seasonal changes due to matrix suction, partial or full capillarity, desiccation, and rainfall (e.g., Lehane et al. 2004; Huffman et al. 2015; Giaceti et al. 2019). In fact, for CPT in residual clayey sands derived from sandstone, Giaceti et al. (2019) showed changes in q_t and f_s in the upper 4 m while less differences at greater depths. Lehane et al. (2004) had two test areas at the same site, one with euclalyptus trees and one in an open area. The CPTU soundings in the open area did not show seasonal changes, while those in the treed area did. Huffman showed some seasonal changes in CPTU readings at a silty site in Oregon.

However, the q_t and f_s profiles at Opelika do not show significant differences in the 2000 and 2016 profiles of cone and sleeve resistances, despite the large changes in groundwater levels.

Figure 5. Fines content and mean grain size at Opelika.

3 GEOCHARACTERIZATION OF PIEDMONT

In this section, selected CPTU interpretations in Piedmont residuum at Opelika will be compared with laboratory results.

3.1 Laboratory testing of residuum

An extensive set of drive samples and undisturbed tube samples were collected for laboratory testing. The lab program included: index testing, grain size, one-dimensional consolidation, triaxial compression, resonant column, direct shear, and permeability (Vinson & Brown 1997).

Results from mechanical analyses using sieves of recovered samples are presented in Figure 5. The measured fines content (FC) and mean grain size (D_{50}) are shown with depth to 16 m. It is evident that the soil particle sizes are at the threshold demarcation between fine-grained soils and coarse-grained soils, i.e. $D_{50} = 0.075$ mm corresponding to the US No. 200 sieve.

The fines content has a mean value FC = 44 % (n = 63), thus the dual symbol ML-SM is seen appropriate for the fine sandy silts to silty fine sands. Average liquid limits and plasticity indices were 46% and 8%, respectively, although many specimens test as non-plastic (Mayne & Brown 2003). Natural water contents typically range between 20 and 40% in the upper 16 m, yet specifically for the earlier set of data, the mean $w_n = 29.9 \pm 6.2$ % (n = 26) that dropped to $w_n = 25.7 \pm 7.0$% (n = 37) in 2016, presumably due to the groundwater drop.

Due to the closure of a nearby marble quarry some 4 km from the site in 2014, the groundwater has now begun a recovery toward its former regime (Anderson et al. 2019).

3.2 Yield stress profiles in Piedmont residuum

Consolidation tests on undisturbed samples from the site are reported by Hoyos & Macari (1999). Figure 6 shows the interpreted profile of yield stress (σ_p') and yield stress ratio (YSR = σ_p'/σ_{vo}') from this test series. Assuming that full capillarity occurs in the overburden, a drop in the groundwater table to 20 m and subsequent rise to a depth of 3 m could explain the apparent preconsolidation stress caused by changes in effective stress at the Opelika site (Mayne 2013).

For CPTU, a generalized first-order evaluation of σ_p' is made from (Mayne et al. 2009):

$$\sigma_p' = 0.33\ q_{net}{}^{m'}\ \text{[units of kPa]} \tag{1}$$

where m' is an exponent that varies with soil type: m' = 1.0 (clays), 0.9 (organic soils), 0.85 (silts), 0.80 (silty sands), and 0.72 (clean quartzitic sands). For the fine sandy silts of the Piedmont geology, a value of 0.83 has been found suitable (Mayne 2013). The profile agrees well with the values from one-dimensional consolidation tests, as evident from Figure 6. The value of m' has also been related to mean grain size (D_{50}), fines content (FC), and material index (I_c), as detailed by Agaiby & Mayne (2019).
Figure 6. Yield stress and YSR at Opelika test site.

3.3 *Triaxial friction angle of Piedmont soils*

A total of 23 triaxial compression tests were performed on tube samples taken from the site (Vinson & Brown 1997; Brown & Vinson 1998). A summary of these tests is presented in Figure 7 giving an overall effective stress envelope represented by the Mohr-Coulomb parameters: c' = 0 and φ' = 35.5°.

At each sample depth, several CIUC type triaxials were conducted where the confining stresses were applied either at the in-situ overburden, or approximately half or about double the effective overburden.

Figure 7. Summary triaxial tests at Opelika test site.

Consequently, an evaluation of the secant effective friction angle at six depths is made in Figure 8. Values of φ' ranged from 33.5° to 37.1°.

4 CPTU EVALUATION OF FRICTION ANGLE

For CPTU in silts, it is not initially clear whether the evaluation should be drained, undrained, or intermediate, such as partially-drained (DeJong et al.

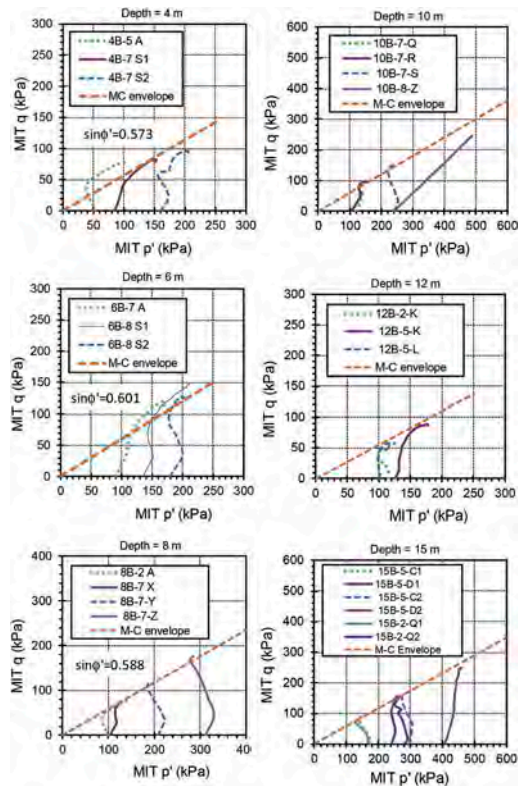

Figure 8. Triaxial results for various depths at Opelika.

2012; Holmsgaard et al. 2016; Bihs et al. 2018). This is a major conundrum for CPTU interpretation in Piedmont fine sandy silts.

4.1 *CPTU evaluation of φ' in sands*

At the standard rate of 20 mm/s, CPTU in clean sands is considered drained response. Various methods for evaluating φ' from CPTU in sands are available (Ching et al. 2017) including an approach from Robertson & Campanella (1983):

$$\phi' = \arctan[0.1 + 0.38 \cdot \log_{10}(q_t/\sigma_{vo}')] \qquad (2)$$

A method based on corrected CPT chamber tests from Kulhawy & Mayne (1990):

$$\phi' = 17.6° + 11.0° \cdot \log_{10}[(q_t/\sigma_{atm})/(\sigma_{vo}'/\sigma_{atm})^{0.5}] \qquad (3)$$

where $\sigma_{atm} \approx 1$ bar = 100 kPa. A modified form of this is given by Robertson & Cabal (2015):

$$\phi' = 17.6° + 11.0° \cdot \log_{10}(Q_{tn}) \qquad (4)$$

where $Q_{tn} = (q_{net}/\sigma_{atm})/(\sigma_{vo}'/\sigma_{atm})^n$ is a normalized net cone tip resistance that has a variable exponent that ranges from about 1 in clays to 0.75 in silts to around 0.5 in sands.

For the Opelika CPTU, the various normalized cone resistance parameters (q_t/σ_{vo}', q_{t1}, Q, Q_{tn}) are shown in Figure 9a. It can be stated that these profiles are quite similar.

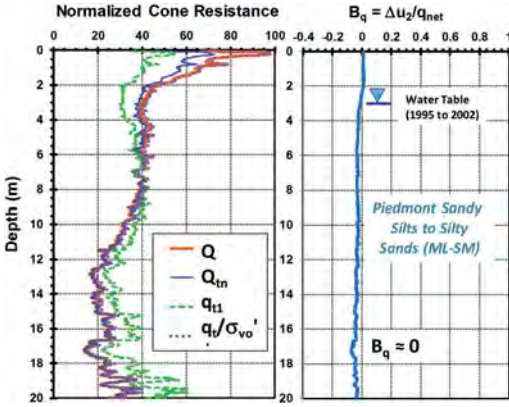

Figure 9. Normalized CPTU parameters at Opelika: (a) cone resistance; (b) porewater pressure ratio.

In fact, a recent study of 27 sands and silty sands that were sampled undisturbed using special freezing methods and/or gel samplers confirmed the relationships given by both (3) and (4) by comparison with laboratory triaxial compression tests (n = 63) and field CPTU (Uzielli & Mayne 2019).

4.2 CPTU evaluation of φ' in clays

At the standard CPTU rate of 20 mm/s in clays, response is taken to be undrained, corresponding to no volumetric strains (DeJong et al. 2012). Clays are identified when the CPT index $I_c \geq 2.95$ (Robertson & Cabal 2015). In consideration of clayey silts, a value of $I_c > 2.6$ is often taken to be "undrained" response.

A limit plasticity solution developed at the Trondheim Institute of Technology (NTH) for CPTU evaluation of φ' under undrained conditions is available from Senneset et al. (1989) that relates Q to φ' and B_q:

$$Q = \frac{\tan^2(45° + \phi'/2) \cdot \exp(\pi \cdot \tan\phi') - 1}{1 + 6 \cdot \tan\phi'(1 + \tan\phi') \cdot B_q} \qquad (5)$$

An approximation for φ' is expressed directly as a function of Q and B_q for the following ranges: $0.05 \leq B_q < 1.0$ and $18° < \phi' < 45°$ (Mayne 2007):

$$\phi' = 29.5° \cdot B_q^{0.121} \cdot [0.256 + 0.336 \cdot B_q + \log_{10}Q] \qquad (6)$$

In fact, data on over 105 different clays tested under both triaxial compression and CPTU have been calibrated to show they give comparable φ' values (Ouyang & Mayne 2018).

4.3 CPTU evaluation of φ' in fissured geomaterials

For the case where $B_q < +0.05$, eqn (6) is not valid and results from CPTUs at Opelika show $B_q \approx 0$, in fact, technically the B_q values are negative and average around -0.02 to -0.05, as evidenced by Figure 9b. Negative porewater pressures are often recorded in fissured geomaterials, such as stiff overconsolidated clays (Mayne et al. 1990), but also observed in residual soils (Schneider et al. 2001; Finke et al. 2001).

From a measurement viewpoint, Campanella & Robertson (1988) showed the u_2 readings in a stiff clay were either slightly negative or slightly positive depending on the specific filter element, and thus u_2 can be affected by the thickness, width, and actual location of the porous element. Furthermore, studies by DeJong et al. (2007) show that type of fluid (water, oil, glycerine, silicone), its viscosity, and degree of saturation play a role in porewater pressure measurements during CPTU. Of final note, the NTH solution cannot handle negative B_q (Sandven 1990).

As such, a value of $B_q = 0$ is assumed at Opelika for CPTU at standard rates of 20 mm/s. An approximation for (5) when $B_q = 0$ can be expressed (Ouyang & Mayne 2019):

$$\phi' = 8.18° \cdot \ln_e(2.13 \cdot Q) \qquad (7)$$

4.4 Effective φ' from I_c relationship

Using the database on 27 undisturbed sands and silty sands, a relationship was also found between φ' and CPT material index, I_c (Mayne 2020):

$$\phi' = 53.0° - 6.9° I_c \qquad (8)$$

for values of $I_c \leq 2.6$.

The profile of I_c at Opelika is presented in Figure 10 showing the intermediate geomaterial more or less follows the threshold value of $I_c = 2.60$ to 11 m depth.

4.5 CPTU evaluation of φ' in Piedmont silts

The above 4 drained equations [i.e., (2), (3), and (4)] one undrained method [i.e., eqn (7)], and CPT index

expression [i.e., eqn (8)] are all applied to the mean CPTU data at Opelika, as shown in Figure 11. Interestingly, all 5 methods approximately agree with each other. Moreover, all CPT expressions agree well and provide comparable profiles to the effective friction angles obtained from the lab triaxial compression test series. This likely only occurs for this very silty fine sand to very sandy silt because of its high fines content (average FC = 44%) and material index at the undrained-drained border of I_c = 2.60, since the mean value of index $I_c \approx 2.7$ for this site.

Figure 10. Profile of CPT material index at Opelika.

Figure 11. Profile of effective friction angle from five CPTU expressions in comparison with triaxial results on natural Opelika sand-silt mixture.

5 CONCLUSIONS

Interpretation of CPTU in residual soils is complicated by their mixed constituency of clay, silt, sand, and rock particles, as well as considerations of partially drained, fully-drained, and undrained behavior, particularly at the standard rate of 20 mm/s. Nevertheless, success was shown for CPTU in residual silts and sands (ML-SM) at the Opelika national test site, located within the Appalachian Piedmont geologic province in eastern USA. Specifically, a means to profile the yield stress ratio (YSR) from a generalized approach that uses net cone resistance and an exponent m' = 0.82. Moreover, a surprising agreement is found in the assessment of effective friction angle ϕ' by use of both drained and undrained CPTU equations that compare well with series of triaxial compression tests.

ABSTRACT: An accurate estimation of the total unit weight (γ_t) of soils and mining tailings is a requirement for several geotechnical engineering applications. In the interpretation of CPT testing data, the value of γ_t is needed for the evaluation of both the total and effective stresses, as well as in the accurate determination of subsequent parameters. Current methods for determining γ_t based CPT data have been developed for a wide range of natural soils where the specific gravity of solids (G) generally ranges from 2.5 to 2.7. However, a large gap exists for soils or mining tailings where G is often higher, such as in the case of bauxite and zinc. This paper presents a compilation of results of CPT tests, and laboratory measurements of specific gravity of solids and total unit weight on bauxite and zinc mine tailings. The application of the literature methodologies was evaluated for this database and the statistical coefficient of determination (r) was presented, which is determined between the measured value and the value estimated by the correlations

1 INTRODUCTION

An adequate geotechnical investigation is necessary for the understanding of soil behavior. Laboratory and field data are generated, which allow the designer to predict the behavior of the studied soil, offering more security for project development. According to Lunne, Robertson & Powell (1997), field and laboratory tests complement each other; however, field tests have some attractions. One of these is the cone penetration test (CPT) or piezocone test (CPTu), which is conducted by driving a set of steel rods and a conical point into the ground with the aid of a reaction system mounted on the ground surface. The following quantities are continuously measured in this test: tip resistance (q_c), lateral friction (f_s), and generated pore pressure (u). Combining these values also makes it possible to determine two parameters used to evaluate the soil behavior, namely the friction ratio (R_f) and the pore pressure parameter (B_q). The literature presents several correlations for obtaining geotechnical parameters from CPTu test results (Kulhawy & Mayne (1990); Schmertmann (1978); Teh & Houlsby (1991); Larsson & Mulabdic (1991)). However, one of the essential information in the interpretation of the test is the value of the natural soil unit weight.

The methods presented in the literature for determining γ_t from the results of the cone test use the tip resistance (q_t), the lateral friction (f_s), and also the value of the shear wave velocity (v_s) through the soil. These methods consist of empirical formulations developed from natural soil databases, encompassing a range of specific gravity of solids (G) values, usually ranging from 2.5 to 2.7 (MAYNE, 2007). Some specific proposals seek to address organic soils, for G values ranging from 1.45 to 2.33 (LENGKEEK *et al* 2018). However, considering the extensive applicability of cone tests, encompassing both soft soil deposits and mining tailings, there is a need to evaluate correlations for estimating soil unit weight for wider ranges of specific gravity of solids values, for which the correlations available in the literature may present limitations.

In this context, the present study compiles and organizes a database of cone tests and laboratory tests, encompassing bauxite and zinc mining tailings soils with a specific gravity of solids values above the average of natural soils. The aim is to verify the applicability of existing specific weight estimation relationships and verify which method best adapts to these data. The study will be based on statistical analysis with the help of the statistical software R Studio®, where the value of Pearson correlation coefficient (r), determined between the measured value and the estimated value of specific weight, will be evaluated. The

Pearson correlation coefficient (r) represents the linear association between two random variables. Usually, the analysis is made by graphical representation of the relation of data, using a scatter diagram. This coefficient varies from -1 to +1 and indicate the tendency of one variable to increase or decrease with the other variable, respectively (PATTEN & NEWHART, 2017; ZHOU *et al* 2016). In this paper, the Pearson correlation coefficient (r) is used to verify the relation between the measured soil unit weight and the estimated value by literature correlations.

1.1 Methods for estimating the natural soil unit weight

There are several proposals in the literature for determining the natural soil unit weight (γ_t); among them, we can mention Robertson & Cabal (2010), Mayne & Peuchen (2012) and Mayne (2014). To develop the correlation proposed by Robertson & Cabal (2010), as can be seen in Equation 1, experiments and correlations between wave velocity and soil unit weight were combined (MAYNE, 2007), along with relationships between unit weight and DMT test results (MARCHETTI, 1980). Thus, Robertson & Cabal (2010) developed approximate contours of unit weight values as a function of dimensionless parameters of resistance (q_t/σ_{atm}) and lateral friction ($Rf = fs/\sigma_{atm}$).

$$\gamma_t/\gamma_w = 0.27\left[\log R_f\right] + 0.36\left[log(qt/\sigma_{atm})\right] + 1.236 \tag{1}$$

where R_f = friction ratio x 100%; q_t = corrected tip resistance; γ_w = water unit weight (kPa); and σ_{atm} = atmospheric pressure (kPa).

Robertson & Cabal (2010) also point out that the vast majority of soils present a specific gravity of solids (G) in the range of 2.5 to 2.7. For soils with G outside this range, some interference may occur in the proposed correlation given by the previous equation, so they proposed Equation 2, where the value of G is introduced.

$$\gamma_t//\gamma_w = [0.27[\log R_f] + 0.36[log(q_t/\sigma_{atm})] + 1.236]G/2.65 \tag{2}$$

As for Mayne & Peuchen (2012), the authors' first evaluation consisted of relating the unit weight of the materials with the respective plasticity index, verifying a tendency of reduction of the specific weight with the increase of the plasticity of the material. As the plasticity index is not obtained using the cone test, the authors investigated and identified a relationship between the plasticity index and the ratio between the tip resistance and the depth, denominated m_q ($m_q = q_t/z$). Analyses were performed and two equations were obtained (Equations 3 and 4).

$$\gamma_t = \gamma_w + m_q/8 \tag{3}$$

$$\gamma_t = 0.636(qt)^{0.072}(10 + m_q/8) \tag{4}$$

A differentiated methodology is proposed by Mayne (2014) to estimate the soil unit weight through CPTu test results, relying only on the relationship of specific weight with the lateral cone friction (fs) measurements. The proposed equation is presented by Equations 5 and 6.

$$\gamma_t = 26 - (14/1 + \left[0.5.\log(f_s + 1)\right]^2) \tag{5}$$

$$\gamma_t \approx 12 + 1.5\ ln\ (f_s + 1) \tag{6}$$

2 DATABASE

In order to achieve the research objective, a database of geotechnical investigation results was analyzed. The database is formed by 197 observations resulting from investigations in 4 different Brazilian bauxite and zinc deposits. The items surveyed in the database were based on the definition of the main parameters to be used in the statistical analysis to apply existing correlations, thus making it possible to verify their performance with the compiled data. The data for bauxite and zinc mining tailings are presented, by depth range, in Tables 1 and 2, respectively.

Table 1. Bauxite mining tailings database – parameters variation.

Depth (m)	γ_t (kN/m³)	q_t (MPa)	f_s (kPa)	G	R_f
1 – 4.75	13.48 – 20.43	0.03 – 0.99	0.5 – 13.36	2.39 – 3.36	0.26 – 14.48
5 – 10	14.48 – 21.45	0.03– 2.0	0.79 – 17.49	2.85 – 3.22	0.48 – 3.58
11 – 15	16.44 – 20.44	0.39 – 0.95	4.48 -23.29	2.88 – 3.14	0.68 – 3.63
16 – 20	15.58 – 20.26	0.73 – 1.95	6.82 – 19.11	2.98 – 3.14	0.93 – 2.74

Table 2. Zinc mining tailings database – parameters variation.

Depth (m)	γ_t (kN/m³)	q_t (MPa)	f_s (kPa)	G	R_f
1 – 5	11.27 – 13.58	0.03 – 0.22	0.14 – 2.57	3.28 – 3.35	0.28 – 1.56
6 – 12	12.6 – 14.3	0.22 – 1.10	1.77 – 16.99	3.29 – 3.37	0.5 – 1.62

3 VERIFICATION OF EXISTING METHODS IN LITERATURE

In this step of the study, the methods present in the literature for natural soils as presented in step 1.1 were used to estimate the soil unit weight, comparing the result obtained by applying the formulations with the values defined in the results of geotechnical tests.

Together with the database formed with the parameters for the analysis of correlations between CPT and CPTu tests, the equations were entered into the Excel software spreadsheet. Each of the correlations was entered in a column, sorted by author and year of development, starting from the oldest to the most recent.

In order to make an evaluation between the values calculated by the correlations of the methods and the unit weight values present in the results of the geotechnical tests, the software R Studio® was used as a statistical tool.

Table 3. Verification of methods with bauxite mining tailings.

Method	Equation	r value
Robertson & Cabal (2010)	Equation 1	0.2
Robertson & Cabal (2010)	Equation 2	0.42
Mayne & Peuchen (2012)	Equation 3	0.2
Mayne & Peuchen (2012)	Equation 4	0.22
Mayne (2014)	Equation 6	0.3

Table 4. Verification of methods with zinc mining tailings.

Method	Equation	r value
Robertson & Cabal (2010)	Equation 1	0.79
Robertson & Cabal (2010)	Equation 2	0.78
Mayne & Peuchen (2012)	Equation 3	0.43
Mayne & Peuchen (2012)	Equation 4	0.64
Mayne (2014)	Equation 6	0.85

The use of Pearson correlation coefficient (r) was chosen to evaluate if those two variables, the measured specific weight and, the estimated specific weight, are related to each other. Furthermore, it is intended to analyze which method demonstrates to have more compatibility with each soil type evaluated. For each type of studied soil and correlations graphs were generated. The results of the analyses are presented by soil type in Tables 3 and 4, being bauxite tailings and zinc, respectively.

The bauxite mining tailings were the first to be analyzed, bringing the strongest correlation value, the method of Robertson & Cabal (2010), in Equation 2, with an $r = 0.42$. This equation presents in its formulation the coefficient of specific gravity of solids (G). And the weakest correlation occurred in two equations of different methods, the first by Robertson & Cabal, Equation 1, and the second by Mayne & Peuchen (2012), Equation 4, presenting an $r = 0.2$. The graphs with the strongest and weakest correlations are illustrated in Figures 1 and 2.

For zinc mining tailings, the results were more positive when compared to bauxite mining tailings. For the Mayne (2014) method, the strongest correlation was obtained, being $r = 0.85$. However, not all results were above $r = 0.7$. Mayne

4 CONCLUSIONS

This paper sought to assemble a database of Brazilian mining tailings soils for verification of methods present in the literature for natural soils.

Through this study, it was possible to define which method in the literature for natural soils best suited the mining tailings data in the database.

The Pearson correlation coefficient (r) values between the measured data and the data calculated by the methods indicated that some of the methods offered a positive result when using the database, but in most cases the results showed that there is a need to generate a new equation that encompasses a range of soils with actual specific gravity of solids values varying more than just the range for normal soils (2.5 to 2.7).

Use of DMT and CPTU to assess the G_0 profile in the subsoil

J. Wierzbicki
Institute of Geology, Adam Mickiewicz University, Poznań, Poland

P. Monaco
University of L'Aquila, L'Aquila, Italy

ABSTRACT: The subject of this article is the analysis of the relationship between G_0/M_{DMT} and K_D, where G_0 is the small strain shear modulus, while M_{DMT} and K_D are respectively the constrained modulus and the horizontal stress index determined from DMT tests. This relationship allows to determine a profile with depth of G_0 from standard DMT test results, useful when data from non-seismic DMT investigations are available. The analysis was based on a large amount of data for a wide range of soils of different origins in Poland. The dataset included OC and NC loams, silts, medium sands, silty sands and fine sands. The overconsolidation ratio (OCR) was estimated from CPTU and DMT tests. The obtained empirical G_0/M_{DMT} vs. K_D relationships were compared with the correlations established by Marchetti et al. (2008) for different soil types. To account for the significant influence of overconsolidation, an original empirical relationship between G_0/σ'_p and K_D, where σ'_p is the preconsolidation stress, was determined based on data from all investigated fine-grained soils.

1 INTRODUCTION

Recent achievements of research on in-situ testing allow to determine a wide range of soil parameters necessary for geotechnical design of a planned investment. The piezocone (CPTU) and flat dilatometer (DMT) tests take up a special position in these investigations. In the group of geotechnical parameters sought for design of foundations of many engineering structures, the parameters related to soil stiffness, such as the small strain shear modulus G_0 and the constrained modulus M, play an important role. The CPTU and DMT tests are particularly convenient for determining the profiles with depth of these moduli in the subsoil. In particular, the seismic piezocone (SCPTU) and the seismic dilatometer (SDMT) tests permit to determine the in-situ depth profile of G_0 from the measured shear wave velocity V_s. The cost of these techniques, however, is higher than the standard non-seismic CPTU and DMT tests, which are preferred in many practical cases. In absence of V_s measurements, G_0 can be estimated from the results of a standard DMT using the empirical correlations proposed by Marchetti et al. (2008). The use of such correlations must be accompanied by the awareness that many independent variables affect the quality of the assessment of the G_0 modulus. It is generally accepted that the quality of a geotechnical parameter depends on two factors: (1)

the quality of the testing technique (Młynarek 2010), and (2) the parameter variability, related to subsoil properties (Lacasse & Nadim 1994). The analysis of the influence of the latter group of factors on the correlation between G_0 and the horizontal stress index K_D from DMT, with particular emphasis on the preconsolidation effect, is the subject of this paper.

2 LOCATION AND BASIC GEOLOGICAL SETTING OF THE TEST SITES

The research was carried out at five test sites located in Poland (Figure 1), four in the area covered by the Late Pleistocene glaciation and one in the impact zone of periglacial processes in the Pleistocene. Two sites, Kaźmierz and Lipno, are located within the Weichsel glaciation, ended about 15,000 years ago. The near-surface geological formations are dominated by loam and glacial sands over 12 m thick. In the subsurface zone loams are mainly originated from melt-out facies and characterized by low preconsolidation. They rest on loams of the lodgement facies with a higher degree of preconsolidation (Kaźmierz site). The clay fraction in glacial clays does not exceed 25%. They are dominated by the sand fraction, even up to 70%. The sites of Jarocin and Koźmin are located in the Riss glaciation zone, in the

Figure 1. Location of the test sites.

foreground of the Weichsel glaciation line. Here the dominant soils are loams of the lodgement facies, characterized by a high (> 10%) calcium carbonate content, a sand fraction lower than the loams of the Weichsel glaciation and an increase (up to 40%) in the silt fraction. These clays are often called 'grey loams' for their characteristic grey-brown color. The Łańcut site is located in the zone of loess covers and loess-like silts. These soils were originated in the Middle and Late Pleistocene as extensive covers of aeolian silty sediments, deposited in the foreland of the Pleistocene ice sheet. The particle size distribution is very homogeneous and characterized by 60-70% of silt fraction and about 20% of sand fraction. A characteristic feature of the loess covers is the frequent occurrence of carbonate cementation, which causes a quasi-preconsolidation effect (Młynarek et al. 2013).

3 ESTIMATE OF *OCR* FROM CPTU AND DMT

The stress history of soil deposits is commonly assessed based on the overconsolidation ratio (*OCR*) or the preconsolidation stress (σ'_p). Profiles with depth of these parameters at the investigated sites were obtained from CPTU and DMT data.

Based on CPTU test results, the *OCR* was estimated using the relationship (Wierzbicki 2010):

$$OCR_{CPTU} = 5.68 \ln Q_t - 15.64 \qquad (1)$$

where Q_t = normalized cone resistance.

The original formula by Marchetti (1980) was used to estimate the *OCR* from DMT:

$$OCR_{DMT} = (0.5K_D)^{1.56} \qquad (2)$$

where K_D = horizontal stress index.

The *OCR* profiles obtained from CPTU and DMT were used to qualify the investigated soil deposits as normally consolidated (NC) or overconsolidated (OC). The *OCR* was found to vary between 1 to 11.

The comparison of *OCR* depth profiles estimated from CPTU and DMT at two representative sites is shown in Figures 2 and 3, along with the profiles of measured and interpreted parameters obtained from CPTU (corrected cone resistance q_t, friction ratio R_f, pore pressure u_2) and from DMT (corrected pressure readings p_0 and p_1, material index I_D). A relatively large difference between the *OCR* estimated from CPTU and DMT is found at the Kaźmierz site in loam

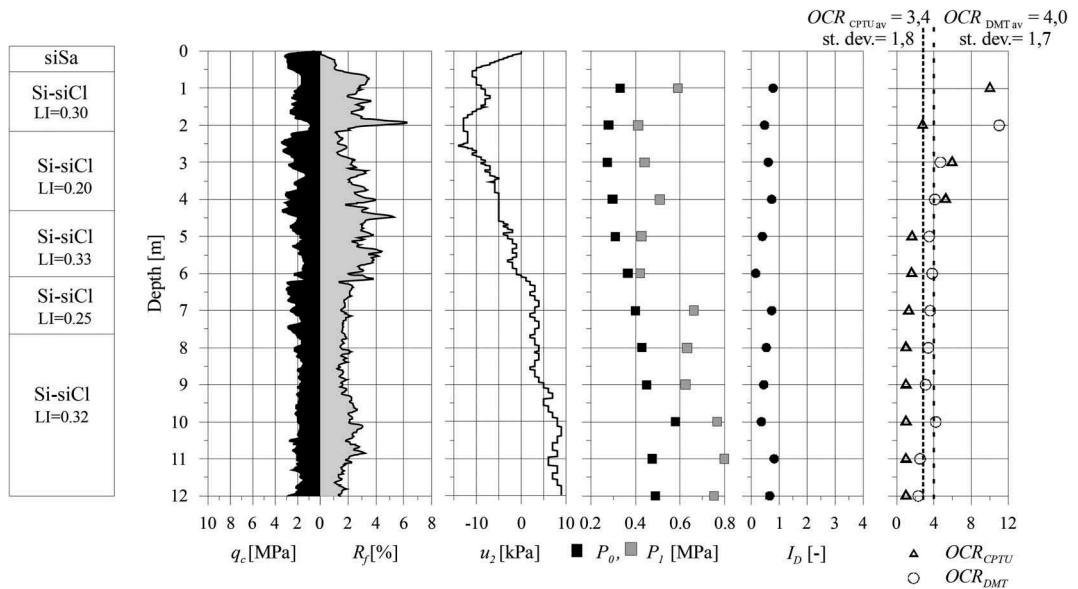
Figure 2. CPTU and DMT test results and estimated *OCR* profiles in loam at Kaźmierz test site (*LI* = liquidity index, saCL = sandy loam, saclSi = fluvioglacial silt, MSa = fluvioglacial sand).


Figure 3. CPTU and DMT test results and estimated *OCR* profiles in loess at Łańcut test site (*LI* = liquidity index, Si-siCl = loess, siSa = fluvial sand).

and sandy loam (Figure 2), particularly in correspondence of thin sand layers. However the mean values of the *OCR* from DMT and CPTU for the entire subsoil profile do not differ significantly (level of confidence interval of statistical analysis α = 0.05). The average values over the 9 m investigated depth show a limited standard deviation. The loess deposit at the Łańcut site (Figure 3) is composed of silty clay and silt with homogeneous macrostructure. The *OCR* estimated from CPTU and DMT are similar, and their average values over the 12 m investigated depth do not differ significantly from the statistical point of view.

4 ASSESSMENT OF THE CORRELATION BETWEEN G_0 AND DMT PARAMETERS

Marchetti et al. (2008) investigated the experimental interrelationship between small strain and working strain stiffness using SDMT. They identified a relationship between the ratio G_0/M_{DMT} and K_D having the functional form shown by Equation 3:

$$\frac{G_0}{M_{DMT}} = f(K_D) \qquad (3)$$

where G_0 = small strain shear modulus obtained from the measured shear wave velocity V_S as $G_0 = \rho \cdot V_S^2$ (ρ = soil density), M_{DMT} = constrained modulus and K_D = horizontal stress index obtained from standard DMT interpretation (Marchetti 1980). Based on data obtained from 34 sites, in a variety of soil types, Marchetti et al. (2008) proposed distinct correlations for clay, silt and sand (Figure 4).

The correlations formulated by Marchetti et al. (2008) were taken as a reference for the comparative analysis with the experimental data obtained in this study. A total number of 989 SDMT test results, obtained from soil deposits of different origin, macrostructure and *OCR*, were analyzed. The analysis of the relationship written in the form of Equation 3 was carried out considering the following soil groups, corresponding to the soil classification adopted by the Polish Standards (1986): clay (clay fraction > 30%); sandy loam (clay fraction = 10-20%, sand fraction 50-90%); loam; silt (clay fraction 10-20%, silt fraction 30-60%); fine/medium sand; fine/silty sand.

Figure 5 shows the datapoints $G_{0(m)}/M_{DMT}$ vs. K_D obtained for all soil groups, where $G_{0(m)}$ is intended as the G_0 determined from V_S measured by SDMT. Figure 5 confirms the conclusions formulated by Marchetti et al. (2008): (i) a functional correlation exists between the ratio G_0/M_{DMT} and K_D; (ii) a correlation between these variables should be constructed for specific groups of soils, at least distinguishing between fine- and coarse-grained soils; (iii) these correlations are affected by the preconsolidation effect, which can be defined by σ'_p or *OCR*.

These findings prove that it is necessary to analyze the relationship between $G_{0(m)}/M_{DMT}$ and K_D in selected soil groups. Figures from 6 to 11 illustrate, for each soil group: (a) the relationship between $G_{0(m)}/M_{DMT}$ and K_D, compared with the equations proposed by Marchetti et al. (2008) for similar soil types (Figure 4); (b) the comparison between $G_{0(m)}$ obtained from measured V_S and $G_{0(c)}$ calculated according to Marchetti et al. (2008).
572

Figure 4. Relationship between the ratio G_0/M_{DMT} and K_D according to Marchetti et al. (2008) (from Monaco et al. 2009).

Figure 5. Relationship between the ratio $G_{0(m)}/M_{DMT}$ and K_D in different soil types from all investigated sites.

Figure 6 refers to clay. The $G_{0(m)}/M_{DMT}$ vs. K_D datapoints (Figure 6a) from the investigated sites (OC clay) plot higher than the correlation proposed by Marchetti et al. (2008) for clay. The moduli $G_{0(m)}$ obtained from the measured V_S differ significantly from the moduli $G_{0(c)}$ calculated according to Marchetti et al. (2008), particularly for the higher values of $G_{0(m)}$, while for low $G_{0(m)}$ the values of $G_{0(c)}$ and $G_{0(m)}$ are closer to the 1:1 correlation line (Figure 6b). The same effect was found by Młynarek et al. (2013) comparing the constrained moduli M from DMT and CPTU tests for Pliocene OC clays. The best-fit relationship for the $G_{0(m)}/M_{DMT}$ vs. K_D datapoints in Figure 6a is given by Equation 4:

$$\frac{G_{0(m)}}{M_{DMT}} = 342.75 \, K_D^{-1.861} \; R^2 = 0.6102 \qquad (4)$$

Figure 7 refers to sandy loam. The $G_{0(m)}/M_{DMT}$ vs. K_D datapoints (Figure 7a) plot relatively close to the correlations proposed by Marchetti et al. (2008) for clay and silt. The moduli $G_{0(m)}$ (Figure 7b) are very similar to the moduli $G_{0(c)}$ calculated according to Marchetti et al. (2008) for clay. Again, the lower values of $G_{0(m)}$ and $G_{0(c)}$ lie near the 1-1 correlation line. The best-fit relationship for the $G_{0(m)}/M_{DMT}$ vs. K_D datapoints in Figure 7a is given by Equation 5:

$$\frac{G_{0(m)}}{M_{DMT}} = 48.785 \, K_D^{-1.284} \; R^2 = 0.7341 \qquad (5)$$

Figure 8 refers to loam. The $G_{0(m)}/M_{DMT}$ vs. K_D datapoints (Figure 8a) plot slightly higher than the correlations proposed by Marchetti et al. (2008) for clay and silt. Accordingly, the moduli $G_{0(m)}$ (Figure 8b) slightly differ from the moduli $G_{0(c)}$ estimated according to Marchetti et al. (2008) for clay. The best-fit relationship for the $G_{0(m)}/M_{DMT}$ vs. K_D datapoints in Figure 8a is given by Equation 6:

$$\frac{G_{0(m)}}{M_{DMT}} = 50.096 \, K_D^{-1.114} \; R^2 = 0.6603 \qquad (6)$$

Figure 9 refers to silt. The $G_{0(m)}/M_{DMT}$ vs. K_D datapoints (Figure 9a) plot rather close to the correlation proposed by Marchetti et al. (2008) for silt. The moduli $G_{0(m)}$ (Figure 9b) are similar to the moduli $G_{0(c)}$ calculated according to Marchetti et al. (2008) for silt. The best-fit relationship for the $G_{0(m)}/M_{DMT}$ vs. K_D datapoints in Figure 9a is given by Equation 7:

$$\frac{G_{0(m)}}{M_{DMT}} = 22.608 \, K_D^{-0.608} \; R^2 = 0.7083 \qquad (7)$$

Figure 10 refers to fine/medium sand. The $G_{0(m)}/M_{DMT}$ vs. K_D datapoints (Figure 10a) plot very close to the correlation proposed by Marchetti et al. (2008) for sand. The moduli $G_{0(m)}$ (Figure 10b) are very similar to the moduli $G_{0(c)}$ calculated according to Marchetti et al. (2008) for sand. The best-fit relationship for the $G_{0(m)}/M_{DMT}$ vs. K_D datapoints in Figure 10a is given by Equation 8:

$$\frac{G_{0(m)}}{M_{DMT}} = 8.7499 \, K_D^{-1.283} \; R^2 = 0.7684 \qquad (8)$$

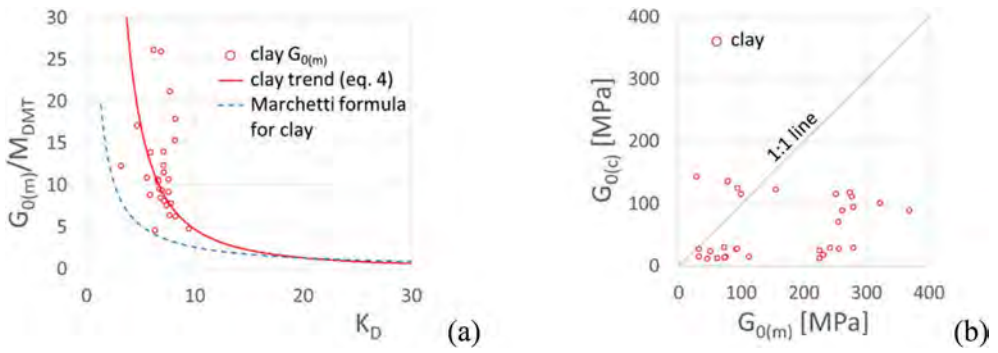
Figure 11 refers to fine/silty sand. The $G_{0(m)}/M_{DMT}$ vs. K_D datapoints (Figure 11a) plot very close to the


Figure 6. (a) Relationship between $G_{0(m)}/M_{DMT}$ and K_D in clay. (b) Comparison between $G_{0(m)}$ obtained from measured V_S and $G_{0(c)}$ calculated according to Marchetti et al. (2008) for clay.

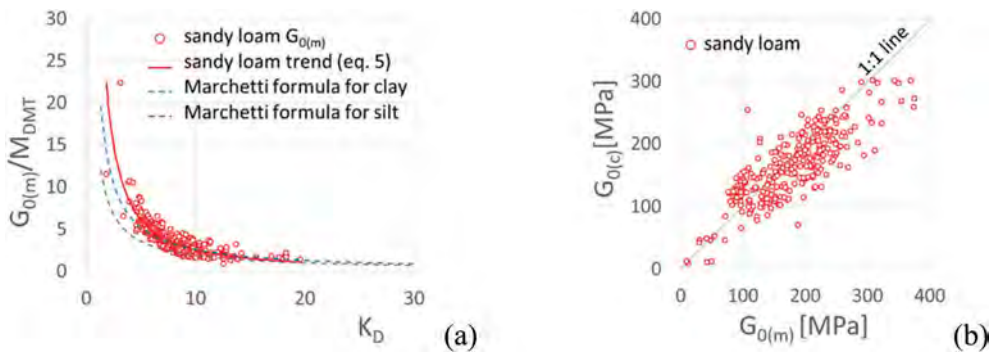
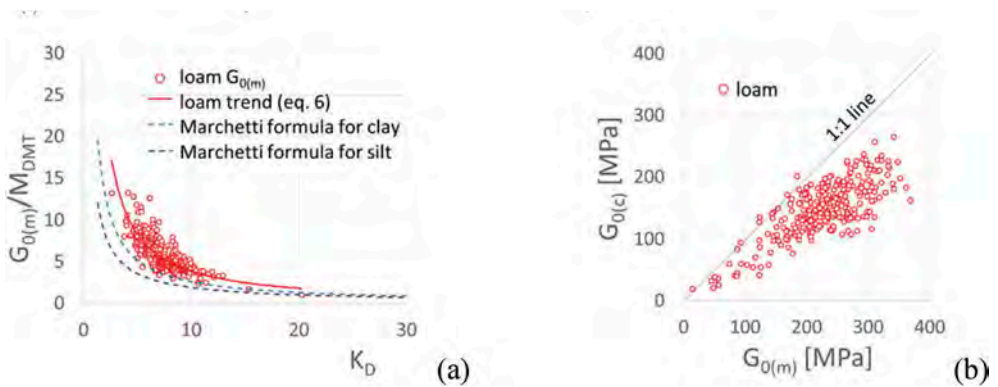
Figure 7. (a) Relationship between $G_{0(m)}/M_{DMT}$ and K_D in sandy loam. (b) Comparison between $G_{0(m)}$ obtained from measured V_S and $G_{0(c)}$ calculated according to Marchetti et al. (2008) for clay.

Figure 8. (a) Relationship between $G_{0(m)}/M_{DMT}$ and K_D in loam. (b) Comparison between $G_{0(m)}$ obtained from measured V_S and $G_{0(c)}$ calculated according to Marchetti et al. (2008) for clay.




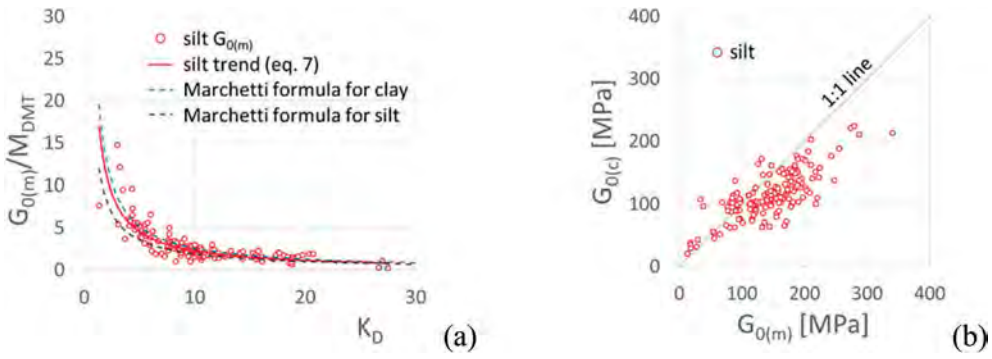


Figure 9. (a) Relationship between $G_{0(m)}/M_{DMT}$ and K_D in silt. (b) Comparison between $G_{0(m)}$ obtained from measured V_S and $G_{0(c)}$ calculated according to Marchetti et al. (2008) for silt.

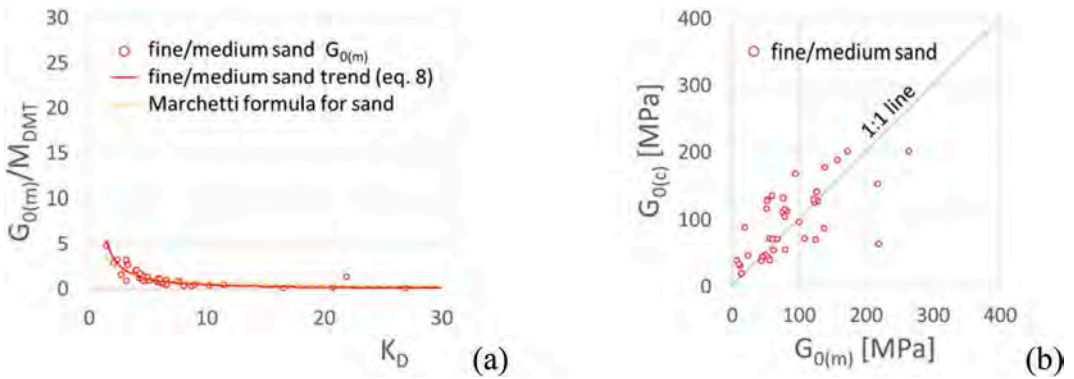

Figure 10. (a) Relationship between $G_{0(m)}/M_{DMT}$ and K_D in fine/medium sand. (b) Comparison between $G_{0(m)}$ obtained from measured V_S and $G_{0(c)}$ calculated according to Marchetti et al. (2008) for sand.

correlations proposed by Marchetti et al. (2008) for silt and for sand. The moduli $G_{0(m)}$ (Figure 11b) are very similar to the moduli $G_{0(c)}$ calculated according to Marchetti et al. (2008) for sand. The best-fit relationship for the $G_{0(m)}/M_{DMT}$ vs. K_D datapoints in Figure 11a is given by Equation 9:

$$\frac{G_{0(m)}}{M_{DMT}} = 16.716 K_D^{-1.184} \quad R^2 = 0.6582 \quad (9)$$

The lowest values of the coefficient R^2, obtained for clay ($R^2 = 0.6102$) and for fine/silty sand ($R^2 = 0.6582$), are very similar to those found by Marchetti et al. (2008) in clay and sand (Figure 4). Possibly in these soils the assessment of the $G_{0(m)}/M_{DMT} - K_D$ relation is affected by local variability in grain size distribution and macrostructure at the various sites.

Due to the significant impact of overconsolidation on the functional shape of the relationship $G_{0(m)}$ vs.

K_D in cohesive soils, a new correlation was established in which $G_{0(m)}$ was normalized by the preconsolidation stress σ'_p. The value of σ'_p was determined from the OCR estimated from DMT.

Figure 12 shows the $G_{0(m)}/\sigma'_p$ vs. K_D datapoints obtained from the tested soils belonging to the group of cohesive soils (sandy loam, loam, clay and silt). The two areas denoted as A and B, that plot far away from the general $G_{0(m)}/\sigma'_p - K_D$ trend line, are related to fissured clays and cemented silts. These soils need a separate interpretation. The best-fit relationship for the $G_{0(m)}/\sigma'_p$ vs. K_D datapoints in Figure 12 is given by Equation 10:

$$\frac{G_{0(m)}}{\sigma'_P} = 1548 K_D^{-1.058} \quad R_2 = 0.6703 \quad (10)$$

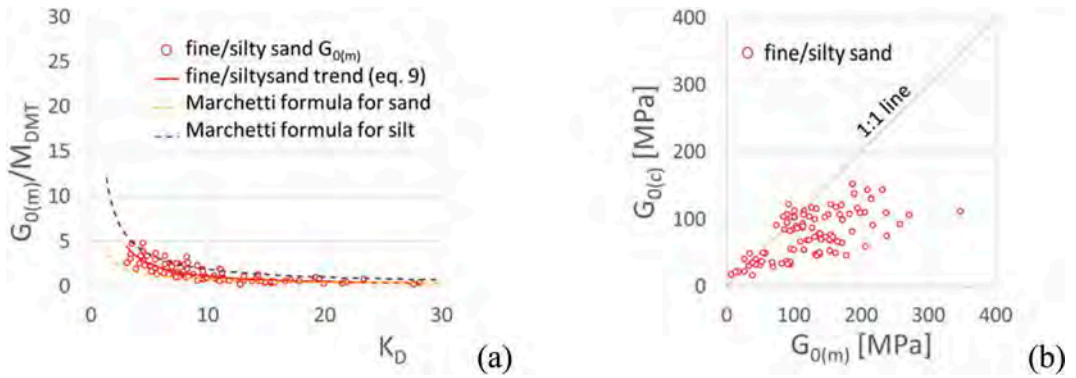
This correlation has a satisfactory statistical evaluation and, in principle, could be applied to all cohesive soils to estimate G_0 based on K_D.


Figure 11. (a) Relationship between $G_{0(m)}/M_{DMT}$ and K_D in fine/silty sand. (b) Comparison between $G_{0(m)}$ obtained from measured V_S and $G_{0(c)}$ calculated according to Marchetti et al. (2008) for sand.

Figure 12. Relationship between $G_{0(m)}/\sigma'_p$ and K_D for sandy loam, loam, clay and silt.

5 CONCLUSIONS

The obtained research results allow to formulate the following general conclusions.

a. In the construction of the correlation $G_0/M_{DMT} = f\,(K_D)$ it is necessary to take into account soil type, with a general distinction between cohesive and non-cohesive soils. This fully confirms the concept by Marchetti et al. (2008).

b. Overconsolidation has a significant influence on the functional form of the $G_0/M_{DMT} = f\,(K_D)$ relationship. For the examined OC loams, especially for clays, the Marchetti et al. (2008) correlations require some correction. Grain size of the soil and overconsolidation are significant. On the other hand, a satisfactory agreement between the G_0 measured and calculated according to Marchetti et al. (2008) was found for medium/fine sands and silts, and in general for NC soils (low K_D).

c. The proposed $G_{0(m)}/M_{DMT} = f\,(K_D)$ correlations have a high statistical significance and may prove useful to determine a continuous profile with depth of G_0 in soils of different origin based on standard DMT test results.

d. Fissured clays and cemented soils require a separate extensive analysis and interpretation.

e. The relationship $G_{0(m)}/\sigma'_p = f\,(K_D)$ can be considered very promising for practical purposes, because it allows to determine G_0 for the whole set of OC cohesive soils.

Physical and numerical modelling of T-CPT for mechanisms of penetration and heat transfer

ABSTRACT: Thermal-Cone Penetration Test (T-CPT) is proposed as a new type of in-situ soil testing method for estimations of both mechanical and thermal properties of soil layers. Physical modelling of T-CPT is conducted in this study to obtained the effects of soil density, penetration depth and heating duration on the penetration resistance and thermal responses. Discrete Element Method (DEM) is then adopted to simulate the processes of penetration, heating and cooling, for investigations of penetration induced stress and temperature distributions in the surrounding soil. The measurements of thermal responses are analyzed to validate the simulation and to evaluate the interpretation method for thermal properties. The results could be used as a benchmark for further analyses of mechanisms of penetration and heat transfer. The interpretation method for T-CPT data is to be developed to improve the performance, with implications to utilization of geothermal energy.

1 INTRODUCTION

Utilization of geothermal energy has become one of the most important and practicable approaches for solving energy shortage with rapidly growing demand and environmental problems (EIA 2009; Capareda 2019). Geothermal energy pile, serving as a new type of pile foundations to extract and/ or inject heat into ground at shallow depths using heat carrier medium in heat exchanger piles, can provide majority of required heating/cooling energy, save energy costs, and reduce fossil fuel demand and carbon footprint (Rotta Loria and Laloui 2017; Sani et al. 2019). However, the measurements and determinations of thermal properties are crucial to the evaluation of geothermal energy in the soil profile and the estimation of heat amount to be extracted or injected into the soil layers (Loveridge et al. 2015). Thermal cone penetration test (T-CPT) is a new in-situ testing method based on the traditional cone penetration test, by introducing additional temperature sensors and/or heating elements, which aims to simultaneously measure both mechanical

and thermal responses of the probe during penetration (Akrouch et al. 2016; Vardon et al. 2019; Mo et al. 2021). As a convenient in-situ testing technique, the T-CPT avoids the sampling disturbance for laboratory tests and overcomes the defects of high cost and long testing time of in-situ thermal response test. This tool is useful and convenient in practical applications by inserting the probe into certain depths and conducting thermal tests during the pause of penetration. It is of great significance to the development and utilization of geothermal energy.

In order to look insight into the macro-micro penetration and thermal mechanisms of T-CPT, a type of T-CPT probe and its testing method are proposed in this study to measure the thermal responses of both heating and cooling stages after certain penetration depths. The penetration and heat conduction of T-CPT are then simulated using discrete element method, with investigation of soil movement, force chain and penetration resistance during probe pushing. The thermal responses during heating and cooling are also examined to evaluate the heat transfer mechanisms and the interpretation methods.

2 PHYSICAL MODELLING OF T-CPT

2.1 *Physical model and penetrometer of T-CPT*

This study attempts to conduct physical model-ling of T-CPT, to develop a new type of in-situ CPT based testing method and to investigate the relations between soil properties and penetration and temperature responses. The testing system is assembled by the container with soil, penetrom-eter, actuator and data acquisition, as shown in the schematic of Figure 1a. This model with 1 m cubic size is small enough to conduct full-size (36 mm diameter) penetration tests without introducing significant boundary effects. A T-CPT penetrometer is proposed in this study, by install-ing a section with heating elements behinds the traditional standard CPTu module (Figure 1b). The heat section is embedded between two insu-lation sections, and three temperature sensors are equipped at different locations in the heat and insulation sections.

The soil used in the experiments is typical sand in Xuzhou, China, with an average diameter of d_{50} = 0.5 mm, uniformity coefficient of c_u = 2.44, and curvature coefficient of c_c = 1.05. The thermal properties are measured by Hot Disk Analyser at CUMT, giving that thermal conduct-ivity $k = 1.15 \text{W/m/K}$ and specific heat cap-acity $c = 850 \text{J/kg/K}$.

The probe is pushed at various depths (i.e. z = 180, 360, 540mm) for heating and cooling tests, and the heating periods are designed with 60, 120, 300, and 600 s, to investigate the effects of stress con-dition and heating time. Temperature sensors are also embedded in the soil at various locations to obtain the temperature distributions during heating and cooling. Note that the physical model is a full-scale model with limited boundary effects, and thus the scale effect for mechanical and thermal measurements should be negligible.

2.2 *Results of penetration*

Th results of cone tip resistance in soils with dif-ferent relative density are presented in Figure 2. The two tests in dense sand with relative density of 80 % provide comparable developments of penetration resistance, validating the repeatability of the testing method. The maximum q_c is reached at a magnitude of 1 MPa after a depth of about 180 mm, which is 5 times of probe diam-eter. This surface influence zone is relatively larger, owing to the stress gradient and the low stress condition without surcharge. The changes of tip resistance after 360 mm of penetration are presumably attributed to the inhomogeneous soil layers and the approximating bottom boundary. The loose sample, with relative density around 50 %, generally shows 40 % smaller cone tip resistance.

Figure 1. Physical model for T-CPT and design of penetrometer.

Figure 2. Cone tip resistance against penetration depth.

2.3 Results of heating and cooling

The heating and cooling tests are conducted following the pause of penetration. The temperature responses of three sensors installed in the probe during the heating for 600 s in dense sand and the subsequent cooling are described in Figure 3a. The temperature of Sensor 1, which is located at the center of heating elements, rises to 58 ºC at 600 s, whereas the increase for Sensor 2 (at side of heating elements) is less than 25 ºC. The Sensor 3 is mounted in the insulation section, which is less affected by the heating elements. However, the gradual increase of 8 ºC is attributed to heat conduction through soil. Both measurements from Sensor 1 and Sensor 2 can be directly used for interpretation of soil thermal properties.

The temperature response of soil is depicted in Figure 3b, based on the three embedded temperature sensors at a similar depth with the heating elements of the probe. The radial distances to the center of probe is 20, 40, and 60 mm, respectively. It is clear to notice that the trends of temperature change are similar to the probe sensors, whereas the curves are more gradual, and the peak appears later with longer distance for heat transfer. It also shows the magnitude of temperature distribution around the probe at a given moment during heating and cooling, contributing as an important benchmark for numerical and theoretical calculations.

The results of Sensor 1 in dense sand, with various penetration depth (i.e. $z = 10$, 20, 30R, R is probe radius) and different heating duration ($t_{heat} = 60$, 120, 300, 600s) are systematically analyzed. Similar trends are obtained, and the traditional interpretation method of ASTM (2014) and Vardon et al. (2019) gives an average estimation of thermal conductivity with $k_{pred} = 1.27$W/m/K, which is 10% overestimation comparing to the calibrated 1.15W/m/K from elementary tests. This indicates that the proposed T-CPT penetrometer and testing procedure with limited heating and cooling durations need to be applied with an improved interpretation method based on further investigation of mechanisms of penetration and heat transfer.

3 DEM SIMULATION OF T-CPT

3.1 Mechanical and thermal properties of soil sample

To investigate the mechanisms of penetration and heat transfer of T-CPT, the testing processes with penetration, heating and cooling are simulated using three-dimensional Discrete Element Method (DEM). The soil is prepared to mimic the Ottawa 20-30 sand, with an average diameter of $d_{50} = 0.725$ mm, uniformity coefficient of $c_u = 1.13$, and curvature coefficient of $c_c = 1.01$. Cubic samples with side length of 13 mm are created using about 5800 spherical particles for triaxial tests, to verify its mechanical behaviour. In order to maintain a similar initial void ratio with $e_0 = 0.650$ before shearing, isotropic consolidation tests under different confining pressures are conducted by setting corresponding frictional coefficient between particle contacts. Considering the calculation efficiency and accuracy, the finish of consolidation is defined by the following criterions according to Zhao et al. (2020):

$$\beta_f = \frac{\Sigma_{Bj\in V}\left|\Sigma_{c\in Bj}(f_j^c + f_j^b)\right|}{2\Sigma_{c\in V}|f^c|} \leq 0.002 \qquad (1)$$

$$\gamma_f = \frac{|p' - \sigma_0|}{\sigma_0} \leq 0.04 \qquad (2)$$

$$\delta_f = \frac{q}{p'} \leq 0.04 \qquad (3)$$

where β_f = unbalanced force ratio, f_j^c and f_j^b = total contact force and body force of the jth particle, f^c = contact force; γ_f = error of mean stress, σ_0 = designed confining pressure, p' = mean stress of particle assembly; and δ_f = ratio of deviatoric and mean stresses, q = deviatoric stress of particle assembly.

Figure 3. Temperature responses of sensors in probe and soil.

The consolidated samples under confining pressure of 0.1 MPa, 2.0 MPa, and 3.5 MPa are adopted to conduct undrained triaxial shear tests with a constant strain rate of 0.08 %/s. The particle-particle friction coefficient is 0.3, and both normal and shear contact stiffnesses are set as 3×10^2 kPa, using linear elastic contact model. The results of triaxial shear tests show that the critical states of samples are reached with large shear strain for $\varepsilon_1 > 30\%$, and the ultimate stress ratios lead to the estimation of internal friction angle with $\phi_{cs} = 21.5°$. The softening phenomenon after peak stress ratio is more obvious for sample with lower confining pressure, and the dilation is restrained under high stress condition, which indicating the reasonability of the mechanical properties of the granular material.

The thermal properties of soil samples in this study are calibrated by elementary tests for one-dimensional heat conduction. The unit thermal resistance T_c in DEM model is defined by the following heat transfer relationship between two contacted particles:

$$\Delta T \cdot n_i = T_c \cdot L \cdot q_i \tag{4}$$

where ΔT = temperature difference between particles, n_i = direction of heat transfer, L = distance between particle centers, q_i = heat flux of unit length. The thermal dilation is also considered to include the thermal effects on stress-strain behaviour of granular material, by defining a linear relation with:

$$\Delta R = \alpha \cdot R \cdot \Delta T \tag{5}$$

where α = coefficient of linear expansion, R = radius of particle, and ΔR = temperature induced change of particle radius.

Taking $\alpha = 2 \times 10^{-7}$ K^{-1} for silicon sand, soil samples with over 10,000 particles and identical particle size distributions are calibrated to examine the variation of heat conductivity against samples with different unit heat resistance and void ratio. Figure 4a presents the stabilized temperature field after 600 s of heat conduction with a constant temperature gradient of 1 K/cm. The results of heat conductivity varying with unit heat resistance and void ratio are shown in Figure 4b, which also serve as a benchmark for the design of thermal properties of granular material.

3.2 Numerical model of T-CPT

According to the axisymmetric model, a quarter model with 90° sector is adopted in this study, while the soil parameters are calibrated through the aforementioned elementary tests. To minimize the calculation time for a physical model of T-CPT, the soil samples with radius of 42 mm and height of 45 mm are prepared as previous

(a) Temperature field after heat conduction

(b) Variation of thermal conductivity with void ratio and thermal resistance
Figure 4. Results of one-dimensional thermal conduction for calibration of thermal properties.

sections, whereas the outer particles (i.e. distance to center larger than 21 mm) are expanded uniformly to reduce the total particle number to around 55,000. The soil samples are initially consolidated by gravity and then compressed with an overburden pressure of 200 kPa, resulting an average initial void ratio of $e_0 = 0.614$. The particle density is 2650 kg/m^3, and frictional coefficient between particles is again set as 0.3.

A penetrometer with diameter of 6 mm and apex angle of 60° is modelled for T-CPT tests, with a proportion of 1/6. The frictional shaft is set behind the cone shoulder with a length of 5 mm, and the heating section is in coincidence with the frictional shaft. To evaluated the scale effect, the ratio of probe diameter and average particle size is approximately 8.3, and the ratio of sample size to probe size is larger than 14 to reduce the boundary effect. The penetration is conducted at a constant velocity of 20 mm/s, and the total penetration depth is about 36 mm. The initial temperature field is set as 20 °C, and the heating and cooling processes are simulated after the pause of penetration. According to the

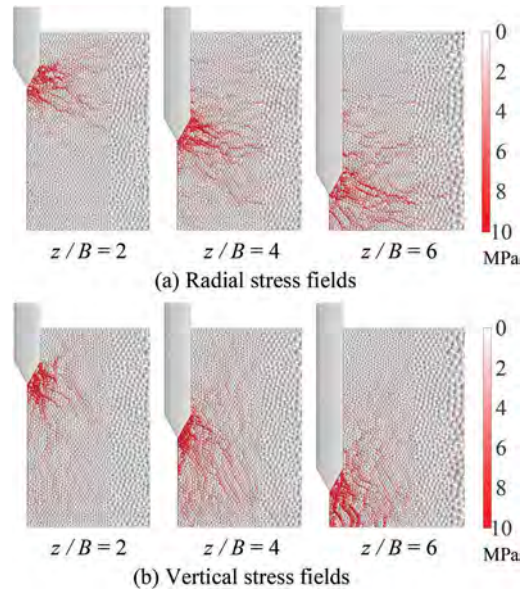
calibration chart of Figure 4b, the unit thermal resistance is set as 2.5×10^6 K/W/m, giving an equivalent thermal conductivity of $k = 1.1$ W/m/K. The specific heat capacity is 960 and 460 J/kg/K for probe and soil, respectively. The heat power is 0.04 W, due to the scaled heating element in the miniatured probe. The heating period lasts for 60 s and the subsequent cooling stage is longer than 420 s. The numerical results of penetration and heat transfer are described in the following sections. With these results, the soil distortion, mechanical developments and heat transfer during penetration, heating and cooling are clear to understand the T-CPT mechanisms, which could contribute to the interpretation of T-CPT data in practical applications.

3.3 Results of penetration

The normalized cone tip resistance q_c/σ'_{v0} against normalized penetration depth z/B is shown in Figure 5. The penetration resistance increases with depth, and tends to reach a relative constant magnitude with 18 times of initial vertical stress after a transition zone with a depth of 2.5 times probe diameter.

Figure 5. Normalized cone tip resistance during penetration.

The penetration induced soil stress distributions at various penetration depths (i.e. $z/B = 2$, 4, 6) are described in Figure 6 for both radial and vertical stress fields. It is clear to notice that the stress distribution around the penetrometer is mainly developed adjacent to the cone tip. Comparing to the development of radial stress, the degradation of vertical stress is generally concentrated in vertical directions below the cone face. Apart from the growing penetration induced stresses, the influence zone is also increased with penetration depth. The results of stress fields provide the meso-scale information of penetrometer-soil interaction, along with the force chain distributions and evolution during penetration.



(a) Radial stress fields

(b) Vertical stress fields

Figure 6. Results of one-dimensional thermal conduction for calibration of thermal properties.

3.4 Results of heat transfer

During the heating and cooling stages after the pause of penetration at $z/B = 6$, the heat flux is transferred from heating element embedded in the probe to the surround soil through heat conduction. The temperature fields at various heating and cooling periods are depicted in Figure 7, showing the evolution of heat conduction. It is obvious to see that the heat transfer in soil is mainly in a spherical profile, owing to the relatively small size of heating element. The contours shown in Figure 7 also describe the influence zone of heating. After 60 s of heating, the surrounding soil with a size of probe diameter is affected by notable temperature change (i.e. 1 ºC). The size of this influence zone increases with time through heat conduction, while the magnitude of temperature dissipates during the cooling stage.

Figure 7. Results of one-dimensional thermal conduction for calibration of thermal properties.

The measurements of temperature in the probe are obtained at both heat section and insulation section, as presented in Figure 8a. The blue curve indicates the temperature at the center of heating element, which rises to 34.9 ºC at 60 s of heating and reduces significantly in the following cooling stage. The element at the heat insulation section is hardly affected, while limited temperature change (<0.8 ºC) is induced by the heat transfer from heated soil.

Figure 8. Results of one-dimensional thermal conduction for calibration of thermal properties.

The interpretation of temperature response is shown in Figure 8b and 8c, based on the methods of Vardon et al. (2019) for both heating and cooling stages. Although the heat power is relatively small and the heat transfer in granular material is complex, the back-calculated heat conductivity is not far from the input value of $k = 1.1 \mathrm{W/m/K}$. The heating data gives the predicted magnitude of heat conductivity $k_h = 1.149 \mathrm{W/m/K}$, with 4.5 % of overestimation. Additionally, the error is larger for cooling data, resulting in $k_c = 1.19 \mathrm{W/m/K}$, even though the cooling stage lasts for over 400 s. It may be contributed to the boundary effect, since the side and bottom boundaries are not far enough from the cone and the they are set as adiabatic. Note that these differences may be attributed to the material properties, especially from the mechanical aspects. Detailed investigation is to be conducted to promote the simulation of penetration and heat transfer and thus to improve the interpretation method with limited heating and cooling time in further studies.

4 CONCLUSIONS

Physical modelling and DEM simulation of T-CPT are conducted in this study to investigate the mechanisms of penetration and heat transfer. A type of T-CPT probe with both temperature sensors and heating elements is proposed, together with its testing method for heating and cooling after a pause of penetration. Apart from the measurement of penetration resistance, the thermal responses of sensors in the probe and soil are obtained to examine the temperature changes and heat conduction during heating and cooling stages. The existing interpretation method is shown to overestimate the thermal conductivity of soil. DEM model is later validated to simulate the processes of T-CPT, after calibration of thermal properties of granular material. The distributions and evolutions of stresses and temperature in soil are presented to illustrate the meso-scale mechanisms of penetration and heat conduction. The simulated thermal responses are analyzed to validate the numerical method, and to evaluate the existing interpretation method. The results of this study are important to understand the mechanisms of probe-soil interactions, which could contribute to the further developments of T-CPT and its testing and interpretation methods.

Soil stratigraphy from seismic piezocone data and multivariate clustering in alluvial soil deposits: Experience in the Lower Tagus Valley region

F. Molina-Gómez, D. Cordeiro, C. Ferreira & A. Viana da Fonseca
CONSTRUCT-GEO, Faculdade de Engenharia da Universidade do Porto (FEUP), University of Porto, Portugal

ABSTRACT: The identification of soil stratigraphy at a given site is crucial for geotechnical analysis and design. This study addresses the delineation of soil stratigraphy from seismic piezocone penetration test (SCPTu) measurements. For this purpose, SCPTu data from an experimental site in the Lower Tagus Valley region (close to Lisbon) were compiled. Soil stratigraphy was obtained by applying a multivariate clustering approach using the direct measurements reported by SCPTu. The hierarchical clustering results were compared against the soil behaviour index profile. Moreover, the differences/similitudes obtained from multivariate clustering were validated by contrasting statistical results against the visual description of samples collected in the experimental site at Lower Tagus Valley using advanced sampling techniques; namely, Gel-Push sampler. The main findings showed that the clustering approach implemented herein detects and groups soil layers with similar soil behaviour types, allowing delineating the soil stratigraphy in multilayer alluvial soil deposits.

1 INTRODUCTION

The identification of soil stratigraphy is one of the main concerns for the characterisation of soils deposits. A realistic identification of the soil variability in depth reduces the failure probability of geotechnical structures. The cone penetration test (CPT) and its enhanced versions provide reliable identification of soil multi-layering due to its simultaneous measurements. Hence, soil stratigraphy can be assessed using CPT data by correlating in situ measurements with parameters inferred by applying a strong theoretical background.

Although no samples are recovered in CPT sounding, the large number of data from this type of testing allows identifying the soil stratigraphy. Therefore, such data can be interpreted by statistical methods. Hegazy & Mayne (2002); Liao & Mayne (2007); Molina-Gómez, Viana da Fonseca, Ferreira, Sousa, & Bulla-Cruz (2021) applied cluster analysis approaches to delineate the stratigraphy in different types of soil deposits. In these studies, the authors compared their statistical analyses against soil behaviour index profiles, originally proposed by (Robertson 1990). Such a comparison showed a good fitting between results, validating the applicability of clustering for delineating the soil stratigraphy.

This study addresses the delineation of soil stratigraphy from seismic piezocone (SCPTu) measurements by applying the clustering approach proposed by Molina-Gómez, Viana da Fonseca, Ferreira, Sousa, & Bulla-Cruz (2021). The SCPTu measurements were carried out in an experimental site located at Lower Tagus Valley, south of Portugal. Embedded layers of sandy and clayey soils with an alluvial origin from the Tagus River compose such an experimental site (Viana da Fonseca, Ferreira, Ramos, & Molina-Gómez 2019). Besides, in such a site, high-quality undisturbed samples were collected using an advanced sampling technique—the Gel-Push (GP) sampler. The visual observation of these samples confirmed the detected stratigraphy from the multivariate clustering.

2 DESCRIPTION OF THE CLUSTERING APPROACH

In this study, the agglomerative hierarchical clustering approach proposed by Molina-Gómez, Viana da Fonseca, Ferreira, Sousa, & Bulla-Cruz (2021) was applied. Such an approach comprises the following phases: (*i*) selection of the data and identification of variables; (*ii*) standardisation of the variables; (*iii*) computation of the distance (or similarity) matrix; (*iv*) application of clustering technique; (*v*) selection of the cut level of the dendrogram, associated with the best partition, for defining the number of clusters; (*vi*) interpretation of cluster results; and (*vii*) validation by comparison against soil behaviour type profiles. Besides, it includes a comparison against visual examination of high-quality undisturbed samples collected using the GP sampler, as a novel validation in such a clustering approach. The clustering procedure adopted for this study is described following.

For the data standarisation, the Zscore method was adopted, as suggested by Hegazy & Mayne (2002):

$$Z_{ij} = \frac{x_{ij} - \bar{x}(X_j)}{s(X_j)} \qquad (1)$$

where Z_{ij} is the standardised value, x_{ij} is the SCPTu measurement at a certain depth of the SCPTu variable, X_j is the SCPTu variable of each profile, $\bar{x}(X_j)$ is the average of the SCPTu variable and $s(X_j)$ is the standard deviation of the SCPTu variable.

The distance among pairs of objects is represented by a matrix $D_{(n \times n)}$ (Härdle & Simar 2015). Equation 2 describes the matrix distance, D, that contains measures of similarity among the n objects, where $d_{i,j}$ are the distances between the measurements of SCPTu variables.

$$D = \begin{bmatrix} d_{1,1} & d_{1,2} & \cdots & \cdots & \cdots & d_{1,n} \\ \vdots & d_{2,2} & \ddots & & & \vdots \\ \vdots & d_{3,2} & & \ddots & & \vdots \\ \vdots & d_{4,2} & & & \ddots & \vdots \\ d_{n,1} & d_{n,2} & \cdots & \cdots & \cdots & d_{n,n} \end{bmatrix} \qquad (2)$$

Nowadays, there are different similarity measurements, including Euclidean distance, Manhattan distance, Pearson, cosine and power (Johnson & Wichern 2007). Härdle & Simar (2015) claimed that no specific rule or theory is available on which to base the choice of similarity measurements. In this study, Euclidean distance was used to compute the matrix D of piezocone data, as recommended by (Liao & Mayne 2007). Such a method estimates the geometric distance—based on the Pythagorean theorem—of two observations in a multidimensional space. Equation 3 describes the Euclidean distance of two observations, where k is the number of variables and i is the variable index.

$$d(P,Q) = d(Q,P) = \sqrt{\sum_{i=1}^{k} (q_i - p_i)^2} \qquad (3)$$

Starting with the matrix D (see Equation 2) an iterative procedure takes place to join/grouping the most similar classes and update matrix D, which ends when all data is grouped in a particular cluster (Bulla-Cruz, Lyons, & Darghan 2021). The iterations are carried out according to a specific aggregation criterion. In this study, the complete linkage method was applied. The algorithm of complete linkage distance is:

$$d(R, P+Q) = \max\{d(R,P), d(R,Q)\} \qquad (4)$$

where $P + Q$ are clustered measurements of SCPTu variables and R is a possible new group.

The best-known result of a Hierarchical Classification is a graphical representation—dendrogram. The quality of SCPTu data grouping (i.e. the number of clusters) can be assessed by comparing the number of soil classes identified by the soil behaviour type (SBT) chart proposed by (Robertson 1990). Afterwards, such a number is validated by the Average Silhouette Method (Rousseeuw 1987). The Average Silhouette Method computes the average silhouette of observations for different numbers of clusters (K), indicating K_{opt} value as the maximum average silhouette over a range of possible values for a different number of clusters.

Figure 1. Experimental site map and location of the investigation points.

As before noticed, the underlying mathematics of cluster analysis is simple to implement. However, it requires extensive calculations because of the large amount of data. Therefore, all computations were conducted in RStudio, which is a free integrated environment for statistical programming and graph plotting (Molina-Gómez, Bulla-Cruz, & Darghan 2019).

3 EXPERIMENTAL SITE

Within the scope of two research projects on soil liquefaction developed in the CONSTRUCT-GEO research centre of FEUP, a vast site characterisation campaign was carried in an experimental site in the Lower Tagus Valley (south of Portugal). The site characterisation comprised the definition of liquefaction risk by microzonation maps (Saldanha, Viana da Fonseca, & Ferreira 2018). This geotechnical test site is located in the municipalities of Vila Franca de Xira and Benavente, covering a zone with 14683 ha area and 50.8 km perimeter. In situ tests for geotechnical characterisation were performed at specific locations, referenced as site investigation points (SI). Figure 1 shows the map and SI locations within the experimental site.

For this study, SI15 was selected since there advanced sampling techniques were implemented for collecting high-quality samples for the first time in Portugal (Molina-Gómez, Viana da Fonseca, Ferreira, Ramos, & Cordeiro 2021). The groundwater level in SI15 was identified at about 2.5 m depth. Moreover, in this point, an SCPTu was carried out. Shear wave velocities (Vs) were measured at each 0.50 m depth. The values of cone resistance (q_c), sleeve friction (f_s) and pore-water pressure generated during cone penetration (u_2) were averaged each ± 0.25 m depth (ranges of 0.5 m), considering the depth of the V_S measurements, to compare the SCPTu data profiles. Figure 2 presents the SCPTu profiles and the averaged values in the specific depths of V_S measurements at SI15.

Figure 2. SCPTu profiles at SI15.

The SCPTu data were analysed using the software Cliq v.3.0. The analyses were carried out based on the unified approach proposed by Robertson (1990), which includes the classification of soil behaviour type (SBT) zones according to the soil behaviour type index (Ic). Ic computation considers the following procedure:

$$Q_t = \frac{q_t - \sigma_{v0}}{\sigma'_{v0}} \qquad (5)$$

$$Fr = \left(\frac{f_s}{q_t - \sigma'_{v0}}\right) 100\% \qquad (6)$$

$$Ic = \left[(3.47 - \log Q_t)^2 + (\log Fr + 1.22)^2\right]^{0.5} \qquad (7)$$

where q_t is the cone resistance corrected for pore water effects ($q_t = q_c + u_2(1 - a)$); a is the cone area ratio; σ_{v0} is the current in situ total vertical stress; σ'_{v0} is the current in situ effective vertical stress.

Figure 3 presents the interpretation of the soil profiles in terms of soil type chart. Classification results indicate that the soil profile at SI-15 has five different soil types, which are characteristic of soil deposits in the Lower Tagus Valley from the Quaternary (Ferreira, Viana da Fonseca, Ramos, Saldanha, Amoroso, & Rodrigues 2020).

The soils of the experimental site appear in zones **3**, **4**, **5** and **6**, thus typically behave as `clay to silty clay', `clayey silt to silty clay', `silty sand to sandy silt' and `clean sand to sand to silty sand', respectively. Points located in Zone **1** were not considered for defining the number of clusters because there is not a well-defined characterisation for these soil types; that is, out-of-range zones with $Ic = \leftarrow$N/A. Based on the above consideration, the clustering of SI15 can be performed considering four groups.

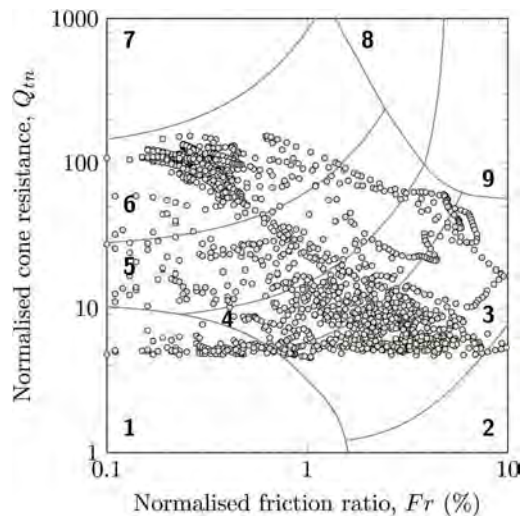

Figure 3. Results of soil classification type.

4 ADVANCED SAMPLING

The collection of high-quality samples is critical to obtain representative test results for soil characterisation in the laboratory (Ferreira, Viana da Fonseca, & Nash 2011). A typical sampling campaign involves the following stages: drilling, sampler insertion, sampler retrieval, tube sealing, transport, soil extrusion, sample storage and preparation for element testing (Hight 2000). Nowadays, sampling processes are conducted using diverse techniques, such as hydraulically activated push tubes, rotary devices and freeze sampling, where the freezing method is the most expensive (Viana da Fonseca & Pineda 2017).

In this research, an advanced sampling technique developed by the Japanese geotechnical company Kiso-Jiban Consultants, to develop a method able to

replace freezing techniques. There are four different variations of GP: GP-Rotary, GP-Drilling, GP-Triple, and GP-Static. In this study, the GP-Static (GP-S) was implemented. This sampling device uses a hydraulic activated fixed-piston and follows the same principle of the Osterberg-type sampler.

On the other hand, the GP is an advanced sampling technique, which uses a viscous polymer gel to collect high-quality undisturbed samples. The gel use, as the main innovation for soil sampling, afforded the name for this technique. The gel must be prepared at a 1 vol% concentration ratio of the viscous polymer in clean water (Mori & Sakai 2016). The purpose of using the viscous gel is to significantly reduce the friction between the sample and walls liner during both the insertion of the sampler into the ground and during the sample extrusion in the laboratory (Viana da Fonseca, Ferreira, Molina-Gómez, & Ramos 2019). Besides, the rheological properties of the polymer gel allow preserving the soil structure of the collected samples.

Figure 4. Schematic of GP sampler components (Molina-Gómez, Ferreira, Ramos, & Viana da Fonseca 2020).

Unlike conventional hydraulic activated fixed-piston, the GP-static device includes three pistons: (i) the stationary piston, (ii) the sampling tube-advancing piston, and (iii) the core-catcher activating piston. At the maximum performance, the GP sampler can collect samples with 71 mm diameter and 1 m length. However, according to the soil type to be sampled, the device can suffer damages in the cutting shoe (Molina-Gómez, Viana da Fonseca, Ferreira, Ramos, & Cordeiro 2021). Details about the performance and quality sampling using the GP sampler are provided in Molina-Gómez, Ferreira, & Ramos (2020). Figure 4 schematises the components of the GP-Static sampler.

The GP sampling was carried out in four boreholes located at about 5 m distance to the SCPTu sounding. During the experimental campaign, a total of 14 GP samples were collected at the SI15 location. The sampling depths were selected considering suitable layers for liquefaction assessment by element testing in the laboratory. The liquefiable layers were defined by detecting zones with $Ic < 2.6$. Figure 5 illustrates the sampling depths for each technique. Moreover, in Figure 5, the sampling depths are contrasted against the averaged soil behaviour index profile of SI15.

Figure 5. Sampling depths for each advanced technique and averaged soil behaviour index profile at SI15.

5 ANALYSIS OF RESULTS

A cluster analysis in terms of the depth (Z) and using the standardised data recorded at SI15 by the four channels of SCPTu (e.g. q_c, f_s, u_2 V_S) was carried out. Liao & Mayne (2007) used normalised data to define the soil stratigraphy by applying a multivariate approach (e.g. Q_t and Fr parameters). However, Molina-Gómez, Viana da Fonseca, Ferreira, Sousa, & Bulla-Cruz (2021) obtained a better groping using standardised raw data instead of standardised normalised data. These authors showed that the differences between clustering were because of the uncertainties associated with the in situ stress-state assessment, which depends on the unit weight (γ). Nevertheless, γ is a physical property that differs according to the CPT correlation applied, although the literature reports several correlations to estimate such a physical parameter, such as Mayne, Peuchen, & Bouwmeester (2010, Robertson & Cabal (2010, Lengkeek, de Greef, & Joosten (2018).

In this study, only the clusters with at least two continuous measurements are considered soil layers, as suggested by Liao & Mayne (2007). Hence, a minimum layer thickness of 1.0 m was defined. Clusters with points without a continuous group of data (single points) were considered as lenses or transition zones (Hegazy & Mayne 2002). The cluster analysis was conducted for obtaining four groups, which correspond to different soil behaviour types or layers previously identified in Figure 3. Such a number of groups was compared against the results of the Average Silhouette Method, which allows estimating the optimum number of clusters, K_{opt}. Figure 6 shows $K_{opt} = 4$, validating the selection of the number of clusters based on the SBT criterion.

Figure 7 presents the dendrogram obtained from the cluster analysis of SCPTu data. This dendrogram shows the clustering of all depths and the distances between the aggregate clusters. A distance of about 5 defined four clusters, which correspond to the layers composing the soil stratigraphy of the studied zone.

Figure 6. Estimation of the optimum number of clusters.

In addition, Figure 7 indicate the SBT zone of each cluster through a comparison against the Ic profile SI15 sounding. This grouping represents the soil

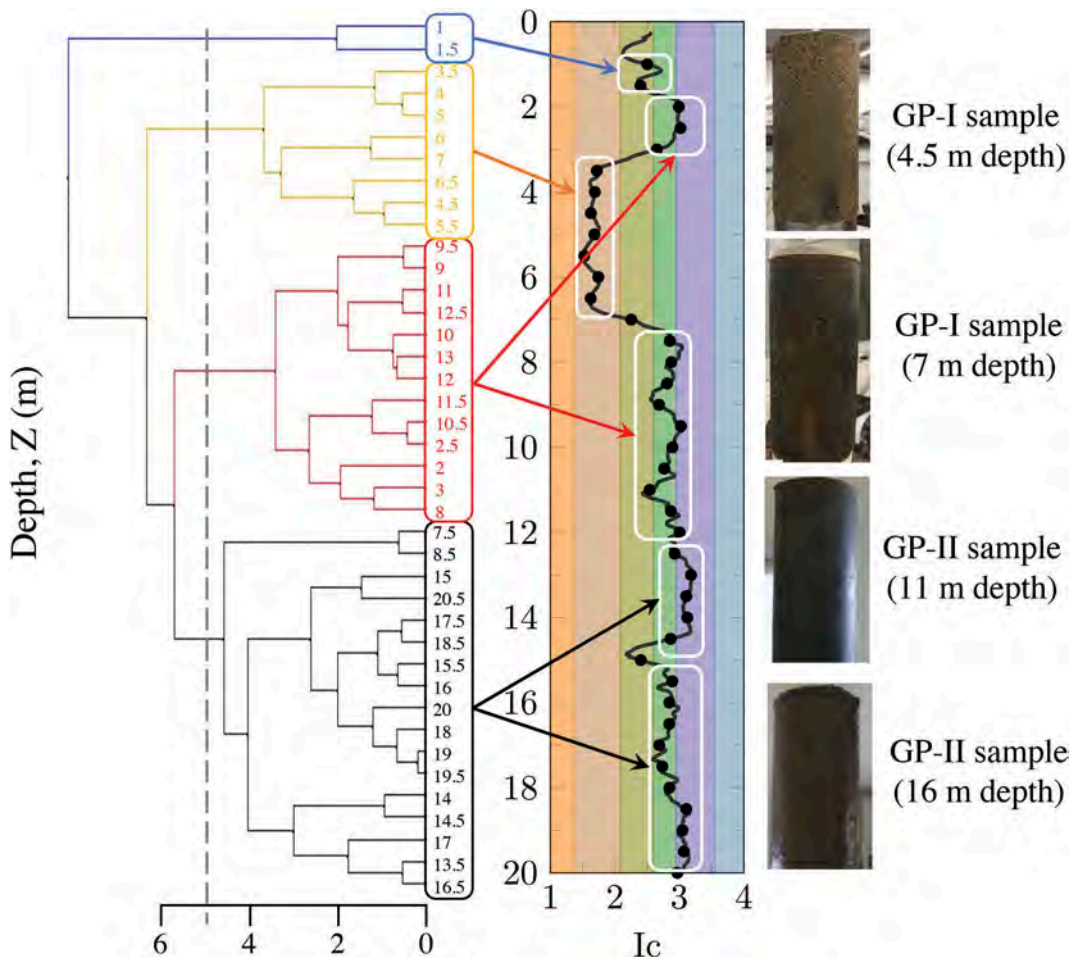

Figure 7. Soil stratrography of SI15 inferred from cluster analysis and comparisons between dendrogram against Ic profile and high-quality samples.

layers that behave as `silty sand to sandy silt' (1 m to 1.5 m depth), `clean sand to sand to silty sand' (3 m to 7 m depth), `clayey silt to silty clay' (2 m to 3 m depth and 8 m 14.5 m depth) and `clay to silty clay' (12.5 m to 14.5 m depth and 15.5 m to 20 m depth). Besides, two transitional layers composed of soils that behave as `silty sand to sandy silt' were identified at 7.5 and 15 m depth.

On the other hand, Figure 7 shows photographs of GP samples collected at representative depths of the layers identified in the cluster analysis (e.g. 4.5 m, 7 m, 11 m and 16 m depth). A visual examination in the laboratory of GP samples supported cluster results; that is, the sample collected at 4.5 m depth is a sand, the sample collected at 7 m depth corresponds to a silt mixture, and the samples collected at 11 m and 16 m depth are clay with different content of granular particles.

The simultaneous comparisons between dendrogram, *Ic* profile and high-quality GP validated the implementation of the clustering approach to define the soil stratigraphy and detect interlayers from SCPTu data. Therefore, the clustering approach proposed herein provided a reliable data grouping for defining soil stratigraphy of alluvial soil deposits of the Lower Tagus Valley—a region with high interlayering. Moreover, this clustering approach can be applied to other datasets from other experimental sites using raw data from the four parameters of the SCPTu. This information provides a method that allows defining soil layers with similar properties and behaviour, useful in the design of geotechnical structures.

6 CONCLUSION

In this paper, a hierarchical clustering approach for defining the soil stratigraphy from SCPTu data at a site investigation point located in the Lower Tagus Valley (south of Portugal) has been applied. The approach comprises a complete-linkage algorithm, formulated in RStudio, which used the Euclidean distance of standardised SCPTu measurements (q_c, fs, u_2 and Vs). The method is objectively capable of classifying similar groups of data in the soil profile, delineating different layer boundaries and soil transitions. The statistical results were validated by comparing the dendrogram against the *Ic* profile and visual examination of high-quality samples collected using the GP sampler. These comparisons are the main contribution of this study since they confirmed the correspondence between the defined stratigraphy (clusters) with the soil behaviour type and soil composing the soil layers. Therefore, this clustering approach can be applied to other datasets from other experimental sites using raw data from the four parameters of the SCPTu.

Undrained strength from CPTu in brittle soils: A numerical perspective

L. Monforte, M. Arroyo & A. Gens
CIMNE-UPC, Barcelona, Spain

ABSTRACT: Static liquefaction of soils that have a brittle undrained response (hydraulic fills, mine tailings or sensitive clays) may lead to sudden failures of large consequence. Given the importance of undrained failure, obtaining precise estimates of peak and residual yield strength is important. The CPTu plays a major role in the geotechnical characterization of these geomaterials and so do CPTu-based estimates of undrained strength. Most of the methods available for CPTu-based estimation of undrained strength are empirical, based on correlation with other laboratory or field tests. When such correlations are established difficulties appear due to variable disturbance affecting the reference laboratory samples and parasitic effects, such as unaccounted for partial drainage during penetration or unknown side friction, affecting the cone results. Such difficulties are not present when using numerical simulation. The paper builds upon a series of CPTu simulations using a model able to represent brittle undrained failure. Confounding factors such as partial drainage and cone side friction are systematically varied to examine their effect on the results. The results are then employed to examine the performance of several empirical methods frequently employed to obtain peak and residual strength from CPTu.

1 INTRODUCTION

Some geomaterials (hydraulic fills, mine tailings or sensitive clays) may exhibit undrained softening upon shearing (static liquefaction): a drastic decrease of the effective mean stress and mobilized undrained shear strength. Static liquefaction is a brittle response that may lead to catastrophic sudden failures, often associated with loss of life and major environmental impact (Gens, 2019). The identification and characterization of these materials is therefore of paramount importance.

The extraction of good-quality samples of these loose/soft soils is challenging and in situ tests are essential for their characterization (Been, 2016; Gens 2019). The interpretation of CPTu soundings in these brittle materials is not always straightforward, particularly as their permeability does frequently result in partly drained conditions (Schnaid, 2021). Nevertheless, several correlations are in use to relate cone metrics and peak and residual undrained shear strength in brittle soils.

Numerical simulation of CPT may offer new insights of the mechanisms during insertion, leading to more reliable interpretation techniques. To this end, Monforte et al (2021) reported a parametric analysis employing the Particle Finite Element method (PFEM) in which several materials with different idealized materials of variable undrained brittleness were considered in the simulation of CPTu. The analysis also assessed the effect of drainage conditions and interface friction angle on cone metrics. In this work we exploit the simulation database of Monforte et al (2021) to assess several cone interpretation techniques frequently employed in current practice to infer undrained strength.

2 NUMERICAL DATABASE

2.1 Simulation method

Numerical simulations (Monforte et al, 2021) have been carried out by means of G-PFEM (Geotechnical Particle Finite Element Method), specially designed for the analysis of problems involving the penetration of rigid structures into fluid-saturated soil masses (Monforte et al, 2017, 2018).

The cone has standard dimensions and is assumed rigid. CPT symmetry allows for an axisymmetric model. The stress state is set up by prescribing a vertical stress of 96 kPa at the top boundary and of 56 kPa at the radial boundary, i.e. a K_0 value of 0.58. The CPT is advanced by 30 diameters into the soil attaining a steady state in all the simulated records.

2.2 Materials simulated

The soil is described by a version of the Clay and Sand Model (CASM) (Yu, 1998; Manica et al. 2021; Arroyo & Gens, 2021). Common constitutive parameters for all cases examined are reported in Table 1. Materials with different brittleness index are obtained by modifying the geometry of the yield surface (shape

parameter, n, and spacing ratio, r), see Table 2. Because of these choices all the simulated materials share the same normal compression line, but their critical state line has different positions on the compression plane. In undrained conditions, all materials share the same peak undrained shear strength, whereas the residual undrained shear strength varies (Table 2).

Example triaxial responses after anisotropic (K_0) consolidation are reported in Figure 1. In undrained conditions, after reaching the peak, deviatoric stresses reduce due to strain softening; material A is the most brittle whereas material H is almost insensitive.

Figure 1. K0 triaxial compression behavior of materials A, E and H: undrained loading, top, and drained loading, bottom.

2.3 Parametric study

For every CASM material, the parametric analysis presented below examines the effect of drainage conditions and soil-cone interface friction angle. Drainage conditions are controlled through permeability values, which have been varied between 10^{-9} m/s and 10^{-3} m/s. To avoid clutter most results below are only presented for three values: 10^{-8} m/s (fully undrained), 10^{-6} m/s (partly drained) and 10^{-3} m/s (fully drained).

The interface friction angles employed ($\delta = 0, 7°, 12°$ and $19°$) correspond to interface efficiencies, $\tan(\delta)/\tan(\phi)$, between 0 and 0.74, since the soil friction angle is $24°$.

Currently, manufactured average roughness, R_a, for CPTu friction sleeves may lie between $0.65\mu m$ and $0.15\mu m$ (EN ISO 22476-1), in a range that aims to approach the roughness that may be later acquired upon use. For fine grained soils the resulting normalized roughness (R_a/D_{50}) will typically vary in the range (10^{-3} to 10^{-1}) that has been experimentally shown (Subba Rao et al. 2000; Eid et al. 2014) to result on interface efficiency between 0.3 and 0.9. On this basis the higher values of interface friction in the parametric study would be representative of testing on clays and fine silts, whereas the lower values would be more representative for testing on coarser silts and sands.

Table 1. Constitutive parameters common for all materials.

κ	λ	M	G (kPa)	K_0	e_0	OCR
0.016	0.053	0.98	3000	0.58	1	1

Table 2. Constitutive parameters varied.

Material	n	r	S_u^{peak} (kPa)	S_u^{res} (kPa)	Ψ
A	10	12	23.5	6.9	0.093
E	8	4	23.8	13.2	0.052
H	4	2	24	22.1	0.026

3 SIMULATION RESULTS AND CLASSIFICATION CHARTS

Figure 2 reports the results in two classification charts proposed by Robertson (1991; 2016). The 1991 chart is expressed using the following normalized parameters

$$Q_1 = \frac{q_t - \sigma_v}{\sigma'_{v0}} \quad B_q = \frac{u_2 - u_0}{q_t - \sigma_{v0}} \quad (1)$$

whereas the 2016 chart is expressed using the following normalized parameters

$$Q_{tn} = \left(\frac{q_t - \sigma_{v0}}{p_a}\right)\left(\frac{p_a}{\sigma'_{v0}}\right)^n \quad F_r = \frac{f_s}{q_t - \sigma_v} \quad (2)$$

where n is an index, which is ultimately dependent on Q_{tn} and F_r, and is established by iteration.

In the B_q vs Q_1 classification graph the dominant effect is that of permeability. The undrained simulations have always $B_q > 0.5$, those drained have $B_q = 0$ and the partly drained ones lie in between. For impermeable materials brittleness plays also a significant

role, with material A (most brittle) generating the larger pore pressures. Interface friction has no systematic effect. According to this chart Material A will classify as sensitive, fine grained, if impermeable, as clay to silty clay if partly drained and as a silt mixture if fully drained.

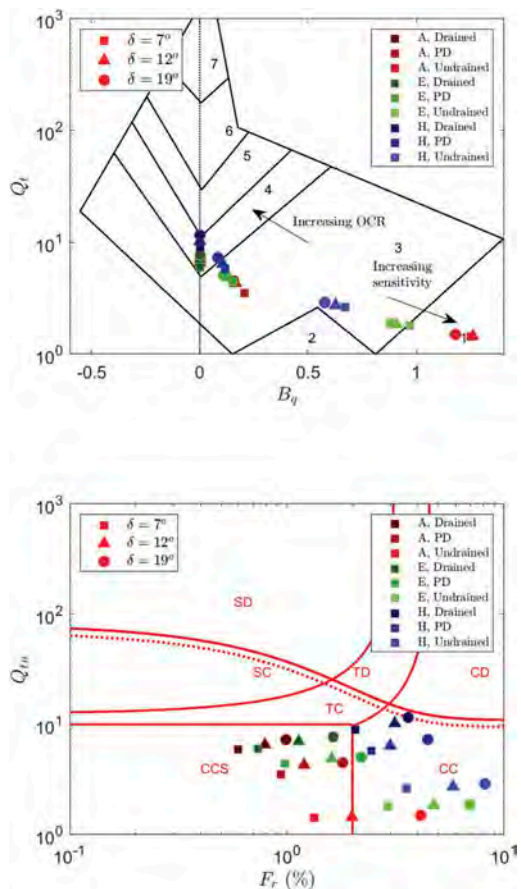

Figure 2. Results of the analyses of CPTu test with different permeabilities and interface friction angles plotted on classification charts. Above: Robertson 1991. Below: Robertson 2016. The marker color indicates undrained brittleness; marker shape indicates side friction values; marker hue indicates pemeability. PD = Partly drained.

In the F_r vs Q_{tn} classification graph all numerical results plot in the "contractive" zone, which is correct as none of the CASM materials were dilatant in shear. For material A most simulated results fall into the "sensitive" zone (CCS), which seems correct. However, this is also the case for material E if partly or fully drained, which seems excessive. There is also some disagreement with the graph when the effect of permeability is considered. Results for all materials and interface frictions shift upwards as permeability is increased. Although this is in line with the trend in the graph, even the fully drained material would

classify as "clay-like" and be expected to behave in an undrained manner under CPTu. Finally, it is noticeable how changes on interface friction result in significant shifts along the F_r axis for the same brittleness and permeability.

4 PEAK UNDRAINED SHEAR STRENGTH

4.1 Cone factors

One of the most frequent and important applications of the CPTu is to obtain estimates of peak undrained strength. The dominant approach uses empirically determined cone factors, that relate cone measurements and undrained strengths. Cone factors based on tip resistance and excess pore pressure are defined as

$$N_{kt} = \frac{q_t - \sigma_v}{s_u} \quad N_{\Delta u} = \frac{u_2 - u_0}{s_u} \quad (3)$$

It has been stressed many times (e.g. Mayne & Peuchen, 2018) that for this approach to make sense the target undrained strength of the correlation should be clearly specified. Peak undrained strengths measured on triaxial compression after anisotropic (K_0) consolidation are adopted here as a target, in line with previous work (e.g. Karlsrud et al. 2005). Another important factor (Lunne et al. 1997) is sample disturbance, as it will affect the laboratory values employed in correlations. Poor sample quality will typically decrease the undrained peak strength measured on the laboratory and thus increase empirically determined cone factors.
Figure 3. Cone factors for peak undrained strength in terms of the brittleness for smooth, undrained simulations.

Figure 3 reports the cone factors in terms of the brittleness index for smooth, undrained simulations. The tip resistance cone factor N_{kt} is far more variable than the pore pressure cone factor $N_{\Delta u}$, something well in line with empirical observations (Lunne et al. 1997). Furthermore, the values of $N_{\Delta u}$ obtained from

these undrained smooth simulations cluster around the value 7.5, well supported by experimental work on Norwegian clays (Paniagua et al. 2019).

The advantage of $N_{\Delta u}$ as a more stable factor disappears when partial drainage is introduced in the picture (Figure 4). Excess pore pressure reduces and the cone factor required to recover peak undrained strength reduces accordingly. The effect of interface friction on this trend appears to be relatively small. The more realistic frictional simulations result on slightly smaller $N_{\Delta u}$ than the empirical average, something that may be explained by a small amount of sampling disturbance.

Figure 4. Simulation results and relations from literature between cone factor $N_{\Delta u}$ and pore pressure parameter B_q.

The variability of N_{kt} is sometimes accounted for using B_q as an auxiliary variable (Lunne et al. 1997; Mayne & Peuchen, 2018). Figure 5 presents the results for frictional undrained and partly drained simulations in that format. The results suggest that the higher cone factors that are sometimes obtained at low B_q may be related to partial drainage. For fully undrained cases, it is also noteworthy that the cone factors for the less brittle material H are only slightly below the value ($N_{kt} = 12$) that empirical studies assign to clays of moderate to low sensitivity (Low et al. 2010). As material brittleness is increased the simulated N_{kt} cone factors reduce. The reduction observed is steeper than what data from general databases, such as that of Mayne & Peuchen (2018) would suggest. This difference is likely to be the result of increased sampling damage for the more brittle soils, something also borne out by the steeper decrease that was observed by Lunne et al (1997), using a more restricted dataset of higher sampling quality.

As noted by Karlsrud et al (2005) a relation between N_{kt} and B_q mediated by $N_{\Delta u}$ is just implied by their definition. According to the results just presented the undrained CASM simulations should then be fitted by

$$N_{kt} = \frac{N_{\Delta u}}{B_q} = \frac{7.5}{B_q} \qquad (4)$$

Which is closely correct for the undrained results and far off the mark for partially drained cases (Figure 6).
Figure 5. Simulation results and relations from literature between cone factor N_{kt} and pore pressure parameter B_q.
Figure 6. Simulation results and relations from literature between cone factor N_{kt} and pore pressure parameter B_q.

4.2 Case-history based correlations

Olson & Stark (2003) back-analyzed case history data of flow liquefaction failures to obtain estimates of stress normalized undrained peak (yield) strength which were then correlated with the results of CPT. This correlation reads

$$\frac{S_u^{pk}}{\sigma_{v0}'} = 0.205 + 0.0143\, q_{c1} \pm 0.04 \qquad (5)$$

$$q_{c1} = q_c \frac{1.8}{0.8 + \left(\frac{\sigma'_v}{p_a}\right)} \quad (6)$$

where the tip and corrected tip resistance q_{c1} are expressed in MPa. The simulated CPT results lie in the range 0.14 to 1.14 q_{c1} for which the correlation predicted upper bound of normalized peak strength is 0.21, only slightly below the input value.

5 RESIDUAL UNDRAINED SHEAR STRENGTH

5.1 Sleeve friction

Empirical observations of the close similitude of sleeve friction to residual undrained strength in clay as measured by vane tests or laboratory test on remolded soil are frequent (Lunne et al. 1997; Robertson, 2010). This can be simply expressed as

$$\frac{S_u^{res}}{\sigma'_{v0}} \approx \frac{f_s}{\sigma'_{v0}} \quad (7)$$

Figure 7 reports the normalized friction sleeve resistance of PFEM simulations in terms of the normalized residual undrained shear strength predicted by CASM; results are plotted for undrained and partly drained conditions. For high interface friction angles and undrained conditions, Equation (7) holds, and the friction sleeve is approximately equal to the residual undrained shear strength. For lower interface friction angles the tangential stress acting on the friction sleeve is lower than the residual undrained shear strength and Equation (7) becomes highly conservative. The importance of sleeve roughness for this correlation is thus clearly demonstrated. Interestingly, the effect of partial drainage is small for the more brittle material A, but large for the less brittle H.

Figure 7. Residual undrained strength and side friction. All results correspond to practically undrained tests.

5.2 Case-history based correlations

Case-history back-analysis by Olson & Stark (2002) in which post-liquefaction geometry was considered led to another correlation of residual undrained strength with corrected tip resistance q_{c1}. Again, the correlation obtained has very little sensitivity to q_{c1} in the range covered by our simulations and the predicted stress normalized residual (liquefied) undrained strength is practically constant. This is interesting, as the stress normalized residual strength is controlled by CASM material parameters and also constant for a given material type. The simulation results are above the recommended limits, but, for the most brittle material A, well within the values supporting the correlation (Figure 8). This comparison is unaffected by partial drainage or sleeve friction values. It is also worth mentioning that although material A is brittle, CASM has been fitted to represent even more brittleness when back-analyzing liquefaction failures (Arroyo & Gens, 2021; Mánica et al. 2021). Despite that Olson & Stark (2002) upper bound might still be somewhat conservative.
Figure 8. Comparison of the numerical results with case-history based correlation of Olson & Stark (2002).

Robertson (2010, 2021) also proposed correlations between residual undrained shear strength and cone metrics based on case history data. For materials with soil behavior type (SBT) index, $I_c > 3$ it is recommended to use the relation -discussed above-with sleeve friction. For materials with SBT $I_c < 3$ a different relation was proposed. The soil behavior type index, I_c is defined as

$$I_c = \left((3.43 - \log Q_{tn})^2 + (\log F_r + 1.22)^2 \right)^{0.5} \quad (8)$$

The relation with undrained strength is based on $Q_{tn,cs}$ a corrected, "clean sand equivalent", value of normalized cone resistance Q_{tn}. This correction is given by:

$$Q_{tn,cs} = K_c \, Q_{tn} \qquad (9)$$

The correction factor K_c is itself also dependent (trough fifth-order polynomials) on I_c.

Robertson relations (2010, 2021) are plotted in Figure 9 alongside the results for the fully drained simulations, which were the only ones resulting on I_c < 3. The relations are postulated as lower bounds and the simulation results plot above them, except for a datapoint that represents high mobilized interface friction for soil H, which is almost non-brittle. For the higher brittleness case A, which is likely more similar to the soils in the database, the degree of conservatism implied by the relation does not appear excessive.

Figure 9. Comparison of numerical results with Roberston (2010, 2021) correlations for normalized residual undrained strength. The marker color indicates undrained brittleness; marker shape indicates side friction values; marker hue indicates permeability.

6 CONCLUSIONS

The ability to simulate CPTu response using realistic geometry and constitutive models is still relatively recent. If exploited systematically it will open a way to reduce the relatively large uncertainty that hinders empirically based correlations, by identifying which parasitic factors may be playing a role in some datasets and/or suggesting ways to adapt general correlations to the local soil characteristics.

This has been illustrated here for the case of soils with a brittle undrained response. The results indicate that partial drainage is a major factor when selecting cone factors for s_{u_pk}. They also suggest that, when aiming for undrained residual strength, Olson & Stark

(2002) proposals are more robust than Robertson (2010, 2021), as these are more sensitive to the possibility of partial drainage and -for fine grained soilsto the state of the cone-soil interface. Still, these results are based on a limited set of simulations and would require confirmation from more systematic parametric analyses.

Assessment of deltaic soil behavior classification using AUT: GMD database regarding CPTu records

Mohammad H. Naghibi, Abolfazl Eslami & Sara Heidarie Golafzani
Department of Civil and Environmental Engineering, Amirkabir University of Technology (AUT), Tehran, Iran

ABSTRACT: Cone penetration tests (CPT and CPTu) are unique geotechnical in-situ tools for soil behavior classification (SBC). Identification and classification of subsurface marine layers help geotechnical engineers analyze, design, and monitor. Thus, a significant database of 398 cases was collected from 58 sites in 18 countries with CPTu soundings, and soil profiling obtained by direct boring and laboratory testing, namely AUT: CPTu&GMD (Amirkabir University of Technology): Geo-Marine CPTu Database. Furthermore, diverse essential parameters such as normalized cone resistance q_t, friction ratio R_f, soil behavior type index I_{SBT} are available at 0.1 m intervals. CPTu-based classification methods were subdivided into three generations, and several methods for marine deposits were examined utilizing 57 case studies from the AUT: CPTu&GMD. The results indicated that directly incorporating all three parameters of q_c, f_s, and u_2 is recognized to be more accurate than utilizing mathematical relationships, which reduces uncertainties and increases accuracy in identifying subsurface layers.

1 INTRODUCTION

Projects constructed in marine environments such as nearshore, offshore and onshore are mainly accompanied by particular foundations suitable for the superstructure regarding the available site soil deposits.

Furthermore, characterizing the subsurface layers in such environments is accompanied by limitations and difficulties heightening the effect of the embedded uncertainties in geotechnical designs. Accordingly, the projects in these areas are highly important, and care should be taken in their designs. Otherwise, irreversible damages will happen, leading to a decrease in the infrastructure's stability, limited or prohibited utilization, and an increase in the projects' preservation costs due to the ambiguities in subsoil depiction. Therefore, identifying and classifying the subsurface marine layers is crucial and assists geotechnical engineers in analyzing, designing, monitoring, and maintaining civil projects. Geotechnical studies are the first and most critical step in construction because they enable the geotechnical engineer to make appropriate decisions based on this information while minimizing existing uncertainties (Eslami et al., 2019).

Identification of subsurface layers is frequently accomplished through laboratory, nondestructive (NDT), and in-situ tests. Laboratory tests have limitations, including intact sample preparation, sample size, sample transport and storage, accurate site stress modeling for laboratory conditions and information discontinuity, and in-depth measurements, and their effects will be more crucial in marine environments. NDT tests lack the necessary precision to determine soil profiles (Eslami et al., 2019, Randolph and Gourvenec, 2017).

Furthermore, the development of geotechnical engineering has led to widespread in-situ testing by standardized penetrometers. The cone and piezocone penetration tests (CPT and CPTu) are some of the most remarkable geotechnical in-situ tools for soil behavior classification (SBC) due to rapid application, accuracy, providing continuous records in-depth, and the possibility of implementation in marine areas. Due to inherent soil uncertainty, measurement, and modeling errors, classifying soils in marine environments by the CPTu test becomes more important. Thus, the application of CPT and CPTu databases can significantly improve the validation and evaluation process and increase the reliability in geotechnical engineering (Eslami et al., 2017, Eslami & Fellenius, 2004, Robertson, 2010). Accordingly, a significant database of 398 cases was collected from 58 sites in 18 countries with adjacent CPTu soundings, namely Amirkabir University of Technology: CPTu and Geo-Marine Database, or AUT: CPTu&GM database. This database consists of offshore, onshore, nearshore, and riverine areas, with the most recorded cases being from Europe, the United States of America, and China. Soil profiling was obtained via direct boring and laboratory testing in this database. Moreover, for all cases, several parameters such as normalized cone resistance Q_t, friction ratio R_f, soil behavior type index I_{SBT} are available at 0.1 m intervals.

Researchers have presented numerous diagrams to identify and classify the behavior of subsurface layers using CPT and CPTu test results. Considering that each diagram is developed based on different databases, the accuracy of each diagram changes. As a result, this research attempted to measure the accuracy of several most common diagrams. The diagrams are compared proportionally to the type of soil, based on 57 case studies of AUT: CPTu&GMD, which will lead to the presentation of a model, allowing geotechnical engineers to select diagrams appropriate to the type of soil available the site to identify the behavior of subsurface layers.

2 AMIRKABIR UNIVERSITY OF TECHNOLOGY: GEO-MARINE-CPT$_U$ DATABASE; AUT: CPTU&GMD

The compiled marine database comprises CPTu test records and soil profiles from boreholes drilled within their vicinity. The records include 398 cases from 58 sites and 18 countries, mainly in the United States, Europe, China, and New Zealand. The gathered sites in the database belong to onshore sites near the shoreline about 21%, nearshore sites located in waters less than 30 meters deep around 26%, offshore sites located in waters deeper than 30 meters nearly 15%, and riverine sites roughly 38%. This database contains approximately 10000 meters of soil profiles and covers a wide range of marine deposits, including clay, sensitive, sand-gravel, overconsolidated clay, and mixed or deltaic soils.

In addition to the CPTu records digitized each 10 cm in-depth and the soil profiles from boreholes, other parameters used via soil behavior classification (SBC) diagrams are also determined using available correlations. Figure 1 shows the details of the AUT: CPTu&GM database in a flowchart.

3 ANALYSES AND ASSESSMENT

In this study, soil behavioral classification diagrams are classified into three generations based on the results of the CPTu test. First-generation (basic-generation) diagrams, such as diagrams of Douglas and Olsen (1981), Campanella et al. (1985) and, Robertson (2010), use only two parameters out of the three parameters obtained from the piezocone test, along with mathematical equations, for soil classification. The cone tip resistance q_c and sleeve friction f_s are the two parameters usually used. Second-generation (middle-generation) diagrams, such as diagrams of Robertson (1990), Jefferies and Davies (1993), Eslami & Fellenius (1997), and Eslami (2019), apply all three parameters of cone tip resistance, sleeve friction, and excess pore water pressure, as well as mathematical equations, to identify subsurface layers. Moreover, Eslami et al. (2015) diagram, which directly uses the three

mentioned parameters without mathematical equations to identify soil, is a third-generation (advanced-generation) diagram since using no mathematical relationships reduces the uncertainties. The use of mathematical relationships is the main difference between the second-generation and the third-generation diagrams. This study aims to assess the performance of seven common SBC diagrams belonging to the three mentioned generations, including 1-Douglas and Olsen (1981), 2-Campanella et al. (1985), 3-Robertson (1990) (Q_t-B_q), Robertson (2010), 4-Jefferies and Davies (1993), 5-Eslami & Fellenius (1997), 6-Eslami et al. (2015) 7-Eslami (2019), using 57 cases from the AUT: CPTu&GM Database. The investigated cases are from 16 countries worldwide as follows: USA: 10 logs, China: 5 logs, Canada: 3 logs, New Zealand: 3 logs, Italy: 3 logs, Norway: 3 logs, Poland: 3 logs, Finland: 3 logs, Sweden: 3 logs, Ireland: 3 logs, Brazil: 3 logs, England: 3 logs, Japan: 3 logs, Portugal: 3 logs, Australia: 3 logs, Turkey: 3 logs.

Additionally, all four types of sites in the database AUT: CPTu&GMD have been evaluated, including 15 Onshore, 20 Nearshore, 4 Offshore, and 18 Riverine cases.

Fifty-seven mentioned cases include 1420 meters of CPTu soundings and soil descriptions from drilling boreholes. Their frequency is such that it consists of 117 meters of sensitive soil, 98 meters of clay, 1135 meters of mixed or deltaic soil, 54 meters of sand and gravel, and 16 meters of over-consolidated soil. Figure 2 demonstrates the distribution of investigated deltaic soils in different SBC charts.

The accuracy of each diagram in predicting each soil type forms the evaluated areas, i.e., clay, sensitive, deltaic (mixed), overconsolidated, and sand-gravel, and has been calculated in percentage according to Equation 1.

$$SR = \left(\frac{L'}{L}\right) \times 100 \qquad (1)$$

Where SR is the success rate; L′ is the total length of correctly identified soil profiles regarding a specific soil type; L is the total length of investigated profiles concerning a particular soil type.

According to Figure 3, each diagram's statistical evaluation results are displayed separately on a radar chart. The radar diagram contains five axes regarding the considered soil types. Axes are calibrated from 0% to 100%. These values indicate the desired diagram's accuracy in identifying the soil associated with each axis.

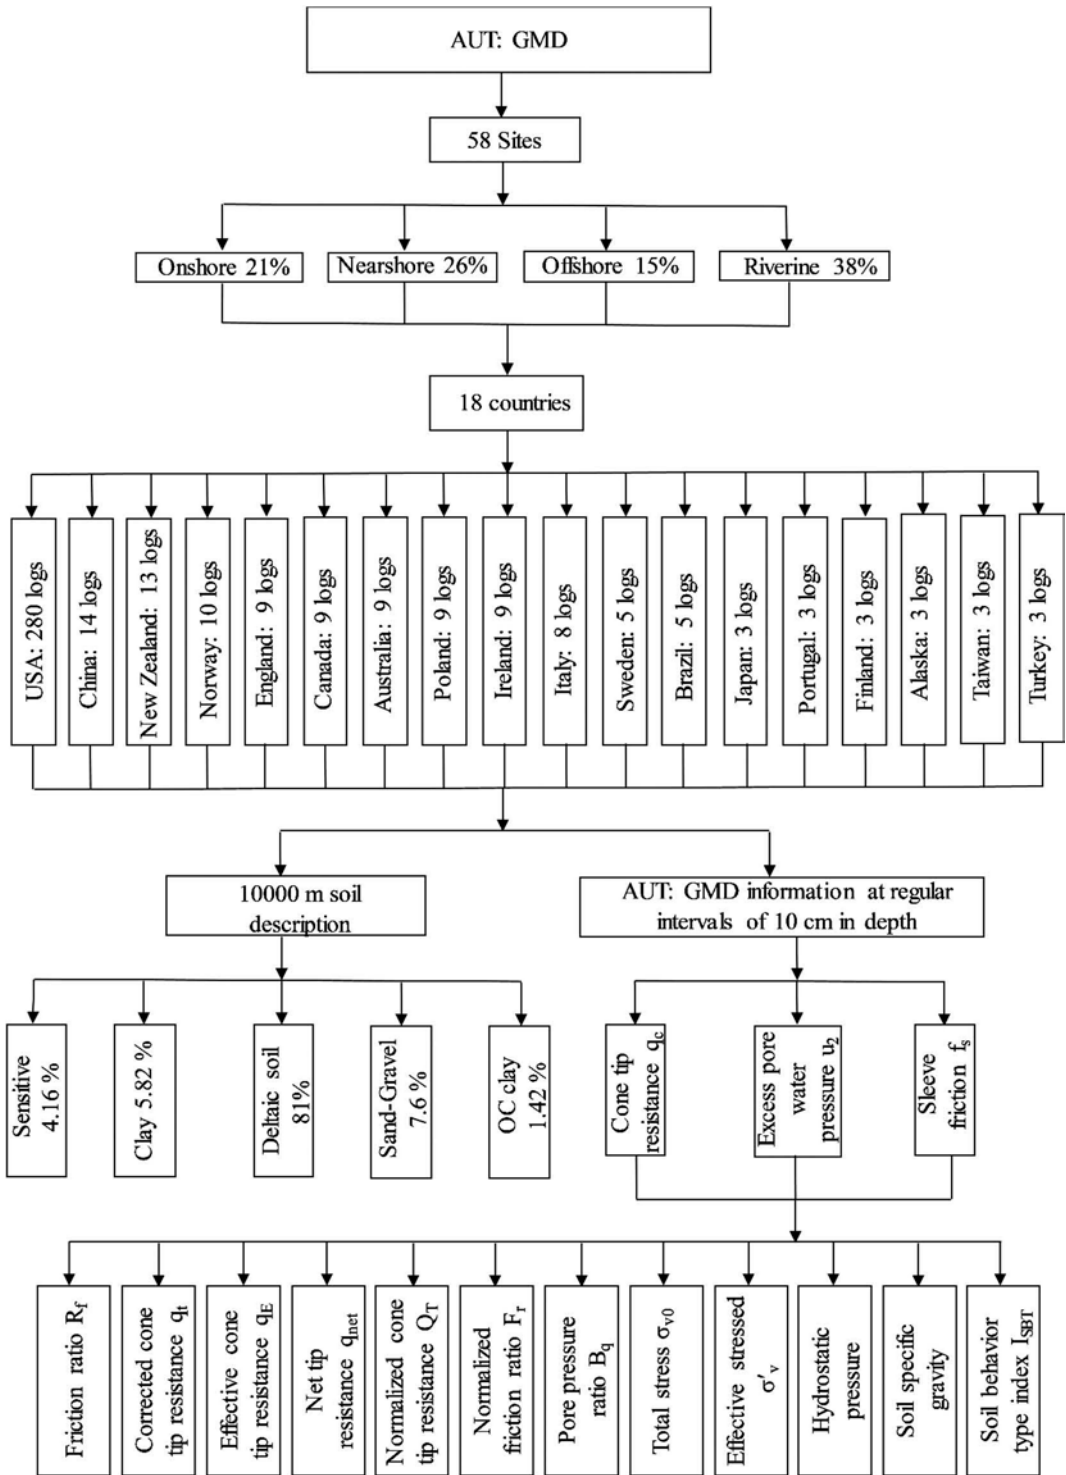
As shown in Figure 3, identifying sensitive soils has improved with the advent of second-generation diagrams that use all three parameters q_c, f_s, and u_2 and mathematical equations for soil classification.


Figure 1. The details of AUT: CPTu&GMD database.

Figure 2. Deltaic soils of AUT: CPTu&GMD on different charts.

Figure 3. The performance assessment of each SBC diagram for the investigated database.

The Douglas and Olsen (1981) and Campanella et al. (1985) diagrams, i.e., the first-generation of the charts, showed a low accuracy in identifying sensitive soils. However, this accuracy has reached more than 80 percent by applying second-generation diagrams. Although this trend continued until the Eslami & Fellenius (1997) diagram showed more than 90% success in identifying sensitive soils, the Robertson (2010) chart has shown a low accuracy in identifying sensitive layers due to using a pattern similar to the first-generation diagrams and not using the excess pore water pressure parameter. That shows the essential role of the excess pore water pressure parameter in identifying sensitive soil. The Eslami & Fellenius (1997), Eslami et al. (2015) and, Eslami (2019) diagrams were able to identify sensitive soils with more than 90% accuracy.

Due to the low cone tip resistance of silts and normally consolidated clays, it seems this parameter plays a minor role in distinguishing clay from silt. The diagrams now mainly use sleeve friction and excess pore water pressure parameters for this purpose. Therefore, it is more challenging to identify clay than the other four soil types for diagrams. However, the maximum accuracy is about 60%, which belongs to Jefferies and Davies (1993), Eslami & Fellenius (1997), and Eslami (2019) charts. Except for Eslami (2019) diagram, other diagrams of the first and second generations identify overconsolidated clay with less than 60% accuracy. The Eslami (2019) diagram has characterized overconsolidated clay with about 77% accuracy. Although the highest accuracy is for the third-generation chart of Eslami et al. (2015), it has identified a success rate of 85% overconsolidated clay. Douglas and Olsen (1981), Campanella et al. (1985), Robertson (1990) (Q_t - B_q), Robertson (2010), and Jefferies and Davies (1993) diagrams identify mixed or deltaic soils with an accuracy of 80 to 90 percent. While the Eslami et al. (2015) diagram detects these soils with less than 20% success, Eslami & Fellenius (1997) and Eslami (2019) diagrams have an accuracy of over 90% for this purpose. First and second-generation diagrams identify layers of sand gravel with 80 to 90 percent accuracy, and only the third-generation chart does so with over 90% success.

4 CONCLUSIONS

Marine deposits are mainly problematic soils due to their formation process, and their characterization increases the reliability of geotechnical designs in onshore and offshore structures. Accordingly, the AUT: CPTu&GMD was compiled, and 57 cases were selected, including offshore, onshore, and riverine sites, to assess the performance of SBC diagrams classified as first, second, and third generations according to their simplifications and assumptions.

The investigated diagrams were 1-Douglas and Olsen (1981), 2-Campanella et al. (1985), 3-Robertson (1990) (Q_t - B_q), Robertson (2010), 4-Jefferies and Davies (1993), 5-Eslami & Fellenius (1997), 6-Eslami et al. (2015), 7-Eslami (2019). Five soil types, i.e., sensitive soils, clay, mixed or deltaic soils, overconsolidated clay, and sand-gravel, were considered to assess the performance of SBC diagrams in predicting the marine soil types.

Results indicated that the accuracy of the diagrams changes with the variation of soil type. Also, assessed diagrams are adequately accurate in identifying deltaic soils, especially diagrams that use all three parameters of q_c, f_s and, u_2 for soil classification. Eventually, Eslami et al. (2015) chart directly implements all three CPTu records, i.e., qc, fs, and u2, which reduces uncertainties in soil behavioral classification instead of applying mathematical correlations and was more suitable for classifying deltaic soils for the investigated database.

A review of methods for estimating undrained brittleness index from the CPT

Y. Narainsamy & S.W. Jacobsz
University of Pretoria, Pretoria, South Africa

ABSTRACT: The Cone Penetration Test (CPT) is a useful tool for soil profiling due to its near continuous data measurements, low cost and repeatability. When conducting designs or safety evaluations of slopes, it is often of interest to understand the undrained response of the soil at large strains. This behaviour can be defined in terms of the Undrained Brittleness Index (I_B) which relates the yield undrained shear strength to the steady state undrained shear strength. Over time, a number of field case histories where strain softening during undrained shear was deemed to have occurred have been assessed, and a relationship between corrected tip resistance and I_B was proposed (Sadrekarimi, 2014). A quick clay test site and a silt test site in Norway included in a recently published open access geotechnical database were assessed. It was found that the method proposed by Sadrekarimi (2014) underestimated the I_B for both the quick clay and silt test sites. It was also noted that there are some limitations with a popular screening method for identifying soils susceptible to strength loss during undrained shear.

1   INTRODUCTION

1.1   Cone Penetration Testing

The Cone Penetration Test (CPT) is a useful tool for soil profiling. It provides near continuous data measurements, repeatable results, is cost effective and tests can be conducted relatively quickly. When designing and conducting safety evaluations of slopes and embankments, it is often useful to understand the undrained response of the soil at large strains. This is important as soils which exhibit strain softening (contractive) behaviour will have a lower strength than soils which exhibit strain hardening (dilative) behaviour. This state is sometimes represented using the state parameter ψ as suggested by Been & Jefferies (1985). The state parameter is the difference in void ratio between the current void ratio and the void ratio at steady state, at the same effective confining stress.

However, the state of the soil simply describes the tendency for contraction or dilation at large strains. For many problems it is of more value to know the extent of the expected contraction, if any. Soils which exhibit a rapid reduction in undrained shear strength are referred to as brittle soils and an example of such behaviour can be seen in Figure 2. Brittle failure mechanisms are of particular concern as failure can initiate rapidly as was seen in the 2019 Feijão tailings dam failure (Robertson et al., 2019). One method of quantifying the brittleness of a soil is to use the Undrained Brittleness Index. The objective of this paper is to investigate the performance of the CPT-based method proposed by Sadrekarimi (2014) on predicting the Undrained Brittleness Index for soils at two test sites in Norway: a quick clay test site and a silt test site.

1.2   Undrained Brittleness Index (I_B)

The Undrained Brittleness Index (I_B) was initially proposed by Bishop (1971), and is used to define a relationship between the yield and steady state undrained shear strength of a soil and is shown in Equation 1.

$$I_B = \frac{s_u(yield) - s_u(steady\,state)}{S_u(yield)} \qquad (1)$$

where s_u *(yield)* is the yield undrained shear strength and s_u *(steady state)* is the steady state undrained shear strength. These parameters are shown visually in Figure 2. I_B ranges from 0 to 1, with I_B = 1 indicating complete loss of shear strength, i.e. a highly contractive response, while I_B = 0 indicates no loss of strength with strain. Note that the undrained brittleness index should not be confused with the modified soil behaviour type index I_B which is used by some researchers (e.g. Robertson, 2016).

2   REVIEW OF EXISTING RELATIONSHIPS

2.1   CPT correlations

Due to the large deformations and stresses induced during CPT probing, it is common to pursue empirical relationships between geotechnical parameters

and measured responses from the CPT. In one such study, a large database of 600 laboratory shear tests were reviewed. An attempt was then made to relate the yield and steady state undrained shear strengths to the corrected tip resistance (q_{c1}), based on field case histories where undrained shearing was believed to have occurred (Sadrekarimi, 2014). As part of this study, a relationship between I_B and q_{c1} was also identified.

When analysing the field case histories, the yield and undrained shear strengths were determined based on results of static limit equilibrium back analyses (Olson, 2001; Muhammad, 2012). The characteristic yield undrained shear strength was determined by varying the shear strength in the soil zones deemed susceptible to strength loss during undrained shear until a factor of safety against failure of 1.0 was calculated using Spencer's method (Spencer, 1967). Drained shear strengths were assumed to be mobilized in the zones above the phreatic surface (i.e. material zones deemed not to be susceptible to strength loss during undrained shear). The liquefied or steady state undrained shear strength was either determined using a simplified force diagram approach with kinematic considerations or a rigorous limit equilibrium approach considering the final failure geometry, depending on the available information. The corrected tip resistance measured in the field was then related to I_B in the form of a screening method as shown in Equation 2.

$$I_B = 0.882 - 0.053q_{c1} \pm 0.06 \qquad (2)$$

where q_{c1} is the corrected cone tip resistance as determined using the equations described by Kayen et al. (1992). Upon review of the field case history database used to develop the relationship, it becomes clear that a biased dataset was used (i.e. the dataset only includes data from sites where strain softening was deemed to have occurred and therefore does not include material that strain hardens).

2.2 *Open access geotechnical databases*

With the rapid advancement of technology and the ease of global communication, there has been a recent development to populate and maintain open access geotechnical databases. Two such databases are: the Premstellar Geotechnik and Norwegian GeoTest Site databases. The former includes hundreds of CPT tests results and associated indicator tests (Oberhollenzer et al., 2021), and the latter is described in more detail below. It is expected that more open access geotechnical databases will be developed and maintained in the future.

3 ANALYSIS

3.1 *NGTS test sites*

In 2017 the Norwegian Geotechnical Institute (NGI) established the Norwegian GeoTest Sites (NGTS). The objective of the NGTS was to develop test sites that could be used for testing and verifying innovative soil investigation methods, as well as facilitate research activities relating to soil behaviour and foundation design (L'Heureux et al., 2017). The NGTS comprise five test sites in different soils, all located in Norway as shown in Figure 1.

A unique aspect of the NGTS is that the field and laboratory test data have been made publicly available through the Datamap web based application (Doherty et al., 2018). In addition to the NGTS data, data from the Australian National Field Testing Facility (NFTF) is also included on the Datamap application. Although six test sites were included in the combined NGTS and NFTF database, only two contained sufficient information for use in this study. These two sites are discussed in further detail below.

Figure 1. Location of the NGTS test sites.

3.2 *The Tiller-Flotten test site*

The Tiller-Flotten geotechnical test site is located in Trondheim in Norway. The site consists of a 50 m thick marine deposit of sensitive clay (L'Heureux et al., 2019). Due to the glacial history of the area, the clays are overconsolidated, with an OCR between 1.5 and 3.0. A rigorous CPTu field testing regime was conducted and Anisotropically Consolidated Undrained Compression (CAUC) triaxial tests were conducted on high quality Sherbrooke block samples obtained from boreholes adjacent to the CPTu test locations. The water table is located between 1 and 2 m below ground level and the pressure distribution is approximately hydrostatic to 5.5 m whereafter the pressure build-up is sub-hydrostatic.

The clays have a bulk unit weight of 18 kN/m³ and are split into two sub-profiles as shown in Figure 4. Unit IIA extends from 2 m below surface to 7.5 m below surface and comprises clay of medium sensitivity and Unit IIB extends from depths greater than 7.5 m and comprises clay of extreme sensitivity. Results from the CAUC triaxial tests, shown in Figure 2, indicate brittle behaviour which is expected of a sensitive clay.

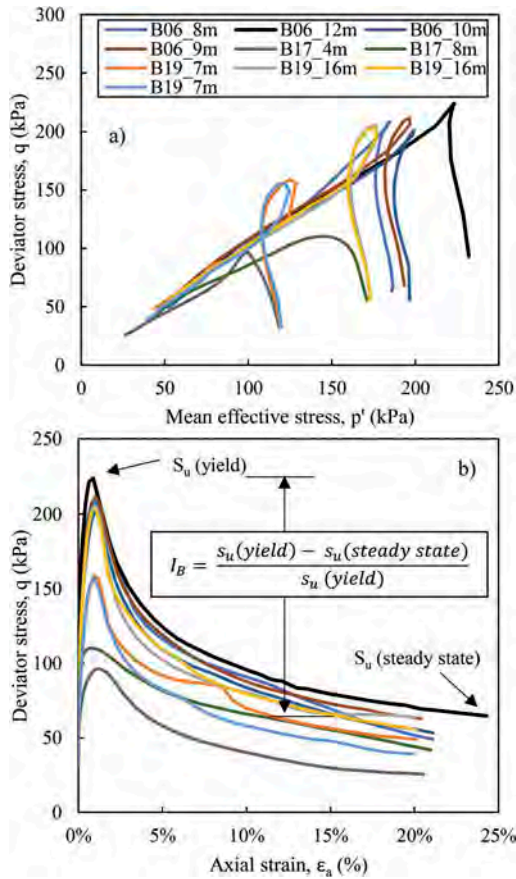

Figure 2. Triaxial test results on the Sherbrooke samples from the Tiller-Flotten test site.

3.3 The Halden test site

The Halden geotechnical test site is located approximately 120 km south of Oslo in Norway. The site consists of a 10 to 12 m thick deposit of fjord-marine, low plasticity clayey silt (Blaker et al., 2019). The silts are normally consolidated and the water table is located 2 m below surface with a hydrostatic profile in the silt layer, changing to sub-hydrostatic in the underlying clays. As with the Tiller-Flotten site, a rigorous CPTu field testing regime was conducted and CAUC triaxial tests were conducted on high quality Sherbrooke block samples obtained from boreholes adjacent to the CPTu test locations.

The silts have a bulk unit weight of 19 kN/m³ and are split into two sub-profiles as shown in Figure 5: Unit II which extends from 5 m below surface to 12 m below surface; and Unit III which extends from 12 m below surface to 16 m below surface. Units II and III are regarded as the same material with the same geologic origin and were separated simply based on the results from the indicator tests which indicated that the silt becomes sandier in the lower Unit III. Results from the CAUC triaxial tests are shown in Figure 3. With the exception of the sample obtained at 9 m depth from borehole 1 (B01_9m) which showed strain softening behaviour, all the other samples showed strain hardening behaviour.

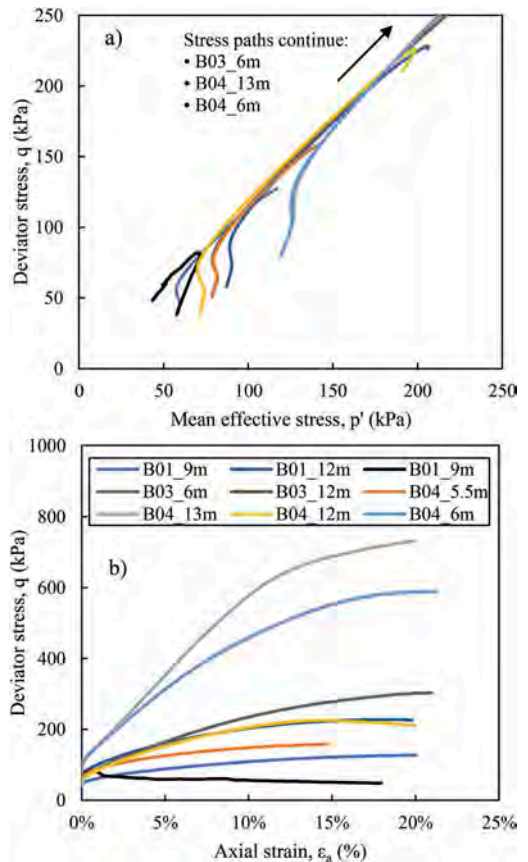

Figure 3. Triaxial test results on the Sherbrooke samples for the Halden test site.

3.4 Analysis of CPT data

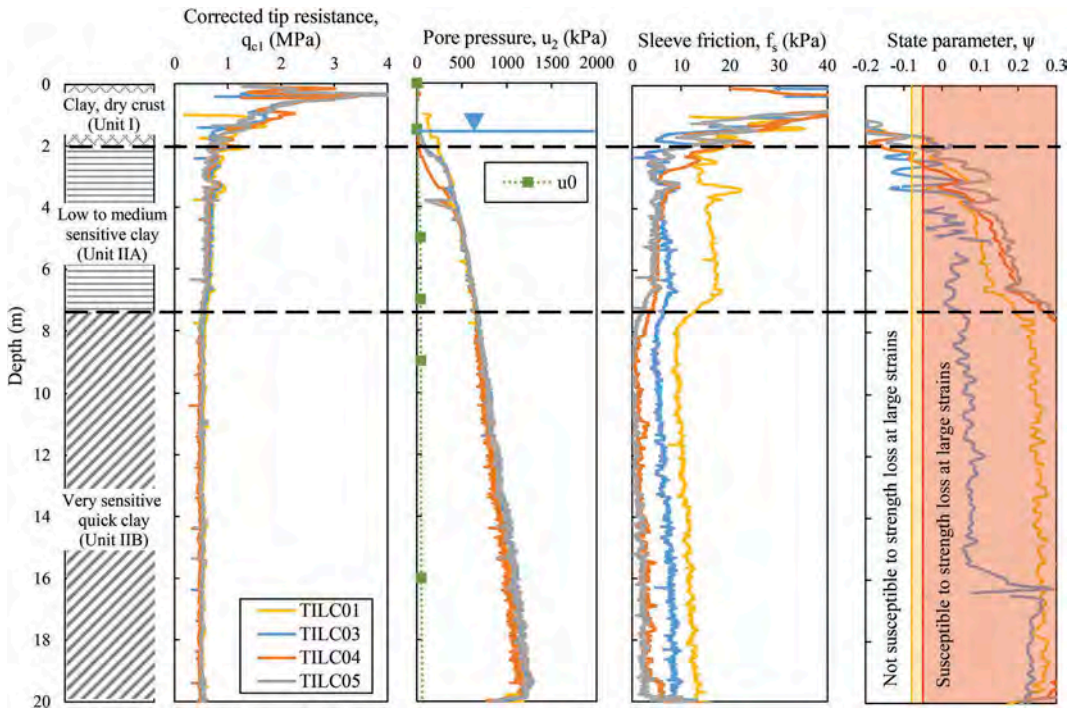
The raw CPT data obtained from the database were processed using version 3.6.2.6 of the CPeT-IT software package developed by Geologismiki (Geologismiki, 2021). When analysing CPT data, it is important to note that the load cells which measure the sleeve friction and tip resistance are geometrically offset on the cone. Therefore, to correct the data such that the


Figure 4. CPT data for selected probes at the Tiller-Flotten quick clay reference site (after L'Heureux et al., 2019).

Figure 5. CPT data for selected probes at the Halden silt reference site (after Blaker et al., 2019).

measured cone resistance and sleeve friction can be compared at the same depth, a vertical shift is applied. This shift distance is a function of the physical location of the sleeve friction and load cell as well as the rigidity of the soil. The Cross Correlation Function (CCF), as proposed by Jaksa et al. (2002) was used for this assessment. The interpreted CPT data for the Tiller-Flotten and Halden test sites are shown in Figure 4 and Figure 5, respectively. Based on the soil behaviour index I_c as proposed by Robertson & Wride (1998) and the pore pressure ratio B_q, it was deemed that the probing through the Tiller-Flotten clay and Halden silt was predominantly undrained. It is therefore appropriate to assess the CPT data in terms of undrained hydraulic conditions.

3.5 Susceptibility to strength loss during undrained shear

Several methods have been proposed to estimate the state of the soil, specifically with regard to the undrained behaviour at large strains. One such method is a screening method proposed by Plewes et al. (1992) where the state parameter (ψ) of the soil is estimated. The method is referred to as a screening method as the state parameter is estimated based only on CPT data and some limitations have been identified (e.g. Torres-Cruz, 2021; Narain-samy et al., 2022). For this assessment, the original implementation of the Plewes method was used. Material with $\psi > -0.05$ was assumed to be susceptible to strength loss at large strains during undrained shear, material with $\psi < -0.08$ was considered not susceptible to strength loss at large strains. A transition zone was defined where $-0.08 < \psi < -0.05$. These limits are commonly used in research and practice (e.g. Jefferies & Been, 2015).

Applying the screening method to the NGTS site results in the ψ with depth charts shown in Figure 4 and Figure 5. Figure 4 clearly shows the Tiller-Flotten clay as susceptible to strength loss at large strains and this correlates well with the observed response from the triaxial data (Figure 2). Figure 5 also shows the Halden silt as susceptible to strength loss at large strains. However this does not correlate well with the observed response from the triaxial data (Figure 3). This emphasises the screening nature of the Plewes method and that more advanced methods may need to be considered in practice.

3.6 Summary of test data analysed

A summary of the test data assessed is shown in Table 1. For the Tiller-Flotten clay site, a total of 10 triaxial tests and 5 CPT tests were assessed. An average q_{c1} of 0.55 MPa and I_B of 0.71 was determined. For the Halden silt site, a total of 9 triaxial tests and 5 CPT tests were assessed, and an average q_{c1} of 0.63 MPa and I_B of 0.05 was determined.

Table 1. Summary of data analysed.

Test site	Tiller-Flotten	Halden
Material	Marine clay	Clayey silt
No of triaxial tests	10	9
Type of test	CAUC	CAUC
Undrained response	Strain softening	Strain hardening
No of CPT soundings	5	5
Susceptible to strength loss at large strains?*	Yes	Yes
Average q_{c1} (MPa)	0.554	0.633
Average I_B	0.713	0.050

* according to the Plewes et al. (1992) screening method

4 RESULTS

The I_B determined from the CAUC triaxial test results, and the average q_{c1} determined from the CPT tests for the Tiller-Flotten clay and Halden silt are shown in Figure 6. Also plotted on Figure 6 are the case histories investigated by Olson (2001) and Muhammad (2012), as well as the relationship proposed by Sadre-karimi (2014). It was found that for the Tiller-Flotten clay, the proposed relationship provided a reasonable estimate of the I_B. However, the Halden silt plots much lower. This is due to the fact that the proposed relationship is simply a function of the corrected tip resistance and not any laboratory test data. Since the Halden silt exhibited strain hardening behaviour during undrained shear in triaxial compression, the material shows no brittleness.

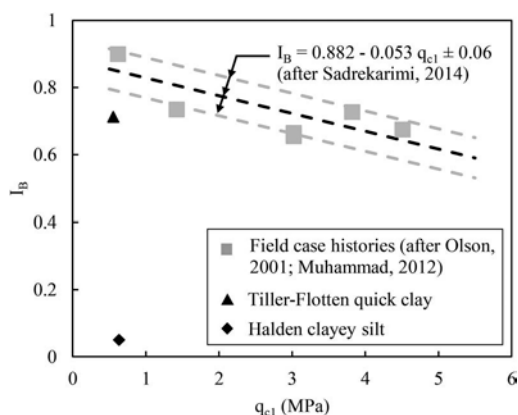

Figure 6. Results from this study compared to previously published data.

This over-estimation of the I_B for a strain-hardening material is expected as the empirical relationship was derived based on field case histories where only strain softening material was involved (i.e. it was a biased database). Care therefore needs

to be taken when using the Plewes screening method, as well as when using the relationship proposed by Sadrekarimi (2014), ensuring that they are applied to materials similar to those from which they were derived and validated against.

5 CONCLUSIONS

CPT and triaxial data from two NGTS research test sites were assessed: the Tiller-Flotten quick clay site and the Halden silt site. A strain softening screening assessment was performed, and the undrained brittleness index was determined for both sites. The following was found:

1. The Plewes et al. (1992) screening method identified that the Halden silt material is contractive at large strains. However, with the exception of one test, the results from the triaxial tests indicated dilative behaviour. Care therefore needs to be taken when using this method to assess soils susceptible to strain softening behaviour during undrained shear.

2. The relationship proposed by Sadrekarimi (2014) between corrected tip resistance (q_{c1}) and undrained brittleness index (I_B) was found to overestimate the undrained brittleness index for both the Halden silt and the Tiller-Flotten clay. This method should therefore only be used as a screening method and a more rigorous assessment is recommended when assessing the undrained brittleness index using the CPT.

ABSTRACT: This paper presents a comparative study on the applicability of three CTPu-based soil classification charts, namely, Robertson's normalized (SBTn) chart (Robertson 2009), Eslami-Fellenius (EF)'s non-normalized chart (Eslami and Fellenius 1997) and Robertson's non-normalized (SBT) chart (Robertson 2010). A well-monitored database of CPTu data at six study sites of different geological conditions was used for the analyses. It is found from the study that when the effective stress (σ'_{v0}) is small, typically smaller than 150 kPa, the EF's and Robertson's SBTn charts results in similar soil types obtained from visual classification procedure (VCP) whereas the Robertson's SBT chart results in similar or slightly coarser soil types. When the σ'_{v0} becomes larger, the Robertson's SBTn chart still results in soil types well matched with those obtained from the VCP but both the non-normalized charts tend to result in coarser soil types. This feature of the non-normalized charts is more pronounced in stiff clayey or dense sandy soils.

1 INTRODUCTION

The CPTu is one of the most versatile and useful field tests in soil investigation and one of its main applications from the test results is soil classification. In the literature, the Robertson's normalized soil behaviour type (SBTn) chart (Robertson 1990, 2009) is the most popularly recommended one. Besides, Eslami-Fellenius (E-F)'s method (Eslami and Fellenius 1997, Fellenius 2021) is also a good alternative. The key difference in input parameters for Robertson's SBTn and E-F's charts is that only basic measurements of the test are required for the E-F's chart whereas effective vertical stress (σ'_{v0}) is additionally required for the Robertson's STBn chart. In many cases, exact value of soil density and in-situ pore pressure (u_0) (and therefore the effective stress) are not available, the Roberson's SBTn chart is therefore less effective in real-time classification (Fellenius 2021).

To facilitate the real-time application to soil classification, Robertson (2010) introduced an updated non-normalized chart (SBT) initially proposed by Robertson et al. (1986) that requires only basic measurements but stressed that this updated non-normalized chat could give reasonable result in the range of effective stress from 50 to 150 kPa.

Robertson (2010) and Robertson and Cabal (2015) recommended that in general the normalized chart (Robertson 1990, 2009) provide more reliable identification of SPT than the non-normalized chart.

The CPTu has been an indispensable field test in soil investigation for nearshore and offshore wind farms projects along the coast of Vietnam these days. The applicability of the charts to new geological conditions, especially to onshore and offshore sites, is merit to be investigated.

This paper presents a comparative study on the applicability of the Robertson's SBTn chart (Robertson 2009), Robertson's non-normalized chart (Robertson 2010) and E-F's chart (Elami-Fellenius 1997, Fellenius 2021). For this, CPTu data from four onshore sites in Vietnam and Korea and two offshore sites in the East Sea (Vietnam) are used for analyses.

2 EXPEIMENTAL TEST SITES

2.1 *Test site location*

In this study, CPTu test results from six study sites of different geological conditions are brought into analyses. The abbreviated names and locations of the sites are given in Table 1, which are graphically illustrated

Table 1. Name and location of the test sites.

No.	Site name	Condition	Longitude	Latitude	Location
1	VSIP	Onshore	106° 42′ 8.98″ E	20° 54′ 52.21″ N	Hai Phong Province, Vietnam
2	KC	Onshore	105° 43′ 44″ E	21° 3′ 22.92″ N	Hanoi, Vietnam
3	TPP	Onshore	106° 12′ 55.54″ E	20° 5′ 55.29″ N	Nam Dinh Province, Vietnam
4	MOC	Onshore	128° 54′ 14.25″ E	35° 5′ 5.8″ N	Busan City, Korea
5	PVN1	Offshore	108° 20′ 56.63″ E	10° 12′ 41.36″ N	East sea, Vietnam
6	PVN2	Offshore	108° 48′ 09.69″ E	07° 55′ 24.40″ N	East sea, Vietnam

in Figure 1. The first three test sites, namely, Vietnam Singapore Industrial Park (VSIP), Kim Chung Residential Complex (KC), and Nam Dinh Thermal Power Plant (TPP), are located in the Red River delta, Vietnam. A research program on consolidation characteristics of clayey soils has been conducted recently by the first author at the sites in which CPTu and elaborate soil sampling for laboratory tests were conducted.

The fourth site, namely, Myeongji Ocean City (MOC), is located in the Nakdong River Estuary of Nakdong River delta, West of Busan city, Korea. The CPTu and soil sampling at the site were conducted by the first author some years ago in a research program on bearing capacity of driven pile foundation (Kim et al. 2012).

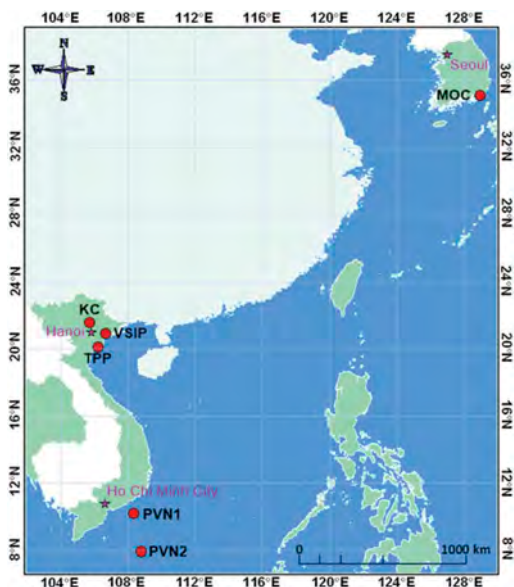

Figure 1. Location of the test sites.

The last two sites, namely, PVN1 and PVN2 are located in the East Sea of Vietnam (Figure 1). The CPTu with soil sampling and other field tests were elaborately conducted by Fugro for PetroVietnam (PVN) in an investigation program for building drill rigs at the sites. The water depth at the two sites was measured using a combination of electronic sensor and echo sounder and the average value at the PVN1 and PVN2 sites was 56.3 m and 119.9 m, respectively.

2.2 CPTu tests

For the first three test sites (VSIP, KC, TPP), the CPTu was carried out using a piezocone of 10 cm^2 cross-sectional area with a filter mounted at the cone shoulder (u_2 position). The test was performed following procedures recommended in the ASTM 5778 – 20 (2020) standard. The key research objective at the sites was on consolidation characteristics of the clayey soils thus the CPTu was carried out in upper clayey and silty soil layers only. The CPTu at MOC site was carried out using a piezocone of 15 cm^2 with also the measurement of pore pressure at the cone shoulder ($u_2$position).

At the offshore test sites, drilling operations were carried out through a motion compensated Furgo Offshore Drilling Rig over a moon pool in the centre of the vessel. On the other hand, sampling was conducted through the open-centre bit using Wison BHA and collars, which facilitated umbilical piston, push and hammer sampling operations. The CPTu was conducted using Fugro's Downhole Wison system with a cone of 10 cm^2 base area, 60° apex, 150 cm^2 cylindrical sleeve, and a filter at cone shoulder to measure u_2. The rate of penetration during testing was kept between 20 mm to ± 5 mm per second throughout the 3.0 m continuous stroke.

Although analyses were fully carried out for the six test sites, typical analysis results from only four sites, namely, VSIP, MOC, PVN1, and PVN2, will be presented in detail due to limited allowance of space.

2.3 Soil profiles

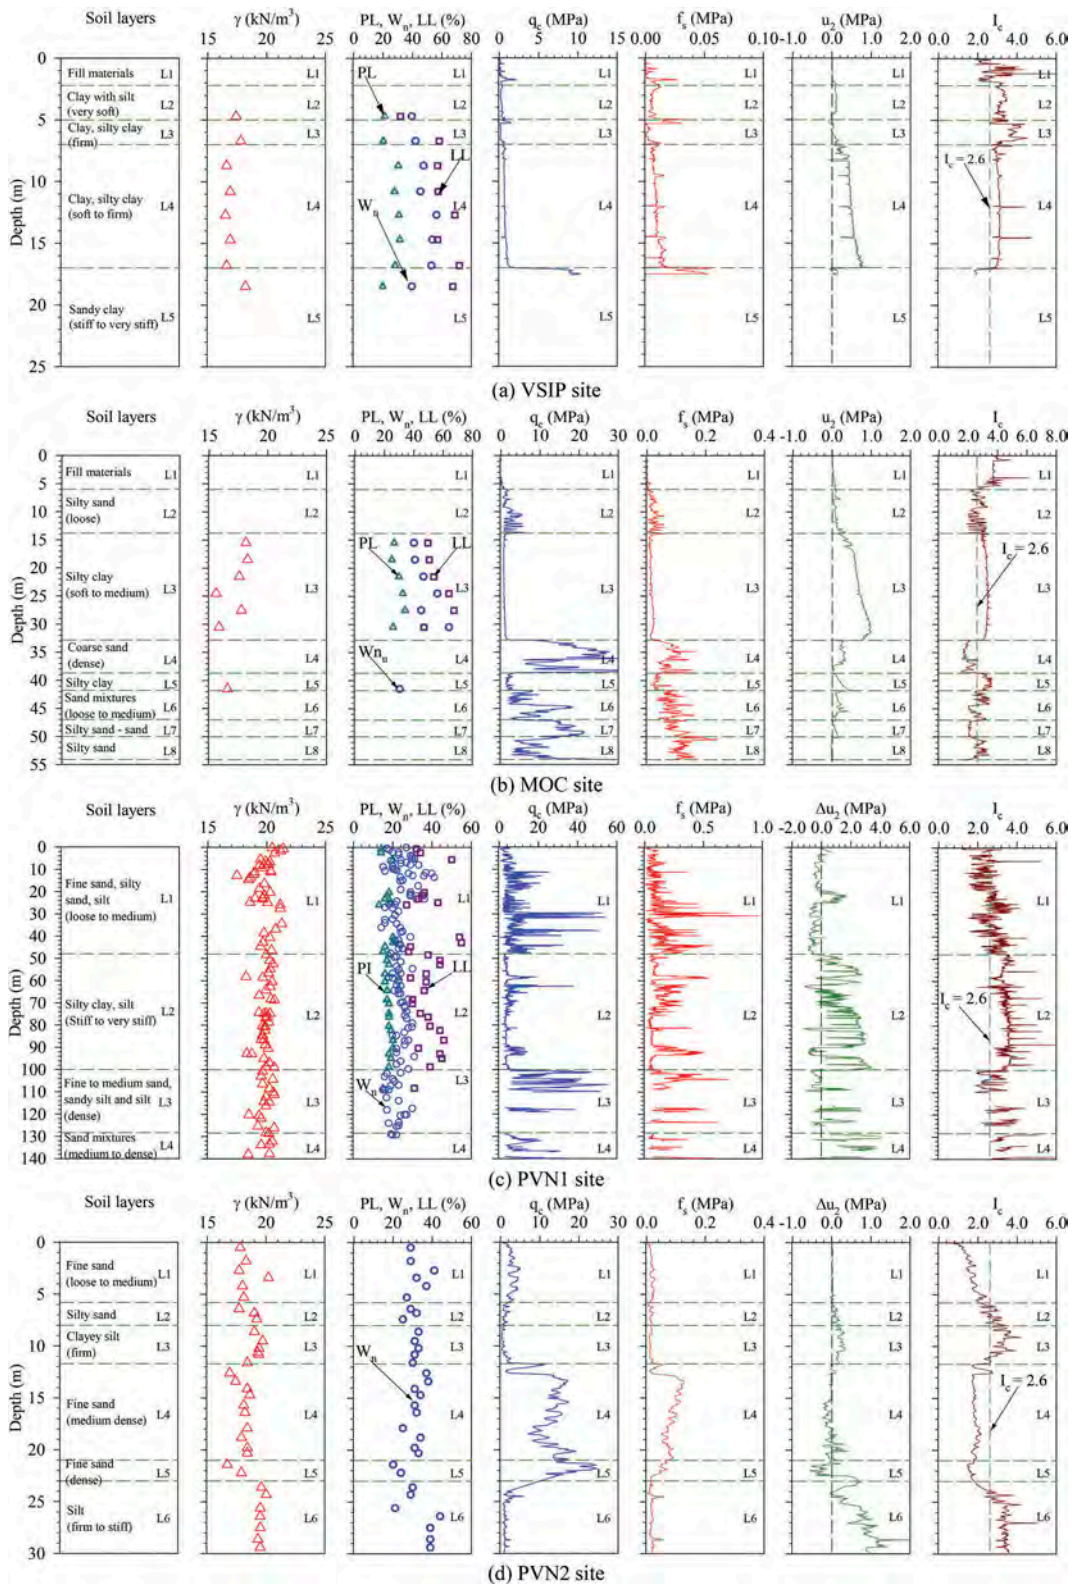
Soil layers at each site were carefully classified based on results from physical tests in the lab with the support of visual classification procedures (VCP) from boring records (e.g., soil sample from the SPT sampler) at the site. Figure 2 shows soil layers and basic soil properties at the four sites. To facilitate the evaluation later, soil layers in each site were simply named from L1 to Ln downwards as shown in the figure.


Figure 2. Soil profiles at the study sites.

612

At the the VSIP site, the CPTu was carried out in soft to firm clay layers up to the depth of 17 m (Figure 2(a). At the MOC site, the CPTu was carried out up the sandy gravel layer (at 55.0 m) (Figure 2(b)), and thus both sandy and clayey soil types are available for analyses.

At the PVN1 site, the soil profile (up to the depth of 140 m) consists of many alternate sub-layers of silty clay, clayey silt, sandy silt and silty sand; however, the soil profile might be broadly divided into four main layers as shown in Figure 2(c). At the PVN2 site, the soil profile (up to the depth of 30.0 m) consists of 6 layers of both clayey and sandy soil types as shown in Figure 2(d).

Figure 2 also shows the cone resistance (q_c), sleeve friction (f_s), pore water pressure (u_2) and excess pore water pressure (Δu_2) diagrams, and soil behavior type index (I_c) (Roberson 2009) from the CPTu at the study sites. It is interesting to note from q_c and u_2 diagrams that the soil layers can easily be identified and are well matched with the classification from physical parameters profile shown in Figure 2. Note that the Δu_2 value of some sandy layers was negative (e.g., 24.0 – 48.0 m at PVN1 and 15.0 – 23.0 m at PVN2). This unusual characteristic is typically found in sandy deposits in offshore environment due to the cavitation phenomenon (Lunne et al. 1997).

The soil behavior type index (I_c) also helps to classify the soil profiles well. For example, at the depths of 0.4 to 17.6 m (VSIP site), 13.8 to 32.8 m (MOC site), 48.0 to 100.0 m (PVN1 site) the I_c is pronouncedly larger than 2.6, indicating that the layers are clayey soils. The index value of other layers is mostly equal or less than this boundary value, indicating the layers are silty to sandy soils.

3 SOIL CLASSIFICATION RESULTS

3.1 Influence of effective stress

The influence of effective stress to soil behaviour type has been discussed extensively in many studies (e.g., Robertson 1990, 2009) and it is examined through the case studies herein. It is found from the cases that when the effectives stress is less than about 150 kPa the E-F's and Robertson's normalized (SBTn) charts provide rather similar soil types for both clayey soil and sandy soil, however the Roberson's non-normalized (SBT) chart tends to indicate similar or slightly coarser grained soil types compared with those from the normalized chart. As an example, Figure 3 shows the three charts applied to layer L4 (silty clay) at the VSIP site. As shown, both E-F's and Robertson's SBTn charts indicate that soil in this layer is clay to silty clay and is well matched with results from lab test results and VCP but the Robertson's SBT chart indicates that the soil is more likely silt mixtures (clayey silt & silty clay). Similar finding is found for the upper layers at the six sites (i.e., the effective stress is relatively small). Note that the parameters of the charts are as follows: the effective cone stress $q_E = q_t − u_2$, where $q_t = q_c + (1-a)u_2$; the normalized cone resistance $Q_{tn} = [(q_t-\sigma_{v0})/p_a] (p_a/\sigma'_{v0})^n$, the normalized friction ratio $F_r = [fs/(q_t-\sigma_{v0})]100\%$, the sleeve fiction ratio: $R_f = 100(f_s/q_c)$.

When the effective stress becomes larger, the influence of effective stress becomes more pronounced and especially the E-F's chart also tends to indicate slightly coarser soil type compared with that obtained from the lab test results and VCP, and from Robertson's SPTn chart. For instant, Figure 4 shows a comparison of classified soil types from the charts applied to layer L4 (stiff to very stiff silty clay – silt)

(a) E-F's chart   (b) Robertson's SBTn chart   (c) Robertson's SBT chart

Figure 3. Soil classification charts for layer 4 at VSIP site.

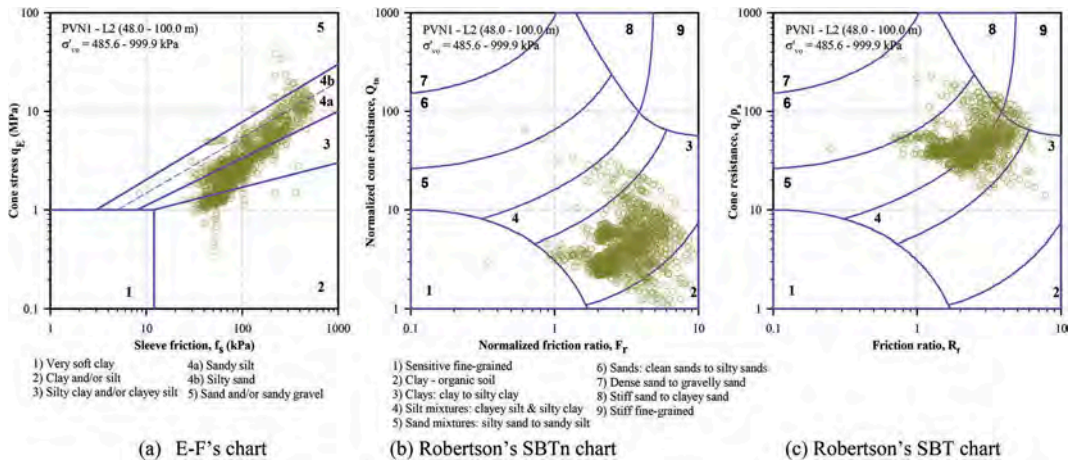
(a) E-F's chart   (b) Robertson's SBTn chart   (c) Robertson's SBT chart


Figure 4. Soil classification charts for layer 2 at PVN1 site.

at PVN1 site. The figure indicates that the Robertson's SBTn chart results in similar soil types obtained from the lab test results and VCP whereas the EF's and Robertson's SBT charts indicate soil types that are likely silt to sandy silt. Besides the influence of effective stress, the discrepancy in this case may also be attributed to the stiffness of this soil layer since the soil layer is stiff to very stiff. The discrepancy is found less pronounced in soft to firm silty clayey soil even at relatively large effective stress (e.g., for the layers L3 and L5 at MOC site).

3.2 *Influence soil types*

It is known that in a normally consolidated, homogeneous clay layer, the cone resistances (q_c or q_t) typically increases linearly with the increase in vertical effective stress (σ'_{v0}). However, in a homogeneous sand layer, the resistances increase nonlinearly with the increase in the effective stress. This is why the stress exponent (n) is applied to the normalized cone resistance (Q_{tn}) and n is often 1.0 for clayey soils and less than 1.0 for sandy soils. The non-normalized classification charts (e.g., E-F's and Robertson's SBT ones) do not take into account this characteristic.

Figure. 5 shows an example of the charts applied to layer L4 (medium dense fine sandy) at PVN2 site. The figure indicates that at relatively small vertical effective stress and medium dense condition, the three charts result in similar soil types and they well match with the soil type obtained from the VCP.

(a) E-F's chart   (b) Robertson's SBTn chart   (c) Robertson's SBT chart
Figure 5. Soil classification charts for layer 4 at PVN2 site.

Figure 6. Soil classification charts for layer 3 at PVN1 site.

Similar finding is obtained from layers L1 & L2 at PVN2 site, L2 at MOC site, L1 at PVN1 site.

When the depth (i.e., the effective stress) becomes larger the influence sandy soil type to the effectiveness of the charts becomes more pronounced. For example, Figure 6 shows a comparison of soil types obtained from the three charts applied to layer L3 (dense, fine to medium sand with sandy silt & silt) at PVN1 site. It is very clear from the figure that the Robertson's SBTn chart results in soil types matched relatively well with the results from the VCP whereas the two non-normalized charts indicate rather coarser soil types. Similar finding was found from layers L4, L6, L7, L8 at MOC site.

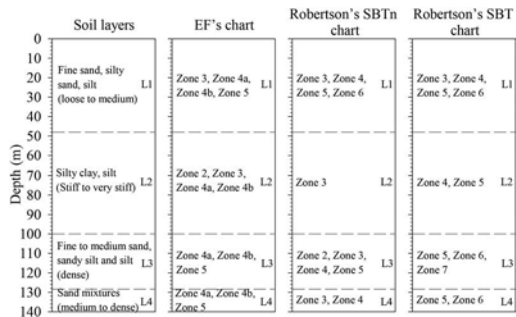

Figure 7. Comparison of soil profiles of soil types from the charts at PVN1 site.

Figure 7 shows a typical comparison of soil types obtained from the lab test results and VCP and from the three classification charts. For simplicity, in each main layer, soil types from the charts are simply noted by zone numbers that data points fall on. It is clear from the figure classified soil types are influenced by large effective stress and sandy soil type as discussed above.

4   CONCLUSIONS

This paper presents a comparative study on the applicability of the three CTPu-based soil classification charts, namely, Robertson's normalized (SBTn) chart, Eslami-Fellenius (E-F)'s non-normalized chart and Robertson's non-normalized (SBT) chart. CPTu data in association with soil sampling at six sites from different geological conditions were used for the analyses. The following key conclusions are drawn from the study.

1) when the effectives stress is less than about 150 kPa the E-F's and Robertson's normalized (SBTn) charts provide rather similar soil types for both clayey soil and sandy soil, however the Roberson's non-normalized (SBT) chart tends to indicate similar or slightly coarser grained soil types compared with those from the normalized chart. When the effective stress becomes larger the influence of the stress becomes more pronounced, and especially the E-F's chart also tends to indicate slightly coarser soil type compared with that obtained from the lab test results and VCP and from Robertson's SPTn chart. This indicates that the non-normalized charts tend to result coarser soil types than the actual soil types when the effective stress is large enough.

2) The characteristic of indicating coarser soil types from the non-normalized charts becomes more pronounced in sandy soils, especially dense sands at large depths.

3) From the analysis results in this study, it might be concluded that the Robertson's normalized chart is most reliable among the three charts.

ABSTRACT: Piezocone penetration tests (CPTu) and seismic flat dilatometer tests (SDMT) present costand time-efficient insitu investigation techniques for onshore as well as offshore projects. Since soil sampling is often related to a strong soil disturbance in fine-grained sediments, parameter identification is frequently based on insitu measurements in combination with correlations. As shown in previous studies, correlations are more difficult to develop in silt-dominated sediments. To overcome this problem, the research project PITS (parameter identification using insitu tests in silts), was launched by Graz University of Technology in cooperation with the Federal Chamber of Architects and Chartered Engineering Consultants. To investigate the influence of time effects (age) and microstructure on the load-settlement behaviour of normallyto slightly underconsolidated sediments, deposits younger than 50 years have been investigated at the water storage reservoir Raggal (Austria) using CPTu as well as Medusa SDMT. Both probes were pushed first through the water and subsequently into the sediments by means of a stand-alone pushing device, where the testing setup was installed on a floating pontoon. In order to prevent buckling of the penetration rods, additional casing tubes (along the water) were used. In a last step, soil sampling was executed using the CPT-Ranger system by Geomil. To characterize and quantify the sediments microstructure, shear wave velocities determined insitu by means of SDMT ($V_{S,SDMT}$) are compared with measurements on reconstituted soil samples using bender elements ($V_{S,BE}$). Ratios $V_{S,BE}/V_{S,SDMT} \approx 1$ indicate the presence of no or moderate soil microstructure. On the other hand, postglacial deposits of similar grain size distribution are characterized by smaller $V_{S,BE}/V_{S,SDMT}$ ratios, indicating a higher microstructure.

1 INTRODUCTION

1.1 *Motivation*

Fine-grained sediments define the soil layering of various basins and valleys within Alpine regions. Many of these basins and valleys were formed during several glacial periods and remained as lakes after the melting. Over thousands of years they have been filled by mainly fine-grained sediments. Therefore, such (geologically) young soils are often characterized by a high groundwater table and are generally in a normally consolidated or slightly under consolidated state. In the area of Salzburg or Bregenz it was observed that such sediments often present unexpected low settlements under static loading on shallow foundations. On the other hand, it was observed that dynamic loads introduced by heavy construction measures (e.g. soil improvement measures, jet grouting) can lead to significant settlements. One possible explanation for this observation might be related to microstructural bonds

within the grain-to-grain matrix, which lead to an increase in strength and stiffness (Leroueil 1992). At the same time, they can easily be destroyed due to heavy construction measures or non-adequate soil sampling techniques. On the other hand, insitu tests and especially seismic measurements (e.g. seismic piezocone penetration test SCPTu or seismic flat dilatometer test SDMT) are becoming increasingly popular to quantify and characterize microstructure (Robertson 2016).

To gain an improved understanding of structure in postglacial deposits by means of insitu tests Graz University of Technology in cooperation with the Federal Chamber of Architects and Chartered Engineering Consultants initiated the research project PITS (parameter identification using insitu tests in silts).

1.2 *Aim*

The present paper tries to investigate how aging can influence the development of microstructure.

Therefore, young sediments with an age of approximately 50 years deposited in the water storage reservoir Raggal (Austria) have been investigated using CPTu, SDMT and laboratory tests (e.g. oedometer, bender element).

Based on the comparison of shear wave velocities, determined insitu (Medusa SDMT) and in the laboratory on reconstituted samples (bender element), the degree of microstructure could be quantified and is further compared with measurements of post-glacial (older) sediments.

2 INSITU TESTS

2.1 *Piezocone penetration test - CPTu*

The piezocone penetration test (CPTu) is a widely used insitu test for soil classification and parameter identification. During test execution, a cone with a cross-section area equal to 10 or 15 cm^2 is pushed under constant penetration rate (2 cm/s) into the soil using a pushing device (e.g. truck, rig or demountable systems). Simultaneously, the tip resistance q_c, sleeve friction f_s and dynamic pore water pressure u_i are measured continuously over depth. The measurement of the pore water pressure is usually performed above the cone at position u_2. Alternatively, the pore water pressure can be measured directly at the cone (position u_1). Normalized parameters can be calculated based on insitu measurements and further used for soil classification (using soil behavior type chart) or in combination with correlations to identify soil parameters.

2.2 *Seismic Medusa flat dilatometer test - Medusa SDMT*

The flat dilatometer is an insitu soil testing equipment developed by Professor Silvano Marchetti in the late 1970s (Marchetti 1980). A steel blade – containing a thin, expandable, circular steel membrane mounted on one side – is pushed into the soil on a constant penetration rate equal to 2 cm/s. The blade is connected to a pneumatic electrical cable running through the penetration rods, up to a control unit at surface. In the standard testing procedure, the penetration is stopped every 20 cm. When performing a classic DMT, the membrane is inflated with gas to obtain two pressure readings at defined deformations of the membrane: the A-pressure (center of the membrane deforms 0.05 mm) and B-pressure (center of the membrane deforms 1.10 mm). A third pressure reading, the C-pressure (closing pressure), can optionally be taken by slowly deflating the membrane soon after B until it returns to position A.

The Medusa dilatometer (Medusa DMT) is a self-contained, fully automated version of the flat dilatometer, able to autonomously perform dilatometer tests without the pneumatic cable and gas tank.

A motorized syringe, driven by an electronic board powered with rechargeable batteries, hydraulically expands the membrane to obtain the A, B and C pressure readings, which are acquired and stored automatically at each test depth (Marchetti 2014). Since the test execution is performed automatically, the influence of operators can be reduced significantly, alternative timing of measurements become feasible and repeated A-pressure readings can be carried out accurately.

The seismic flat dilatometer is a combination of the flat dilatometer (or Medusa DMT) with the seismic module for measuring the shear wave velocity V_S behind the blade. The seismic module is a cylindrical element situated above the DMT blade and equipped with two receivers fixed at a vertical distance of 0.50 m. The measurements are commonly performed at depth intervals equal to 50 cm while stopping the penetration procedure. The shear wave source – located at the ground surface or in the present case at the lake floor bottom - generally consists of a S-hammer which strikes horizontally a rectangular steel plate pressed against the soil. The generated shear wave first reaches the upper receiver, then, after a delay, the lower receiver. The seismograms acquired by the two receivers, amplified and digitized at depth, are transmitted to a computer at the surface for real-time interpretation of V_S (Marchetti et al. 2008).

3 TEST SITE WATER STORAGE RAGGAL

3.1 *General information*

The water storage reservoir Raggal (see Figure 1), located in the western part of Austria, is operated by the energy operator *illwerke vkw* and is part of the hydropower plant *Oberstufe Lutz*. Due to natural sedimentation, about 50,000 m³ of material are deposited within the storage every year. To prevent blockage of important water intake points and to pass the annual inflow of sediments through the dam, these sediments are regularly removed near the dam using a dredger (see Figure 1).

3.2 *Investigation*

In a first step, the thickness of the sediments was investigated by means of echo soundings. The excavation works on the one hand and the location of insitu tests on the other hand have been designed/defined based on the latter. With increasing distance from the dam, the flow velocity rises and the deposited sediments become coarser. This relationship could be confirmed based on aerometer and sieve analyses on soil samples, recovered from the reservoir. In the front third of the water reservoir - where the finest sediments are deposited - *illwerke vkw* carried out excavation works during our investigation campaign. In order not to hinder the excavation work and to ensure all safety regulations, the insitu tests

were carried out approximately 300m behind the concrete-dam (see Figure 1). Based on echo soundings it could be ensured to investigate sediments of approximately 20 m thickness. All insitu tests were carried out starting from a floating pontoon within a rectangular area of approximately 10 x 5 m to ensure the comparability of test results (see Figure 1).

The insitu campaign consisted of piezocone penetration tests (CPTu) with pore water pressure measurements at position u_1 and u_2, seismic Medusa flat dilatometer tests (Medusa SDMT) and soil sampling by means of CPT-Ranger. All tests were executed in collaboration with the companies mjp ZT GmbH and Studio Prof. Marchetti.

Figure 1. Water reservoir Raggal: Overview and location test site.

4 TEST EXECUTION

4.1 *Floating pontoon and pushing device*

Since the reservoir was filled with water during test execution, all insitu tests were executed from the floating pontoon presented in Figure 2a (which is usually used for sediment transportation). The construction is composed of four air-filled steel boxes (two boxes each side), connected by three 2.8m long IPE300 profiles. The external dimensions and weight of the barge amount to 10 m x 8 m and 13 tons respectively. The mobile stand-alone system by Geomil (Fox-150) was used as pushing device for all insitu tests. Thereby, a separate power pack, driven by a petrol motor, powers the Fox-150 hydraulically. In order to avoid any tilting during test execution, it was tried to fix the penetration device on the floating-pontoon center. In a first step, HEA profiles were clamped onto the IPE300 profiles. Subsequently, the "stand-alone system" was attached to the (longitudinal assigned) HEA profiles using two GEWI bars (see Figures 2b and 2d). Free areas were covered by wooden constructions to ensure work safety during test execution (see Figures 2e and 2f). Finally, the floating pontoon was moved to the desired position using a motorboat and additionally fixed at the shore using four steel cables (see Figure 2g).

4.2 *Piezocone penetration test and seismic Medusa flat dilatometer test*

The water depth and the thickness of the sediment deposits were approximately 7 m and 20 m respectively during test execution. In order to prevent any buckling of penetration rods along the water section, additional casing tubes (with a slightly larger inner-diameter than the outer diameter of the pushing rods) were used to increase the cross-section and moment of resistance. In a first step, CPTu or SDMT probes were lowered to the lake floor bottom ensuring an embedment depth of approximately 2 m. Afterwards, casing tubes were lowered by using the stand-alone system. Once the casing tubes reached the lake bottom (sediment top surface) the penetration process was continued by means of pushing rods. Consequently, casing tubes were installed along the water section only. Due to the buckling problem and the limited weight of the pontoon, the sediments were investigated down to a depth of approximately 15 m. After reaching the final testing depth, first the casing tubes and subsequently the penetration rods were pulled back.

To determine the shear wave velocity, the S-hammer shown in Figure 3a was designed and built in cooperation with Studio Prof. Marchetti and Behensky. The shear wave is triggered using a 45kg drop-weight. Since water does not allow the transmission of shear waves, the S-hammer was lowered from the floating pontoon to the lake bottom using two winches (see Figures 3b and 3c). During the lowering procedure, additional casing tubes were continuously attached to the head of the structure to verify its position. A rope was used to lift and release the 45kg drop weight from the floating pontoon (see Figure 3c). The shear wave velocity was determined at 50 cm intervals.

4.3 *Soil sampling and laboratory testing*

In a final step, soil sampling for laboratory testing was executed in 5 depth levels using the CPT-Ranger system. All recovered samples (length = 50 cm, diameter = 7 cm) were carefully transported to Graz University of Technology and further investigated at the geotechnical laboratory. The sediments were characterized with respect to their particle size distribution, Atterberg limits, natural density, natural water content and oedometer stiffness. Furthermore, the shear wave velocity of reconstituted soil samples was determined at different insitu stress levels using bender element tests within a triaxial cell. All reconstituted soil samples were artificially mixed considering the insitu density and water content.

Figure 3. Test execution: Seismic measurements.

5 RESULTS

5.1 *Insitu and laboratory results*

The sedimentation history of the water reservoir Raggal is composed of a sequence of fineand coarse-grained layers. As shown in Figure 4, these sand-silt alterations are characterized by an erratic distribution of CPTu measurements over depth (lithology L1). The tip resistance q_c and sleeve friction f_s vary between 0.7 - 3.5 MPa and 5 - 50 kPa respectively. The measured pore water pressure u_2 corresponds to the hydrostatic (insitu) pore water pressure u_0 within sand-dominated layers and rises ($u_2 > u_0$) with higher fines content. This varying trend is also reflected by DMT intermediate parameters I_D (= 0.4 - 5), K_D (= 0.5 - 6) and E_D (= 0.5 – 12 MPa) in Figure 4.

The soil behaviour type index I_C – based on Robertson 1990 – classifies the sediments as "silty sand to sandy silt" and "clay to silty clay" (see Figure 4d). The DMT classification system according to Marchetti (1980) is based on the material behaviour index I_D and leads to a similar result ("silty sand to sand" and "clayey to sandy silts").

In a second step, all recovered soil samples have been classified based on their particle size distribution and Atterberg limits according to EN ISO 14688-1 and ASTM 2487-11 (USCS). The particle size distribution of five depths is presented as a bar chart in Figure 5a (red = clay, green = silt, blue = sand). It is evident that sections with increased sand content are represented by higher I_D (DMT) and lower I_C (CPTu) values. On the other hand, four soil samples - classified as clayey, sandy silts (cl' sa' Si) according to EN ISO 14688-1 - have been recovered within fine-grained sections. These sediments present a fines content (<0,075mm) larger than 90 % and are classified as organic silts (OL, OH) based on USCS (see Figure 5c). Due to their high organic

content (2-3 %), all points are situated below the A-line within the Casagrande diagram.

A small insitu density ($\rho_d \approx 1.2$ g/cm³, $\rho_{sat} \approx 1.75$ g/cm³) and a high natural water content $w_{nat} > 40$ % was expected and furthermore determined within fine-grained (under-consolidated) layers. Nevertheless, it should be noted that natural water contents decrease and insitu densities increase with increasing particle size distribution.

5.2 *Microstructure*

The insitu shear wave velocity $V_{S,SDMT}$ determined by means of Medusa SDMT is presented in Figure 4e. As described earlier in section 4.1 for CPTu and DMT measurements and intermediate parameters, also the shear wave velocity is strongly influenced by the particle size distribution. Thereby, layers of higher sand-content are characterized by higher V_S values.

In order to quantify the degree of microstructure, bender element tests were performed in a second step on reconstituted soil samples using a triaxial device. It is important to note that material of soil samples recovered at -6.8 m, -8.1 m, -13.3 m and -16.1 m (all characterized by a similar particle size distribution as shown in Figure 5a) was used for this experimental approach. After a K_0-consolidation, the shear wave velocity was determined for different insitu stress levels. The bender element results are shown in Figure 6a by blue triangles and are compared with SDMT results. Thereby, a regression (grey dotted) line - which goes through fine-grained sections where soil sampling was executed - is used for comparison. Based on the ratio $V_{S,BE}/V_{S,SDMT}$ it is evident that shear wave velocities determined in the laboratory by means of bender elements ($V_{S,BE}$) and in situ using Medusa SDMT ($V_{S,SDMT}$) are in good agreement. Since $V_{S,SDMT}$ and $V_{S,BE}$ differ only slightly, it can be assumed that the investigated sediments within the reservoir Raggal are characterized by no or moderate microstructure.
6 CONCLUSION

Alpine regions are often characterized by basin landscapes, which were filled by fine-grained sediments after the last glacial period. These (normally to slightly under-consolidated) sediments often show small settlements under static loading, leading to the assumption that they might be characterized by a microstructure. Various authors (e.g. Robertson 2016) showed that structured soils present a higher shear wave velocity compared to unstructured (ideal) soils. The present paper investigated whether and to what extent young sediments, deposited in the water storage reservoir Raggal, are characterized by microstructure. In a first step CPTu, Medusa SDMT and soil sampling was performed from a floating pontoon using a mobile pushing device. The investigated sediments are composed of sand-silt alternations and are characterized by a small insitu density and a high water content $w_{nat} > 40$ %. In a second step bender element tests were performed on reconstituted soil samples and compared with the SDMT results. It was shown that shear wave velocities determined on reconstituted soil samples are in good agreement with SDMT results ($V_{S,BE}/V_{S,SDMT} \approx 1$), indicating no or little microstructure. Within the research project PITS, similar investigations have been performed in older sediments (e.g. rhine valley, basin of Salzburg) too. In these cases $V_{S,BE}/V_{S,SDMT}$ ratios were significantly smaller than 1, indicating a stronger microstructure in postglacial deposits. The present contribution showed that $V_{S,BE}/V_{S,SDMT}$ ratios are a potential indicator to quantify and characterize soil microstructure.

ABSTRACT: The conventional interpretation of CPTu tests is typically based on empirical and semi-empirical correlations based on very crude descriptions of soil behavior, such as the total stress approach coupled with the Terzaghi-Rendulic pseudo-3d consolidation theory for modeling the time evolution of excess pore water pressure. The aim of this work is to show that a more rational interpretation of the coupled deformation and flow processes occurring in the soil during a CPTu test is possible by resorting to the numerical solution of the relevant governing equations, incorporating a realistic constitutive model for the soil. In order to deal with the large displacements and deformations induced by the cone penetration, the Particle Finite Element Method code G-PFEM, recently developed for geomechanical applications, has been used for this purpose. A key feature of the present work is the use of a finite deformation version of a non-associative isotropic hardening plasticity model for structured geomaterials - the FD_Milan model. The model is equipped with a *structure-related* internal variable which provide a macroscopic description of the effects of structure in natural, fine-grained soils. In order to deal with strain localization, typically observed in structured geomaterials upon yielding, the model has been equipped with a non-local version of the hardening laws, which has demonstrated capable of regularizing the pathological mesh dependence of classical FE solutions in the post-localization regime. A number of PFEM simulations of CPTu tests on a soft structured natural clay has been performed in order to assess the effects of the initial bond strength and permeability on the predicted results of the test, as well as on the spatial distributions of accumulated plastic strains, internal variables and excess pore water pressures. The results obtained represent a promising step towards a more rational interpretation of the CPTu tests in structured geomaterials and for their use in the calibration of advanced soil models.

1 INTRODUCTION

The Cone Penetration Test (CPT) is a widely used investigation tool for the characterization of both coarse-and fine-grained soils, for its simplicity, reliability and its relatively low cost. The development of the piezocone, featuring piezometers for the measurement of pore water pressure p_w at different positions on the cone tip, has significantly improved the capabilities of this site investigation tool - now referred to as CPTu test - and opened the way for a more rational interpretation of the test results.

The conventional interpretation of CPT tests is currently based on empirical and semi-empirical correlations, the last based on very crude descriptions of soil behavior, such as the adoption of a total stress approach. The excess pore pressure measurements in CPTu tests are typically used to

identify fine-grained soils (where Δp_w are large) from coarse-grained soils (where Δp_w are small or negligible), or to measure the soil coefficient of consolidation from pore pressure dissipation stages, where the tip advancement is stopped.

The aim of this work is to show that a more rational interpretation of the coupled deformation and flow processes occurring in the soil during a CPTu test is possible by resorting to the numerical solution of the relevant governing equations for the penetration process, and by adopting a realistic constitutive model for the soil. In early attempts to simulate the CPT test with the ALE-FE method, the extreme deformations imposed to the soil by the penetration of the piezocone have represented a substantial difficulty, due to strong mesh distortions which resulted in significant loss of accuracy or loss of convergence at relatively small penetration depths.

An effective alternative to the FEM which has proven to be quite efficient in simulating the cone penetration process is the Particle Finite Element Method (PFEM, Oñate et al. 2011). The PFEM shares many similarities with the updated Lagrangian approach of non-linear FEM, but it is capable of handling the problem of severe mesh distortion by a frequent mesh re-triangulation and h-adaptive refinement, using very efficient algorithms based on extended Delaunay tesselation. The nodes of the spatial discretization - performed with low-order linear triangles or tetrahedra - are treated as material particles, the motion of which is tracked during the numerical simulation. Applications of PFEM to the modeling of CPTu tests have been reported, *e.g.*, by Monforte et al. (2017), Monforte et al. (2018), Monforte et al. (2021), Hauser and Schweiger (2021) and Carbonell et al. (2022).

As far as modeling CPTu tests in clays is concerned, most of the works cited have been carried out adopting the classical MCC model for the soil. Although this critical state model is capable of capturing the essential features of soft, lightly overconsolidated clays, it fails to reproduce the behavior of natural structured clays, characterized by the presence of intergranular bonds of various origin. To investigate the effects of bonding on the soil response to the piezocone advancement, in this work the isotropic hardening elastoplastic model for natural, structured soils proposed by Nova and co-workers (Tamagnini et al. 2002, Nova et al. 2003) has been extended to finite deformations adopting a multiplicative decomposition of the deformation gradient into elastic and plastic parts (see, *e.g.*, Borja & Tamagnini 1998). The finite deformation plasticity model thus obtained - referred to in the following as the FD_Milan model - has been implemented in a geomechanics-oriented PFEM code (G–PFEM, Monforte et al. 2017) and has been used in this work to simulate CPTu tests in a relatively soft natural clay.

The remainder of the paper is as follows. A brief overview of the FD_Milan model is provided in Sect. 2, while the details of the CPTu simulations program are given in Sect. 3. A selection of the results obtained in the PFEM simulations is presented in Sect. 4. Sect. 5 provides the main concluding remarks and suggestions for further studies.

2 THE FD_MILAN MODEL

2.1 *Local version*

The FD_Milan model is a non-associative, isotropic hardening finite-deformation plasticity model for structured soils and weak rocks, developed by Oliynyk et al. (2021) based on the multiplicative decomposition of the deformation gradient and on the adoption of a suitable free energy function to describe the elastic response of the material. Its

evolution equations in the spatial setting are briefly summarized here:

$$\overset{\triangledown}{\tau} = \mathbf{a}^e(\boldsymbol{d} - \boldsymbol{d}^p)\,(\text{hyperelastic eq.}) \qquad (1)$$

$$\boldsymbol{d}^p = \dot{\gamma}\frac{\partial g}{\partial \tau}\,(\text{flow rule}) \qquad (2)$$

$$\dot{P}_s = \dot{\gamma}\rho_s P_s\big(\hat{V} + \xi_s \hat{D}\big)\,(\text{hardn. law for } P_s) \qquad (3)$$

$$\dot{P}_t = -\dot{\gamma}\rho_t P_t\big(|\hat{V}| + \xi_t \hat{D}\big)\,(\text{hardn. law for } P_t) \qquad (4)$$

subjected to the Kuhn-Tucker complementarity conditions:

$$f(\tau, P_s, P_t) \le 0 \quad \dot{\gamma} \ge 0 \quad \dot{\gamma}f(\tau, P_s, P_t) = 0 \qquad (5)$$

In the above equations, τ and $\overset{\triangledown}{\tau}$ are the Kirchhoff stress and its Jaumann objective rate; d is the rate of deformation tensor; $\boldsymbol{d}^p$ is the plastic rate of deformation tensor; $\mathbf{a}^e$ is the spatial hyperelastic tangent stiffness of the material; $\dot{\gamma}$ is the plastic multiplier; f and g are the yield function and the plastic potential, respectively (see Oliynyk et al. 2021 for details); P_s and P_t are internal variables; the functions

$$\dot{\gamma}\hat{V} = \dot{\gamma}\,\text{tr}\left(\frac{\partial g}{\partial \tau}\right) \quad \dot{\gamma}\hat{D} = \dot{\gamma}\sqrt{\frac{2}{3}}\left\|\text{dev}\left(\frac{\partial g}{\partial \tau}\right)\right\|$$

are the plastic volumetric and deviatoric rates of deformation; and ρ_s, ξ_s, ρ_t and ξ_t are material constants.

The first internal variables P_s (*preconsolidation pressure*) accounts for the hardening/softening effects due to volumetric and deviatoric plastic strains. The second, P_t (*bond strength*), quantifies the effects of material structure (fabric and bonding). A representation of the yield surface in the Kirchhoff stress invariants space $P{:}Q$, highlighting the role of the internal variables, is given in Figure 1.

For $\xi_s = 0$, eq. (3) reduces to the classical volumetric hardening law of critical state soil mechanics. Plastic volumetric compaction produces an increase of P_s while plastic dilation is accompanied by a reduction of P_s.

A positive value of the bond strength P_t results in an expansion of the elastic domain in stress space. On the positive part of the P axis, the isotropic yield stress in compression is increased by a quantity $P_m = kP_t$, with k a material constant. On the negative axis, the vertex of the yield surface is displaced from the origin of the stress space to $P = -P_t$. Therefore, the structured material possesses a true cohesion and a non-negligible tensile strength. The region in the stress space contained between the actual yield surface (full black line in Figure 1) and
Figure 1. Yield surface and plastic potential of the FD_Milan model.

$$\dot{E}_v^p = \dot{\gamma}\hat{V} \quad \dot{E}_s^p = \dot{\gamma}\hat{D} \quad \dot{N}_v^p = \dot{\gamma}|\hat{V}| \qquad (8)$$

and P_{s0} and P_{t0} represent the initial values of the internal variables. Once E_v^p, E_s^p and N_v^p are chosen as alternative state variable, their values can be spatially averaged in a neighborhood Ω of each material point $x = \phi(X,t)$ at time t. The spatial averages are computed numerically by the following expressions:

$$\overline{A}(\boldsymbol{x}_i) = \frac{1}{\sum_{x_j \in \Omega} w(\boldsymbol{x}_i, r_{ij})} \sum_{x_j \in \Omega} w(\boldsymbol{x}_i, r_{ij})A(\boldsymbol{x}_j) \qquad (9)$$

where the symbol A stands for one of the variables E_v^p, E_s^p or N_v^p. In eq. (9), $r_{ij} = \|x_j - x_i\|$ is the distance between points located at x_j and x_i, and w is a suitable weighting function, for which the expression proposed by (Galavi & Schweiger 2010):

$$w(\boldsymbol{x}, r_{ij}) = \frac{r_{ij}}{\ell_c} \exp\left\{ -\left(\frac{r_{ij}}{\ell_c}\right)^2 \right\} \qquad (10)$$

has been adopted. The scalar quantity ℓ_c appearing in eq. (10) is a material constant providing the length scale sought after. Once the non-local quantities $\overline{E}_v^p$, $\overline{E}_s^p$ and $\overline{N}_v^p$ are known, the stress-like internal variables P_s and P_t are computed by eqs. (6) and (7).

the intrinsic yield surface of the unstructured material (with $P_t = P_m = 0$, black dashed line in Figure 1), represents the so-called *structure-permitted space*, which is accessible only by the combined effects of fabric and intergranular bonding. As a consequence of the microstructural rearrangement of the soil fabric and the concurrent breakage of intergranular bonds, the structure of the material is progressively destroyed. From a macroscopic point of view, this process induces a progressive reduction of P_t with increasing accumulated plastic deformations. This process is described by the hardening law of eq. (4), in which the RHS is always negative. The final asymptotic value for P_t is zero (full destructuration): the bond-permitted space reduces to zero and the yield surface coincides with the intrinsic yield surface.

2.2 *Non-local version*

In order to provide a characteristic length scale to the constitutive equation, to regularize the numerical solution in presence of strain localization phenomena, the integral non-local approach of Oliynyk et al. (2021) has been adopted, in which the internal variables P_s and P_t are treated as non-local, spatially averaged quantities over a neighborhood Ω of the material point. The size of this neighborhood is controlled by a material constant ℓ_c, called *characteristic length*.

Let us rewrite the hardening laws (3) and (4) in the following equivalent integrated form:

$$P_s = P_{s0} \exp\left\{\rho_s\left(-E_v^p + \zeta_s E_s^p\right)\right\} \qquad (6)$$

$$P_t = P_{t0} \exp\left\{-\rho_t\left(N_v^p + \zeta_t E_s^p\right)\right\} \qquad (7)$$

where E_v^p, E_s^p and N_s^p are three strain-like internal variables, whose evolution equations are provided by:

3 SIMULATION PROGRAM

In the PFEM simulations of CPTu tests, a standard piezocone, with radius $R = 1.78$ cm and a cone tip angle of $60°$ is inserted in a calibration chamber with radius $B = 0.45$ m and height $H = 1.05$ m, filled with a fully saturated clay. The problem has been assumed as axisymmetric. A sketch of the problem geometry along with some snapshots of the spatial adaptive PFEM discretization at 3 different tip advancement depths is given in Figure 2.

The piezocone is wished-in-place at an initial depth $z_0 = 0.25$ m and then displaced downwards at a constant penetration speed of 2.0 cm/s, up to a depth $z = z_0 + 20R$. The piezocone tip and its lateral surface are modeled as rigid, impervious surfaces, and a smooth contact interface with the soil is adopted. Given the relatively small dimensions of the calibration chamber, the self weights of the pore water and of the soil have been ignored. The initial pore water pressure has been assumed uniform and equal to zero.

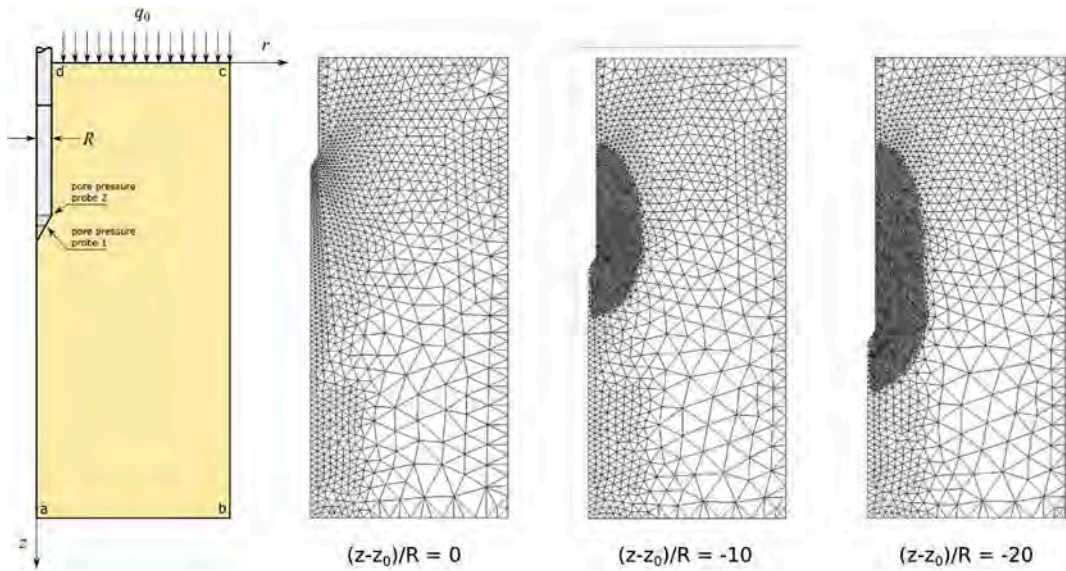
The material constants adopted in the simulations have been obtained by calibrating the model on the available experimental data for the Osaka clay (Adachi et al. 1995) and are reported in Table 1. The


Figure 2. Problem geometry and spatial discretizations at 3 different tip advancement depths.

Table 1. Sets of material constants adopted in the CPTu test simulations (see Oliynyk et al. 2021 for details on the meaning of each constant).

flow rule has been assumed as associative, so the plastic potential coincides with the yield function.

All the PFEM simulations have been performed as fully coupled hydromechanical problems, adopting the mixed u-Θ-p_w formulation of Monforte et al. (2017). The bottom and lateral surfaces of the calibration chamber have been assumed as rigid, impervious and perfectly rough boundaries. At the top surface of the soil body a uniform normal pressure $q_0 = 100$ kPa and a constant pore water pressure $p_w = 0$ have been imposed. Consistently with these boundary conditions, the initial Cauchy effective stress in the soil mass has been assumed axisymmetric, with components $\sigma_z = 100$ kPa and $\sigma_r = K_0\sigma_z$ and $K_0 = 0.5$. The initial value of P_s has been set to 120 kPa.

4 SELECTED RESULTS

Six simulations have been performed considering 4 different hydraulic permeabilities, k_h, in the range 1.0e-9 to 1.0e6 m/s, and 3 different initial values for

the bond strength, P_{t0}, from 0 to 60 kPa. With these initial conditions and the material properties listed in Tab. 1 the apparent peak undrained strength $c_{u,p}$ of the soil ranges from 41 to 106 kPa.

The effects of the initial degree of bonding are shown in Figures 3 and 4. The simulations reported have been performed with $k_h = 1.0$e-9 m/s. For such a low permeability value, the penetration process occurs in almost undrained conditions. Figure 3 shows the profiles, relative to the cases of P_{t0} equal to 0, 30 and 60 kPa, of net cone resistance, q_n and excess pore water pressures computed at the cone base (Δp_{w2}) and at the cone tip (Δp_{w1} as a function of the normalized penetration depth $Z = (z - z_0)/$R.

Figure 3. Profiles of net cone resistance, excess pore pressure $\Delta p_{w,2}$ and $\Delta p_{w,1}$ for different initial values of bond strength P_{t0} and $k_h = 1.0$e-9 m/s.

After an initial transient stage up to $Z = 5$, all the profiles reach a stationary state up to the final value of the penetration $Z = 20$. It can be observed that the stationary values of q_n, Δp_{w1} and Δp_{w2} increase with increasing P_{t0}: the higher is the initial structure of the soil, the higher are the cone resistance and the excess pore pressures developed during the cone advancement.

Figure. 4 shows a comparison of the contour maps of E_s^p, P_s, P_t and Δp_{w1} for the two extreme cases of $P_{t0} = 0$ and 60 kPa. In the unstructured soil, the plastic zone around the piezocone extends by about $3R$ around the shaft and the cone, with contour lines following the shape of the penetrating device. In the structured soil, on the other hand, the observed pattern of plastic shear deformations is much more irregular and show the presence of localized shear zones which originate at about $3R$ below the cone tip and bend upwards as the cone advances. The presence of shear localization is most likely due to the softening behavior associated to soil destructuration. In both cases, the preconsolidation pressure P_s is only slightly affected by the penetration process, due to the virtually undrained nature of the soil deformation. In the structured soil, the contour map of P_s highlights the presence of a region of decreasing P_s, located at the boundary of the plastic region, where plastic dilatancy is occurring. The contour map of the bond strength for the structured soil clearly indicates that, in most of the plastic region around the piezocone, the destructuration process is almost complete. Yet, the presence of structure maintains a non-negligible effect on both the cone tip resistance and the spatial distribution of the pore water pressures, as shown in the contour maps of p_w.
The effects of soil permeability on the predicted CPTu results are shown in Figure 5, reporting the profiles of q_n, $\Delta p_{w,1}$ and $\Delta p_{w,2}$ with Z for the four k_h values considered. From the figure, the impact of the soil permeability on the computed excess pore pressures at the two piezometers locations is immediately apparent. In the simulation with the highest permeability value the soil deforms in almost drained conditions, with a maximum Δp_w of about 50 kPa at the position of the piezometer no. 1. The maximum Δp_w are obtained at both piezometers for the lowest K_h value (1.0e-9 m/s), and only slightly smaller values of excess pore water pressure are registered at piezometer no. 2 for the next to smallest permeability. This value of k_h (1.0e-8 m/s) appears to mark the transition from fully undrained to partially drained soil response.

Figure 5. Profiles of net cone resistance, excess pore pressure $\Delta p_{w,2}$ and $\Delta p_{w,1}$ for different soil permeabilities and $P_{t0} = 30$ kPa.

As expected, the q_n profiles show a larger cone resistance in the "drained" case, as compared to the "undrained" one, with the two intermediate cases profiles remaining close to the two extremes. Surprisingly, the difference between the different profiles of q_n is not very large, being on average around 13%.

The contour maps of E_v^p in Figure 6 and of E_s^p, P_s, P_t and p_w in Figure 7, for the two limiting cases of the smallest and highest permeability values adopted, indicate that, apart from the large differences observed in the final pore water pressure fields, the collapse mechanisms around the advancing cone tip is fundamentally different in the two cases. In the "undrained" case, the plastic region around the advancing piezocone is quite large, extending for about 6R both vertically, below the cone tip, and horizontally from the piezocone axis. The plastic zone in characterized by a complex pattern of accumulated volumetric and deviatoric plastic deformations, with clearly visible bands of localized shear and volumetric deformations. On the other hand, in

Figure 4. CPTu tests results: contour maps of E_s^p, P_s, P_t and p_w at the maximum penetration depth, for $P_{t0} = 0$ kPa (top) and $P_{t0} = 60$ kPa (bottom).

Figure 6. Contour maps of E_v^p for the maximum and minimum permeabilities considered.

Figure 7. CPTu tests results: contour maps of E_s^p, P_s, P_t and p_w at the maximum penetration depth, for the minimum (top) and maximum (bottom) permeabilities considered.

the "drained" case, the penetration mechanism is more similar to a "punching" process, with a much smaller and homogeneous plastic zone around the cone tip and shaft. This certainly has a major effect on the stress distribution in the soil, which could explain the relatively modest differences registered in the stationary values of q_n in the two cases.

5 CONCLUDING REMARKS

The results of this preliminary study appear consistent with the observed CPTu profiles in similar soils and demonstrate that the soil response to the penetration of the piezocone in CPTu tests can actually be modeled quantitatively in a rational and computationally efficient way. The quality of the results obtained depends crucially on the capability of the constitutive model adopted to capture the essential features of the soil response during the penetration process. The FD_MILAN model presented in this work appears particularly well suited in this respect for a wide range of natural geomaterials, ranging from natural clays to porous soft rocks. The multiplicative plasticity model recently proposed by Oliynyk & Tamagnini (2020), based on the breakage mechanics, can represent a possible alternative for coarse-grained soils with crushable grains and collapsible weak rocks. The numerical simulations, performed with different initial bond strengths and soil permeabilities, show that the coupled non-linear PFEM model is capable of capturing: a) the development of plastic deformations induced by the advancement of the cone tip; b) the destructuration associated with plastic deformations; c) the space and time evolution of pore water pressure during the test. A characteristic of the plastic deformations pattern in presence of structure is the appearance of shear bands below the cone tip which propagate laterally as the tip advances and remain stationary thereafter. This feature is most likely associated to the softening mechanism induced by soil destructuration, as described by the FD_MILAN model. These results represent a promising step towards a more rational interpretation of the CPTu tests in structured geomaterials and for their use in the calibration of advanced soil models. The extension of the proposed model to incorporate thermal coupling effects (see, *e.g.*, Tamagnini and Ciantia 2016) will allow the interpretation of T-CPTu tests, which represent a promising development for the thermal characterization of soils in the design of low-enthalpy energy geostructures.

Effect of the scatter between CPTU measured parameters in soil classification

P. Paniagua
Norwegian Geotechnical Institute & Norwegian University of Science & Technology, Trondheim, Norway

J.-S. L'Heureux
Norwegian Geotechnical Institute, Trondheim, Norway

ABSTRACT: Using piezocones from different manufacturers may yield different results even if the equipment complies with international standards. This causes problems when soil investigation contractors, using different cones, operate in the same area, and especially on the same project. Studies done in soft clay, sand, silt, and quick clays from different Norwegian sites show that repeatability for the cone resistance measurements and penetration pore pressure is good and that it has improved from one cone type to another. However, the scatter in the measured sleeve friction, and hence the friction ratio, is still very significant. Here, an attempt is made to qualitatively describe the impact of the scatter in the soil classification based on CPTU parameters. The most common soil classification charts are used to illustrate this scatter.

1 INTRODUCTION

Performing piezocone tests (CPTU) with cone penetrometers from different manufacturers may give different results even though the equipment is aligned with international standards. Previous studies (Lunne et al. 1986, Gauer et al. 2002, Powell & Lunne 2005, Tigglemann & Beukema 2008, Lunne 2010, Cabal & Robertson 2014 Lunne et al. 2018) have shown that all three measured parameters, cone resistance q_c, friction sleeve f_s and pore pressures u_2, could vary significantly, and in particular for f_s, depending on the equipment used.

Recent advances in electronics and cone design have been incorporated in the design of the new cones and motivated further field testing. The establishment of the Norwegian GeoTest Sites (NGTS) (L'Heureux & Lunne 2019) has given the opportunity to different companies to do testing at the silt (Paniagua et al. 2021), sand (NGI 2020), quick clay (Lindgård et al. 2019) and soft clay (Lunne et al. 2018) sites. In general, after these tests, it was observed that the measured u_2 and q_c (or corrected cone resistance, q_t) showed little variation between different cone types, while the f_s measurement gave relatively large scatter between different cone types. Then, the question that arises is how much this scatter in the CPTU parameters influence further treatment of the data like for example soil classification based on CPTU.

The present article investigates the impact of varying CPTU equipment and its scatter on the most common CPTU soil behaviour charts. The paper focuses on the effect of the scatter between different types of piezocones. Further analyses regarding the statistical distribution of scatter with depth and between piezocones for each site is done in Lindgård et al. (2018), Lunne et al. (2018), Paniagua et al. (2020) and NGI (2020).

2 METHODOLOGY

Two relevant CPTU data sets selected at the NGTS study sites in Norway have been chosen for this study. The data sets selected correspond to the ones giving the largest scatter between them, i.e., the maximum (data in red in the figures) and minimum (data in blue in the figures) values. In other words, the selected data sets come from the cones which provide extreme profile results. The difference between the two data sets presented here are measured in terms of its CPTU parameters q_t, u_2 and f_s, and then the data was plotted in terms of the classification systems presented in this paper.

The data sets are then plotted in the soil classification charts proposed by Robertson (1990), Schneider et al. (2008) and Senneset et al. (1989). The data plotted in the soil classification charts has been filtered to represent just the layer where the main soil material for the site is to be found.

It should be clarified that the discussion about the validity of the soil classification charts mentioned above for Norwegian soil conditions is out of the scope of this study. Therefore, it is assumed that the soil classification charts may represent fairly well the soil types studied in the present paper.

The observations presented here assume that the requirements and recommendations given in ISO 22476-1:2012 (Geotechnical investigation and testing - Field testing - Part 1: Electrical cone and piezocone testing) and Norwegian Geotechnical Society (NGF) Guideline No. 5 (2010) are followed. Some of these are:

– Zero readings to be taken before and after each test with the cone penetrometer at a temperature as close as possible to ground temperature.
– It is important to wait until the readings have stabilized before taking zero readings.
– The thrust machine shall push the rods so that the axis of the pushing force is as close to vertical as possible.
– The pore pressure measurement system shall be saturated to give good pore pressure response during penetration.
– For deep CPTUs, it is important to correct the penetration length for inclination effects.
– Recommended minimum distance between a CPT and adjacent boreholes is 2 m.

2.1 Test sites

The NGTS sites selected for the present study are well portrayed in the following publications and are shortly described as follows:

– *Tiller-Flotten quick clay* (L'Heureux et al. 2019): The site consists of thick marine clay deposit of a low to medium sensitivity (1-7,5 m) deposit over a high sensitivity (quick) clay (7,5-20 m depth).
– *Onsøy soft clay* (Gundersen et al. 2019): The site consists of a high plasticity marine clay (1--8 m depth), a medium plasticity clay (8--13 m depth) and a high plasticity clay (13-20m).
– *Halden silt* (Blaker et al. 2019): The silt layer varies between 5-15 m and consists of a uniform marine natural silt.
– *Øysand sand* (Quinteros et al. 2019): The site consists of fluvial and deltaic gravelly-sandy-silt sediments with a gravelly sand layer from 0-14 m, a silt layer from 14-17,5 m depth and a sand layer down to 20 m depth.

2.2 Derived CPTU parameters studied

The soil classification charts are a combined representation of the in-situ behaviour characteristics of the soil under a CPTU. The CPTU might be able to measure up to seven independent parameters like cone resistance, q_c, friction sleeve, f_s, pore pressure, u_2, shear wave velocity, V_s, and when performing dissipation tests, the time for 50% consolidation, t_{50}, in situ pore pressure, u_o, and hydraulic gradient, i.

Usually the most common parameters (i.e., q_c, f_s and u_2) are normalized to be represented in soil classification charts. Before normalization, the parameter q_c is corrected for unequal pore pressure effects by the formula $q_t = q_c + a (1-u_2)$, where the parameter a relates the cross-sectional area of the shaft and projected area of the cone.

Robertson (1990) relates the normalized parameters Q_t, B_q and F_r, noted as normalized cone resistance, pore pressure parameter and normalized friction ratio, respectively.

Schneider et al. (2008) and Senneset et al. (1989) make use of some of the normalized parameters (i.e., Q_t and B_q) and relate them to either $\Delta u/\sigma_{vo}$' for Schneider et al (2008) or q_t for Senneset et al. (1989).

3 RESULTS

The main observations for all sites are given and discussed below. However, due to space limitation focus will mainly be given to the results obtained at the Halden and Onsøy sites, and some specific observations for Tiller-Flotten and Øysand. The complete figures for Tiller-Flotten and Øysand can be sent to the interested readers upon request to priscilla.paniagua@ngi.no.

3.1 Tiller-Flotten quick clay site

The testing of eight different cones from five CPTU manufacturers) showed less variability for the u_2 parameter. The q_t value showed a larger variability than u_2 but lower than f_s (Lindgård et al. 2018). In fact, there are more uncertainties associated to the f_s value since some of the cone types gave good repeatability for f_s readings, while some show relatively large variation.

The following observations were made at Tiller-Flotten:

– For the Robertson (1990) Q_t-B_q plot, the data sets with largest variability all fall in the same soil behaviour type "clay-sensitive" clays. This observation is valid no matter where the largest scatter is in the CPTU parameters.
– For Robertson (1990) Q_t-F_r plot, when the variability focuses in f_s, the data plots in two neighbouring areas (sensitive clay and the limit sensitive clay-clay). When the variability appears in the q_t or u_2 value, then the data plots in the same soil type, however, with a tendency to cover opposite areas in the same or neighbouring soil types.
– For Schneider et al. (2008) (Q_t-$\Delta u/\sigma_{vo}$') chart and Senneset et al. (1989) (q_t-B_q) chart, no clear difference is observed between the data sets showing largest scatter, for q_t and u_2 parameters. The quick clay is classified as sensitive clay (1c) in Q_t-$\Delta u/\sigma_{vo}$' plot and over the soft to very soft clay area in the q_t-B_q plot. However, the variation in f_s for Senneset et al. (1989) shows that the soil can be classified as stiff clay-silt.

3.2 Onsøy soft clay site

Seven different cone penetrometers from five manufacturers were used in the comparative testing program and

it was concluded that u_2 was the parameter that showed better repeatability, followed by q_t which generally varies somewhat more (Lunne et al. 2018). Some of the cone types give good repeatability for f_s readings, while some show relatively large variation.

When looking at the derived CPTU parameters in the soil classification charts, the following aspects are observed (see Figure 1):

– In Q_t-B_q and Q_t-F_r charts from Robertson (1990), the soil type is classified in soil types 1 and 3 (sensitive clay-clay) independently of the scatter in any of the CPTU parameters. However, for Q_t-F_r chart, when the scatter is in the u_2 and f_s parameter, the data moves also towards a soil type 2 (organic soils).
– Regarding the charts of Schneider et al. (2008) (Q_t-$\Delta u/\sigma_{vo}$') and Senneset et al. (1989) (q_t-B_q), no difference is observed between the data sets showing largest scatter, for q_t and u_2 parameters. The clay is classified as clay (1b)-sensitive clay (1c) in Q_t-$\Delta u/\sigma_{vo}$' plot and soft-very soft clay in q_t-B_q plot. However, the variation in f_s for Senneset et al. (1989) shows that the soil can be classified as fine silt-medium clay.

3.3 Halden silt site

After testing five different cone penetrometers on this site, it was concluded that u_2 and q_t showed good repeatability between the measurements, while f_s gave the largest variation (Paniagua et al. 2020).

Figure 2 presents the CPTU data sets that give the largest scatter for each of the CPTU parameters in the soil classification charts. Observations made are as follow:

– In the chart Q_t-B_q from Robertson (1990), the soil type is classified in soil types 3 and 4 (silty clay-silt mixtures) independently of the scatter in any of the measured CPTU parameters. However, for Q_t-F_r chart, when the scatter is in the f_s parameter, the data mainly plots in two different soil types (either type 3 or 4). A similar observation applies when the scatter is in the q_t parameter but does not apply when the scatter is in the u_2 parameter.
– For the other charts relating Q_t-$\Delta u/\sigma_{vo}$' (Schneider et al. 2008) and q_t-B_q (Senneset et al. 1989), no difference is observed (i.e., both CPTU data sets plot on top of each other in roughly the same soil types: silts (1a)-transitional soils (3) and silt-fine silt, respectively. An exception is observed when the scatter is in u_2 for the Schneider et al. (1998) plot, where the data sets tend to move to neighbouring soil types (one to soil type 3 and the other one to soil type 1a).

3.4 Øysand sand site

The CPTU parameters from nine cone penetrometers types tested showed results more dependent on the

varying soil conditions for the site. Quinteros et al. (2019) explained this as consequence of the depositional history of the site and the influence of the deltaic foresee beds dipping at an angle of 20-25 degrees. By adjusting the CPTU results in depth, the sand layers appeared to be more homogenous. The relative variation in q_t and u_2 was small and for all practical purposes negligible. However, sleeve friction results showed a large scatter between the different cone types. The variation in sleeve friction also seemed to increase with depth.

Comparison of CPTU data from Øysand on the soil classification charts leads to the following observations:

– In Q_t-B_q and Q_t-F_r charts from Robertson (1990), the soil type is mainly classified from soil types 4 to 7 (silt mixtures to gravelly sand) independently of the scatter in any of the measured CPTU parameters.
– A similar observation applies for the charts of Schneider et al. (2008) (Q_t-$\Delta u/\sigma_{vo}$') and Senneset et al. (1989) (q_t-B_q), where no difference is observed between the data sets showing largest scatter. The deposit is classified as transitional soils (type 3)-sands (type 2) in Q_t-$\Delta u/\sigma_{vo}$' plot and from silt to sand/hard stiff soil in the q_t-B_q plot.

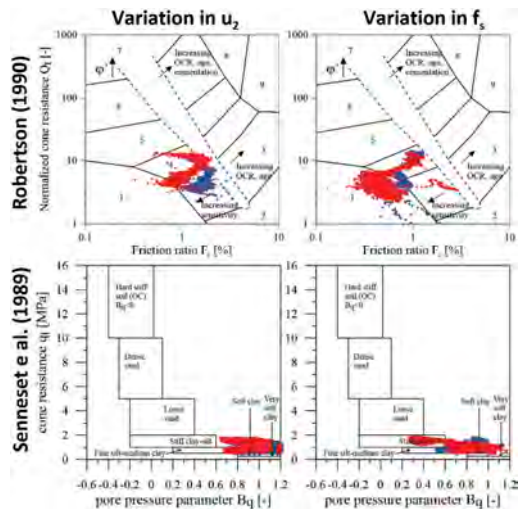

Figure 1. Two CPTU data sets from Tiller-Flotten plotted in two classification charts for two CPTU parameters showing extreme values (min-blue and max-red).

4 DISCUSSION AND CONCLUSION

Generally, previous research om NGTS sites has shown that the measured u_2 shows less variation for one cone type to another while, while q_t shows somewhat larger variation and f_s the largest variation. F_r shows much larger variation compared to B_q.

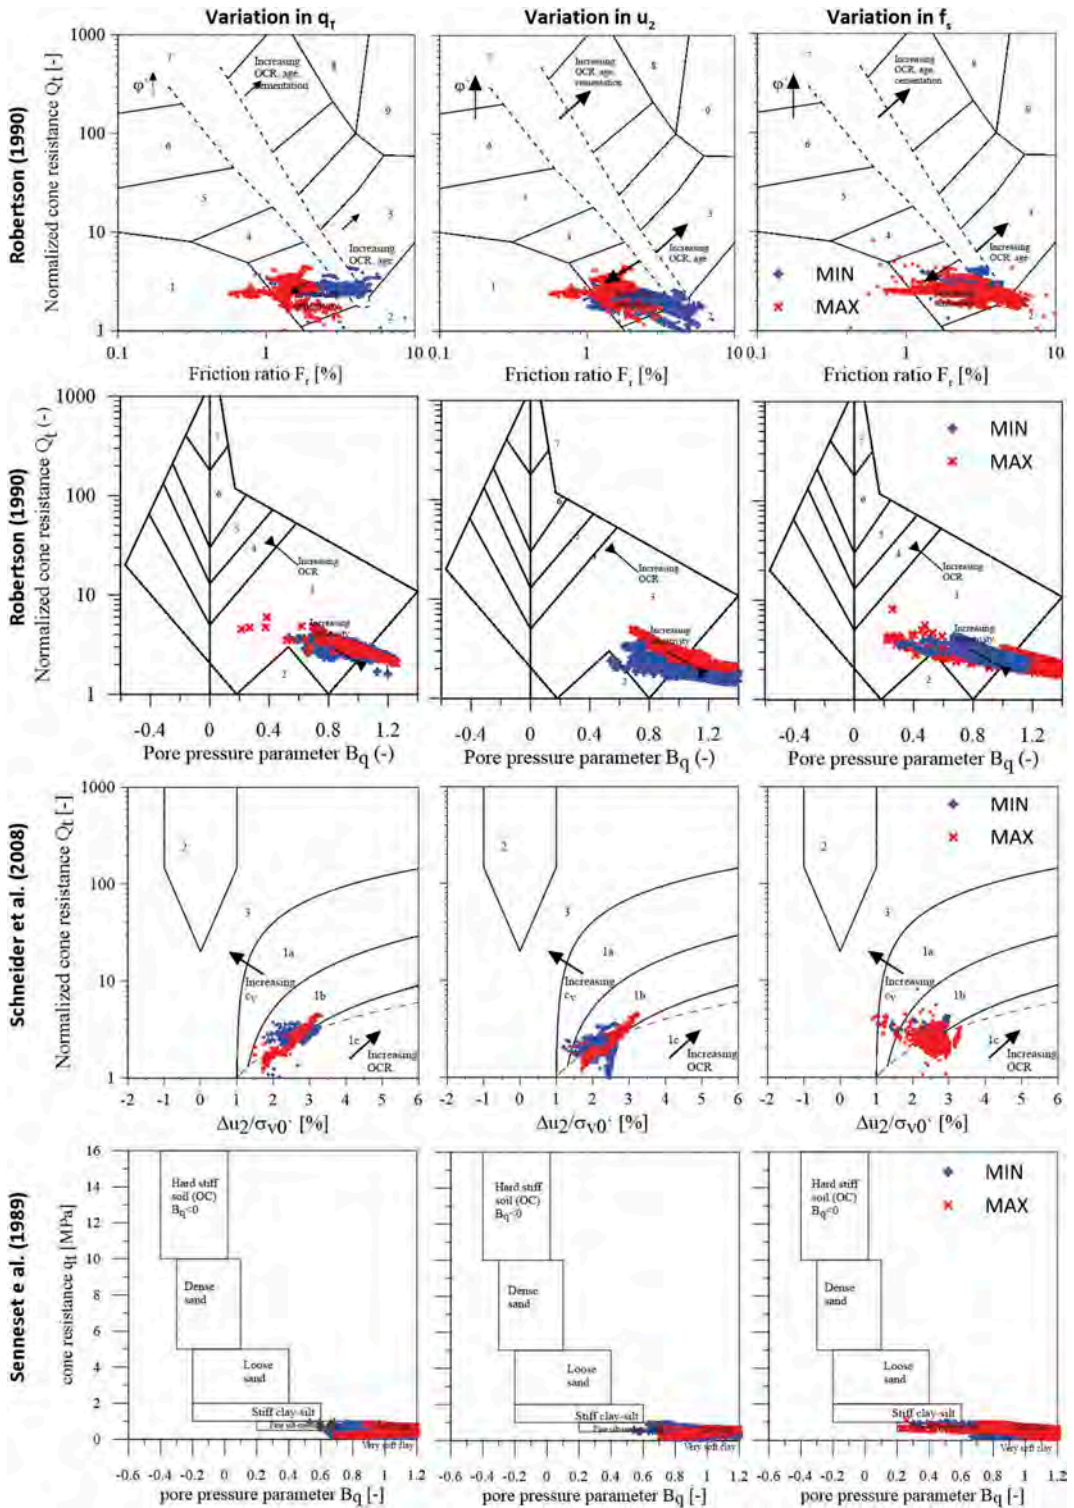
Therefore, this study has investigated the impact of using CPTU data from different cone types or manufacturers and its influence on the interpretation


Figure 2. Two CPTU data sets from Onsøy plotted in the different classification charts for each of the CPTU parameters showing extreme values (min and max).
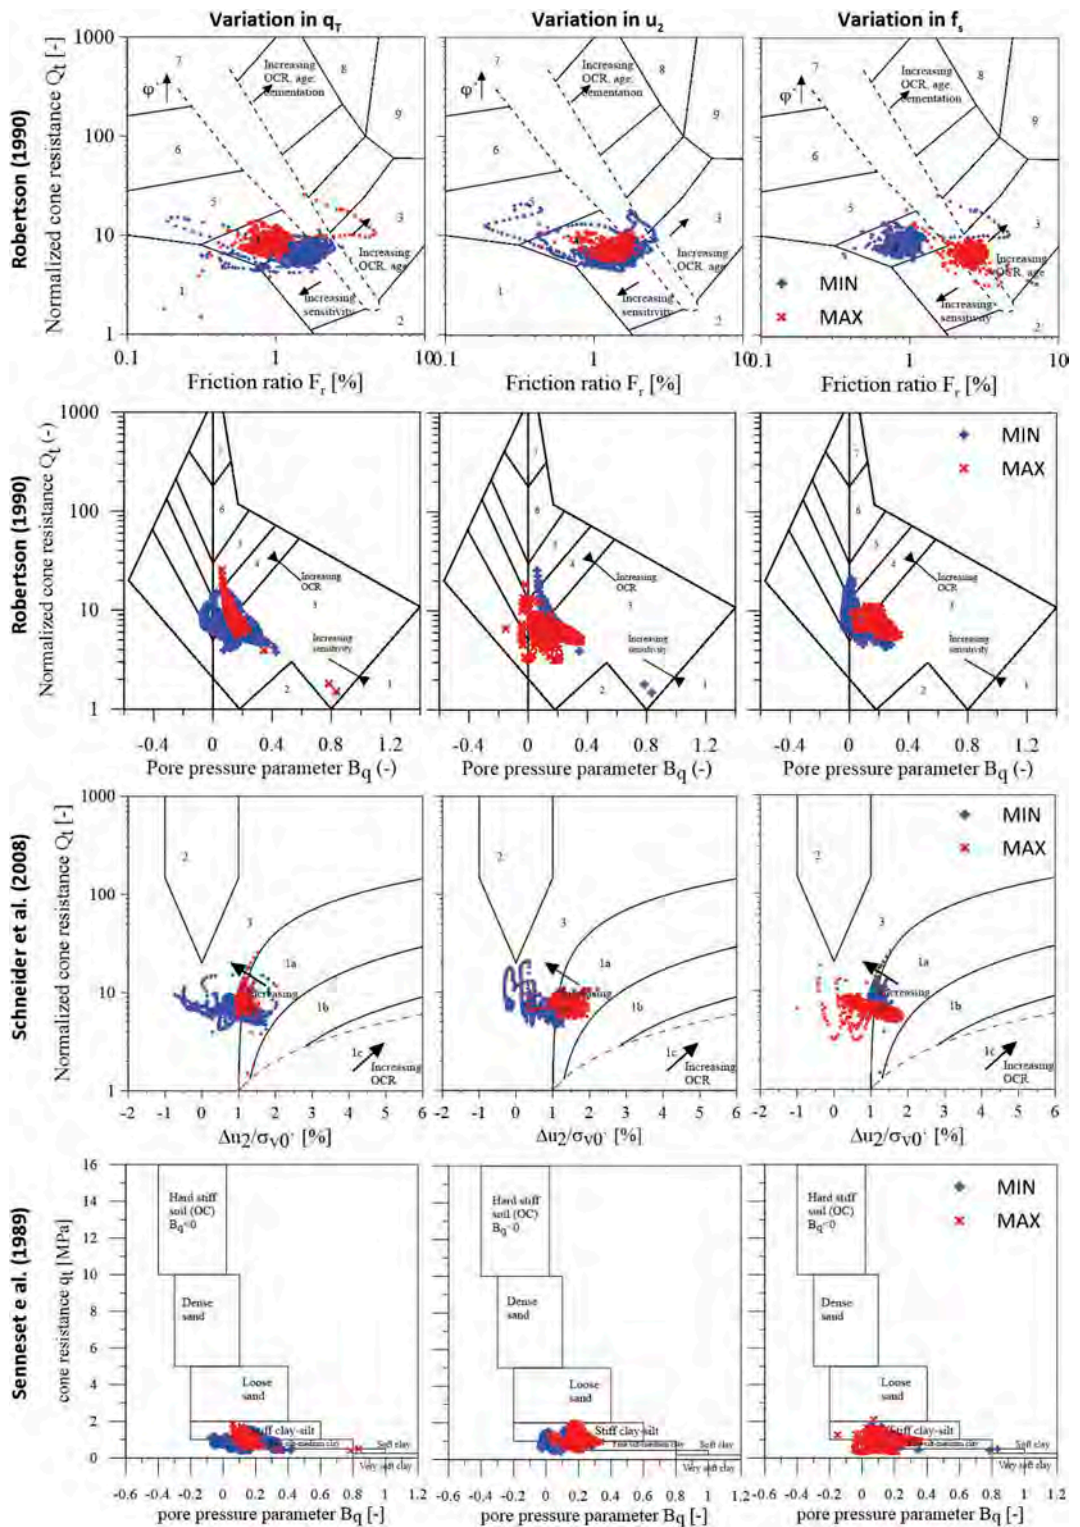

Figure 3. Two CPTU data sets from Halden plotted in the different classification charts for each of the CPTU parameters showing extreme values (min and max).
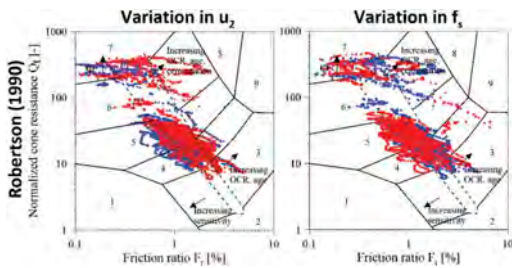

Figure 4. Two CPTU data sets from Øysand plotted in two classification charts for two CPTU parameters showing extreme values (min-blue and max-red).

of soil behavior. The most common soil classification charts have been used in four different soil types.

In general, soil behavior charts using pore pressure measurement and/or derived parameters involving u_2 seem to show less variability in soil classification between the different charts and all soil types. A similar trend is also observed for the cone resistance. In other words, the variation of u_2 and q_t between data sets for a defined soil type do not seem to give a different soil classification in the charts studied here.

The previous observation does not apply when using charts based on sleeve friction measurements. This was highlighted for the Halden silt when the classification chart involved a parameter derived from f_s. It seems that the variation in f_s for Tiller-Flotten clay and Onsøy clay does not have such a strong impact in the classification of the material using the different charts. This seems to also apply for Øysand sand, however, the observations for this site could be influenced by the natural variability of the deposit and therefore it is difficult to conclude.

Finally, due to the large uncertainties with the f_s readings, once should be careful using this parameter, and F_r, when interpretating soil parameters for design. Since the measured u_2 appear to frequently be the most reliable parameters it should be used in addition to q_t for deriving soil parameters.

Evaluation of shear wave velocity profiles in alluvial and deltaic soils using a CPT database

J. Paredes & F. Illingworth
Subterra, Ecuador

ABSTRACT: A seismic piezocone SCPTu database from Guayaquil (EC), consisting of Holocene alluvial and estuarine deltaic soil deposits, is evaluated in this document through V_s mapping when comparing more than 600 CPTu profiles and 45 seismic downhole testing locations. Shear wave velocity downhole measurements were used to adjust CPT-based V_s estimates and compared with cone resistance values. A suitable fit is observed between Robertson (2009a) calculation and downhole measurements, but it tends to over-estimate by 20-30% in soft clayey soils. An age correction factor as a function of normalized s_u/σ'_v ratio has been determined for clayey soils while a V_s-q_t correlation is provided for clays and all soils. A V_{s30} map has been developed based on proposed shear-wave velocity calibration.

1 INTRODUCTION

The alluvial plain and estuarine deltaic deposit of Guayaquil, located on the Ecuadorian coast, correspond geologically to the Holocene age. The stratigraphy usually includes layers of soft to firm clayey soils interbedded with loose sands susceptible to liquefaction in the top 30 meters. It is common to find organic soil, peat and sensitive clay in the estuarine deltaic area. Neighboring the city, stands the Chongón-Colonche Mountain Range that favors the existence of colluvial soils in the north and west area, so there are also soil profiles with high impedance contrast.

In most of these special cases of geotechnical behavior, local standards recommend site-specific response analysis (SRA), where measurement of shear-wave velocity (V_s) profiles results relevant. In addition, V_{s30} criterion is used for site seismic classification, thus V_s profile constitutes an important input for most Guayaquil construction projects.

In 2014, Vera presented a detailed geotechnical characterization of the Guayaquil soils, studying their static and dynamic response. In that research, a geotechnical zoning map was implemented, in which estuarine deltaic geotechnical zones and alluvial zones were identified, according to the geological context and the geotechnical framework. The database used in that study, includes mainly geotechnical information from boreholes, laboratory tests, geophysics estimates and CPT measurements in at least 14 sites locations. The applied methodology was plausible, because until recent, the common practice in Guayaquil for geotechnical research consisted mainly of boreholes, and for measuring V_s, the usual

practice was to execute geophysical exploration (e.g., multichannel analysis of surface wave and microtremors array measurement). However, SCPTu has also been performed in the last few years, thus, it is convenient to analyze an updated database that includes these CPTs and downhole measurements.

Therefore, this paper synthesizes an existing Guayaquil metro area soundings database with emphasis on CPT and downhole tests, carried out in an effective area of 450 km^2. By comparing existing CPT-based V_s estimates with downhole measurements or correlating cone tip resistance with shear-wave velocity, it is possible to develop equations that allow estimating V_s values more accurately than with conventional estimations, while capturing local behavior of Guayaquil alluvial and estuarine deltaic soil deposits. This analysis is appropriate because in geotechnical research of unconventional soils, it is always advisable to calibrate the geotechnical parameters estimated from the CPT, with measurements obtained in other in situ and laboratory tests (Mayne, 2007b; Robertson, 2012).

Therefore, this paper proposes analyze: 1) a correlation between downhole V_s measured values and those estimated according to Robertson (2009a), as a function of normalized undrained shear strength (s_u ratio), 2) a V_s - q_t correlation for clays and 3) a simplified geotechnical zoning of Guayaquil and the surrounding area through V_{s30} using V_s calibrated values.

This research goes in the same line of the theoretical framework proposed by Andrus et al. (2007), where an age correction factor was encountered. Besides, follows the sense of previous investigations, in which correlations have proposed between CPT measurements and Vs in different types of soils

(Robertson & Campanella, 1983; Baldi et al., 1989; Mayne & Rix, 1995; Hegazy & Mayne, 1995; Robertson, 2009a).

With the obtained results, it will be possible to have a more accurate and cost-efficient tool for seismic classification and site response analysis, than traditional geophysical methods.

2 DATABASE CHARACTERISTICS

All CPTu soundings conducted by Subterra between 2012 and 2020 were registered into an ArcGIS map. For each test, the following characteristics were noted: coordinates, year, total depth, rigid stratum depth, among others. Then, soundings from several geotechnical companies were compiled and a geotechnical exploration campaign was implemented based exclusively on CPTu tests distributed in different sectors of Guayaquil, especially towards the northeast and south of the city, where information available was scarce at the moment.

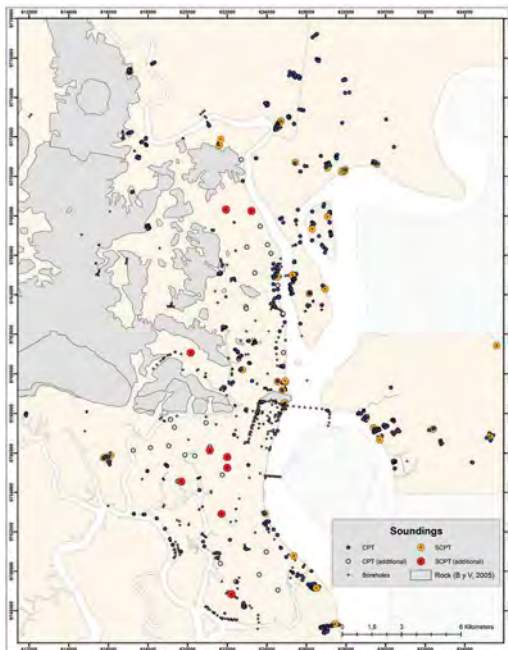
The total database consisted of 1432 soundings which includes 615 (42.9%) CPTs and 817 (57.1%) boreholes. From the 615 CPTs, 38 were exclusively carried out for this study. Downhole V_s profiles have been measured in 45 CPTs (SCPTu) at 36 different sites, as illustrated in Figure 1. Regarding timeline, 77% of the soundings were carried out after year 2010, while 91% after year 2000. Explored depths range between 2.3 m (shallow rock) and 145.2 m (avg. =


Figure 1. Guayaquil database sounding locations. Rock outcrop (Benítez & Vera, 2006).

27.7 m and σ = 12.0 m). In addition, 63% of soundings have a depth greater than 24 m, while 83% have a depth greater than 16.5 m.

Geotechnical zoning has been evaluated considering several geotechnical parameters from such database (e.g., average I_c and undrained shear strength every 5 meters, liquefaction potential), in order to have a complete and true understanding of Guayaquil soils. The work of Paredes (2020) can be reviewed for a thorough analysis of Guayaquil geotechnical zoning.

Considering only the 615 CPTs, average total depth is 23.5 m, with a standard deviation of 8.2 m (95% of CPTs underwent refusal conditions). The rigid stratum has been detected at an average depth of 22 m.

3 SHEAR-WAVE VELOCITY EVALUATION

In situ testing was executed with a standard 10 cm^2 cone, compression type, and 150 cm^2 sleeve friction. The pore pressure filter (u_2 position) is made out of bronze, and saturated with silicone oil. The piezocone is pushed at 2 cm/s with a 15-ton Pagani TG-63 equipment recording measurements every cm. A seismic module with two triaxial series of geophones is adapted behind the cone for recording shear-wave time arrival every meter.

An initial database filter of shear-wave measurements was applied to discard signals with poor amplitude or profiles located in unfavorable testing conditions like partially flooded ground surface, where contact area between seismic source and ground surface deemed inappropriate for obtaining a clear V_s profile. Thus, 733 downhole seismic readings between 2 and 25 m deep were compiled for this study. Shear-wave velocity values ranged between 50 and 390 m/s (avg. 120 m/s).

3.1 Calibration factor

Seismic CPT has been performed in Guayaquil and the surrounding area since 2014 and it was notable throughout the years that Robertson (2009a) V_s estimate, which is based on vast experience of normalized SBTn chart considering uncemented Holoceneand Pleistocene-age soils, tends to over-estimate shearwave velocity by 20-30% in soft clayey soils, both in estuarine and alluvial zones. However, a good overall trend in the soil profile was always observed if a correction factor was applied to the estimate. As an example, Figure 2a to Figure 2c illustrate several V_s downhole profiles (red dots) and corresponding CPT-based V_s.

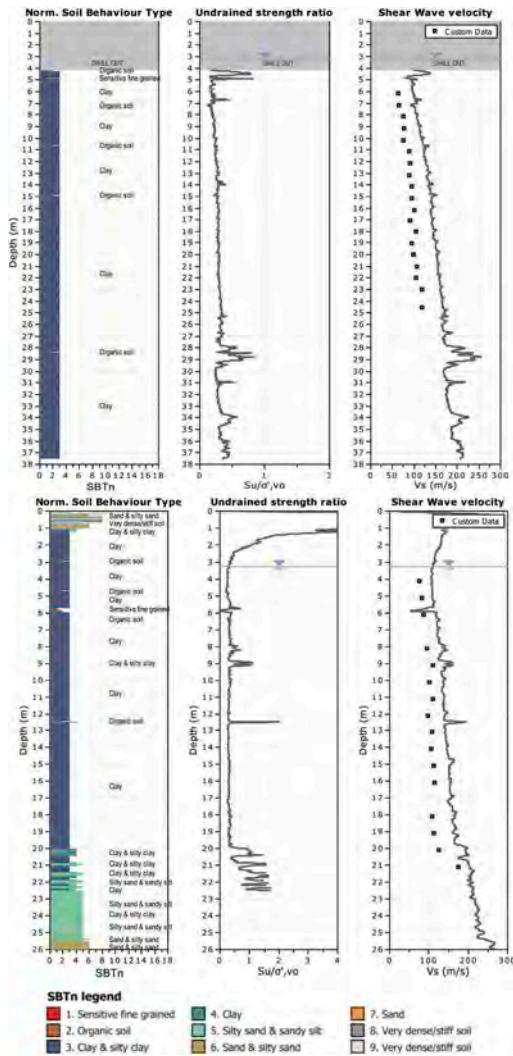
There appears to be some scattering when analyzing CPT-V_s pairs, primarily due to the difference between depth interval measurements where readings are taken (e.g., 1 cm for CPT and 1 m for V_s). Thus, data has been filtered based on standard deviation of CPT index I_c (σ_{Ic}), limiting random variability. Also, shallow downhole readings may lack some quality at times due to short time arrivals and thus,


Figure 2a. SBTn (Robertson), s_{u-rat}, V_s downhole and estimated profiles, from two Guayaquil soundings located in estuarine zone.

greater percentage errors. Reason why only data pairs at depths greater than 5 m have been considered in every filtered trend analysis presented in this paper.

A calibration coefficient was calculated for each one-meter avg. CPT-based V_s and downhole V_s measurement. Given a strong relation was initially observed with estimated normalized shear strength ratio ($s_{u-rat} = s_u/\sigma'_v$), measurements were filtered by $\sigma_{Ic} < 0.10$, $I_c > 2.6$ and $s_{u-rat} < 2$, the latter two corresponding to clayey soils. Undrained shear strength was calculated from F_r-based N_{kt} factor (Robertson 2012).

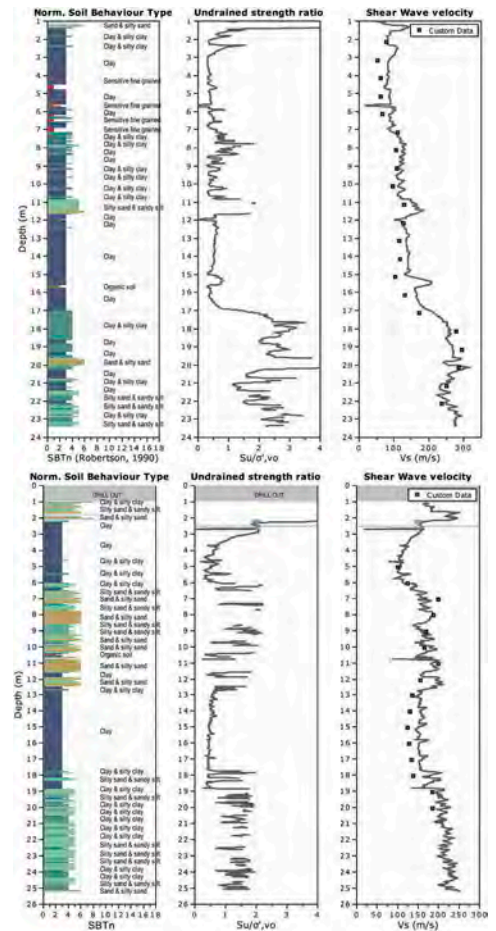
Figure 3 shows a simplified regression analysis performed on 324 pairs to calculate correction factor (μ_{vs}) in clays and transitional soils given by:


Figure 2b. SBTn (Robertson), s_{u-rat} and V_s profiles, in alluvial zone of Samborondón and Guayaquil.
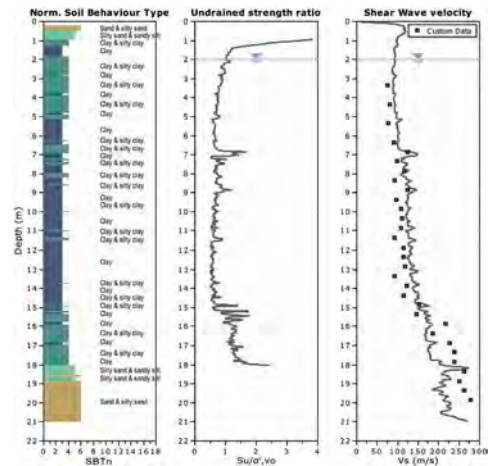

Figure 2c. SBTn (Robertson), s_{u-rat}, V_s downhole and estimated profile, from Durán sounding.

$$\mu_{vs} = \frac{V_{s-measured}}{V_{s-Robertson}} = 0.38\left(s_u/\sigma_v'\right) + 0.60 \qquad (1)$$

For sandy soils with $I_c < 2.6$, μ_{vs} ranged between 0.8 and 1.2, with an average value of 0.98. More research is necessary in order to evaluate an accurate calibration factor in these soils. Thus, shown database correction from Figure 3 does not apply for sandy soils.

Robertson (2009a) database included Holocene and Pleistocene soils while 25% higher estimates have been reported for Pleistocene soils. Andrus et al., (2007) even proposed a correction factor as function of deposit age. Therefore, it would be reasonable for Guayaquil soils deposits, where shallow layers date mainly from the Holocene, that estimated values are slightly higher than those measured. However, for deeper soil layers with a higher degree of consolidation (older soils with signs of cementation), Robertson's estimate fits better, and in some cases an underestimation is also observed. This apparent underestimation could be related to cementation that tends to increase V_s (Schneider, et al 2004), while resistance to penetration captures to a lesser extent the effects of age and cementation (Robertson, 2012). The correction factor applies best for a ratio s_u/σ_v' between 0.2 and 1.5, yielding a coefficient that varies between 0.6 and 1.18.
deposits are generally homogeneous compared to sandy layers which are rather intercalated throughout the profile, being apparent a better trend when filtering for $I_c > 2.6$. Considering both datasets, a general V_s-q_t trend is proposed in the following expression:

$$V_s = a(q_t)^b \qquad (2)$$

where, cone resistance q_t is in MPa, V_s in m/s and regression variables are

$$\text{clay}: a = 117.67, b = 0.49 \ (n = 388, \ R^2 = 0.85)$$

$$\text{alldata}: a = 112.82, b = 0.35 \ (n = 733, \ R^2 = 0.75)$$

A similar equation has been presented by Mayne and Rix (1995) from 31 natural clay sites. Clays varied from intact to fissured materials with wide ranges of plasticity, sensitivity and OCR. Variables provided in this paper, corresponding to Equation (2) are $a = 133.06$, $b = 0.63$.

The filtered proposed V_s - q_t correlation shows an excellent correspondence in clays, especially for $q_t < 2$ MPa. When including all data, at $q_t > 2$ MPa, V_s-q_t trend is much lower than that filtered.

Figure 3. V_s calibration factor as a function of normalized $s_u/\sigma'_v < 2$ ($I_c > 2.6$, $\sigma_{Ic} < 0.10$).

Figure 4. Correlation between shear-wave velocity and cone tip resistance in Guayaquil.

3.2 V_s-q_t regression

Two statistical regression analyzes were performed to further evaluate the existing database: one with 733 CPT-V_s pairs (all data) including different geomaterials, and another with 388 resulting from filtering by $I_c > 2.6$ and $q_t < 8$ MPa with low heterogeneity average intervals ($\sigma_{Ic} < 0.15$), at depths greater than 5 m. The observed trend between V_s and q_t for Guayaquil is presented in Figure 4.

As expected, a higher R^2 value is obtained from filtered data by avoiding values with considerable lenses across one-meter intervals. Guayaquil clay

3.3 V_{s30} mapping

On an effort to consolidate previous findings, a V_{s30} map has been developed for Guayaquil based on 615 CPTs. It is plausible to apply Equation (2) for clay in soft homogeneous clayey soils with $I_c > 2.4$ and $q_t < 2$ MPa, while correction factor from Equation (1), limited by 1.18, for the rest of clayey soils with $I_c > 2.4$.

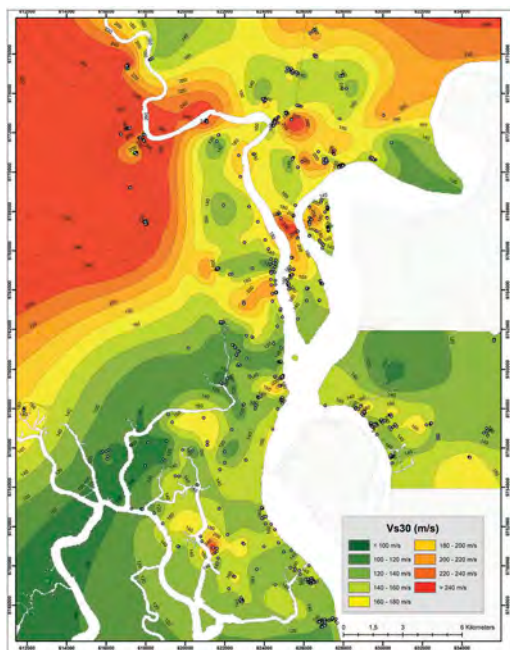
With regards to V_s values for sandy material, since the database is relatively limited, it would seem appropriate to, conservatively, correct Robertson (2009a) equation by a coefficient μ_{vs} of 0.85 for

contractive shallow sands and 0.95 for dilating sands, although the latter could certainly be 20% higher. Yet a correction value of 0.90 for sandy material $I_c < 2.4$ was employed. Figure 5 shows Guayaquil V_{s30} map by applying iterative finite difference interpolation methodology in ArcGIS.

Given that 25% and 66% of CPTs underwent refusal conditions at more than 30 and 20 meters deep, respectively, V_s estimate was extrapolated from those estimated in deepest layers, provided that refusal conditions were effectively present. So, V_{s30} values are rather conservative in these cases.

4 CONCLUSIONS

The presence of geotechnical profiles with special characteristics is very common in the alluvial plain and estuarine deltaic deposit of Guayaquil. For a better understanding of the variation of geotechnical parameters, a database has been compiled with geotechnical information obtained in recent years, consisting of 1432 soundings, with an average depth of 27.7 m. This database has 615 CPTs, from which 45 V_s downhole profile have been obtained while the relationship with CPT has been analyzed, in order to consolidate results through a map of V_{s30}, and for its extended use in the construction projects of the city.

A V_s correction factor for calibrating Robertson (2009a) estimate has been obtained through a direct proportionality with s_u ratio in soils with index I_c (SBTn) > 2.4. The proposed correction ranges between 0.6 and 1.18, for s_u ratio < 1.5. Furthermore, a V_s-q_t


correlation is proposed for Guayaquil soft homogeneous clays with $q_t < 2$ MPa.

In Guayaquil, local standards require SRA in most projects where soil profiles with special features are encountered. One of the most important input parameters in this type of analysis is V_s profile. Traditionally, geophysics is used to determine this seismic parameter. However, the accumulated experience and proposed equations will allow using a more efficient and accurate methodology when downhole testing or geophysical methods are not available.

ABSTRACT: In 2020, the Dutch government published 1 500 000 synthetic CPT profiles for use in development of the Hollandse Kust (west) Wind Farm Zone, offshore Netherlands. The scale of this approach was novel at that time and possibly first-ever. The synthetic CPT profiles were derived from a training data set of 122 actual CPTs and ultra-high-resolution (UHR) seismic reflection traces, using machine learning by a convolutional neural network. The synthetic CPT profiles were limited to positions along the 162 UHR survey track lines (2D) and were limited to cone resistance to a depth of 50 m below seafloor. The UHR track lines were spaced at about 400 m. This paper explores upscaling the synthetic CPT approach to voxel (3D) models and adding (S)CPT-based parameters such as shear modulus at small strain G_{max}. Future added-value is expected from post-2020 improvements seen in seismic reflection data resolution, attribute extraction and neural network architecture.

1 INTRODUCTION

Reducing ground risk is important for the development of an offshore wind farm. This requires understanding of the geological and geotechnical conditions to depths in the order of 30 m to 100 m below seafloor (BSF), depending of type of support structure for the wind turbines.

The understanding of ground risk is typically expressed by a ground model or multiple ground models (ISO 2021). These models typically rely on integrated interpretation of geological information, geophysical (UHR and UUHR multichannel seismic reflection) data and geotechnical data (particularly cone penetration tests, CPTs).

Since the 1990's, there has been increasing focus on deriving geotechnical properties directly from geophysical data using methodologies developed in the oil and gas industry (e.g. Nauroy et al. 1998). More recently, trials were made with synthetic CPTs and geotechnical properties generated by interpolating CPT data between investigated locations (Forsberg et al., 2017) and using statistical methods and multi-attribute regression through an artificial neural network (Sauvin et al. 2019). The general approach is covered by ISO 19901-10 Marine Geophysical Investigations (ISO 2021).

This paper describes the status quo for 2020 and explores future opportunities for upscaling the synthetic CPT approach. The status quo is presented by an example in the public domain (www.offshore wind.nl): the Hollandse Kust (west) Wind Farm Zone, HKW WFZ (Figure 1), offshore Netherlands (Fugro 2020a and 2020b). HKW WFZ data acquisition, data analysis and advice were largely completed in 2019 and 2020. The 1 500 000 synthetic CPT profiles were generated at no schedule impact. DNV GL (2020) sees this cutting edge development as *'a huge step forward in terms of project area overview with respect to geotechnical site conditions and also as a valuable tool to improve and understand the correlation between future geological, geophysical and geotechnical investigations.'*

2 HOLLANDSE KUST (WEST) WIND FARM ZONE

The site for the HKW WFZ is located approximately 53 km from the Dutch coast, covering an area of roughly 176 km2 in water depths ranging from 18 m to 36 m LAT.

Ground model input mainly included:
– Geological information;
– Geophysical data: multibeam echosounder, side scan sonar, magnetometer, sub-bottom profiler and 2D-UHR single channel and multi-channel

Figure 1. Location of the future Hollandse Kust (west) Wind Farm Zone.

seismic reflection data. The data were acquired according to a draft version of ISO (2021);

– Geotechnical data acquired from 57 boreholes with sampling and cone penetration testing (CPT) to a maximum depth of 90 m below seafloor (BSF), 122 seafloor CPTs to a maximum depth of 56 m BSF, 30 seafloor seismic cone penetration test to maximum depth of 56 m BSF, and laboratory testing. The data were acquired according to ISO (2014).

The acquired geophysical and geotechnical data were integrated into a traditional quasi-3D ground model, with seismic reflections tied to geotechnical boundaries derived from seafloor CPT and borehole information (Figure 2). The ground model comprised eight geological soil units, each having a distinct seismic character and spatial distribution.

Figure 2 provides cross sections that illustrate how the traditional ground model was enhanced by 1 500 000 synthetic CPT (cone resistance) profiles and associated error predictions to 50 m below seafloor (Carpentier et al. 2021). The presented cross section has a length of 11 500 m with 4 actual CPTs and about 9000 synthetic CPTs to a depth of 50 m.

The HKW WFZ synthetic CPT profiles were derived from a training data set of 122 actual CPTs and ultra-high-resolution seismic reflection traces, using machine learning by a convolutional neural network. The synthetic CPT profiles were limited to positions along the 162 UHR survey track lines (2D). The UHR track lines were spaced at about 400 m.

Figure 3 shows example checks on predictions. In general, the predicted and measured net cone resistance values showed reasonably good agreement, particularly in the upper 20 m BSF. Below 20 m, prediction was more trend-type. In addition, a trend-type prediction also applies to transitional and strongly layered (<1 metre scale) soil. It can be concluded that the prediction quality for the synthetic CPTs is such that added value can be derived to enhance the general ground model. The HKW WFZ prediction quality is inadequate for geotechnical design.

Reasons for the observed trend-type predictions include data conditioning, resolution of 2D-UHR seismic reflection data and limitations in refinement of the interpreted geological units. Data conditioning was applied by down sampling the CPT data to align

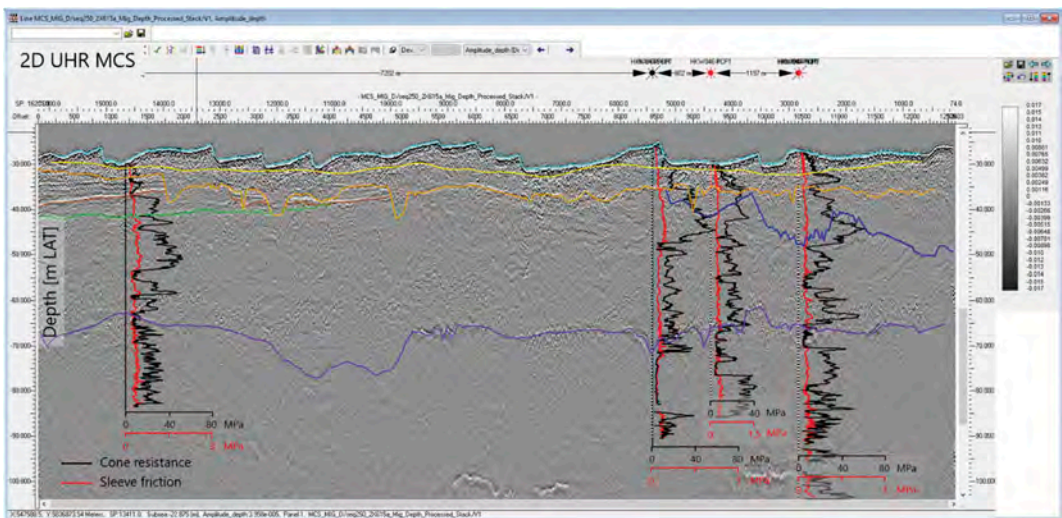

Figure 2a. Example of integrated interpretation of 2D-UHR multi-channel seismic line, aligning geophysical horizon interpretation to identified geotechnical boundaries from seafloor CPT and borehole data.
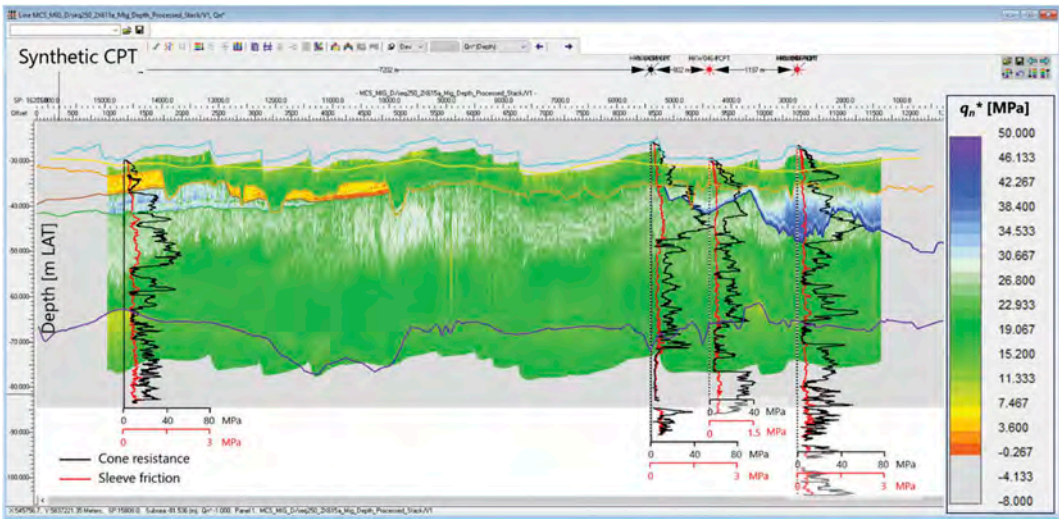

Figure 2b. Predictions of cone resistance (qn*) from 2D-UHR seismics (colors ranging from orange to purple) plotted together with measured cone resistance (black traces) and sleeve friction (red traces). See Figure 2a for comparison.

with vertical resolution of the 2D-UHR seismic data (i.e. sample rate of 0.1 m for prediction input versus 0.02 m as measured). Down sampling reduces net cone resistance effects of soil layering. The resolution of the 2D-UHR seismic data decreases with depth. This also affects the ability to identify additional geological units. This effect becomes more pronounced below approximately 20 m BSF.

As expected, training of the convolutional neural network showed decreasing prediction accuracy with increasing lateral distance between the seafloor CPT location and the nearest seismic trace along the 2D-UHR line. This is particularly significant where the correlation distance for spatial soil variability is less than the distance between the seafloor CPT location seismic trace selected for training.

Figures 3 and 4 illustrate prediction quality by means of a quality indicator per geological unit. It can be seen that the lower limits of the quality indicator can provide statistical values for q_n^* that fall outside credible ranges for these specific soils.

3 UPSCALING

3.1 *Opportunities for future added value*

The following opportunities for upscaling are discussed:

– Enhanced geophysical interpretation
– Improved data pairing for training
– Impact of technology developments
– Predictions for multiple parameters
– Voxel model by geo-statistics
– Voxel model by 3D geophysics

Figure 3. Comparison of actual net cone resistance (black line) versus synthetic net cone resistance (red line). The red halo represents the interval in which predictions are likely to fall (5th and 95th percentiles of the error misfit). Other colour infills indicate geological units.
Figure 4. Statistical values for q_n^* that fall outside credible ranges (green box).

The opportunities can be considered individually. However, combinations are expected to lead to a step change in added value.

The following sections discusses potential opportunities for a time window of 2020 to 2025.

3.2 Enhanced geophysical interpretation

Figure 2b Indicates that the synthetic CPTs can allow for further refinement of the geological model. This, in turn, helps steering future, turbine-specific geotechnical data acquisition, increasing safety and cost-efficiency.

For example, light green colours can be seen between approximately 40 m and 50 m LAT. These strength insights (i.e. trends in net cone resistance) may justify refining the geological model at this depth, by assigning a new geological soil unit to encompass these geotechnical conditions. It should be noted that this potential additional geological soil unit could not be identified from 'regular' seismic data (e.g. seismic amplitudes) alone. The example also indicates that synthetic CPT results (1) can give further insight into potential soil heterogeneity, (2) may aid in identifying areas of higher geotechnical uncertainty and (3) can identify where geotechnical conditions deviate from regional trends.

3.3 Improved data pairing for training

Quality of input data is important for success of machine learning.

Attention should be given to accuracy of spatial positions of paired data derived for actual CPT locations and seismic reflection data points: the closer the better. Particularly, logging of spatial trajectories of deep CPTs should be considered, compared to conventional assumptions for a vertical CPT. Seismic reflection survey should consider specific positioning of the source(s) and specific positioning of multiple points along the streamer(s). This is particularly important for situations where correlation distance for soil spatial variability is limited.

Mitigation options for pairing of spatially distant data can include point-specific matching checks and adjustments, using marker points in the profiles.

3.4 Impact of technology developments

For marine geophysics, significant technology developments are taking place, with high potential for added value in de-risking for ground conditions. For geophysical data acquisition, these include improvements in acoustic sources and streamer control. For processing methodology, notable improvements include de-ghosting algorithms, multiple removal algorithms and velocity models). These improvements will result in opportunities for very high resolution data and high quality seismic attributes.

Fast developments are taking place in neural network architecture. Technology developments for marine soil investigation (CPTs, other in situ testing and laboratory testing) are expected to be 'incremental', i.e. at a slow pace compared to marine geophysics and neural network architecture.

3.5 Predictions for multiple parameters

The HKW WFZ choice for synthetic profiles for cone resistance is obvious: input cone resistance data are accurate (Peuchen & Terwindt 2015) and typically show good correlation with geological units and other geotechnical parameters. Shear modulus at small strain G_{max} is another candidate for synthetic predictions. Comments for G_{max} are as follows:

– G_{max} is an important parameter for geotechnical design of monopiles used for support of offshore wind turbines;
– G_{max} is a low-strain soil parameter. Seismic reflection data are also low-strain and good predictive capability would seem obvious;
– Good predictive capability may be impeded by higher uncertainties (compared to CPT cone resistance) for actual G_{max} profiles (Parasie et al. 2022) required for training a neural network. Actual G_{max} values are typically derived from seismic cone penetration tests. These tests rely on time and distance measurements. Data processing requires estimates of input soil density. Premises include theories on acoustic wave propagation and assumptions about heterogenous soil behaving as an isotropic elastic medium.

3.6 Voxel model by geo-statistics

Commonly (2022), visualisation of a ground model is by means of 2D cross sections and 2D charts, i.e. in pixels. In some cases, 3D visualisation (e.g. Figure 5) is implemented, allowing interpretation in terms of voxels. Voxel data are typically generated by geo-statistics on a soil-unit basis. Synthetic CPTs can enhance this approach.

An important consideration is the volume of data. Can the information be made available within tight schedules required for energy transition? Can it be easily assessed for decision making?

3.7 Voxel model by 3D geophysics

ISO 19901-10 Marine Geophysical Investigations (ISO, 2021) covers acquisition of 3D UHR seismic reflection data. Currently (2022), acquisition of these data in the foundation zone (upper 100 m BSF) is performed only for occasional offshore wind sites, with some indications of growth in applications of this technology. The availability of 3D UHR seismic reflection data in combination with generation of synthetic geotechnical parameters has the potential for a step-change in voxel ground models and associated added value to offshore developments.

Automated CPT interpretation with a Convolutional Neural Network

M. Pippi, R. Vink & J. Haasnoot
CEMS Crux Engineering MicroServices BV, Amsterdam, The Netherlands

S. Bersan
CRUX Engineering, Amsterdam, The Netherlands

ABSTRACT: Cone Penetration Tests are widely used in the Netherlands, due to their ease of execution in the Dutch delta deposits and their relatively low cost. As the amount of performed CPTs increases, an automated soil interpretation becomes more and more relevant. Attempts to automate soil classification have been done in the past, but the empirical formulas commonly used do not always provide a satisfactory interpretation for engineering purposes. Besides that the soil type is often not interpreted correctly, there is also the problem that the classification is provided for each measurement (every 2 centimeters) and no strategy is provided to aggregate those tiny layers. This paper shows how a data driven approach can yield better results than the traditional empirical methods. A machine learning model is presented which is based on a Convolutional Neural Network. The Neural Network has been trained on 1800 pairs of CPTs and boreholes that met the condition of being less than 6 meters apart. An algorithm based on the theory of signals is applied to the classification given by the model to group measurements into soil layers. The paper explains the theory behind the model, shows a comparison with the soil classification given by the Robertson correlation and shows how the model can be used in the geotechnical practice.

1 THE DATA

1.1 *Open source data*

In the past decades the Netherlands have been able to perform and store a large amount of soil investigation. Part of this data have been made available to everyone by the no-profit organization TNO through the website DINOloket (TNO, 2021).

Since 2020, the organization BRO (Basis Registratie Ondergrond) is responsible for the management of the National Data Repository. Every type of soil investigation that is performed for a project financed by the public administration must be registered and stored in the national database.

The reasons behind this approach is given by the fact that making soil investigation available to everyone will improve the estimation of the subsurface and therefore reduce the risks related to incorrect modelling of the soil. Figure 1 give an overview of the CPTs that are available on DINOloket (these are indicated as brown dots).

1.2 *Data format*

Before the year 2000 the output of the cone penetration test was available in a digital form according to a customer specific format. This seemed to be an ideal situation, as the customers would get the output in the format they asked for. However, the result was that there was still a number of formats, which were hard to be interchanged thus being a hindering for a sustainable storage of these data.

The variation in formats lead to waste of time and the related costs are estimated to amount to at least NLG 600000 or Euro ≈ 270000 a year (price level 1999).

This situation induced the development of a standard format: the GEF (Geotechnical Exchange Format). The characteristic and requirements of the format are specified in the document "Geotechnical Exchange Format for CPT-data" (CUR, 2006).

1.3 *Parsing of the data*

In order to be able to read and use the data in a program, it has first to be parsed. For this task an open source Python library, *pygef,* has been developed. The library is able to read gef formats of CPTs and boreholes and store their content into a *DataFrame* object. The library provides also a traditional way to classify a CPT: via the Robertson (Robertson, 2010) or Been & Jefferies (Been, K., & Jefferies, M. G. 1992) classification methods. The Roberson classification method provided by the Python library has been used for the validation metrics of the model presented in this paper.

Figure 1. Map of CPTs available in Dinoloket (TNO, 2021).

2   THE CEMS MODEL

2.1   *Data-driven iteration*

A data-driven approach, in a country where so much open source data is available, seems to be the best way to proceed. In order to train the model roughly 49000 CPTs and 40000 boreholes were checked, from which 1800 pairs met the condition of being less than 6 meters apart. These have been used as labeled data for the first model training. The model is retrained periodically whenever new data are available that meet the condition of being not more than 6 metres apart.

2.2   *Decision factors*

Machine learning is often beneficial with high dimensional data. In this case, the amount of data dimensions is relatively low. When training powerful ML models, like Neural Networks (Multi Layer Perceptron architecture) or Gradient Boosting Trees, on this data, we see comparable results with each other. The results are quite reasonable, but they do not reflect the decision factor of a geotechnical engineer.

An essential part of the decision making is based on the location where the CPT is taken. And when a CPT, for instance, is taken at sea, they can tell by the curve of the line that a certain layer consists of seashells.

If we want a model to be able to take the same decision factors into account as a human does, the model needs to be able to make decision based on the same information.

2.3   *Model architecture*

The model is based on a Neural Network architecture with convolutional layers that can apply feature extraction on the input signal (Sassi, A. et al., 2019). The model is enhanced with location-based embedding, in this way the model could learn its own location embedding and could learn the probabilities of soil type conditional on a certain location. Furthermore, most of the bore-hole data show that layers consist of multiple soil components in variable percentages. Therefore we should predict the total soil distribution per layer.

In Figure 2 an example of the result of the model is shown. The model predicts the soil distribution over the depth. Qualitatively the predictions of the model seem very reasonable and align with a geotechnical mapping.

Figure 2. Example result of the CPT interpretation model.

2.4   *Location embedding*

From the 1800 pairs, 48 location clusters were created by applying K-means algorithm on the location data.

In Figure 3 the locations of the clusters are indicated on the map of the Netherlands. The colors represent a similarity measure between the clusters based on the cosine similarity. Clusters close to each other on the color scale are likely to have similar soil distributions.

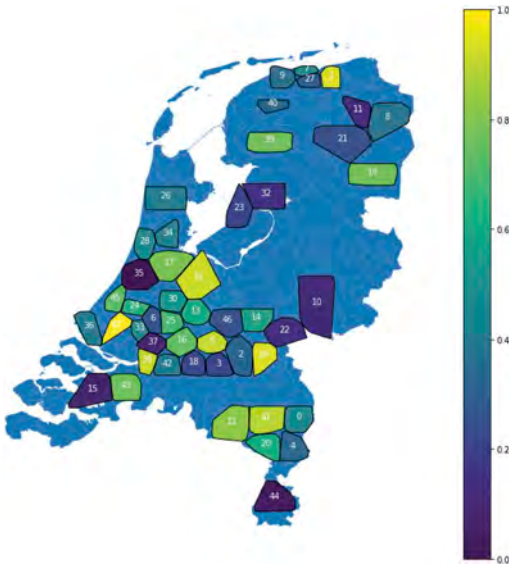
Besides comparing the clusters by similarity, we can also run inference for the embedding by nullifying the features. Intuitively this can be regarded as the soil classification you would expect if you only know the location and not considering the information in the CPT. Figure 4 shows the biases that can be applied per location.


Figure 3. Location clusters.

Figure 4. Biases per location.

3 VALIDATION METRICS

3.1 Training metrics

When training a machine learning model usually we have "ground truth labels" being binary True or False, i.e. $y \in (0,1)$. However, the soil labels are never 0 or 1 but they are distributions. Every layer contains different volumetric percentages of soil components, but the sum of all volumes adds up to 1.

For this reason the metrics used to train the model are the Kullback-Leibler divergence (Van Erven, T., & Harremos, P., 2014) and the Wasserstein distance (Hou, L et al., 2016).

3.2 Comparison with Robertson

Comparing the outputs of the model with Robertson requires some translation. Robertson does not predict a soil distribution, but assigns soil types, e.g. 'Silt mixtures: clayey silt & silty clay' and 'Sand mixtures: silty sand & sandy silt'. To be able to make a comparison these classification were transformed into a soil class {Gravel, Sand, Loam, Clay, Peat}.

3.3 A simple validation

A simple way of doing a validation is by looking at precision and recall scores (F1 score) by transforming the probability distributions to main soil classes. In Table 1 the F1 scores are shown, where 0 is a bad prediction and 1 would be a perfect prediction. The column "Support" indicates the number of soil layers with that type of soil as the main type.

Table 1. F1 scores.

Soil type	Support	Robertson	KL-divergence	Wasserstein
Gravel	3731	0.15	0.15	0.1
Sand	137998	0.86	0.83	0.85
Loam	0	0	0	0
Clay	91523	0.64	0.7	0.67
Peat	21398	0.37	0.57	0.74

This comparison is not accurate since a lot of information is lost if we reduce a distribution to a number by taking the mode. If we look at the loam soil type, we can observe that this validation does not consider its prediction. Loam is almost always a subtype in soil layers so it will never come out as the main soil, making it seem that no model can predict this class.

3.4 A better validation: Error distribution

Since we are talking about probabilities, the error distributions show the error margins. In the tables below the Mean Absolute Error (MAE) per soil type is reported. We consider the absolute errors on two subsets of the test set.

Table 2. Precision based absolute errors (lower is better).

Soil type	MAE Robertson	MAE KL-divergence	MAE Wasserstein
Gravel	0.77	0.29	0.22
Sand	0.23	0.31	0.22
Loam	0.93	0.05	0.06
Clay	0.35	0.29	0.3
Peat	0.56	0.28	0.37

Table 3. Recall based absolute errors.

Soil type	MAE Robertson	MAE KL-divergence	MAE Wasserstein
Gravel	0.18	0.24	0.17
Sand	0.22	0.29	0.2
Loam	0.14	0.04	0.05
Clay	0.44	0.34	0.35
Peat	0.3	0.23	0.22

A subset where the true distribution has non-zero probability for that class can intuitively be regarded as *recall*. A subset where the models assign a significant probability to that class $P(y) > 0.025$ can intuitively be regarded as *precision*.

4 THE GROUPING ALGORITHM

4.1 *The motivation*

The output of the model is a prediction given for each measurement of the CPT. Although this is probably the most accurate representation of the soil stratigraphy, it is impossible to use 1000+ layers in the traditional software, hence we need to group these tiny layers into macro layers. This is done using an algorithm that is based on considering the CPT measurement a signal.

4.2 *The theory*

The measured cone resistance and friction ratio are signals and as such we can assume that they follow a Gaussian distribution, as shown in Figure 6.
Figure 5. Gaussian signal.

The likelihood of this signal is determined by:

$$L(X_t, \mu, \sigma) = \prod_{t=1}^{n} P(x_t|\mu, \sigma)$$

If we consider the signal in Figure 6, the likelihood of two sub-signals coming from two Gaussians, separated by change point τ, is higher than

Figure 6. Two Gaussian signals with changepoint τ.

the likelihood of the whole signal coming from one Gaussian.

This observation can be turned into an optimization problem. We search for the minimal negative likelihood by adding new change points τ_i for every point

K in the signal. To prevent having change points at every data point, we introduce a penalty λ.

$$\min \sum_{i=1}^{k+1} [-L(x_{t-1:x_t})] + \lambda$$

4.3 *Final result*

Applying the grouping algorithm to the prediction of the model results in a manageable amount of soil layers. By changing the penalty λ we can choose to have more or less layers. A higher penalty will generate less layers, a lower value will generate more layers, as illustrated in Figure 7.

Figure 7. Influence of the penalty parameter on the discretization into soil layers.Fig (a): penalty=2; Fig (b): penalty=1.

5 USAGE OF THE CEMS MODEL

5.1 Web API

The model can be accessed with a HTTPS call via a web REST API, if using the language Python the library *requests* could be used to make the call. In this way the users can incorporate the prediction of the model in their own workflow. The documentation of the REST API can be found on the website (CEMS, 2022). Please note that authentication is needed when using the model, visit the CEMS website at https://cemsbv.nl/ to learn how to get access.

5.2 Examples

As the soil interpretation is often the first step of a geotechnical design, this building block can be used in many geotechnical applications. So far the CPT interpretation tool has been used in a number of applications including: pile design, levee assessment and improvement, prediction of vibrations induced by the installation of sheet piles.

In case of levees, the model is used to automatically generate longitudinal lithological profiles along the levee as the one shown in Figure 8. These projects often involve a lot of soil investigation which is otherwise difficult to visualize.

Figure 8. Example of geotechnical longitudinal profile.

Moreover, the automated soil classification can be combined with the geometry of the dike to build calculation files for stability calculations. In the example in Figure 9 the results of soil investigation on the crest and at the toe of the dike have been automatically combined with Lidar measurements of the ground surface and bathimetry data.

5.3 Conclusions

A CPT interpretation based on data proved to be better than empirical formulations. The gain in terms

Figure 9. Example of input for a levee stability calculation.

of time when using it in an automated process for geotechnical design is considerable.

The model has been trained only on Dutch soil data. Even though it would probably still give a reasonable prediction outside of the Netherlands, it cannot apply any biases for the location. Future development could include the expansion of the geographical limits of the model, by including CPTs and boreholes from other countries and the definition of location biases and clusters based on expert knowledge.

Watch out for the use of global correlations and "black box" interpretation of CPTU data

J.J.M. Powell
Geolabs Limited, Watford, UK

L. Dhimitri
In Situ Site Investigations Ltd, UK

ABSTRACT: Many people interpret soil properties from CPTU measurements based on correlations embedded in software packages without ever questioning the validity of those correlations. This could be termed the 'black box' approach! This paper aims to show how dangerous this can be but also the power of the CPTU in helping to show the variations in soil properties within profiles. Based on correlations properties can be both over and under-estimated, which can of course result in both unsafe design and over design. Too often one correlation must be used to derive a soil property required in another correlation, further compounding the potential for errors. A range of sites will be examined with a range of soils varying from very soft clays and silts to stiff clays, sands and soft rocks.

1 INTRODUCTION

The Cone Penetration Test (CPT) or Cone Penetration Test with pore water pressure measurement (CPTU) is almost certainly the most widely used in-situ test both onshore and offshore. Its equipment and operation are well standardised (ISO 22476-1 and ASTM D5778). If these standards are followed and the necessary quality checks are performed, then reliable measured results should be easily obtained and can then be used to derive estimates of the geotechnical parameters to assist the geotechnical design. This is when problems start. Most of the interpretations are semi-empirical in nature and over the years many correlations have been published, linking the measured CPT/U data to the required soil properties. Many people interpret soils from CPTU based on these correlations, which have also been embedded in various software packages without ever questioning their validity. Unfortunately, this is being increasingly done and could be termed the 'black box' approach!

Clients are forcing/encouraging CPT contractors to derive soils properties without providing any additional input. It should be acknowledged that these derivations might be guesses, not even best estimates.

Processing of CPT/U raw data starts from converting voltages to engineering units, plotting the results on soil behaviour type charts and ends on generating all possible soils properties. This is an easy electronic process even without proper user input.

This paper aims to show how dangerous data processing without the proper input can be and how knowledge is required on reliable interpretations. But it also shows how if done with care, the power of the CPTU in determining the variations of soil properties is still so very worthwhile. Based on correlations, properties can be both over and under-estimated, which can of course result in both unsafe design and over-design. Too often one correlation must be used to derive a soil parameter required in another correlation. To further confuse the situation, some of the derived parameters are obtained by using values from other derived/ guessed parameters, adding more errors. It is not intended to mention correlations by name, but to point out the problems that can occur if outputs from software are taken without any user interaction. The packages used are commercially available. No pre-selection of correlations has been made.

For this purpose, 18 commercial sites and 14 test bed sites, which include 100s of CPTUs with a maximum depth of 40m have been studied. Different soils examined vary from very soft to stiff clays, silts, sands and soft rocks. Data cannot be presented for all the sites, but the conclusions are drawn based on all the data that the authors have reviewed. Guidance and advise will be given where possible.

2 SOFTWARE DERIVATION

2.1 *Parameters*

Some of the geotechnical parameters that can be derived from CPTU test results by using various correlations published in the literature and incorporated into various software packages are listed in Table 1.

Table 1. List of possible parameters to derive from correlations available in the literature.

Parameters	Symbols	Unit
Relative Density	D_r	%
Undrained Shear Strength	s_u	kPa
Water Content	w_c	%
SPT number	N_{60}	-
Shear Wave Velocity	v_s	m/s
Unit weight	γ	kN/m
Small Strain Shear Modulus	G_0	MPa
Small Strain Youngs Modulus	E_0	MPa
Constrained Modulus	M	MPa
Coefficient of volume change	m_v	m^2/MN
Compression Index	C_c	-
Overconsolidation Ratio	OCR	-
Friction Angle	φ'	°
Effective Cohesion	c'	kPa
Sensitivity	St	-
Coefficient of Lateral Earth Pressure	K_0	-
Rigidity Index	I_r	-
Hydraulic Conductivity	k (k_h and k_v)	m/s

The process of deriving all geotechnical parameters from CPTU results after gathering the measured data from site, which consists of cone resistance q_c, sleeve friction f_s, and porewater pressure u_2 starts with generating the corrected cone resistance, q_t and friction ratio, R_f through very simple calculations which involve measured results only. At this phase of data processing Soil Behaviour Type, SBT can be plotted on one of the charts available based on q_c/q_t and R_f.

To derive more soil properties, it is nearly always necessary to have information on groundwater conditions, GWL and density/unit weight, γ to establish total and effective vertical stresses, σ_{v0} and σ'_v, to derive pore pressure ratio, B_q and other normalized parameters, Q_t and F_R.

Information about GWL from the CPTU can only be obtained if full dissipation tests are run and this is seldom done. Hence, guessed GWL must be used as an input to the software if the client cannot supply any information from monitoring it on site. Regarding γ more details are given in the following section.

2.2 *Unit weight/ density (γ) and water content (w_c)*

When γ is derived from the equations available in the literature and found in many software packages q_t, f_s, and specific gravity of solids, G_s are required to run these calculations. One of the correlations require also shear wave velocity, V_s which is one of the parameters that will be discussed later in the paper.

In Figure 1 are shown some examples of derived γ which are compared with laboratory γ. A significant and consistent underestimation of γ for the glacial till at Cowden (Powell & Butcher, 2002) in England and the silt at Lierstranda (Lunne, 2002) in Norway can be observed. The same behaviour was present at 2 other till sites and 2 more silty clay sites.

In the same figure results from the London clay site at Canons Park (Powell et al., 2003) are also included. Again, derived γ profiles are on the low side of the measured profile. One of the correlations is giving results on the opposite direction of the measured. This pattern of results was apparent for all 5 London clay sites investigated by the authors and was similar in other heavily overconsolidated and aged clay sites. Underestimation is not always the case. γ results for the soft clay at Cran (Shields et al.,

Figure 1. Examples of underestimated and overestimated γ derived from various correlations in use.

1996), in France are highly overestimated, as can be seen from the last graph in Figure 1.

Some packages give also w_c as an output parameter. As might be expected, these results tend to be mirror images of the density profiles using a selected G_s.

2.3 Relative Density (Dr)

When considering sand then D_r is often a desired parameter. In order to derive D_r from CPTU results, q_c, q_t, σ_{v0} and σ_{atm} are typically necessary input. Figure 2 shows results from the sand site at Dunkirk (McAdam et al., 2020), which is partially placed and partially natural deposit. The wide range of derived D_r results after using some of the correlations available in the software is worrying. Generally, underestimation is seen at shallower depths and overestimation at deeper depths. Incorporating the correct γ values and the correct GWL, will significantly improve the results and better define the two layers that comprise this site. The second graph in Figure 2, shows derived D_r before and after compaction of a sand fill. Four different correlations available in the specialist software are used to derive D_r, noted in the figure as C1, C2, C3 and C4 Pre and Post, respectively. Once again, the wide range of results, especially those being highly overestimated after compaction is worrying.
2.4 Overconsolidation Ratio (OCR)

When considering OCR or alternatively yield stress, CPTU is known to be a powerful tool to profile it. Some correlations can estimate OCR based on q_t, u_2, Δu, σ_{v0}, σ'_v and σ_{atm}. Some others require φ' and G_0, which on the other hand require q_c, q_t and/or Q_t and γ. The long list of measured and derived parameters to estimate OCR makes its calculation prone to errors. It is worth mentioning, that OCR is the parameter with the largest number of correlations available.

Figure 3 shows results from some of the sites studied and it can be observed that the shape of the profiles generally follows the sites best estimate. However, the absolute values vary considerably. From all the results we have processed, one of the correlations consistently gives the same results of OCR around 1 for all ground conditions and soil types!

Looking into more details, for the glacial till at Cowden some of the profiles match well with the site best estimates, especially below 22m, where OCR increases. There are results from correlations that highly overestimate OCR, which are not correct. The first attempt for Cowden was done using the default value of γ set up in the specialist software. The second analysis of the results was carried out used the true γ of 22kN/m^3. Using the correct γ rather than the software generated values for this site, improves the derived OCR results, especially for correlation 6 which is now closer to the best estimate site characteristic values. Although, it is worth mentioning that two of the correlations that seem to not agree are both based on porewater pressure.

At a London Clay site in Canons Park the results presented in this Figure show significant underestimation compared to the site best estimated values,

Figure 2. Examples of derived D_r in sands showing under and overestimation of site best estimate values.

Figure 3. Examples of derived and site best estimate OCR results for 4 sites comprising glacial till, London clay and clayey sand.

although in most cases generated graphs have the correct shape, with values being reduced with depth.

Things can go very wrong indeed, a clayey sand site in Jossingny (Shields et al., 1996), shows unrealistic overestimation as seen in Figure 3.

Using these correlations without questioning the applicability of them in certain soil conditions is seen to give wildly wrong results. Uniform sites (like Cowden) have been examined to show that some correlations respond to changes in OCR caused by erosion. However, what happens if the geology changes, as well? Turning back to the examples above and many more results that authors reviewed for the purpose of this paper, it is not uncommon that a value of around 1 is derived for the full profile-raising concerns on applicability of this specific correlation.

OCR is one of the parameters most influenced by the GWL. Even 1m of GWL change can affect the predicted OCR results from as little as 5% for stiff clays to as high as 45% for soft clays. Therefore, correlations involving GWL as input parameter should be avoided when this information is not accurate.

2.5 Standard Penetration Test (SPT) N Value

The SPT, love it or hate is still one of the widely used in-situ tests worldwide. It has been said that "the best way to get reliable N values is from correlations with CPTU". The correlations available use q_c, Soil Behaviour Type Index, I_c and σ_{atm} to calculate N. Figures 4 and 5 show CPTU derived SPT profiles and compare them to the in-situ measured SPTs. Four different sites in England are chosen as representative examples, which include the London Clay site of Heathrow Terminal 5 (Hight et al., 2002b) and three commercial sites in Glasgow, Hull and Hemel Hempstead of mixed glacial deposits, silt mixtures underlain soft clay and silt underlain Chalk, respectively.

For London clay at T5, it can be seen that although the generated scattered CPTU profile has almost the same shape, it is below the in-situ measured profile.

Figure 4. Examples of derived SPT profiles in London and soft clay showing under and overestimation of measured values.

This pattern has been observed on many other clay sites studied, including the soft clays in Glasgow.

However, on two sites presented in Figure 5 results are over and underestimated, in sandy layers and in clayey layers, respectively. Regarding soft rocks, in the second graph below are shown the Chalk results, where in the upper meters in the very weathered Chalk, all SPT profiles seem to agree well. When penetrating through competent Chalk there is a greater difference, with derived results being higher than the measured ones.

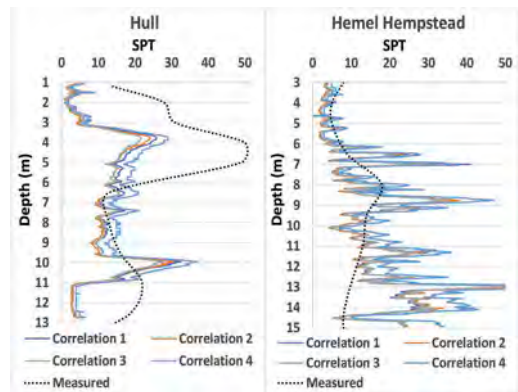

Figure 5. Examples of derived SPT profiles in other soils.

An interesting observation for silt layers from all the studied sites (two also included in Figures 5, the silt layer 6-9.5m in Hull results and 2-6m in Hemel Hempstead results) indicates that measured and derived results show a better agreement in this soil type.

2.6 Shear wave velocity (V_s) and Small Strain Stiffness (G_0)

When V_s and G_0 are considered, it is needed to ensure that anisotropy in the ground is not ignored. This affects the strength and the stiffness of the soils. Results generated from standard geophysical tests, which are typically referred to as downhole and crosshole can be different because of anisotropy. There is a less common crosshole test that allows a third orientation of stiffness to be considered (Butcher & Powell, 2004). As a result, is not enough to know what is being measured, but also which measured direction (vertical or lateral) is the most appropriate for design. For clarity, the following subscripts have been added to V and G to define the orientation of the values: vh for downhole tests and seismic cone, hv for standard crosshole tests and hh for results in a true horizontal plane. The importance of V_s and G_0 means that these parameters are widely desired and therefore derived from measured CPTU results.

Their derivation involves q_t, f_s, σ_{v0} and γ. In the following graphs, derived results are compared with the measured ones from seismic cone tests and are noted as V_{vh}. Figure 6 presents results from four sites, with different geology.
Figure 6. Comparison between measured and derived V_{vh} results in clay sit, sand, glacial till and stiff clay.

Pentre (Lambson et al., 1993) represents a clayey silt site, where the measured V_{vh} profile fall in between the derived one.

For the sands at Dunkirk, which show the largest scatter of derived results the measured V_{vh} profile falls towards the upper bound of the derived values. For the glacial till deposits at Cowden the measured V_{vh} falls towards the lower bound of derived profiles. Although the scatter here is not as large as the one observed for Dunkirk, below 16m derived V_{vh} are overestimated. Furthermore, big differences between are also seen for the stiff clays in Madingley (Butcher & Lord, 1993). Surprisingly, the greatest differences noticed are when deriving V_{vh} from the correlation which is suggested to work best in clays. This indicates that even if some correlations are recommended for one soil type, big differences can still be present. Does this mean that soil type is not the only limitation to the applicability of some correlations?

However, overestimation is not always the case. Figure 7 shows results from very stiff clays in Banbury and dense sands in Machynlleth, where derived V_{vh} are significantly lower than the measured one.

The behaviours seen in Figures 6 and 7 for V_{vh} are also noticed for derived and measured G_{vh}, Figure 8.

The results patterns for G_{vh} match those of Powell (2017) using a wider range of correlations, with the measured values for normally and lightly overconsolidated soils resulting in between derived ones. Meanwhile, the measured G_{vh} for heavily overconsolidated clays fall in the lower bound of derived results.

Derivations of G_{vh} is generally linked to CPTU data. However, derived V_{vh} and γ can be used to calculate G_{vh}. In this case, even if V_{vh} is realistic G_{vh} could have errors for incorrect γ. Results from Dunkirk support this. The G_{vh} profile generated from the software is closer to the site measured profile when correct γ is used. This again shows the importance of accurate input parameters to derive more parameters. Powell and Butcher (2004) and later Powell et al. (2016) suggested that it was the horizontal stresses and stiffnesses that influence q_t and that q_t correlates better with G_{hh}. This idea is further supported by

Figure 7. Examples of underestimated derived V_{vh} results.

Figure 8. Examples of derived and measured G_{vh} profiles.

Long (2022) who, using the same and additional data suggests that V_{hh} correlates better to q_t than V_{vh} does.

2.7 Other parameters

Undrained shear strength, s_u is highly affected by the choice of cone factor, N_{kt}. This is the principal

problem, although γ and GWL should ideally be known. Some of the software can generate N_{kt} values. Great care must be taken when this is done. It has been found on the studied sites that it can lead to under and overestimation of s_u. Values of N_{kt} should ideally be selected by the designers based on past experiences and the shear test types required, for example compression, extension or simple shear.

Another problem is the assessment of coefficient of lateral earth pressure, K_0. Correlations exist and are incorporated into software, as well. But, realistic assessment of K_0 from CPTU is still extremely weak and should be treated with great caution.

Another parameter that needs to be treated with growing awareness is permeability (hydraulic conductivity), k, which is widely required for settlement calculations as an input parameter in design software. k from CPTU is a rough guide of possible values for each SBT, giving lower and upper bounds. The importance of dissipation tests to estimate coefficient of consolidation, c_v is crucial. c_v is acceptable when dissipations are carried out below GWL. When GWL is unknown, dissipation tests need to run to equilibrium.

3 DISCUSSIONS AND CONCLUSIONS

In this paper has been suggested that the use of software to process CPTU results into geotechnical information should be done with care. Although these packages perform the mathematical calculations correctly, they are often used with too little basic information, experience and/ or knowledge.

It has been shown that many of the embedded correlations are not suitable for ALL soil types.

In addition, the following points can be made:

- Correct γ and GWL can improve the results of many derived geotechnical parameters;
- Derived parameters obtained based on other previously derived parameters should be avoided;
- Different correlations can give very different derived parameters for the same soil type;
- Sometimes agreements between measured and derived parameters have been found to be purely fortuitous. Two incorrectly derived parameters appearing to give a correct answer, this is worrying!

Correlations used in similar soil types are valuable, as are site specific ones. Parameter profile shape is often promising, but the absolute values between correlation vary wildly.

Can we find correlations that use soil type in terms of I_c as input parameter? It looks unlikely.

Why derive parameters that can be easily measured, like V_{vh}. However, site specific correlation can be useful for example, between q_t and measured V_{vh} from SCPTU, when used with other CPTUs on a site.

The importance of linking CPTU parameters with results from quality laboratory tests cannot be overstressed if efficiency in design is to be achieved.

Correlations can be very useful but should only be used when all influences in their derivation are understood.

Finally, always revisit processing when site specific information becomes available and site-specific correlations are established. They are far from foolproof. Soils properties should be treated with caution if they are derived without basic input information.

New methods for assessing Plasticity Index and Low-strain Shear Modulus in fine-grained offshore soils

N. Ramsey

Fugro Australia Marine Pty. Ltd., Perth, Western Australia, Australia

K.K. Tho

Fugro Singapore Marine Pte. Ltd., Singapore

ABSTRACT: This paper introduces a new method for predicting Plasticity Index, PI, directly from CPT data. Plasticity Index values predicted using the new method have been designated "PI_{CPT}" to emphasise their CPT-based origin. The new PI_{CPT} method has, in turn, enabled a new method of assessing Low Strain Shear Modulus, G_{max}, to be proposed, based on a well-established equation published by Viggiani & Atkinson (1995). As an additional benefit, the predicted PI_{CPT} profiles have proven very useful as a simple means of identifying soil-type variations and layer boundaries. This paper presents details of the new formulae that have been developed to estimate PI_{CPT} and G_{max}, the database that has been used to calibrate the formulae, and the results that have been obtained. Some limitations of the method are presented and discussed, as well as some of the benefits.

1 INTRODUCTION

This paper introduces new methods for estimating PI and G_{max} directly from CPT data, in fine-grained offshore soils. The new method for estimating PI is also shown to be a simple means of differentiating soil-type variations and layer boundaries.

This paper presents details of the formulae that have been developed, the database that has been used to calibrate the formulae and the results that have been obtained. Some limitations of the method and some discussion on the additional benefits are also presented.

2 DATABASE AND SELECTED SITE DETAILS

2.1 General

The PI database used for this paper comprises approximately 200 PI measurements taken at more than a dozen sites. The sites were purposely chosen to be from a variety of geological environments, and to provide data with a range of plasticity. The majority of the sites comprised predominantly silica soils, but one site comprised high plasticity carbonate silt. The chosen sites were also widely distributed geographically, and from a range of water depths.

The CPT data were gathered by four different geotechnical contractors, using cones made by three different manufacturers. Most of the tests were performed with standard piezocones with projected tip areas of 10 cm^2 or 15 cm^2 cones; but, at one site a cone with a projected tip area of 5 cm^2 cone was used.

Several sites in the database included G_{max} measurements from Resonant Column (RC), Bender Element (BE) or Seismic Cone (SCPT) tests.

Four sites have been selected for more detailed presentation and discussion of PI and G_{max} predictions. These sites were chosen because, together, they covered a wide range of plasticity index and liquidity index. At all four sites, the CPTs and sampling boreholes were performed in close proximity, and G_{max} measurements had been made via RC and/or BE testing. One site also included SCPT measurements.

General details of the soil conditions at the four selected sites are presented in Table 1.

Table 1. General details of site conditions.

Site Name	Plasticity Symbols	~PI %	~OCR -	Notes
A	CI-CH	15-40	5-10	
B	CI	10-20	1.5-10	
C	CVH-CEH	55-75	1-2	
D	MH	15-25	1-3	Carbonate

The ranges of soil conditions at the selected sites, are also considered representative of the ranges in the database.

3 ASSESSING PI FROM CPT DATA

3.1 *General*

The general form of the proposed formula for predicting Plasticity Index from CPT (PI_{CPT}) data is presented in Equation 1:

$$PI_{CPT} = \frac{C_1 * R_{ft} * \left(1 + B_q\right)^{C_3}}{\left(0.33 * Q_t\right)^{C_2}} \quad (1)$$

where R_{ft} is the ratio of sleeve friction, f_s, to total cone resistance, q_t; B_q is the ratio of excess pore-water pressure, Δu, to net cone resistance, q_{net}; and Q_t is the ratio of q_{net} to in-situ vertical effective stress, p_o'.

Although, Equation 1 is essentially an empirical formula, it is based on some well-established concepts. The basic premise of the formula is that friction ratio is primarily affected by the soil's mineralogy, stress history and lateral effective stress. So, by removing the effect of stress history and lateral effective stress, the friction ratio becomes primarily affected only by the soil's mineralogy, which is manifested in terms of the measured Plasticity Index.

As both B_q and Q_t are strongly influenced by stress history, it would seem reasonable that both these parameters could be used to try and reverse the effects of stress history on the measured skin friction. Reversing the effects of effective lateral stress is more challenging, as the B_q parameter is not significantly influenced by lateral effective stress – as may be observed in normally consolidated clay, where B_q can be almost constant over several tens of metres. At first glance, Q_t might also seem to fall into this category. However, it may be by remembered that mechanically induced Overconsolidation Ratio, OCR, may be written in terms of the current effective vertical stress and an additional vertical effective stress, Δp that has been removed at some point in time (Equation 2). Hence, as the Q_t parameter is normalised by the current vertical effective stress, it will tend to reduce gradually with depth, if Δp in the soil-layer is constant and greater than zero.

$$OCR = \left(p'_0 + \Delta_p\right)/p'_0 \quad (2)$$

Initial attempts to assess appropriate coefficients were encouraging, as it was clear that the general trends of measured PI values were being correctly predicted. However, when low values of the C_1 coefficient were chosen, it was necessary to use relatively high C_2 and C_3 coefficients, which made the predicted PI very sensitive to small changes in B_q and Q_t. Whereas when high values of the C_1 coefficient were chosen, it was not possible to choose C_2

and C_3 coefficients that gave consistently acceptable agreement with the measured data. Therefore, an iterative approach was used to optimise the C_1, C_2 and C_3 coefficients, using the following criteria:

- When viewed on an overall basis, a clear majority of measured PI values, in the database, should be reasonably close to corresponding PI_{CPT} values.
- When viewed on an individual-site basis, a clear majority of measured PI values, should be reasonably close to, and follow the trends of, corresponding PI_{CPT} values.

Based on the two criteria above, a best fit was achieved using C_1, C_2 and C_3 coefficients of 17.5, 0.31 and 1.2 respectively, as shown in Equation 3.

$$PI_{CPT} = \frac{17.5 * R_{ft} * \left(1 + B_q\right)^{1.2}}{\left(0.33 * Q_t\right)^{0.31}} \quad (3)$$

where both R_{ft} and PI_{CPT} are percentage-values, in accordance with standard industry practice. Consequently, from now on, PI_{CPT} will be presented, and used, as a percentage.

3.2 *Direct comparisons*

Figure 1 presents a combined plot of measured PI values plotted directly against automatically picked corresponding PI_{CPT} values, from all the sites. Automatic picking was used to avoid unconscious human bias influencing the picked values. Only values that were clearly inconsistent were removed – for example where a measured PI value was close to a soil-type boundary, but where the CPT data clearly indicated a different boundary elevation.

Figure 1. Comparison of all measured PI and PI_{CPT} values.

Figure 1 confirms that, overall, measured PI values, in the database, are reasonably close to corresponding predicted PI_{CPT} values – and when the error is greater than the ranges shown, there is often a clear and identifiable reason. For example:

a) As shown on Figure 1, extremely high plasticity active clays, often including soil descriptors such as "slickensided" or "organic" tend to be underpredicted.
b) Strongly structured soils tend to be more difficult to predict. In the example shown on Figure 1, the soils were described as "fissured", and PI_{CPT} values were greater than measured PI values. However, it is considered possible that PI_{CPT} could over-predict or under-predict measured PI in strongly structured soils.
c) It is well known that a coarse inclusion, such as a piece of coarse gravel in a fine-grained matrix, can cause temporary variations in both pore-water pressure and sleeve friction – and these variations can lead to erroneous PI_{CPT} predictions. The example highlighted in Figure 1 was caused by an inclusion that was observed in the corresponding soil sample.

3.3 Example sites

3.3.1 General
The section presents comparisons of measured PI and PI_{CPT} at four selected sites. It may be noted, however, the consistency of agreement shown for these four sites is considered typical of the consistency observed at other sites in the database. Even at the "slickensided" site, highlighted in Figure 1, a reasonably consistent difference between predicted and measured values was observed, suggesting the error was systematic rather than random.

3.3.2 Site A
Figure 2 presents a simplified soil profile (based on the adjacent sampling borehole log) to illustrate the interbedded nature of this site. Even so, it may be seen that the predicted PI_{CPT} profile is in good agreement with measured PI values. Furthermore, if PI_{CPT} ≥7% is used to define fine-grained soils, the PI_{CPT} profile can be seen to provide a simple means of differentiating fine-grained and coarse-grained soil - and soil-type variations and layer boundaries.

3.3.3 Site B
This site was chosen because of the relatively low Plasticity Index and the relatively large number of measurements. It may be seen from Figure 3 that the predicted PI profile is in good agreement with the measured values. For example, where the measured PI values are uniform in the upper 20 metres, the predicted PI profile is uniform. Below 20 metres there is more variability in the measured PI values, and this is also seen in the predicted profile. Finally, the decrease in measured PI values below 40 metres is also observed in the predicted PI profile (although there is some variability).

Figure 2. Site A – Measured and inferred PI versus depth.

Figure 3. Site B – Measured and inferred PI versus depth.

659

3.3.4 Site C

This site was chosen because of its very high to extremely high plasticity. As shown in Figure 4, the PI_{CPT} profile generally slightly underpredicts the measured PI values; but, at some locations, the difference was greater, for example in the range 30-40 metres. It is notable, however, that in this depth range, "organic staining" was included in the corresponding soil descriptions. This might suggest the greater differences were caused by locally higher organic content. Although, no direct organic content measurements were made on the corresponding samples – it is notable that organic contents in the same soil unit, at the same site, did indicate local variations in organic content.
Figure 4. Site C – Measured and inferred PI versus depth.

3.3.5 Site D

This site was chosen because it comprised high plasticity carbonate silt. The agreement between predicted and measured PI values at this site was better than expected. However, we would not consider it wise to assume that a similar level of agreement would be achieved at all carbonate silt/clay sites.
Figure 5. Site D – Measured and inferred PI versus depth.

3.4 Discussion

Generally, the predicted PI_{CPT} values are in good agreement with measured data, at the sites within the database, provided the soils are not organic or significantly structured. However, obviously, the ability to make reliable predictions is highly dependent on the reliability of the input data. Consequently, the following potential sources of error must be avoided or taken into account when interpreting the results:

- Errors in cone zero measurements – particularly the friction sleeve zero measurement.
- Errors in friction sleeve measurements caused by temperature effects – for example when the cone has passed through very dense sand.
- Cone dimensions – particularly friction sleeve dimensions - that are outside the allowable tolerances given in ISO 19901-8 (2014).
- Cone measurements that do not achieve ISO 19901-8 (2014) Application Class 1 limits.
- Incorrect calculation of q_t, q_{net}, R_{ft} and Q_t.
- Sleeve friction measurements not suitably corrected for friction sleeve area effects (Ramsey, 2022).

An additional benefit of the PI_{CPT} formula was that it proved useful for defining the boundaries

between fine-grained and coarse-grained soils. Based on the sites investigated, it also appeared to predict the thickness and plasticity of interbedded layers reasonably reliably.

A further benefit of being able to predict PI, reasonably reliably, is that it enables PI to be explicitly included in G_{max} assessments based on CPT data – and this aspect is discussed in the next section.

4 ASSESSING LOW-STRAIN SHEAR MODULUS USING CPT DATA

4.1 General

The new method for assessing G_{max} directly is an adaptation of the well-established G_{max} formula published by Viggiani & Atkinson (V&A) in 1995, and shown in Equation 4:

$$\frac{G_0}{p_r} = A\left(\frac{p'}{p_r}\right)^n R_0^m \quad (4)$$

where, G_o is equivalent to G_{max} (kPa), R_o is equivalent to OCR, p_r is a reference stress (equal to 1 kPa), p' is the mean effective stress (kPa) and 'A', 'n' and 'm' are coefficients that depend on Plasticity Index (%).

The advantage of the V&A (1995) formula over most popular CPT-based methods of assessing G_{max}, is that it explicitly accounts for the principal factors that influence G_{max}, which are OCR, p' and PI. So, as the PI_{CPT} formula can now be used to estimate PI, all the required V&A (1995) input factors can now be directly estimated from CPT data, using Equation 5:

$$G_{max} = p_r * A(PI_{CPT}) * \left[\frac{p'}{p_r}\right]^{n(PI_{CPT})} * OCR^{m(PI_{CPT})} \quad (5)$$

Further details of the methods used to calculate the input factors are discussed in the next sections; followed by profiles comparing predicted and measured G_{max} values, at the four selected sites.

4.2 Estimating the A, n and m coefficients

In the Viggiani & Atkinson (1995) paper, the coefficients 'A', 'n' and 'm' are graphically related to PI (%), and lines that "indicate only the general trends of the data" are annotated on explanatory graphs. Nevertheless, V&A's general trend lines have been used as the basis for the formulae proposed in this paper, which are presented in Equations 6 to 8:

$$A(PI_{CPT}) = 10^{(3.52 - 0.022 * PI_{CPT})} \quad (6)$$

$$n(PI_{CPT}) = 0.27 + 0.35 * \log(PI_{CPT}) \quad (7)$$

$$m(PI_{CPT}) = 0.17 + 0.002 * PI_{CPT} \quad (8)$$

Equations 7 and 8 generate 'n' and 'm' coefficients that are similar to the "general trends" lines shown by V&A (1995). Whereas Equation 6 generates 'A' coefficients that lie slightly below V&A's "general trends" line, because doing so produced a better overall fit with the measured G_{max} values in our database.

4.3 Assessing OCR from CPT data

OCR is one of the key input parameters in Equation 5. Various formulae for predicting OCR from CPT data were assessed, including a new formula that accounted for plasticity. However, it was concluded that the formula presented in Equation 9 (Kulhawy & Mayne, 1990) and illustrated in Figure 6, provided reasonable agreement between predicted and measured OCR values. It is notable that the four data points lying significantly below the "1 to 1" line, in Figure 6, were measured in soils that were considered to have been desiccated by sub-aerial exposure. This is considered to suggest that the yield stress ratio may be underpredicted when the yield stress has increased due to desiccation rather than being mechanically induced – and is, therefore, a limitation on the accuracy of G_{max} predictions made using the new method.

$$OCR_{CPT} = Q_t/3 \quad (9)$$

4.4 Assessing mean effective stress from CPT data

Mean effective stress has been calculated using the Equation 10:

$$p' = (1 + 2 * K_o)/3 * p_0' \quad (10)$$

where K_o is the lateral earth pressure at rest, and p_o' is the current in-situ vertical effective stress.

K_o has been calculated using Equation 11, using the approach proposed by Mayne & Kulhawy (1982) and assuming an angle of internal friction of 30° (which is considered sufficiently accurate for the intended purpose):

$$K_o = 0.5 * (OCR_{CPT})^{0.5} \quad (11)$$

The preferred method for estimating current in-situ vertical effective stress, p_o', is to use laboratory data from nearby sampling boreholes. However, if

no local data are available, then there are published relationships for assessing submerged unit weight from CPT data, such as Robertson & Cabal (2010).

Figure 6. Comparison of predicted and interpreted OCR.

4.5 Comparisons between predicted and measured G_{max} values

4.5.1 General

The four examples that follow are comparisons between predicted and measured G_{max} values at the same four sites, as the PI comparisons.

4.5.2 Site A – G_{max} predictions

Figure 7a) illustrates that the laboratory measurements and SCPT measurements were in good agreement with the predicted G_{max} profile, at this interbedded sand, silt and clay site.

4.5.3 Site B – G_{max} predictions

Figure 7b) presents predicted and measured G_{max} values from Site B. At this, there was initially poor agreement between predicted and measured values. However, on closer inspection, the laboratory test specimens had been consolidated to the estimated vertical effective stress, rather than the mean effective stress. After accounting for this discrepancy, the predicted values are much closer to the measured values, albeit systematically higher. The difference is considered likely to be due to correction errors.

4.5.4 Site C – G_{max} predictions

Figure 7c) indicates very good agreement between predicted and measured G_{max} values, which might seem surprising given that the PI_{CPT} profile at this site was consistently underestimated (see Figure 4). However, at high PI, the $A(PI_{CPT})$ and $n(PI_{CPT})$ coefficients become less sensitive to changes in PI, which probably explains the good agreement.

4.5.5 Site D – G_{max} predictions

The predicted G_{max} profile is in good agreement with the three of the four measured values at this high plasticity carbonate silt site. The reasons for the discrepancy with the lowest laboratory measured value is not completely clear. However, local zones of higher cementation were observed at this site, so it is considered possible that the laboratory test was affected by a locally higher degree of cementation.

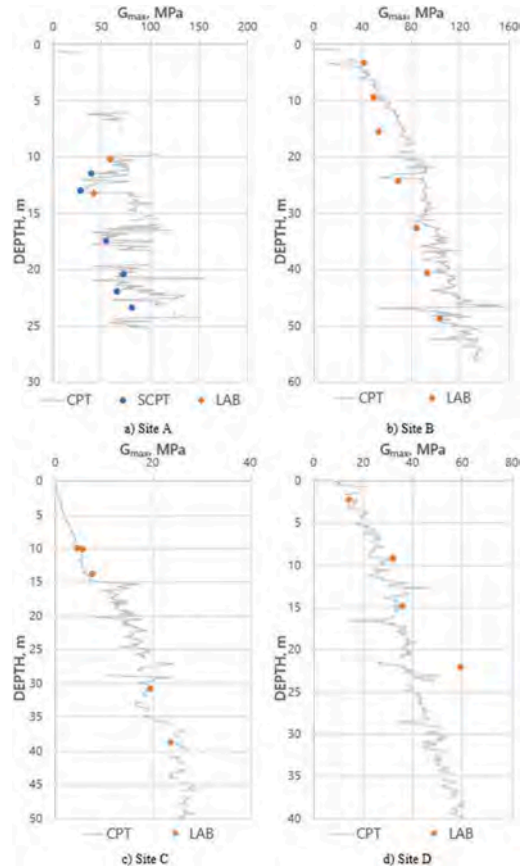

Figure 7. Comparison of predicted and measured G_{max} values.

4.6 G_{max} discussion

- Generally, the new method of predicting G_{max} directly from CPT data, is considered to provide good predictions of G_{max} values at the sites within our database. However, the initial lack of agreement between predicted and measured values at Site B, highlights the need to ensure that any corresponding laboratory tests are consolidated appropriately. Also, as the method is dependent on reliable PI_{CPT} predictions, the same potential sources of error, discussed in Section 3.4, need to be avoided, or taken into

account, when processing the results. Finally, potential errors caused by inaccurate OCR predictions in sub-aerially exposed soils, should be taken into account.

5 CONCLUSIONS AND RECOMMENDATIONS

- A new method of prediction PI values directly from CPT data is proposed. Generally, the predicted PI_{CPT} values are in good agreement with measured PI values in the database.
- An additional benefit of the predicted PI_{CPT} profiles is that the profiles can be used as a simple means of differentiating soil-type variations and layer boundaries.
- A limitation of the proposed new method for predicting PI_{CPT} is that the quality of the predictions is dependent on high quality CPT measurements. Fortunately, this limitation can be mitigated by ensuring all tests are performed with cones that comply with the tolerances and accuracies specified in ISO 19901-8 (2014) for Class 1 testing.
- The new PI_{CPT} formula has enabled a new method for predicting G_{max} to be proposed, based on a well-established equation proposed by Viggiani & Atkinson (1995).
- The predicted G_{max} values are in good agreement with measured G_{max} values in the database.

- The limitations of the proposed new method for predicting G_{max}, are generally similar to the limitations of the new PI_{CPT} method - with the addition of potential errors caused by inaccurate OCR predictions in sub-aerially exposed soils.

Cone penetration testing and interpretation in the holds of two ore-carrying vessels

N. Ramsey
Fugro, Australia

ABSTRACT: This paper provides details of two in-situ testing programmes performed to assess ore properties in the holds of ore carrying vessels. The first case comprised CPTs in the hold of an iron-ore carrying vessel - at both the ports of loading and discharge – enabling assessment of the ore properties after loading and the changes caused by the voyage. The second case comprised two CPTs and one Seismic Dilatometer Test (SDMT) in the hold of a coal carrying vessel shortly after loading – enabling assessment of the coal properties after loading, and direct comparison of CPT and SDMT interpretations.

1 INTRODUCTION

Ore-liquefaction can be caused by cyclic loading induced by ship-motions. If liquefaction occurs, the ore may lose most, if not all, its inter-particle frictional strength and may flow like a viscous fluid. If flow does occur, one potential consequence is an irredeemable lateral shift in the ship's centre of gravity – a shift that could have potentially catastrophic consequents.

This paper presents details of two high-quality in-situ testing programmes that were performed in the holds of ore carrying vessels, to provide reference information for ore liquefaction and stability assessments. Full details of these assessments are beyond the remit of this paper. However, opportunities to perform in-situ tests on ore mounds in ships' holds are rare – so, it is hoped that the data and interpretations, presented herein, will be of interest to the geotechnical community.

2 PROJECT DETAILS

2.1 *Case 1 – iron-ore*

2.1.1 *Fieldwork*
The fieldwork was performed in two phases. Phase 1 comprised, three CPTs at the port of loading and Phase 2 comprised three CPTs at the port of discharge. Each test was performed from the top of the ore mound to the base of the mound. The tests were performed on an approximate one-metre grid, so the maximum separation between any test was approximately two metres.

As may be seen in Figures 1 and 2, different CPT rigs were used at the ports of loading and discharge. However, similar Class 1 piezocones were used at both sites.

Figure 1. CPT equipment at iron-ore port of loading.

Figure 2. CPT equipment at iron-ore port of discharge.

2.1.2 *Iron-ore CPT results*
Reference CPT data, for the iron ore mound, are presented on Figure 3 (port of loading) and Figure 4 (port of discharge). The test data are generally consistent at

the port of loading (except for some variability in CPT NP2 in the upper 2.5 m). In contrast, significantly more variability is apparent at the port of discharge – in particular, the sleeve-friction measurements are significantly higher. The measured pore-water pressure values were negligible, indicating fully drained behaviour at both ports.

Figure 3. Case 1 – CPT data – Iron-ore port of loading.

Figure 4. Case 1 – Basic CPT data – Iron-ore port of discharge.

2.2 Case 2 – coal

2.2.1 Fieldwork

The fieldwork was performed shortly after the ship was loaded. The fieldwork comprised CPTs at two locations, approximately 7.6 m apart. CPT PK1 was performed on the top-centre of the coal mound, whilst CPT PK2 was performed closer to the edge of the coal mound. A Seismic Dilatometer (SDMT) test was performed approximately 1.6 m from CPT PK1. Dilatometer measurements were made at 2 m intervals and shear-wave measurements at 4 m intervals.

Figure 5 Illustrates that some preparation of the coal mound was considered necessary to enable the testing rig to be installed in a safe and stable manner. For operational reasons, the test programme was performed at night (Figure 6).

Figure 5. Coal mound at port of loading.

Figure 6. CPT and SDMT equipment on coal mound.

2.3 Coal – CPT results

Reference CPT data are presented on Figure 7. CPT PK1 indicates high variability of cone resistance within the upper seven metres of testing. This is considered likely to be a product of the initial mound levelling works, as the results for CPT PK2 (where less preparation was performed) were highly

variable only in the upper two metres. Beneath the highly variable zones, both CPTs indicated a steady trend of increasing cone tip resistance. Localised peaks of cone resistance below the upper variable zone, are considered likely to be caused by the presence of larger coal fragments. Pore-water pressure values were generally negligible, except between 6-7 m in CPT PK1. This zone of measurable pore pressure was considered likely to be due to a localised zone of higher water and fines contents.

Figure 7. Case 2 - Basic CPT data – Coal port of loading.

3 INTERPRETATIONS

3.1 *General*

In each case, the average bulk density of the ore', in the ships hold, was calculated as the ratio of the volume of the ore mound (surveyed using a laser-scanning technique), and the mass of ore deposited into the hold during loading.

In each case, maximum and minimum dry density values were provided by the Client, so exact details of the methods are unavailable for this paper. However, it is understood that maximum dry density assessments were based on a standard "Proctor" approach, and minimum dry density assessments were made using a funnel-type approach.

3.2 *Case 1 – iron-ore*

The CPT results were used to infer density and void ratio profiles at the port of loading and the port of discharge. Changes in these profiles, caused by the ship's movements during sailing,

could then be inferred by comparing corresponding results.

3.2.1 *Iron-ore reference data*
Average dry density, ρ_{dry} = 1.94 Mg/m^3
Maximum dry density, $\rho_{d\ max}$ = 2.66 Mg/m^3
Minimum index dry density, $\rho_{d\ min}$ = 1.76 Mg/m^3
Particle density, PD = 3.96 Mg/ m^3

3.2.2 *Methodology for inferring relative and dry density profiles*
The average dry density profile in the ore-mound was inferred using a three-step iterative process.

Step 1 – infer nominal relative density profiles from the CPT data

Step 2 - use the maximum and minimum dry density data to convert the nominal relative density profiles to equivalent dry density profiles.

Step 3 – iterate until the inferred relative density and dry density profiles are plausible and the average inferred dry density is the same as the average dry density (calculated from survey measurements of the mound volume and the measured weight of the loaded ore).

The formulae used to perform these calculations are discussed in the following section.

3.2.3 *Density and void ratio calculations*
Relative Density, D_r, is an estimate of the state of material packing, relative to reference maximum and minimum values. Relative density is defined as:

$$D_r\ (-) = \ (e_{max}\ -\ e)\ /\ (e_{max}\ -\ e_{min}) \quad (1)$$

Based on testing in a large calibration chamber, Baldi et al. (1986) published the generic formula presented in Equation 1, for estimating the nominal relative density of silica sands.

$$D_r(-) = \ \left(\frac{1}{C_2}\right)\ln\left(\frac{q_c}{C_0 * (\sigma_m'^{C_1})}\right) \quad (2)$$

The C_0, C_1 and C_2 coefficients that provided the best agreement for Ticino sand are summarised in Table 1. These values were used as a starting point for assessments of the iron-ore mound at the port of

Table 1. Summary of coefficients used to estimate relative density profiles in the iron-ore mound.

Material	C_0	C_1	C_2	K_0
Ticino Sand	181	0.55	2.61	0.4
Iron-ore	118	0.55	2.61	0.4

loading. It was concluded that plausible profiles could be obtained simply by changing the C_0 coefficient, as shown in Table 1.

Dry density was calculated using Equation 3:

$$\rho_d \left(Mg/m^3 \right) = \frac{\rho_{d\ max} * \rho_{d\ min}}{(1 - D_r).\rho_{d\ min} + D_r\ \rho_{d\ max}} \quad (3)$$

Void ratio and volumetric strain profiles were calculated using Equations 4 and 5, respectively. The results are presented on Figure 9, together with the change in volumetric strain between the ports of loading and discharge.

$$\text{Void ratio e}(-) = \frac{PD}{\rho_d} - 1 \quad (4)$$

$$\text{Volumetric strain,}\ \varepsilon_v(\%) = \frac{e - e_0}{1 + e_0} * 100 \quad (5)$$

Figure 8 presents composite profiles of inferred nominal relative density, dry density, and void ratio. Although the profiles tend to be relatively consistent below approximately 8 m depth, there is much more variability in the upper material. To enable clearer identification of trends, the void ratio data were averaged over 1 m increments. Figure 9 presents the results of this averaging process, in terms of predicted void ratio, change in void ration and volumetric strain. It may be seen that the trends are much clearer in Figure 9. In particular the average volumetric strain profile indicates a steady reduction in
Figure 8. Inferred relative density, dry density, and void ratio profiles at the ports of loading and discharge.

volumetric strain, from greater than 4 % in the upper metre, reducing to less than 1% below 4 m. Of course, the magnitude of these inferred changes was dependent on the metocean conditions encountered during the ship's voyage. Discussion on these aspects is, however, beyond the remit of this paper.

Although the profiles presented on Figures 8 and 9 are inferred, it is interesting to note that the average inferred volumetric strain is in excellent agreement with the average volumetric strain calculated from detailed surveys of the ore-mound geometries at the ports of loading and discharge.

Figure 9. Changes in void ratio and volumetric strain incurred between ports of loading and discharge.

3.3 Case 2 – coal

3.31 General approach
The objectives of the testing at the port of loading were to assess density and stiffness variations in the coal, shortly after loading in the ship's hold. The CPT data were used to infer dry density profiles using the same three step approach used for the iron-ore. The CPT data were also used to infer low-strain shear stiffness, G_{max}, and constrained modulus profiles, to enable for comparison with profiles estimated using the SDMT data.

3.3.2 Coal reference data
Average dry density, r_{dry} = 0.95 Mg/m³
Maximum dry density, $r_{d\ max}$ = 1.05 Mg/m³
Minimum dry density, $r_{d\ min}$ = 0.71 Mg/m³
Particle density, PD = 1.37 Mg/ m³

3.3.3 Density and void ratio calculations
As for the iron-ore, it was found that the general form, given in Equation 2, could be adapted for use

667

in the coal mound. However, in the case of the coal mound, all three coefficients were changed in order to infer plausible profiles. The C_0, C_1 and C_2 coefficients that provided the best agreement are summarised in Table 2.

Table 2. Summary of coefficients used to estimate relative density profiles in the coal mound.

C_0	C_1	C_2	K_o
17	0.4	3.9	0.4

Inferred profiles of relative density, dry density and void ratio are presented on Figure 10.
Figure 10. Inferred relative density, dry density, and void ratio profiles at the port of loading.

3.3.4 Constrained modulus calculations

Constrained Modulus, M, was inferred from the SDMT measurements using Equation 6 (Marchetti et al., 2001).

$$M = 0.85 * 34.7 * (P_1 - P_0)/1000 \qquad (6)$$

Baldi et al (1986) developed a correlation for estimating M in silica sands (for a vertical strain of approximately 0.1%) by comparing one-dimensional compression results with cone resistance data measured in a calibration chamber (Baldi, 1985). The correlation, which is presented in Equation 7, considers cone resistance, q_c, in-situ stress conditions, σ_m', and over-consolidation ratio, OCR.:

$$M = C_0 * p_a * \left(\frac{\sigma m'}{p_a}\right)^{C_1} * OCR^{C_2} * \exp(C3 * Dr) * q_c \qquad (7)$$

The original coefficients published by Baldi et al. (1986) are presented in Table 3, together with the coefficients that provided better agreement with M values inferred from the SDMT measurements.

Table 3. Summary of coefficients used to estimate constrained modulus in the coal mound.

Material	C_0	C_1	C_2	C_3
Baldi et al (1986)	14.48	-0.116	0.313	-1.123
Coal mound	5.4	-0.116	0.313	-0.4

The right-hand graph on Figure 11 presents M, profiles results of both CPT and SDMT interpretations – it is considered that there is acceptable agreement over whole profile.

Figure 11. Inferred G_{max} and M profiles at the port of loading.

3.3.5 Low-strain shear modulus calculations

Direct measurements of shear wave velocity were performed during the SDMT testing adjacent to Test PK1. Low-strain shear modulus, G_{max}, values between individual test locations were then calculated using Equation 8:

$$G_{max} = \rho_{bulk} * v_s^2 \qquad (8)$$

Equations for estimating G_{max} from cone data were also published by Baldi et al. (1986). However, in the case of the coal mound, it was found that acceptable agreement with the SDMT G_{max} measurements could be obtained simply by increasing the C_0 coefficient in the Baldi et al. (1986) Constrained Modulus equation, by a factor of 4.5 - as shown in Equation 9.

$$G_{max} = 24.3 * p_a * \left(\frac{\sigma m'}{p_a}\right)^{-0.116} * OCR^{0.313} * \exp(-0.4 * Dr) * q_c$$

$$(9)$$

The results of the G_{max} interpretations, which are presented on the middle graph on Figure 11, indicate good agreement between the CPT interpretations and the SDMT measurements.

4 DISCUSSION AND CONCLUSIONS

1) As expected, ore properties were inferred to vary much more in the upper part of the ore-mound, with variability gradually reducing with depth.
2) A general trend of increasing nominal relative density with depth was inferred in all tests. This would be expected, as the standard "high-energy air-pluviation" method used to load the ore vessels would inevitably lead to more compactive effort being applied to materials at greater depths.
3) It was possible to obtain good agreement between material properties inferred from CPT data, and material properties inferred from survey data and the weight of material loaded into the ships' holds.
4) As expected, the CPT measurements implied that vessel-movement induced densification occurred from the top of the iron-ore mound downwards.
5) The consistent increase in sleeve friction noted in the iron-ore mound at the port of discharge, was considered to suggest that there had been a wave-induced increase in K_o. However, as no testing was performed to quantify any change in K_o, a constant value of K_o was assumed in the calculations. This is considered a potential source of error in the post-voyage calculations of relative density (and hence dry density and void ratio).
6) No significant zones of pore pressure were measured at the ports of loading. This was interpreted to suggest that there had been no significant tendency of the ores to saturate at the base immediately after loading.
7) Good agreement between stiffness properties inferred from CPT data and equivalent properties inferred from SDMT results could be obtained by making ore-specific amendments to published correlations.

SYMBOLS AND ABBREVIATIONS

CPT	Cone Penetration Test (with pore-pressure measurements)
D_r	nominal relative density (%)
e	void ratio (-)
e_0	initial void ratio (-)
f_s	CPT measured sleeve friction (MPa)
G_{max}	low-strain shear modulus (MPa)
I_c	Soil behaviour type index (-)
K_o	Coefficient of earth pressure at rest (-)
M	secant constrained modulus (MPa)
OCR	overconsolidation ratio
p_a	reference stress equal to 98.1 kPa
PD	particle density of ore (Mg/m^3)
P_0	corrected dilatometer pressure reading when the membrane first breaks away from the seating.
P_1	corrected dilatometer reading when the membrane movement is 1.1 mm away from the seating.
p_o'	effective overburden pressure (kPa)
q_c	CPT measured cone resistance (MPa)
SDMT	Dilatometer test with shear-wave measurements
u	CPT measured pore-water pressure (MPa)
v_s	measured shear wave velocity in soil (m/s)
ρ_{dry}	dry density of soil (Mg/m^3)
ρ_{bulk}	bulk density of soil (Mg/m^3)
$\rho_{d\,max}$	maximum dry density (Mg/m^3)
$\rho_{d\,min}$	minimum dry density (Mg/m^3)
σ_m'	mean effective stress at test depth (kPa)

Suction influence on CPT and DMT for some Brazilian tropical soils

B.P. Rocha

R.A. Rodrigues & H.L. Giacheti
Department of Civil and Environmental Engineering, São Paulo State University (Unesp), Brazil

ABSTRACT: Suction plays an important role in geotechnical engineering practice since it influences the mechanical behavior of unsaturated soils. Interpretation of in situ test data at unsaturated soil sites must consider both spatial and seasonal variability, especially in strength and stiffness parameters. This paper presents and discusses CPT and DMT performed at different seasons at two sites with tropical sandy soils. CPT and DMT data were interpreted considering the influence of soil suction. Suction was estimated from water content profiles and soil water retention curves (SWRC). Failure to consider the effect of soil suction in the site investigation of unsaturated soils can lead to inappropriate soil classification as well as significant and unconservative overestimates of geotechnical parameters.

1 INTRODUCTION

Site characterization can be defined as the process of identifying the geometry of relatively homogeneous zones and developing index, strength, and stiffness properties for the soils within these zones. Some *in-situ* testing methods can be used as an alternative to the traditional approach of drilling, sampling, and laboratory testing.

Many geotechnical works (e.g., shallow foundations, embankments, and slopes) are performed on unsaturated deposits. Suction increases the shear strength and stiffness of these soils (Alonso *et al.* 1990). Such influence on the geotechnical soil behavior is well understood based on laboratory tests, however they are expensive and time-consuming since it involves undisturbed soil sampling.

In-situ tests, such as the cone penetration (CPT) and the flat dilatometer (DMT) tests allow combining stratigraphic logging with specific measurements, which is a modern approach available for site characterization and could be used to improve the site characterization in unsaturated soils. Only few studies deal with in situ test interpretation in unsaturated soils, as well as the influence of soil suction in the interpretation (Lehane *et al.* 2004; Pournaghiazar *et al.* 2013; Lo Presti *et al.* 2018; Giacheti *et al.* 2019; Rocha *et al.* 2021).

This paper presents and discusses the influence of soil suction on CPT and DMT carried out in two unsaturated tropical soil sites from Brazil. CPTs, DMTs and water content profiles were determined in

different periods of the year. The tests data are presented and interpreted considering the soil-water retention curves (SWRC). Soil suction influence was incorporated to the effective stress following Bishop's (1959) equation to interpret the in-situ tests data.

2 BACKGROUND

Interpretation of in-situ tests usually assumes pore pressure equal to zero in unsaturated soils. Therefore, the total stress (σ_v) is assumed to be equal to the effective stress (σ_v'). Moreover, the interpretation does not consider the suction contribution to the effective stress.

Soil suction should be incorporated into the interpretation of in-situ tests on unsaturated soils. Suction can be incorporated into effective stress following Bishop (1959), when σ_v' is defined by Equation 1:

$$\sigma_v' = \sigma_v + \chi(u_a - u_w) \qquad (1)$$

where χ is the effective stress parameter, u_a is the pore air pressure and u_w is the pore water pressure. Soil suction is the difference between u_a and u_w. χ is equal to 1 for saturated soils and 0 for dry soils, and it can be assumed to be equal to the degree of saturation (S_r) (Öberg & Sällfors 1997; Robertson *et al.* 2017).

The interpretation of CPT data starts by calculating the normalized cone resistance (Q_{tn}) (Eq. 2).

$$Q_{tn} = \left(\frac{q_t - \sigma_v}{p_a} \right) \left(\frac{p_a}{\sigma'_v} \right)^n \qquad (2)$$

where σ_v is the total stress, $\sigma_v{'}$ is the effective stress, p_a is the atmospheric reference pressure in the same unit as q_c and σ_v, $(q_c \ e \ \sigma_v)/p_a$ is the dimensionless net cone resistance, $(p_a/\sigma_v{'})^n$ is the stress normalization factor, and n is the stress exponent that relates q_c to σ'_v and can be defined in power law relationships defined according to Robertson (2009). The stress exponent (n) is 1.0 for most fine-grained soils, and ranges from 0.5 to 0.9 for coarse-grained soils.

Similar approach can be used to interpret DMT in unsaturated soils. DMT data interpretation begins by determining three intermediate parameters: material index (I_D – Eq. 3), horizontal stress index (K_D – Eq. 4), and dilatometer modulus (E_D – Eq. 5).

$$I_D = (p_1 - p_0)/(p_0 - u_0) \tag{3}$$

$$K_D = (p_0 - u_0)/\sigma'_v \tag{4}$$

$$E_D = 34.7(p_1 - p_0) \tag{5}$$

where p_0 is the corrected first reading, p_1 is the corrected second reading, and u_0 represents the pre-insertion in-situ equilibrium pore pressure.

Lutenegger (1988) reported little change in the I_D profile and a decrease in the K_D and E_D profiles with a reduction in soil suction. So, since the soil suction influences DMT interpretation, it should be incorporated into K_D and E_D values. Soil suction can be incorporated in the $\sigma_v{'}$ to calculate the K_D value. However, effective stress is not included in Equation 5. In this way, Equation 6 (Janbu 1963) was used to incorporate soil suction into the E_D value.

$$E_D = K_E p_a \left(\frac{\sigma_v{'}}{p_a}\right)^n \tag{6}$$

where n is a stress exponent (0.5 for coarse-grained soils), K_E is the modulus number and p_a is the reference pressure assumed equal to 100 kPa.

Two steps were used to determine the measured E_D values without and with considering the soils suction:

- K_E was calculated by Equation 6 considering the soil suction value in the $\sigma_v{'}$ by Equation 1.
- The normalized E_D value was calculated by Equation 6 considering K_E previously defined and, assigning soil suction equal to zero to calculate $\sigma_v{'}$.

Such approaches allow soil suction to be incorporated into the interpretation of CPT and DMT data. Suction can be incorporated in $\sigma_v{'}$ by using χ and soil suction based on the water content profiles and soil-water retention curves (SWRC). That was used by Giacheti *et al.* (2019) and Rocha *et al.* (2021) and provided a better CPT and DMT data interpretation for unsaturated soils.

3 STUDY SITES

3.1 *Unesp and USP research sites*

The Unesp research site are in the city of Bauru, state of São Paulo. The soil at the site is an unsaturated red clayey fine sand with high porosity. It is classified as a soil from SM Group in the Unified Soil Classification System (USCS). The top 13 m is a colluvium soil overlaying a residual soil derived from the weathering of sandstone. The colluvium soil has lateritic soil behavior (LA'). The groundwater level was not found up to 30 m deep.

The USP research site are also located on the central part of São Paulo state in the São Carlos city, which are around 150 km apart from Unesp - Bauru research site. The site profile is a saprolitic sandstone residual soil layer covered by a lateritic clayey sand (LA') layer (6 m thick colluvial soil - Cenozoic sediment) (Machado and Vilar 1998). A 0.2 to 0.5 m thick layer of pebbles separates the Cenozoic Sediment layer from the residual soil. Both layers are classified as a soil from SC Group by USCS. The groundwater level varies seasonally between 9 and 12 m below the ground surface. Table 1 shows typical values for the grain size distribution, void ratio (e), dry unit weight (γ_d), unit weight of solids (γ_s) and consistency limits (w_{LL} and w_{LP}) for both sites.

Table 1. Physical indexes, grain size distribution and USCS classification for the soils from each site.

	Unesp	USP
e	0.65 – 0.81	0.60 – 1.05
γ_d (kN/m³)	14.8 – 16.5	12.5 – 16.6
γ_s (kN/m³)	26.5 – 26.9	27.1 – 27.5
Sand (%)	78 – 83	60 – 69
Silt (%)	4 – 8	5 – 14
Clay (%)	12 – 17	17 – 28
w_{LL} (%)	17 – 23	39 – 45
w_{LP} (%)	non-plastic	19 – 25
USCS	SM	SC

3.1.1 *Previously performed laboratory tests*

Drying soil-water retention curves (SWRCs), oedometer and triaxial tests were carried out on undisturbed soil samples collected from each site. Samples were collected at 1, 3 and 5 m depth for Unesp, and 2, 5 and 8 m depth for USP. The laboratory test campaigns were carried out to study the influence of soil suction on soil strength and stiffness parameters. The main purpose of the laboratory investigation was to assess the influence of suction on the soil behavior.

The SWRCs were obtained using the suction-plate, pressure-chamber, and filter-paper. The results for the tested samples were adjusted according to the van Genuchten (1980) equation. Triaxial compression and oedometer tests were performed on saturated and non-saturated samples. Controlled suction tests were carried out by imposing the desired suction according to axial translation technique (Hilf 1956). Figure 1 and 2 presents the SWRCs for Unesp and USP sites, respectively. The suction effects in the cohesion intercept (c) and preconsolidation stress (σ'_p) are presented in Table 2 for Unesp site and in Table 3 for USP site. The air entry value is very low for the soils from both sites as can be seen in the SWRCS. They are typical sandy soils curves in that most of the water is extracted by a small change in soil suction. The interpretation of soil suction influence on pre-consolidation and cohesion intercept combined with SWRC allows to define two regions in SWRCs for Unesp (Figure 1) and for USP sites (Figure 2).
Figure 1. Soil-water retention curves for the soil samples collected at 1.0, 3.0 and 5.0 m depths for Unesp site (adapted from Fernandes *et al*. 2017).
Figure 2. Soil-water retention curves for the soil samples collected at 2.0, 5.0 and 8.0 m depths for USP site (adapted from Machado 1998).

For the Unesp site, water content values higher than 6 to 7% (Region A) the cohesion intercept and preconsolidation stress values were slightly affected. However, the opposite occurs for water content lower than 6 to 7% (Region B). It is noted that in this region of the curves, a slight variation in water content can substantially affect soil suction.

Table 2. Cohesion (c) and preconsolidation stress (σ_p) for different depths and soil suctions for Unesp site (adapted from Fernandes *et al*. 2017).

Suction (kPa)	c (kPa)			σ_p (kPa)		
	1 m	3 m	5 m	1 m	3 m	5 m
0	0	1.2	5.3	30	36	69
50	3	6.5	10.3	77	135	176
100	-	-	-	108	163	205
200	11	13.4	24.2	140	200	221
400	16	21.5	28.3	176	221	229

Similar behavior can be observed for USP site. c and σ_p values are slightly influenced by soil suction for water content higher than 15 to 16%, i.e., Region A of SWRCs (Figure 2). In Region B, both c and σ_p vary markedly with suction, for water content values below 15 to 16% (Figure 2). In this region a slight variation in water content substantially modifies soil suction.

Table 3. Cohesion intercept and preconsolidation stress for different depths and soil suctions for USP site (adapted from Machado 1998).

Suction (kPa)	Cohesion intercept (kPa)			Preconsolidation stress (kPa)		
	2m	5m	8m	2m	5m	8m
0	0	10.5	26.9	41	122	171
40	14.9	26.7	44.6	-	-	-
50	-	-	-	150	181	291
80	21.1	29.6	57.6	-	-	-
100	-	-	-	189	207	310
120	23.1	36.1	51.9	-	-	-
160	30.1	43.9	53.4	-	-	-
300	-	-	-	316	331	351
400	-	-	-	430	-	461

3.1.2 *Previously performed in-situ tests*

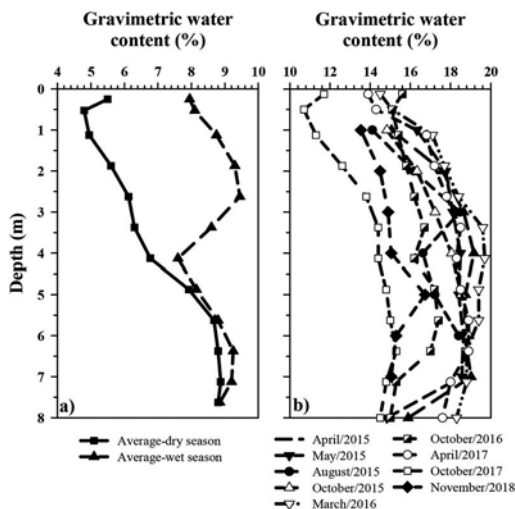
CPTs and DMTs were previously performed in both sites to study the effect of the unsaturated condition on the interpretation of these tests. Water content profiles (Figure 3) and soil water retention curves (Figure 1 and Figure 2) were employed to evaluate such effects.

Figure 3a presents the average water content profiles obtained for the wet and the dry seasons at the Unesp site, while Figure 3b shows moisture content profiles measured between 2014 and 2017 for the USP site. It can be seen in Figure 3a (Unesp site) that there is a significant variation in water content up to 4 m depth, where the soil interacts with the atmosphere, and decreases with increasing depth. The water content in the soil down to 4 m depth is lower than 7% in the dry season and vary from 7% to 10% in the wet season. It can be observed in Figure 3b (USP site) that March/2016 was the period with higher water content and October/2017 was the lowest at the end of the dry season.

It is important to point out that there are trees in both sites. The extraction of water via the roots of the trees during the dry season brought the degree of saturation to approximately 30-40% and, consequently, high values of soil suction (Lehane *et al.* 2004; Giacheti *et al.* 2019; Rocha *et al.* 2021).

Giacheti *et al.* (2019) presented and discussed CPT data to illustrate the seasonal variability for the Unesp site. Soil suction significantly influenced CPT data up to a depth of 4 m at the Unesp site. Rocha *et al.* (2021) presented and discussed the influence of soil suction on DMTs carried out at the USP site. Both papers incorporated soil suction into σ_v' by using χ and soil suction (Eq. 1), as estimated from the degree of saturation and SWRCs, respectively, for better interpretation of CPT and DMT data.

3.2 *CPT, DMT and soil sampling*

Two campaigns were performed in 2019 at the Unesp site, one in the wet season (April) and one in the dry season (September). Two CPTs, two DMTs and one soil sampling were carried out for each campaign. Two in situ testing campaigns were also carried out at the USP site (March/2016 and October/2017). Three CPTs


and one soil sampling were conducted for each campaign. A multi-function penetrometer (150 kN thrust capacity) was used to perform the in situ tests. Soil sampling was carried out from ground surface up to 8.0 m depth by using a helical auger to collect samples every 0.75 m to determine the water content profile.

3.3 *CPT and DMT at the Unesp site*

Figure 4 and Figure 5 presents the difference between CPTs and DMTs carried out under different water content conditions in terms of average q_c and f_s (Figure 4) and average I_D, K_D and E_D (Figure 5). The data show the soil influence on CPT and DMT up to approximately 5 m depth in the, mainly on the q_c, K_D and E_D. Such behavior can be explained from SWRCs (Figure 1). The water content values determined in April/2019 are greater than 6% and tend to be in Region A in the SWRCs (Figure 1), while the water content values determined in September/2019 are lower than 6% and tend to be in Region B of the SWRCs (Figure 1). In Region A of the curve, water content varies greatly with slight variation in suction, and the opposite trend occurs in Region B, where suction values vary significantly with little variation in water content.

Soil suction was incorporated in σ_v' by Equation 1 to improve CPT and DMT interpretation. The estimated soil suction was defined from water content profiles (Figure 4a and Figure 5a) and the SWRCs (Figure 1). It was found that soil suction values can be higher than 1 MPa up to 5 m depth in the September/2019 campaign. Khalili & Khabbaz (1998) highlighted that soil suction varies from 0 to 600 kPa for most practical applications in geotechnical engineering. An average suction value equal to 300 kPa was used in this analysis. χ was assumed to vary linearly with the degree of saturation (S_r) for the Unesp site (Robertson *et al.* 2017; Giacheti *et al.* 2019; Rocha *et al.* 2021). Table 4 presents the average χ parameter for each test campaign and the assumed soil suction value obtained from Figure 1 and Table 1.

Figure 3. Water content profiles for (a) Unesp and (b) USP sites (adapted from Rocha *et al.* 2021; Giacheti *et al.* 2019).

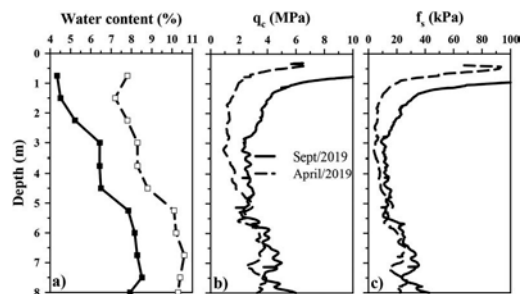


Figure 4. Average q_c, f_s and water content profiles from each test campaign for the Unesp site.

Table 4. Assumed values for χ and soil suction for each test campaign - The Unesp site.

|	χ	Soil suction (kPa)
April 2019	0.38	8
Sept/2019	0.25	300

Figure 5. Average I_D, K_D, E_D and water content profiles from each test campaign for the Unesp site.

Figure 6 and Figure 7 showing, respectively, the profiles of Q_{tn} and of K_D and E_D were elaborated without considering the soil suction influence, following *item 2* presented earlier in this paper. The stress exponent (*n*) was assumed equal to 0.70 for both saturated and unsaturated conditions to determine Q_{tn} for the Unesp site. When the suction values from each test campaign were incorporated into the effective stresses, the average profiles of Q_{tn}, K_D and E_D were similar and equivalent to the profiles without soil suction.

3.4 *CPT at the USP site*

Figure 8 shows the water content profiles and average q_c and f_s determined for March/2016 and October/2017 campaigns. It is interesting to note in this figure that the variation in soil suction was significant up to approximately 6 m depth.

These differences can be explained by the SWRCs and water content profiles (Figure 2 and Figure 8a). CPTs carried out in March/2016 tend to be in Region A, and October/2017 CPTs in Region B. The estimated soil suction values are lower for March/2016 (water content values higher than

Figure 7. (a) K_D and (b) E_D, considering soil suction influence on σ'_v for the Unesp site.

15.6% - Region A) and higher for October/2017 (water content values lower than 15.3% - Region B).

The CPT interpretation starts from normalized cone resistance (Q_{tn}) calculation by Equation 2. The soil suction was incorporated into σ_v' following Equation 1. Table 5 presents the average χ parameter for both campaigns and the assumed soil suction value determined by Figure 2 and Table 1. The stress exponent (*n*) was assumed equal to 0.97 to calculate Q_{tn} for both saturated and unsaturated conditions. All Q_{tn} profiles from each campaign are similar (Figure 9) when the soil suction is included in effective stresses (Eq. 1 and Table 5).

Table 5. Assumed values for χ and soil suction for each test campaign - The USP site.

	χ	Soil suction (kPa)
March/2016	0.65	10
October/2017	0.42	150

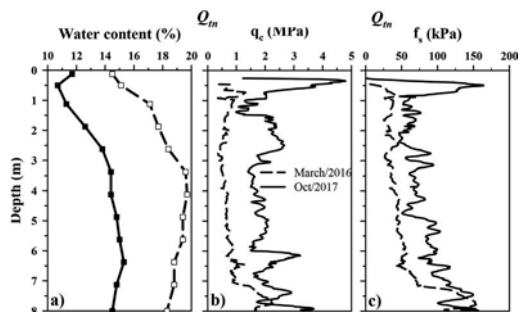

Figure 8. Water content and average CPT profiles from each campaign for the USP site.
Figure 9. Average Q_{tn} profiles incorporating soil suction for the USP site.

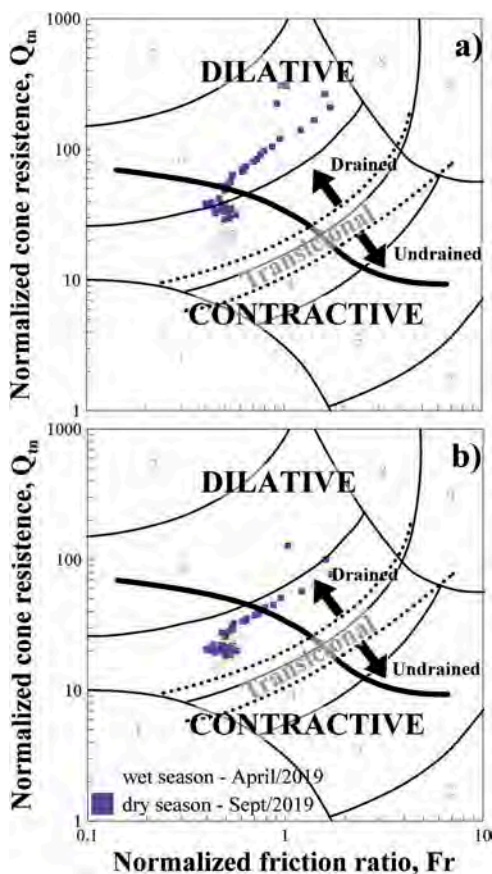

Figure 10. Average CPT data from both wet and dry seasons plotted on the Robertson (2009) classification chart (a) without and (b) with consideration of soil suction into σ_v'.

4 CPT CLASSIFICATION AND SOIL SUCTION

The influence of suction on CPT classification was evaluated for the Unesp site. Figure 10 presents the average CPT data to the depth of 5 m (active zone) plotted on the CPT classification chart (Robertson 2009) with and without incorporating soil suction into σ_v'. It can be seen in this figure that all CPT data are plotted in the drained penetration zone, which is an appropriate classification for this soil type in unsaturated condition (Yang & Russell 2016).

It can be seen in Figure 10a that when soil suction is not included in σ_v', the soil is classified predominantly as sands (zone 6) during the dry season (high suction) and as sand mixtures (zone 5) during the wet season (low suction). Figure 10a also indicates that the soil is more contractive during the wet season, while it is more dilative during the dry season. When a suction value equal to 300 kPa was incorporated into σ_v', the soil behaves in the same way as during the wet season (low suction), i.e., contractive sand mixtures (Figure 10b). This agrees with the dispersant-free particle size distribution curve (Table 1), as well as the change in soil volume during shear (Fernandes *et al.* 2017).

5 CONCLUSIONS

The data presented show the influence of seasonal variation in water content and soil suction profiles and how they influence soil behavior CPT and DMT data are significantly influenced by soil suction. In general, the effects of suction are more pronounced for lower soil densities and confining stresses. It was observed that soil suction significantly influenced CPT data up to a depth of 6 m at the USP site and up to 5 m depth for the Unesp site The same behavior was also observed for the DMT for the Unesp site.

The effective stress approach allows soil suction to be considered into CPT and DMT data interpretation. The influence can be incorporated in σ_v' by using χ and soil suction based on the water content profiles and SWRC. Such approach provides a better CPT and DMT interpretation for unsaturated soils.

ABSTRACT: Field penetration tests are widely used in geotechnical engineering for site investigation. The most common in-situ penetration tests are: the Standard Penetration Test (SPT), the Cone Penetration Test (CPT), and the Dynamic Probing (DP). Since there are limitations on their test methodologies and equipment, equations that can describe the relationship between their data are important in geotechnical engineering. This study presents a review of SPT-CPT and CPT-DP correlations for sandy soils, and discusses the uncertainties involved in some previously published correlations in literature. It is also recommended adjustments accounting for variations in soil properties input. Linear regression and residual analysis were carried out in several experimental data sets from different sandy soils and locations. The observed sandy soils' heterogeneity implies in the need of correlations obtained at a regional level. Thus, this study does not aim to exhaust the subject about in situ penetration tests correlations, but rather to recommend and stimulate the critical evaluation and use of previously published correlations and those that will be formulated in the future

1 INTRODUCTION

Site investigation is one of the most important aspects of the preliminary design or viability studies of the geotechnical structures' safety evaluation. Field penetration tests are widely used in geotechnical engineering for site investigation and prediction of bearing capacity and settlement for foundation design. The most common in-situ penetration tests are: the Standard Penetration Test (SPT), the Cone Penetration Test (CPT), and the Dynamic Probing (DP). Since there are limitations on their test methodologies and equipment, equations that can describe the relationship between their data are important in geotechnical engineering.

The Standard Penetration Test (SPT) is a simple and relatively low-cost test routinely used to subsoil investigation in a variety of ground conditions. SPT execution involve the driving of a sampler in the soil, by the repetitive hit of a standard hammer loose in free fall. The SPT test result is known as N-value (N_{SPT} or N_{60} when corrected to a hammer energy efficiency of 60% as recommended by the ISSMFE (1989). In addition to energy efficiency calculation, other corrections are recommended in the literature in order to reduce the spatial and depth variability of the N-Values (Sitharam & Samui 2007).

The Cone Penetration Test (CPT) obtains the soil tip resistance (q_c) and sleeve friction (f_s) by the pushing of a 60° conical tip with a 20mm/s velocity. Although the CPT does not recover samples in depth like the SPT, CPT data are near-continuous with theoretical background (Robertson 2009). In the piezocone test (CPTu) is also possible to obtain the pore pressure in depth and dissipation tests can be performed do obtain the permeability in situ of materials.

The Dynamic Probing test (DP) determines indirectly the soil resistance by the blow count necessary to prospect the equipment. Therefore, the execution of DP test is similar to the SPT test, in which a hammer is loose in free fall and the blows are counted during the prospection. The DP is usually used as a complementary test to the SPT test, in verification of compacted fills. The blow count can be transformed to a tip resistance (q_d) using the Dutch Formula, which considers the Law of conservation of energy: the soil resistance must be proportional to the initial potential energy, before the free falling. The ISSMFE (1989) recognizes four types of DP equipment, which differs in the hammer mass, drop height, stem and tip characteristics. Thus, there are the Dynamic Probing Light (DPL), the Dynamic Probing Medium (DPM), the Dynamic Probing Heavy (DPH) and the Dynamic Probing Super Heavy (DPSH).

Empirical correlations between CPT and SPT results commonly relate the ratio of the CPT tip resistance (qc, qt) and SPT blow count N_{60}, to

particle/grain size information (mean particle size D_{50} or fines content) (Robertson 1990, Santos & Bicalho 2017), soil behavior (Jefferies & Davies 1993, Mayne 2006), or a constant value for certain soil types (Robertson 1990).

This paper investigates correlations between the SPT-CPT and DP-CPT results obtained in Brazilian sandy soils. These correlations allow the evaluation and expansion of data, minimizing complementary campaigns which could be onerous and long standing. Thus, correlations of this type are useful in civil and geotechnical engineering and were studied by many researchers, as Schmertmann (1970), Martins & Miranda (2003) and Souza *et al.* (2012). Nonetheless, as correlations are empirical it is important to highlight some of their limitations: they are applicable only in similar conditions in which they were elaborated, as test standard and soil type; and statistical treatment must be consistent. In this paper, empirical correlations were obtained using linear regression with the verification of the residue's normality. In SPT-CPT correlation the influence of variation of relative density (DR) and depth were also investigated.

2 MATERIALS AND METHODS

SPT-CPT and CPT-DP results empirical correlations were obtained for sandy soils in the metropolitan region of Grande Vitória (GV-ES), located in the state of Espírito Santo (ES), Brazil. The region is geologically characterized by a sedimentary formation attributed to the action of transgression and regression of the sea level during the Quaternary Period. Therefore, soils of the area are composed of marine heterogeneous sediments, with variable relative density. (Castello & Polido 1988, Souza *et al.* 2005).

Tests were driven in shallow subsoil stratum, with depth up to 6m in the saturated zone. The soil was identified as clean quartz sands, presenting angular and sub-angular grain shape, with less than 5% of fines (< 0.074mm), mean particle size between 0.3 and 0.7mm, and relative density varying from loose to dense.

Correlations were developed applying linear regression in N_{60}, q_c and q_d data. SPT and CPT tests were carried out by Brazilian standard proceeding's: ABNT NBR 6484:2020 and ABNT NBR 12069:1991 (mechanical CPT were used). There is not a standard to the DP test in Brazil. So, it was used a modified DPL and DPSH recommended by ISSMFE (1989).

N_{SPT} were corrected to a 60% energy (N_{60}) considering a Brazilian SPT 75% efficiency as follows:

$$N_{60} = \frac{N_{SPT} \cdot 75}{60} = 1,25 \cdot N_{SPT} \qquad (1)$$

The influence of depth was also investigated in SPT-CPT correlations, as soils in greater depth are more confined and may affect the blown count. This correction transforms N_{60} in to $(N_{60})_1$, in which the effective stress is corrected to 1 atm by:

$$(N_{60})_1 = C_N \cdot N_{60} \qquad (2)$$

where C_N is the correction coefficient for the confinement, in this paper adopted equal to Liao & Whitman (1986) method, valid for normal consolidated sands and presented in Equation 3. It was considered a sand's bulk density of 20 kN/m³ and water table level at 1.5m.

$$C_N = \sqrt{100/\sigma'_V} \qquad (3)$$

The blow count obtained in DPL and DPSH tests were transformed to tip resistance (q_d) using the Dutch Formula presented in Equation 4, with M the hammer's mass, H the fall height, N the blow count obtained in DP test, A the tip probe area, s the penetrated length, g the gravity acceleration and M' the stems' mass.

$$q_d = \left(\frac{M \times g \times H \times N_s}{A \times s} \right) \left(\frac{M}{M + M'} \right) \qquad (4)$$

SPT-CPT data correlation was written as $q_c = K_c N_{60}$, while DP-CPT correlation was written $q_c = K_e q_d$ (i.e., $K_c = q_c/N_{60}$ and $K_e = q_c/q_d$. N_{60}' unit is given in blows/300mm while q_d and q_c are given in MPa).

To form q_c x N_{60} data pairs, q_c was taken between the depth of z + 150 and z + 450 mm, to be compared to the last 300mm which N_{SPT} represents. DP data were registered in situ for each 20 cm, while the CPT results were registered for every 25 cm. Thus, data pairs were taken considering the medium of results of a tested meter.

To verify if the correlations are consistent, with a normal distribution of the residue's as required in the Quadratic Leart Squares, graphical and hypothesis tests were carried out using the R software. Residues indicates data's natural variation, analytically defined in Equation 5:

$$r_i = y_i - \mu_i \qquad (5)$$

Where r_i is the ordinary residue, y_i is the observed data and μ_i is the estimated value in a regression.

To investigate the desired normal distribution of residues, a graphical approach using histogram was carried out. Results are satisfactory if the histogram is symmetrical as illustrated in Figure 1.
Figure 1. – Histogram example of data presenting normal distribution.

The hypothesis tests were carried out using the Kolmorogov-Smirnov test, which considers the following hypothesis:

- H_0: data follow a normal distribution
- H_1: data does not follow a normal distribution

Hypothesis H_0 can be validated if the test result (D_{KS}) is less than the critical value D'_{KS} given in Equation 6, for n number of observations. On contrary, if D_{KS} is higher than D'_{KS}, the normal distribution of residues can be rejected with 1α confidence. In this study, α was adopted equal a 0,05 (95% confidence, which means that the results are in the interval of 95 of 100 observations).

$$D'_{KS} = \frac{1.36}{\sqrt{n}} \qquad (6)$$

3 RESULTS AND DISCUSSION

3.1 *SPT-CPT data correlations*

Considering 34 data pairs of N_{60} and q_c obtained in GV-ES sands, the linear regression was determined and presented in Figure 2, the coefficient of determination value (R^2) was found to be 85%. The $K_c = 0.44$ for GV-ES sandy soils is in reasonable agreement with the coefficient values found by Folque (1976) where K_c varies from 0.4 to 0.45; Ajayi & Balogun (1988) where $K_c = 0.44$; Acka (2002) where $K_c = 0.47$; and Mayne (2006) where $K_c = 0.438$. However, note that Acka (2002) studied soils with strong cementation, characteristic not observed in GV-ES sands. The sand relative density influence could not be observed in the correlations between CPT and SPT results for the investigated sand in the tested site (Figure 2). Cubrinovski & Ishihara (1999) added the mean particle size D_{50} in their empirical correlation between N-value and sand relative

density values. D50 in this study ranges from 0.2 mm to 0.6 mm. K_c values tend to increase with the D_{50} (Santos & Bicalho 2017).
Figure 2. CPT–SPT data correlation and q_c x N_{60} dispersion graphic.

Figure 3 presents the graphical approach to verify the residues' distribution. Although the histogram is not perfectly symmetrical as required, D_{KS} was found to be 0.19, once to a sample size of 34 $D'_{KS} = 0.23$, $D_{KS} < D'_{KS}$ and the normal distribution of residues could be verified. This means that $K_c = 0.44$ can be classified as a strong coefficient with 95% confidence by the Kolmorogov-Smirnov test.

Figure 3. – Residues' histogram for q_c x N_{60} correlation.

Note that in Figure 2 N_{60} were classified by the relative density (DR) using the intervals from ABNT NBR 6484:2020, in which GV-ES sands were found varying from loose to very dense. Table 1 presents the variation of K_c in terms of DR values suggested by the Brazilian standards ABNT NBR 6484 (2020).

Souza *et al.* (2012) observed that K_c is higher in very loose sands and decreases in very dense sands. The tendency of decreasing K_c with the increasing DR

Table 1. Variation of K_c values in terms of DR values.

DR	N_{SPT} interval*	K_c
	Blows	Blows/300mm
Very loose	≤ 4	0.84
Loose	$5 - 8$	0.49
Medium	$9 - 18$	0.42
Dense	$19 - 40$	0.44
Very Dense	> 40	0.43

* ABNT NBR 6484 (2020).

Table 3. Variation of K_c with depth (m).

Depth	K_c (N_{60})	K_c $(N_{60})_1$
m	Blows/300mm	Blows/300mm
1.3	0.58	0.29
2.3	0.20	0.14
3.3	0.30	0.23
4.3	0.16	0.13
5.3	0.37	0.33
6.3	0.56	0.53

could not be observed in GV-ES sands, as K_c slightly varies from loose do very dense sands. It was worth to mention that $K_c = 0.84$ for very loose sands was found in a sample of 4 data pairs, and the coefficient must be used with caution, once the sample size is small.

Table 2 shows the result of the nonparametric Kolmorogov-Smirnov hypothesis test for each DR interval investigated herein. As $D_{KS} < D'_{KS}$ in all cases, all coefficients shown in Table 1 can be classified as strong with 95% confidence. Exception is for dense soils, where D_{KS} is higher than D'_{KS} and a normal distribution of residues can be rejected with a 95% confidence. For very dense soil, D_{KS} is very close to D'_{KS} and the normal distribution of residues can be classified as questionable. Thus, specially in this two cases, the indicated K_c in Table 1 should be used with wariness.

Table 2. K_c x DR – Residue's analysis.

DR	D_{KS}	D'_{KS}
Very loose	0.25	0.68
Loose	0.22	0.61
Medium	0.13	0.35
Dense	0.97	0.45
Very Dense	0.75	0.78

Table 3 shows results of K_c for each tested meter. In both data treatments (N_{60} and $(N_{60})_1$) it was not possible to confirm a clear tendency of decreasing or increasing K_c with depth. For this purpose, authors suggest that depths greater than 6.3 m must be investigated.

Worth to mention that Schmertmann (1970) and Sanglerat (1972) suggest that the SPT-CPT correlation should be independent of depth. Naime & Fiori (2002) suggest that the independence with depth is valid only in young soils, but K_c decreases with depth in mature soils.

3.2 DP-CPT data correlations

For correlations between 66 data pairs of q_c and q_d, obtained using CPT and DP tests, respectively, the coefficient $K_e = q_c/q_d$ was found to be 2.34 (R^2 = 93%). Dispersion graph and histogram are presented in Figure 4 and 5 bellow, in which normality could not be verified:

Figure 4. – Dispersion graph for q_c x q_d correlation.

Figure 5. – Residues' histogram for q_c x q_d correlation.

The Kolmorogov-Smirnov hypothesis test returned a D_{KS} of 0.18. For a 66 sample size, D'_{KS} is 0.17. As $D_{KS} \approx D'_{KS}$ and the normality of residues is questionable. Therefore, the correlation must be used with caution.

Gadeikis *et al.* (2010) recommend a K_e between 1.3 to 2.25 using the DPSH, while Czado & Pietras (2012) found this coefficient between 0.5 to 2.3 using the DPH. Thus, although there is a doubt in the consistency of GV-ES found K_e, its value is similar to those observed in the published literature on this topic.

Waschkowski (1983) suggests that $K_e = 1.0$ ($q_d = q_c$), which was not verified in this study. Similar results were reported by Viana da Fonseca (1996), and the equivalency must be valid only in homogeneous soils, which is not the case of GV-ES sands.

On the other hand, the researchers believe that the blow counts from the DP tests should be corrected to an international reference like is done in SPT, as some energy losses can occur during the test, like in friction, sonorous and thermic energy. This correction should be made before applying the Dutch Formula, as it considers the potential energy before the free fall of the hammer. In this way, the effect of different types of DP and standards would be minimized in the DP results.

4 CONCLUSIONS

This paper presented SPT-CPT and CPT-DP correlations for sandy soils located in the region of Grande Vitória – ES, composed of marine heterogeneous sediments, with variable relative density values.

SPT-CPT correlations were in form of $K_c = q_c/N_{60}$. The GV-ES K_c was found to be 0.44. This value is similar to those found in literature (Folque (1976), Ajayi & Balogum (1988), Mayne (2006)). The linear regression was validated once the residues could be classified in a normal distribution.

It was not possible to find a clear tendency of variation of K_c with relative density as suggested in Souza *et al.* (2012), as well as it was found that K_c does not have a clear dependency with depth variation. This last observation is also found in Schmertmann (1970) and Sanglerat (1972).

CPT-DP results correlation was presented in form of $K_e = q_c/q_d$. The value of K_e around 2.34 was observed for the investigated sands from GV-ES. Although this value is similar to those found in literature (Gadeikis *et al.* 2010, Czado & Pietras 2012), by means of the histogram and Kolmorogov-Smirnov hypothesis test the normal distribution of residues are questionable, and the correlation must be used with caution.

Waschkowski's (1983) suggests that $K_e = 1.0$, but it was not verified to GV-ES sands. It can be observed that supposedly $K_e = 1.0$ is valid only in homogeneous soils. And, it may be recommended that the blow count from the DP data be corrected to an international reference value as applied to the SPT data. This correction must adjust the blow counts considering that are many sources of energy loss during the fall of the hammer, as losses by friction, sound, and thermic energy.

The correlations presented in this study are valid for sandy soils located in the region of Grande Vitória-ES, Southwest Brazil. It is important to recognize that empirical correlations are limited for the soil type, tests conditions and data treatment. It is always recommended a critical evaluation of previously published correlations.

Correlation between SPT and CPT tests in liquefiable deposits

Rashid Shahgholian, Cristiana Ferreira & António Viana da Fonseca
CONSTRUCT-GEO, Faculty of Engineering of University of Porto, Porto, Portugal

ABSTRACT: Cone penetration test (CPT) started being used for soil investigation almost four decades after the standard penetration test (SPT). Despite their differences, both tests estimate the resistance of the soil against penetration of a probe. Although it is expected that the results of these tests are comparable and directly correlated, different driving mechanisms (static versus dynamic), sensitivity, type and frequency of measured parameters, operational errors, among others, compromise such correlations. In addition, the diverse nature of soils in terms of grain size, packing and fabric, shear strength, permeability, and other soil characteristics also limit the derivation of a unique correlation between CPT and SPT. Many authors have studied these in situ tests, recognizing that such correlation would be valuable, as it would enable the use of design methods and other libraries of correlations available for each individual test. A variety of formulas and charts has been proposed in the literature to describe this relationship, which demonstrates that this is a complex, not a global and simply predictable correlation. In this research, some of the most usual CPT-SPT relations are evaluated for a large dataset of field measurements from a pilot site on liquefiable soils, near Lisbon in Portugal. The extensive analysis of these data showed that the application of previously established, tested, and published correlations, available in the literature for specific sites, requires great care. One of the requirements is the verification of applicability, by comparison between the type of soils under study and those in the literature. Specific correlations for each geological condition must be defined before making engineering estimations based on correlated parameters.

1 INTRODUCTION

Comparison between the results of different geotechnical tests in a site is essential for a correct estimate of the geotechnical parameters of the soil profile. The Standard Penetration Test (SPT) and the Cone Penetration Test (CPT) are two of the most common site characterization techniques, which have advantages and weaknesses over each other. Besides, the literature shows that these tests have different libraries of formulas and relations behind. Correlation of these two tests has a history over seventy years and extensive research indicates there is not a unique relation between them, which may result from the fact that these penetration tests are differently influenced by various factors, including geological conditions, available machinery and tools, operator skills, etc. The application of the empirical equations and charts available in the literature needs to be performed with great care; a certain level of similarity should be assured between the site and the region from which the empirical correlations were developed.

2 METHODOLOGY

Recent investigations on the assessment of liquefaction hazard around Lisbon, in Portugal, were combined with previous geotechnical studies, namely for the construction of a motorway at the same region, providing a valuable geotechnical data bank. The site is located in the Greater Lisbon region, in the municipalities of Vila Franca de Xira and Benavente, on the left bank of the river Tagus. Boreholes with SPT adjacent to CPT tests were carried out along 9 km of the motorway alignment as shown in Figure 1. More details are available in Ferreira et al. (2020).

In order to correlate the SPT and CPT results, the closest (in plan) CPT point to each SPT borehole was selected, defining a SPT-CPT pair (Figure 1). As a result, techniques such as the inverse distance weighted average method (Zhao & Cai, 2015) is not used. In the present case of a heterogeneous environment, such as recent sedimentary deposits, condensing the CPT records to define the soil profile can be particularly challenging.

In fact, the choice of the size of the averaging window and its adjustment in terms of the most appropriate depth leads to considerable variation in the results. Even relying on just "averaging" may have negative influence over correlation because it neglects the fact that CPT records are influenced by the stiff layers in front of the tip, even before its penetration. As Figure 2 schematically shows, tip resistance and sleeve resistance at the same recording of the CPT correspond to adjacent (not identical)
Figure 1. Selected SPT and CPT locations for this study.

depths. On the other hand, the influence of transition zones is considered to be the same for both the CPT and SPT tests. In addition, most researchers believe that the presence of interbedded thin layers will decrease the correlation of the N values and q_c (after Zhao & Cai, 2015).

Figure 2. Mismatch of the measuring zone of SPT, with tip resistance and sleeve resistance of CPT.

In this research, CPT values (q_c and f_s) are averaged over the same 30 cm interval of each SPT record, following Jefferies & Davies (1993). Although CPT probe senses ahead of its tip, it is not a clear mechanism to be involved in calculation of equivalent CPT exactly over the same 30 cm depth of the SPT.

To eliminate the influence of non-equal end effects, qt is used instead of qc in this study (Campanella et al., 1982).

SPT test results, N_{SPT}, are assumed to correspond to N_{60}, since the energy ratio measured in Portuguese SPT testing campaigns is typically 60%. The corrections to the SPT records including rod length, borehole diameter and effective overburden stress have been applied to the measured SPT values, for obtaining the normalized SPT values, $(N_1)_{60}$.

A total of 285 SPT-CPT pairs of data have been compiled out of the 21 boreholes and their adjacent CPT profiles. The maximum measurement depth reaches 26.5 meters, while the majority of the measurements correspond to depths lower than 21 meters.

The tested soils have been classified according to the soil behavior type index (SBT) (Robertson & Wride, 1998); while samples mainly classified as "clay", nothing belongs to the "gravel". The classes suggested by Cubrinovski et al., (2019) are adopted in this research. Unified soil classifications, based on laboratory grading tests are only available for two boreholes (named SI1 and SI7).

In this paper, some of the correlations between CPT and SPT tests available in the literature are presented and discussed (Table 1). Selected SPT-CPT correlations were applied to the existing database to evaluate their performance. Finally, the overall trend of the available data bank is presented and discussed.

3 BACKGROUND ON SPT-CPT CORRELATIONS

3.1 Ratio methods

Shahri et al. (2014) cited forty formulas that were developed between 1959 and 2003. Similar set of formulas is cited by Zhao & Cai (2015). The appearance of these formulas is either n = q_c/N or n = (q_c+f_s)/N, which do not differ considerably since sleeve friction (f_s) rarely reaches more than 10% of the tip resistance (q_c). Depending on the soil type, it is shown that usually 0.1<n<1 MPa, although higher values have also been reported or shown in the literature. By normalizing q_c with atmospheric pressure)P_a=101 kPa(, the dimensionless domain of n would be 1<n<10.

Schmertmann (1978) believed that n=4 is generally acceptable for most soils; sensitive clays are an exception, because SPT in sensitive clays approaches to zero and n increases significantly. The range of n is also approved by many recent researches, namely Akca

(2003), Shahri et al. (2014), Jarushi et al. (2015) and Aral & Gunes (2017) among others. Akca (2003) reported occasionally very high n-values in his research that may be caused by specific (and less frequent) soil conditions, such as cementation, higher density layers, shell fragments, gravels, and other heterogeneities.

Recent research confirms the domain of variation of n but there is considerable scatter in the measurements (Aral & Gunes, 2017). Asci et al. (2015) also reported a trend of n for SPT values below 13, but as SPT values increase, the trend completely differs.

Besides the ratio method, Zhao & Cai (2015) proposed two other correlation categories between SPT and CPT measurements: "function methods" which are more advanced expressions considering more than just the ratio, usually based on statistical analyses but ignoring soil properties; and, "soil parameter methods" which directly address these properties in the correlations.

3.2 Function methods

Referring to the investigation by Jefferies & Davies (1993), SPT is related to the tip resistance and soil behavior type index (I_C). Equations 1 and 2 show the expressions for I_C according to Robertson & Wride (1998) and Jefferies & Davies (1993), respectively.

$$I_c = \sqrt{[3.47 - log(Q_n)]^2 + [1.22 + log(F_r)]^2} \quad (1)$$

$$I_c = \sqrt{[3 - log(Q \times (1 - B_q))]^2 + [1.5 + 1.3 \times log(F_r)]^2} \quad (2)$$

In these equations, Q and Q_n are normalized tip resistance. F_r is normalized friction resistance and B_q is pore pressure ratio in CPT test.

The correlation proposed by Jefferies & Davies (1993) is shown in Equation 3. Lunne et al. (1997) proposed a small modification to the same formula (Eq. 4).

$$N_{60} = \frac{q_c \ (MPa)}{0.85 \times \left(1 - \frac{I_c}{4.75}\right)} \quad (3)$$

$$N_{60} = \frac{\left(\frac{q_c}{p_a}\right)}{8.5 \times \left(1 - \frac{I_c}{4.6}\right)} \quad (4)$$

Robertson (2012) found that the above listed equations under-predict N_{60} in some clays. He proposed the modified formula as in Equation 5. Shahien & Albatal (2014) found these equations do not fit their data bank so they developed Equation 6 for silty sand deposits in Nile Delta.

$$\frac{\left(\frac{q_c}{P_a}\right)}{N_{60}} = 10^{(1.1268 - 0.2817 \times I_c)} \quad (5)$$

$$\frac{\left(\frac{q_c}{P_a}\right)}{N_{60}} = \frac{0.26 \times e^{8.22 \times \left(1 - \frac{I_c}{4.5}\right)}}{\left(\frac{q_c}{P_a}\right)^{0.65}} \quad (6)$$

Although all these formulas show the correct trend of the measurements, scatter of the real measurements is considerable. It demonstrates that other factors also play a relevant role in the correlation. One of those factors may be the difference between crushable and non-crushable grains (Ahmed et al., 2014). In natural deposits with different mixture of these components, the measurements would not easily obey a single formula. This shows the importance of geotechnical similarity between sites when using the literature correlations. To apply these properties in correlation equations, various attempts have already been made leading to the third group of correlations, based on geotechnical indexes.

3.3 Soil parameter methods

3.3.1 Grain size
Grain size distribution plays a significant role in both SPT and CPT test results. Robertson et al., (1983) presented a graph showing that $n = q_c/N$ increases as D_{50} increase. These kind of correlations are mathematically formulated, as in Equations 7-9 (Shahri et al., 2014). Other similar formulas are cited by Shahien & Albatal (2014) and Ahmed et al. (2014). Non-unique formulas for n as a function of D_{50} indicates that n is influenced by more than just D_{50}.

$$\frac{\left(\frac{q_c}{p_a}\right)}{N_{60}} = 7.735 \times (D_{50})^{0.28} \quad (7)$$

$$\frac{\left(\frac{q_c}{p_a}\right)}{N_{60}} = 6.53 \times (D_{50})^{0.26} \quad (8)$$

$$\frac{\left(\frac{q_c}{p_a}\right)}{N} = 5.44 \times (D_{50})^{0.26} \quad (9)$$

3.3.2 Fines content (FC)
In some cases, SPT and CPT results can be best correlated according to the fines content (Shahri et al. (2014) and Shahien & Albatal (2014)). Equations 10-12 are samples from the collection.

3.3.3 Correlation based on other parameters

Other correlations regarding D_r, V_s, both the D_{50} and I_c, etc., have been studied as well. Available data bank does not cover all the required parameters with sufficient number of data points so they are not covered in this text.

$$\frac{\left(\frac{q_c}{p_a}\right)}{N} = 4.25 - \frac{FC\ \%}{41.3} \tag{10}$$

$$\frac{\left(\frac{q_c}{p_a}\right)}{N_{55}} = 4.7 - 0.05 * FC\ \% \tag{11}$$

$$0 \leq N < 10 :$$

$$\frac{\left(\frac{q_c}{p_a}\right)}{N} = 0.0026 \times\ FC^2 - 0.263 \times FC + 12.34$$

$$10 \leq N < 30 : \tag{12}$$

$$\frac{\left(\frac{q_c}{p_a}\right)}{N} = 0.00085 \times\ FC^2 - 0.12 \times FC + 8.733$$

$$30 \leq N, FC \leq 20 :$$

$$\frac{\left(\frac{q_c}{p_a}\right)}{N} = 0.001 \times\ FC^2 - 0.059 \times FC + 5.59$$

4 RESULTS AND DISCUSSIONS ON THE PERFORMANCE OF SPT-CPT CORRELATIONS

4.1 Ratio of the CPT/SPT values

Figure 3 Shows the scatter plot of the arithmetic average over CPT records versus SPT values. The records of the borehole SPT S208 and its relevant CPT measurements, CPT2, appeared as outliers so these were ommited here. In order to organise the database and narrow down the correlation, Cubrinovski *et al.*, (2019) ranges over SBT were used as the boundaries of different groups of soil. Critical SBT boundaries from their point of view are: 1.3, 1.8, 2.1 and 2.6, also adopted by Ferreira et al. (2020).

Scatter of the measurements seems reasonable as coarse materials (low SBT values) have higher q_t and vice versa but the trend, even in each sub-group, is not so clear. Frequent measurements have fallen outside the proposed boundaries as well.
Figure 3. Relation between q_t and N_{60}.

4.2 Correlation between SPT and I_c (Soil behavior type index from CPT)

Figure 4 presents the scatter plot of measurements versus I_c. The distribution of the measurements do not follow even complicated relations as Equations 3-5.

4.3 Correlation between SPT and CPT based on D_{50} (grain size)

Grain size distribution is only available for boreholes SI1 and SI7. It refers to 48 cases out of 285 in this database. Figure 5 shows the measurements, which do not follow the trends proposed in the literature.
Figure 4. Scatter of the data using Equations 3-5.

4.4 Relation of SPT and CPT based on fines content

Based on the fines content (FC), different correlations of SPT and CPT tests are suggested in the literature. Figure 6 shows that the measurements from
Figure 5. Measured data and published curves in literature (mean grain size, D_{50}, obtained from sieve analysis).

this database do not follow the trend suggested by Kulhawy & Mayne (1990).

4.5 *The best-fit correlation between SPT and CPT for the current data bank*

The most suitable graphs to represent the correlation between CPT and SPT in this site are presented in Figure 7. In this figure, the clean sand equivalent of CPT records is used, which is normalized for the effective overburden pressure ($q_{1N,cs}$) (Boulanger & Idriss 2014). The figure shows $q_{1N,cs}/(N1)_{60}$ versus $(N1)_{60}$ for different groups of soils according to SBT index and Cubrinovski *et al.*, (2019) classification.
Figure 6. CPT-SPT ratio vs. laboratory fines content and comparison with a literature proposal.

The trends show a variance, which may be related to the mismatch of the CPT and SPT profiles, due to the occasional large distances between the CPT and SPT locations in plan. Variation of the soil properties including grain size distribution, relative density, fines content, variations in cementation etc., may also have some effect; however, parts of those effects are

implemented in the normalized parameters as $q_{1N,cs}$. An important aspect of these graphs is that none of the boreholes has been removed, even the ones that appeared as outliers in previous plots. Figure 7a shows the best fitted curve for sandy soils while silty soils (Figure 7b) show an acceptable trend as well. Figure 8 shows for any specific value of SPT, clean sand has the maximum value of $q_{1N,cs}/(N_1)_{60}$; as the fines content increases, this index decreases. Similar trends can be observed for different soil classes. It is clear that for finer non-liquefiable soils ($Ic>2.6$), the correlation scatter increases considerably. However, the number of available data points in some of the best-fitted groups is not very large; more populated data banks should be checked to show how general such trends are. Other soil classifications may lead to different trends.

In sum, based on the current data, this approach should only be applied to granular non-plastic soils.

5 CONCLUSIONS

Different scatter plots of the available SPT-CPT data set were prepared, and trends were compared with the most common correlations published in the literature. In most cases, the current data does not follow the published correlations. The characteristics of each site, which are embedded in its corresponding correlation equation, restrict its validity to the most similar sites. The existence of a wide range of different correlation proposals is demonstrative that a universal correlation cannot yet be formulated.

Even though the current data bank compiles results by different geotechnical companies over a large period of time (since 2004), the scatter in the graphs shown in Figure 7 evidence clear trends of the measurements, providing an adequate level of confidence in the available data.

Some of the difficulties of correlation between CPT and SPT profiles may be caused by the procedure adopted to condense CPT values over SPT depths. Non-negligible distances in plan between the CPT locations and the nearby SPT were found to have negative influence over the correlation.

All the samples from different boreholes generically follow the trend defined for the relevant soil class, which means that the proposed trends include all data points, since none has been considered as outlier. The trends in coarse granular materials are clearer than at higher I_C classes. However, since this research focused on the characterization of liquefiable deposits, the obtained trends are within the relevant range of applicability. The standard rule of thumb that granular soils show higher values of n ($=q_n/N$) is confirmed in the proposed correlations.

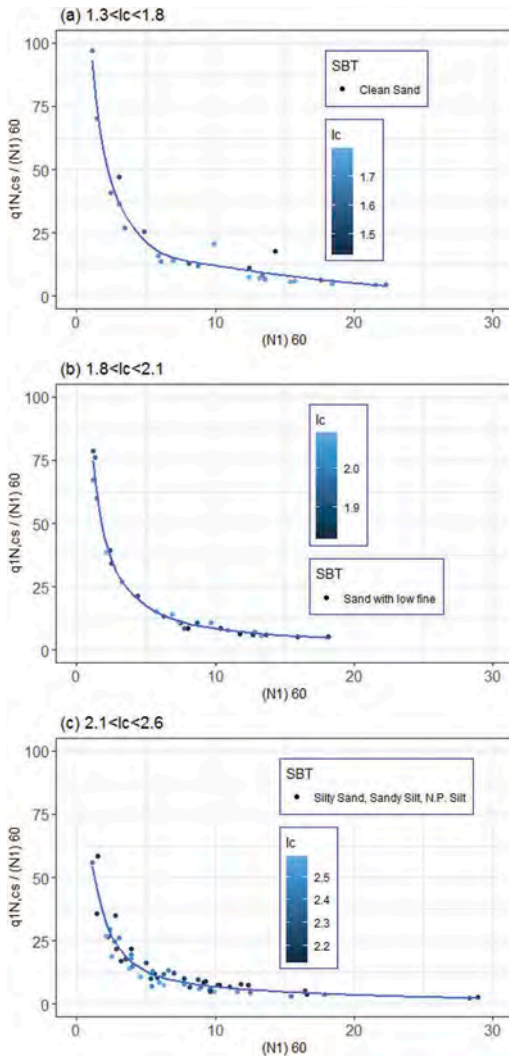
These correlation trends should be controlled with measurements in other liquefiable sites to assess whether these correspond to general relations or are just a result of the geological and geotechnical


Figure 7. SPT-CPT correlation for different classes of soil.

Figure 8. SPT-CPT correlation for different soil classes (in log scale).

characteristics of this specific site. However, based on this research, it can be concluded that this approach to the SPT-CPT correlation is applicable in granular non-plastic soils, such as liquefiable soil deposits.

ABSTRACT: The detection of thin clay layers (i.e. ≤ 20 cm) is challenging for all conventional geotechnical field investigations techniques, including high quality CPTU tests. During the last two years, a research program has been carried out in the geotechnical laboratory at NTNU in Trondheim. The work aims to identify possibilities and limitations in detecting thin clay layers and assess their properties using the CPTU tool. Tests were run in a pressurized chamber where thin horizontal clay layers of both pottery clay and natural, sensitive clay were embedded in a homogenous, medium dense sand. Both a standard piezocone (10 cm^2) and a mini-piezocone (5 cm^2) have been utilized. The results show to what degree the CPTU response in thin layers is influenced by the surrounding sand, and how this influence in practice may lead to serious overestimation of shear strength in thin layers. In addition, the effect of depth-offset of measurements in connection with soil type characterization was evaluated.

1 INTRODUCTION

Analyses of past landslides along the coast of Norway have shown that thin clay layers in sandy shoreline deposits often act as a sliding plane (L'Heureux et al. 2010). An example of a landslide that caused fatalities with these characteristics is the Finneidfjord landslide, which occurred in 1996 (Longva et al. 2003). The clay layers may be so thin (i.e. < 20 cm) that even high quality survey techniques, alike the CPTU, struggle to detect the layers.

This is the background of an ongoing research program at NTNU. A large-scale pressurized model testing facility has been set up and samples are built-in with clay layers of various thicknesses embedded in sand. CPTU-soundings are conducted on chamber samples with the aim of determining if thin layers can be properly identified, and to which degree it is possible to determine the properties of these layers. This article will mainly focus on the executed laboratory experiments and the most important results.

Similar research on the topic has been conducted by e.g. van der Linden et al. (2018) and de Lange

et al. (2018), with main focus on liquefaction potential and pile resistance.

2 METHODOLOGY

In the research program at NTNU, six experiments have so far been conducted (E1-E6). Each experiment consists of constructing a chamber sample, pressurizing it, performing soundings on the chamber sample followed up by excavation with supplementary laboratory testing of soil properties. Clay type, layer thicknesses and stress levels have been systematically varied during the experimental program. This chapter describes the methodology in general, for further details it is referred to MSc theses of Skrede (2021) and Hammer (2020).

Chamber samples were built into a testing chamber of about 1.5 meter height, using reinforced concrete cylinders (sewage manhole rings) with an internal diameter of 1.2 meter. In the base of the chamber an outlet was installed to allow for regulation of the water level. A pore pressure sensor was installed on the outlet.

The bottom 10 cm of the chamber was filled with gravel, covered by a filter cloth. This allowed for an evenly distributed in and outflow of water across the chamber cross-section during the building procedure, preventing interior channelling in the sand. Above the filter cloth a first sand layer of 10 cm was built in. Pressure cells of the Geokon 3500-3 model were placed on top, four horizontally and one vertically (Figure 1). The cells were calibrated by inserting them into a special designed casing and imposing air pressure within the casing. Unfortunately, the cells suffered from some sensitivity drift. This was dealt with by correcting the data linearly from start to end.

The sand used in the chamber came from Kvål, with a d_{50} of 0.492 mm; C_u of 4.24; and e_{min} and e_{max} of respectively 0.502 and 0.873. Two types of clays were used in the tests. The first clay was an industrially made kaolin pottery clay (K148 by Sibelco) delivered in bricks ($31 \times 11 \times 12 cm^3$). The second clay type was a natural sensitive clay extracted from 8 to 10,5 meters depth at Flotten, a Norwegian Geo-Test Site, sampled by using a mini-block sampler providing cylindrical samples with 16 cm diameter (Emdal, et al. 2016).

All the pottery clay bricks had almost identical properties. The very sensitive, quick clay extracted from Flotten, is well-documented based on-site investigations reported by L'Heureux et al. (2019). The key properties of the clays are presented in Table 1.

The procedure of constructing sand layers aimed at a homogeneous, medium densely packed sand (relative density $D_r \sim 40$-60%) in order to resemble a natural sand deposit. Details about the procedures are found in the MSc theses (Hammer, 2020; Skrede, 2021).

In all experiments except the last, pottery clay was utilized. From each brick of pottery clay a specimen was cut to a preferred dimension with a thread saw. Several specimens were then laid together side by side and carefully clamped to form a clay "unit". The purpose of uniting several specimens was to make the clay layer wide enough to act as if it was a continuous horizontal layer. It was still made with limited horizontal extension and did not cover the entire cross section of the chamber partly to save material, but primarily to allow water to flow vertically in the chamber during sample construction and testing.

In the last experiment (E6) mini-blocks (diameter of 16 cm) of natural sensitive clay from Flotten were utilized. Assemblance of units proved to be feasible also for the quick clay but required considerable precision and careful execution. Each clay layer was designed and placed so that the CPTU soundings would be close to the centre of the clay unit as illustrated in strength

*Rough, values based on range of results around 8-10 m depth.

Figure 2 (layer set-up for tests E1-3 and E5).

Two penetrometers were utilized, firstly a standard sized ($10 cm^2$) NOVA-probe from GeoTech AB with a measurement frequency of about 1Hz. Secondly a mini electrical probe ($5 cm^2$) with an approximate measurement frequency of 8Hz that was kindly made

Table 1. Properties of pottery clay and clay from Flotten.

| Parameter	Symbol	Pottery clay	Natural clay*	Unit
Water content	w	~24	~45	%
Liquid Limit	w_L	32.7	~28-33	%
Plastic limit	w_P	18.8	~20	%
Plasticity index	I_P	13.9	~8-13	%
Liquidity index	I_L	0.4	~2.4	-
Sensitivity	S_t	~2.5	50-350	-
Undrained shear	$s_{u,CAUC}$	27.5	~75	kPa

Figure 2. Cross-section of chamber with dimensions of both the clay set-up from experiment 1-3 and 5; and of the overlaying metal disc with its 10 soundings holes (1S, 2a-4c). Each of the 3 clay units shown here in grey are built from 4 specimens cut from bricks of pottery clay.

available from Geomil Equipment B.V. This probe was exclusively used in the last experiment (E6). The rate

of penetration was set to 15 mm/s for all experiments to increase the spatial resolution, thus providing more continuous curves, still operating in accordance with European standard (EN ISO 22476-1:2012).

Further details about the chamber sample set-ups, and about how the signal processing was done to increase precision are found in the master's thesis (Skrede, 2021).

To simulate stress states at larger depths, the surface of the chamber samples was subjected to an over-

burden load. The vertical stresses were imposed by a circular metal disc pushed down by three air-bellows fastened to an upper supporting metal framework, see Figure 3.

The chamber was designed with ten possible positions for CPTU testing. Three in-line holes were placed in 3 radial sectors 120 degrees apart, denoted sectors a, b, c. The centre hole is referred to as the S position. The holes were in addition numbered from the centre as 1,2,3 and 4. Thus position 1S is in centre while 4c is closest to the concrete wall in sector c. The reference system is shown in Figure 2. Multiple test positions were used for each chamber sample, these were divided into two rounds consisting of "primary soundings" and "secondary soundings". The primary soundings consisted of tests with significant distance to walls and previously tested positions. These were thus considered to reflect undisturbed soil. Secondary soundings were run after the primary soundings in neighbouring positions as reserve for validation, though the measurements reflect disturbed soil.

For each chamber sample, after CPTU testing, a meticulous excavation phase followed, where lab tests were conducted on both the clay and the sand to analyse the soil profile for density and strength.

3 THEORETICAL BACKGROUND

3.1 Stress state in chamber – The silo effect

The stress level in the chamber was influenced by the silo effect or the arching effect caused by vertical shear stresses on the wall. The formula by Janssen (1895) was used with effective stress parameters, Equation (1), to quantify the effect. The decay length, l', was estimated using the given surcharge, q; and the earth pressure cells at the base, to determine the stress $\sigma'_v(z)$ over the height of the chamber.

$$\overline{\sigma'_v(z)} = \gamma' l' + e^{-\frac{z}{l'}}(q - \gamma' l') \qquad (1)$$

3.2 CPTU-parametrizations

The conventional procedure to classify soils from CPTU results is to normalize the corrected tip resist-

ance, q_t, the sleeve friction, f_s, and the pore pressure, u_2 with respect to in-situ stress. This provides the normalized tip resistance, Q_t, the normalized friction ratio, F_r, and the pore pressure ratio, B_q; In Equations (2)-(4) q_n is the net cone resistance, see Equation (5).

$$Q_t = \frac{q_n}{\sigma'_{v,0}} \qquad (2)$$

$$F_r = \frac{f_s}{q_n} \cdot 100\% \qquad (3)$$

$$B_q = \frac{\Delta u_2}{q_n} \qquad (4)$$

$$q_n = q_t - \sigma_{v,0} \qquad (5)$$

Figure 3. The overburden loading framework on the chamber. Above: the actuator and the probe fixed to a framework.

To estimate the undrained shear strength, s_u, in the clay layers, the empirical relations suggested by Karlsrud et al. (2005) have been used, see Equations (6)-(8). The cone factors, N_i, in these formulas are based on OCR, S_t and I_P. These parameters were estimated for each specimen by using interpolated data from the Flotten site report (L'Heureux et al. 2019).

$$s_{u,kt} = \frac{q_n}{N_{kt}} \qquad (6)$$

Figure 4. Experiment 5. Left: CPTU-measurements. Mid: Shear strength estimations for the clay layers, note that $s_{u,\Delta u}$ is approximately zero for all layers. Right: Sand density samples results and estimated stress distributions.

$$s_{u,\Delta u} = \frac{\Delta u_2}{N_{\Delta u}} \qquad (7)$$

$$s_{u,ke} = \frac{q_t - u_2}{N_{ke}} \qquad (8)$$

4 RESULTS

4.1 *Soundings from experiment 5*

The results of experiment 5 (Figure 4) illustrates typical trends that unveiled upon penetrating clay layers interbedded in sand. The clay layer thicknesses were respectively 2, 4 and 8 cm from the top. The surcharge was set to 40 kPa for soundings in holes 2a and 2b, 80 kPa for 2c. These were the primary soundings, while secondary soundings were performed in the number 3 holes. The latter are not presented in this figure.

The u_2-measurements were depth-shifted to account for the distance between the position of the pore pressure sensor and the cone tip (the depth of q_t), while f_s was corrected to the end of the sleeve closest the tip, see ch. 5.2 for

explanation. The sample preparation was quite successful in experiment 5 with a fairly constant relative density, D_r, in the sand over the depth of the chamber. Comparing various tests, it is confirmed that q_t varies considerably with relative density and stress level.

4.2 *Normalized profiles*

To study the variation of q_t through layers of varying thicknesses, a compilation of q_t-profiles is shown in Figure 5. The depth has been normalized with respect to the cone diameter, d_c. The q_t-profiles in the graphs are indexed X-Y-Z for respectively experiment number; surcharge on top of chamber sample in kPa; and sounding hole. The colour of the profiles is according to the surcharge level, with primary and secondary soundings respectively solid and dashed. The jagged appearance of the mini-cone profiles is due to the different approach used in post data treatment for the mini cone. The profiles include a penetration through a 36 cm high pottery clay unit as a reference for the characteristic tip resistance, q_t^{char}, of the pottery clay (E4-40-3b). Here q_t^{char} is defined as the expected tip resistance in an infinitely thick layer for the specific stress level.

5 DISCUSSIONS

5.1 *The thin layering effect*

To what degree the measured q_t in the thin layers is higher than q_t^{char} depends on the ratio of the layer thickness over the cone diameter, H/d_c, and on the contrast between q_t^{char} in the clay and the tip resistance in the sand. The effect H/d_c is shown in Figure 5 where the mini-cone profiles from E6: 4b and 4c have equal sensing- and developing depths compared to the standard-cone profile 1S, when normalized. The "depth terms", sensing- and developing depths, denote respectively the distance ahead of an interface where q_t is influenced by the next layer; and the distance after the interface q_t retain influence from the previous layer.

The test results show that the q_t-profiles through interbedded layers are not symmetric, as the developing- and sensing distances are different for the upper and lower interface of each clay layer, as apparent in Figure 4 and Figure 5. The characteristics of q_t-profiles during transitions thus have some degree of uniqueness, which then might be used in an attempt to back-calculate layer thicknesses and q_t^{char}.

The tip resistance approaches the characteristic value asymptotically with increasing interbedded layer thicknesses. This implies that calculated s_u based on Equation (6) and (8) provide overestimations of the "true s_u" (i.e. s_u based on triaxial CAUC-test) whenever the developing depth is not surpassed. As to illustrate, overestimation magnitudes (with reference to calculated extremal value) are listed for all experiments on pottery clay in Table 2. The table does in addition include the magnitude of underestimation when calculated s_u is based on Equation (7), which is a consequence of the excess pore pressure build-up never approaching the characteristic value. From the reference test (E4-40-3b), the developing depth of q_t was about 5-5.3 d_c (18-19 cm) after the interface.

5.2 *Depth offset*

During penetration through thin layers of clay, all CPTU-parameters starts to approach their characteristic value, yet these approaches are "cancelled" upon closing in on the second interface. As measurements are saved as data points versus time, the measurements from the pore pressure sensor are actually made about 1 cone diameter behind the cone tip. This means that the extremal value of u_2 is saved at a different depth than the extremal value of q_t, consequently lowering the extremal value of the pore pressure ratio, B_q, see Figure 6. For the soundings on the natural sensitive clay (E6-1S;4b;4c), the effect of correcting the depth-offset altered the B_q extremal value up to 0.15. Moreover, due to the short distances of excess pore pressure build-up in thin layers, B_q never approach levels which are close to the reference values, requiring extra care upon interpreting CPTU.

Accounting for the depth-offset is more complicated for the sleeve friction measurements, as each measurement is the product of stresses working on the entire friction sleeve. Therefore, it can be stated that the sleeve's length entails a smoothening effect, making it a component of less depth accuracy and maybe relevance regarding transitions. However, from the experiments, a consistent pattern is apparent: As the probe transits from the sand to the clay the sleeve friction increases drastically when the front end of the sleeve hits the original level of the interface (prior to deformation), whereupon it is decreasing (ref. E4-40-3b). Due to this phenomenon f_s may turn out to be quite useful for identifying thin layers of clay embedded in sand. However, this part is associated with great uncertainty as field measurements of f_s can be rather high in sand, while low in clay, and in addition, f_s varies a lot with probe types. Consequently, this aspect requires further research.

With regards to the previous paragraph, the choice of depth correction for f_s is not obvious. Upon correcting the data points upwards on the sleeve, the extremal magnitude of F_r is smoothened with respect to both lower and upper bounds, making a distinction between materials more difficult (Figure 7). Ironically and conceptually incorrect, the greatest magnitude of F_r is reached if no corrections are made at all.

In conclusion, depth-offset has a big impact on the classification parametrizations during transitions, greatly impacting the identification of the materials and the layer thicknesses. It should however be underlined that offset corrections do not influence s_u-estimations except for $s_{u,ke}$ with a negligible magnitude.

Table 2. The ratios between the extremal value of the CPTU-s_u-parametrizations within a clay layer compared to the "true s_u" of the clay, presented for different clay layer thicknesses. For $s_{u,kt}$ and $s_{u,ke}$ the ratio of overestimation is presented, while for $s_{u,\Delta u}$ the ratio of underestimation is presented.

| Layer thickness	2 cm	4cm	8cm	12 cm
$s_{u,kt,min}/s_u$	6.3-10.5	2.3-4.6	1.4-2.1	1.1
$s_{u,ke,min}/s_u$	5.0-7.7	2.0-3.5	1.3-1.7	0.9-1.0
$s_u/s_{u,\Delta u,max}$	80-125	35-65	4-25	1.8-3.4

Figure 5. Rotated tip resistance profiles of penetration of clay layers (surface towards left, chamber base towards right), normalized with respect to the cone diameters. The thicknesses of the layers penetrated by respectively the standard cone and the mini-cone were 2, 4, 8 and 12 cm; and 2.8, 5.7 and 8.5 cm. Soundings in natural sensitive clay are marked with orange (E6).

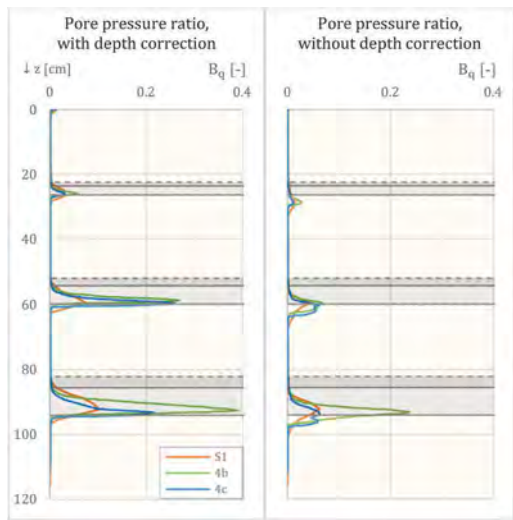

Figure 6. Relative difference of B_q when depth-offset is corrected (left), and not corrected (right) (E6-1S;4b;4c).

Figure 7. Left: Profile with f_s-readings (E6-1S) not corrected with respect to depth offset (blue) and profiles adjusted for different positions on the friction sleeve. Right: Resulting F_r-graphs based on data from the graphs in the left profile.

6 CONCLUSIONS

Thin, weak and possibly sensitive interbedded clay layers are not easily detected as characteristic reference values are not reached before the cone leaves the layer. In this respect, depth correction proves to be very important for the magnitude of the normalized ratios F_r

and B_q. Furthermore, calculations of s_u based on the correlations $s_{u,kt}$ and $s_{u,ke}$ will lead to overestimation of s_u as the recorded tip resistance does not approach the characteristic tip resistance of the thin layer. Likewise, calculation of s_u based on the correlation $s_{u,\Delta u}$ will lead to severe underestimation due to the small excess pore pressure build-up in thin layers.

Determination of hydraulic conductivity using HPT & CPTu

M. Slowiok, S. Oberhollenzer & R. Marte
Institute of Soil Mechanics, Foundation Engineering & Computational Geotechnics, Graz University of Technology, Graz, Austria

ABSTRACT: In geotechnical engineering insitu tests are becoming increasingly popular to determine the hydraulic conductivity of soils. Direct push methods such as piezocone penetration test CPTu or the hydraulic profiling tool HPT allow characterizations along a linear profile. The determination of hydraulic conductivity with HPT is an alternative to CPTu for drained and partially drained conditions. Thereby, water is continuously injected from a small screened port at the probe into the soil. Based on the required pressure to inject the water into the soil and the constant flow rate, the hydraulic permeability can be determined for a certain range of drainage conditions. The present article compares HPT and CPTu results with slug tests, executed at different test sites in a wide range of grain size distributions. Based on this comparison, a new correlation was elaborated for HPT which enables an improved characterization of hydraulic conductivity.

1 INTRODUCTION

The hydraulic conductivity K of soils is an important soil parameter for a wide range of geotechnical problems (e.g. excavations in combination with dewatering works). In order to determine K, the fluid velocity v and the hydraulic gradient i can be used based on Darcy's law. Hydraulic conductivity can vary between approximately ten orders of magnitude ($K = 10^{-2} - 10^{-12}$ m/s) and is strongly influenced by the grain size distribution, density, void ratio and anisotropy. Furthermore, it was shown earlier that the horizontal hydraulic conductivity can become up to ten times larger compared to the vertical one in sediment deposits (Boley 2019).

In the laboratory, the vertical hydraulic conductivity K_v is determined based on permeameter tests with constant or variable pressure head. In general, the quality of sampling has a great influence on the determined permeability. On the other hand, direct push (DP) methods are time- and cost-efficient alternatives, which became more popular over the last decades. Especially piezocone penetration tests (CPTu) enable a determination of K based on the soil behavior type index I_c or dissipation tests. Thereby, the determined permeability - in contrast to the laboratory tests - is a combination of the horizontal and vertical one. The hydraulic profiling tool (HPT) represents an alternative investigation technique and enables a continuous characterization over depth. Thereby, water is injected under constant rate into

the subsoil. Based on the required pressure to ensure constant flow, K can be determined based on correlations, which were often calibrated based on slug-tests (and might rely therefore on site-specific data).

In the present article different insitu & laboratory tests are compared with reference to the hydraulic conductivity. The main focus is related to direct push methods (HPT, CPTu) in order to characterize their application limits. In a final step, a new correlation to determine K is elaborated for HPT based on additional slug tests.

Four test sites, carried out within Austria (state Salzburg), represent the basis of the present work. The investigation program includes CPTu, HPT, slug-tests and additional laboratory tests. All applied methods (insitu & laboratory tests) are described in the following section.

2 APPLIED METHODS

2.1 *Piezocone penetration test (CPTu)*

The piezocone penetration test (CPTu) represents a widely used direct push technique for soil characterization. Thereby, a penetrometer is pushed at constant rate (equal to 2 cm/s) into the subsurface. Simultaneously, the tip resistance q_c, sleeve friction f_s & dynamic pore water pressure u_i are measured at the cone continuously over depth. The friction ratio $R_f = f_s/q_t$ (%) can be used as a first indicator for

characterizing the soil behavior type. Thereby, the corrected cone resistance q_t is defined as

$$q_t = q_c + u_2(1 - a) \qquad (1)$$

where a is the area ratio of the cone and u_2 is the dynamic pore water pressure measured behind the tip. The cones used for all field investigations present a cross-section area equal to 15 cm² and the porewater pressure was measured at position u_2.

The hydraulic conductivity can (mainly) be determined based on two approaches: The first method is based on the soil behavior type classifications and provides a continuous K-profile over depth. These classifications can be estimated based on the soil behavior type index I_c (Robertson & Wride 1998).

$$I_c = \left[(3,47 - \log Q_{tn})^2 + (\log F_r + 1,22)^2 \right]^{0,5} \qquad (2)$$

where Q_{tn} is the normalized cone resistance

$$Q_{tn} = [(q_t - \sigma_v)/p_a](p_a/\sigma'_{v0})^n \qquad (3)$$

with the total vertical stress σ_{vo} and the effective vertical stress σ'_{vo} and the normalized friction ratio F_r

$$F_r = [(f_s/q_t - \sigma_{v0})]100 \ \% \qquad (4)$$

The soil behavior type index I_c is defined by the radius of concentric circles within the soil behavior type diagram according to Robertson (2010). Higher I_c values represent soils with higher fines content & lower hydraulic conductivity. The empirical correlation to characterize the hydraulic conductivity in m/s based on I_c is shown in equations 5 and 6:

When $1.00 < I_c < 3.27 \qquad K = 10^{(0.95 - 3.04\,I_c)} \qquad (5)$

When $3.27 < I_c < 4.00 \qquad K = 10^{(-4.52 - 1.37\,I_c)} \qquad (6)$

The second approach to determine the hydraulic conductivity is based on CPTu-dissipation tests, measuring the pore water pressure decay after stopping the penetration process. The dissipation process is mainly governed by the horizontal coefficient of consolidation, defined as:

$$K_h = (c_h \gamma_w)/M \qquad (7)$$

where K_h represents the horizontal hydraulic conductivity, M the 1D constrained modulus at the insitu stress level and γ_w the unit weight of water. In order to back-calculate K_h, c_h & M must be calculated using existing correlations. Based on Teh & Houlsby (1991) or Robertson et al. (1992) c_h (m²/s) can be calculated based on t_{50} (time for 50 % of excess pore water dissipation).

$$c_h = 1.50 \left(1.67 * 10^{-6} \right) 10^{(1 - \log t_{50})} \qquad (8)$$

for 15 cm² piezocones.

The constrained modulus M can also be determined based on Robertson (2009) using:

$$M = \alpha_M (q_t - \sigma_{v0}) \qquad (9)$$

when $I_c > 2.20$:

$$\alpha_M = Q_{tn} \qquad \text{when } Q_{tn} \leq 14 \qquad (10)$$

$$\alpha_M = 14 \qquad \text{when } Q_{tn} > 14 \qquad (11)$$

2.2 Hydraulic Profiling Tool (HPT)

The Hydraulic Profiling Tool belongs to the direct push methods too. A probe is pushed into soil under constant penetration rate equal to 2 cm/s. Simultaneously, water is injected at constant flow rate via a small port at the side of the probe. A pressure sensor inside the probe (near the outlet) records the required injection pressure while flow remains constant. Based on the ratio between flow rate and pressure the hydraulic conductivity can be estimated in combination with correlations. In a first step the measured pressure p_{tot} is corrected by the atmospheric pressure p_{atm} and the piezometric pressure p_{piezo}. The piezometric pressure can be calculated based on dissipation tests for selected depths.

$$p_{corr} = p_{tot} - p_{atm} - p_{piezo} \qquad (12)$$

In this study two approaches (McCall & Christy (2010), Borden et al. (2021)) are used to calculate the hydraulic conductivity.

The first (empirical) correlation according to McCall & Christy (2010) was calibrated based on slug tests:

$$K_h = 3.53 \cdot 10^{-6}[21.14\ln(Q/0.15P_{corr}) - 41.71] \qquad (13)$$

It should be noted that the approach according to McCall & Christy (2010) is limited to K-values between $2.65 \cdot 10^{-4}$ and $3.53 \cdot 10^{-7}$ m/s.

The enhanced correlation according to Borden et al. (2021) considers Q (mL/min), P_{corr} (kPa) and additionally the penetration rate v (mm/s) as well as probe diameter d (mm),

$$K_h = 7.13 \cdot 10^{-6} \frac{0.12 \ v \ d^2 + 0.12 \ Q}{\left(0.15 \ P_{corr}\right)^{1.02}} \qquad (14)$$

In addition, the HPT tool offers the measurement of electrical conductivity (EC) using a four-point Wenner array near the tip of the probe. Based on this measurement qualitative estimations regarding the permeability are possible. An increased electrical conductivity is an indicator for a higher fines content and lower hydraulic conductivity.

2.3 Direct Push Slug Test (DPST)

Slug tests are a reliable and cost-efficient technique to determine the permeability of soils insitu. First, an excess porewater pressure is created artificially, before measuring the drop in porewater pressure over time.

The change in water head can be created by adding or removing water within the rods. In our case, the slug test was performed using direct push equipment. After pushing the penetration rod into the desired depth, the penetration procedure is stopped and a filter body (4/8 mm gravel) is created by pulling the rods about 50 cm. While pulling the rods, a lost tip remains in the soil and the filter material is poured through the rod to create a filter length equal to 50 cm.

When the filter section is created, a water head is applied by filling a defined volume of water into the penetration rods. Afterwards, the pressure drop is recorded over time by a sensor. In each depth at least two slug tests were performed and analyzed in combination with the software-package SlugIn (IGME) by using the interpretation methods according to Cooper et al. (1967), Hvorslev (1951) and Bouwer-Rice (1976).

2.4 Laboratory test with constant pressure head and grain-size analysis

At two test sites additional soil sampling was executed using the CPT-Ranger system. The recovered samples present a diameter d and height h equal to 6 cm and 50 cm respectively. Each sample was trimmed down to $d = 5$ cm and $h = 12$ cm to enable permeameter tests. The tests were carried out with a constant pressure head of $\Delta h = 3.6$ m. Consequently, the vertical hydraulic conductivity can be calculated based on the measured discharge Q over time t, the hydraulic gradient $i = \Delta h / \Delta l$ and cross-section area A.

$$K_v = \frac{Q \ \Delta l}{A \ \Delta h \ t} \qquad (15)$$

Furthermore, the grain-size distribution was analyzed for each soil sample in order to enable classifications based on Chapuis (2012).

3 TEST SITES

Insitu tests and additional soil sampling was carried out at four test sites within the state of Salzburg, Austria. The investigated soils at Flachau (TS1), Siggerwiesen (TS2), Bruck/Großglocknerstraße (TS3) and Salzburg (TS4) are characterized by a wide range of different grain size distributions (see Figure 1).

Test site 1 (TS1) mainly consists of coarse-grained deposits which are interrupted by silty layers. For TS2 Siggerwiesen (SIG) the subsoil is composed of a heterogeneous aquifer which is followed by a low permeable silty fine sand. The top layer (0-6m) at TS3 is classified as peat and is underlaid by sand-silt mixtures. The fourth testing site is situated close to the main train station of Salzburg. The subsoil conditions are characterized by 3 main lithologies: sandy gravel (0-4m), sand-silt alterations (4-9m) and clayey silts (9-25m).

CPTu and HPT-soundings were carried out at all four test sites. Additional slug tests were carried out at three depth levels on each site. At TS3 and TS4 additional soil sampling (for permeameter tests and determination of grain size distribution) was executed.

4 RESULTS

CPTu and HPT measurements (q_t, R_f, EC, P_{corr}) are presented for the different test sites in Figure 1. A low corrected tip resistance q_t and high friction ratio R_f represent fine-grained layers. As mentioned earlier, fine grained sections, presenting a low permeability, are characterized by a high electrical conductivity EC and high P_{corr} values.

TS1 – Flachau consists of a fine-grained layer between 2 and 3 meters, which can be detected based on q_t, R_f, EC and P_{corr}. A second silt-dominated lens follows between 5 and 6 meters. The lower aquifer (6-10m) presents low friction ratios R_f and small P_{corr} values, indicating a high permeability.

At *TS2 – Siggerwiesen* backfill material is present between 0 and 4 meters which is followed by a silty fine sand layer with increasing fines content.

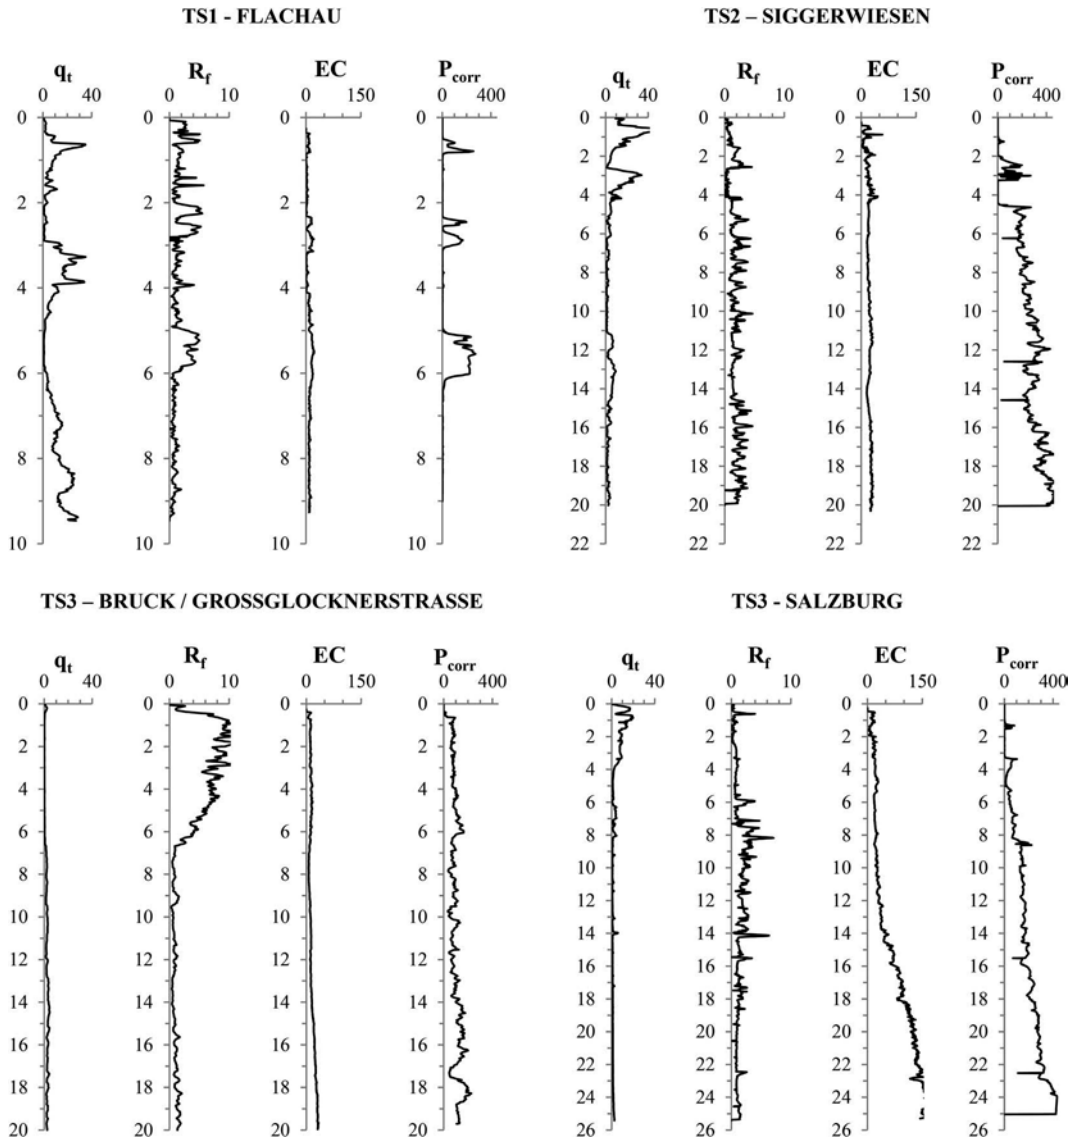
The subsoil at *TS3 – Bruck/Großglocknerstraße* consists of a peat layer within the first 5 meters, followed by sand mixtures. Within the top layer, the friction ratio R_f amounts to approximately 10 %. On the other hand, HPT pressures P_{corr} indicate rather high permeabilities within this layer. The following sandy section (7 – 20m) presents increased q_t, and small R_f values. P_{corr} & EC present a rising trend over depth.


Figure 1. Results from Direct Push stratigraphic profiling over depth (m) – tip resistance q_t (MPa), friction ratio R_f (%), electrical conductivity EC (mS/m) & corrected HPT pressure P_{corr} (kPa).

The subsoil at *TS4 – Salzburg* is composed of backfill material within the upper 4 meters. The fine-grained "Salzburger Seeton" (9 to 25m) is characterized by a small q_t and increased R_f, EC- as well as P_{corr}-values.

In a second step the hydraulic conductivity was evaluated based on CPTu (I_c, dissipation test), HPT, slug tests and laboratory tests (permeameter test, grain-size distribution). Figure 2 presents the determined K values based on different interpretation techniques as well as test sites. A continuous K profile over depth can be evaluated from CPTu (I_c) and HPT data. Select-ive permeability tests in certain depths complement the test program and are used for comparison.

For *TS1 – Flachau* hydraulic conductivity based on I_c yields to the lowest results. Both HPT-correlations lead to similar results within the same order of magni-tude. Slug tests are evaluated based on Hvorslev (1951). The latter results are situated between CPTu (I_c, dissipation test) and HPT results. The slug tests identify the impermeable lens in 5 meter depth. How-ever, the sensitivity of the different tests differ strongly. Slug test data verify the soil layering and are situated between CPTu and HPT results.

At *TS2 – Siggerwiesen* the high permeable aquifer in a depth of 4 meters is recognized by all methods. The fine grained layer from 4 to 20 m indicates low permeablilty for both CPTu methods. The slug tests

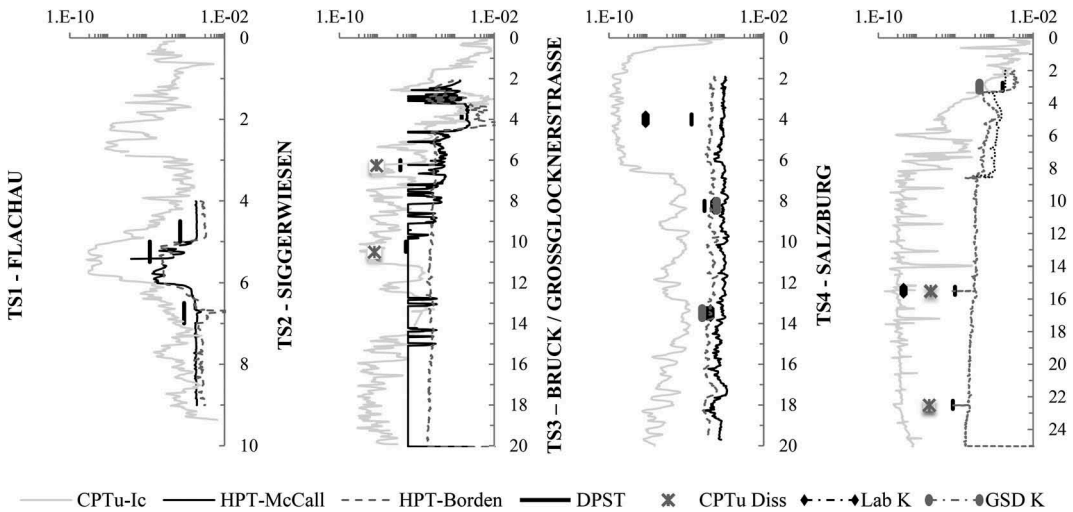
700


Figure 2. Hydraulic conductivity K (m/s) from different approaches over depth (m) – cone penetration test soil behavior type index *CPTu-I$_c$*, Hydraulic Profiling Tool *HPT*, Direct Push Slug Test *DPST*, cone penetration dissipation test *CPTu Diss*, Laboratory permeameter test *Lab K* & Grain Size Distribution correlation *GSD K*.

suggest a higher permeability whereas McCall & Christy (2010) HPT approach reach the lower K limit.

The continuous readings of *TS3 – Bruck/ Großglocknerstraße* yields to similar trends: CPTu-I_c results lead to the lowest and both HPT-correlations lead to the highest hydraulic conductivity values. The organic layer within the upper 5 meters present a high scatter in K (up to five orders of magnitude). For the lower silty sand layer, the scatter becomes smaller.

At *TS4 – Salzburg* the same trend (between CPTu and HPT results) is given. Again, the difference in K rises in fine-grained layers. Within the so-called "Salzburger Seeton" slug tests indicate a higher permeability, whereas laboratory and CPTu (dissipation, I_c) results lead to smaller conductivities.

In order to investigate the scatter in K, all insitu and laboratory results are compared within Figure 3. The scatter was evaluated considering the soil behavior type index I_c. To enable a comparison, the data from CPTu and HPT was assigned over an interval equal to 50 cm meters using the median. Vice versa "punctual" K measurements (e.g. dissipation test) were assigned to a median I_c.

As shown in Figure 3, with increasing fine-content the difference in K rises strongly. For small I_c values (indicating coarse-grained material) the variation of the different interpretation techniques is approximately one order of magnitude. As mentioned above, HPT-correlations yield the upper K-end, whereas K values based on CPTu-I_c mark the lower K-end. For sand-silt mixtures the discrepancy increases. This trend continues with increasing fines-content, where HPT-correlations reach the end of applicability. CPTu dissipation,

CPTu-I_c and laboratory results indicate rather low hydraulic conductivity within this section.

In the last step, existing HPT correlations where evaluated. McCall & Christy (2010) suggested for their correlation a lower K limit of $3.5 \cdot 10^{-7}$ and a higher K limit equal to $2.7 \cdot 10^{-4}$ m/s. Their logarithmic approach (see Figure 4) was calibrated
Figure 3. Hydraulic conductivity K (m/s) vs. Soil Behavior Type Index Ic (-).
Figure 4. HPT correlations in comparison with slug test and CPTu-Ic in K (m/s) vs. P_{corr} (kPa) space.

based on slug tests and exhibits an asymptote for high P_{corr}. At the low K end permeability changes strongly along a small range of P_{corr} values. On the other hand, Borden et al. (2021) defines a straight line within the K-P_{corr} space. In comparison with the available slug test and CPTu-I_c data, the correlation according to McCall & Christy (2010) is in good agreement with the results. It should be noted, that for P_{corr} values between 10 and 100, the correlation leads to rather high permeabilities. On the other hand, Borden et al. (2021) leads to significantly (unrealistic) high results.

In order to achieve a better agreement with our test results two best-fit curves were defined. The new correlation is based on a potential function which is further subdivided:

$$K_h = 1.65 * 10^{-8}(Q/P_{corr})^{10}$$

$$\text{when } 1.36 < Q/P_{corr} < 1.90 \tag{16}$$

$$K_h = 6.53 * 10^{-6}(Q/P_{corr})^{2/3}$$

5 SUMMARY

The objective of this study was to compare and evaluate different insitu and laboratory tests in order to estimate the hydraulic conductivity. Based on investigations at 4 test sites, it was shown that direct push techniques (CPTu, HPT and Slug test) lead to realistic K-results and are reproducible. In addition, it was shown that different investigation techniques present a stronger scatter with increasing fines content. Here, K-values from CPTu-I_c mark the lower boundary, whereas K-values from HPT-correlations mark the upper boundary. It was proven, that existing HPT correlations (McCall & Christy 2010, Borden et al. 2021) should only be used between $K = 1 \cdot 10^{-6}$ and $5 \cdot 10^{-4}$ m/s, which is for many geotechnical projects (e.g. dikes, dewatering) sufficient. Both HPT correlations are realistic representations to determine K by Q/P_{corr}. In addition a new HPT correlation was presented.

DEM-FDM coupling simulation of cone penetration tests in a virtual calibration chamber

Y. Song, X.Q. Gu & J. Hu
Tongji University, Shanghai, China

ABSTRACT: We performed numerical simulation of the cone penetrating process with discrete element method (DEM) coupled with finite difference method (FDM) to investigate the mechanics of granular soil interacted with a cone penetrometer. The efficacy of particle size amplification method to estimate soil physical indexes has yet to be established and it was validated in this work. The effects of cone-particle chamber size, confining stress and sand modulus on cone tip resistance are analyzed. The results show that the effect of confining stress is consistent with the empirical relationship and the cone tip resistance correlates positively with the number of particles contacting with the cone penetrometer. Furthermore, the distribution of radial stress agrees well with the cavity expansion theory that a nearly linear relation between cone tip resistance and radial stress near the cone penetrometer can be observed.

1 INTRODUCTION

Cone penetration testing can be used for soil classification, determination of soil physical and mechanical parameters, evaluation of pile bearing capacity and liquefaction site discrimination (Yu & Mitchell, 1998). Till now, the relationship between tip resistance and soil parameters is established mainly through bearing capacity theory, cavity expansion theory, finite element simulation or cone penetration calibration chamber test. Chen & Juang (1996), Sokolovskii (2016) proposed a formula to calculate the cone probe coefficient based on the bearing capacity theory and developed an empirical relationship to determine the volumetric strain. The bearing capacity theory fulfill the equilibrium equation and yield criterion, however the kinematics and initial stress state around the penetrometer are disregarded, and the stiffness and compressibility of soil are not carefully accounted. The resulting prediction of cone tip resistance could be spurious. Compared with the bearing capacity theory, the cavity expansion theory not only considers the elastic deformation of soil during penetration, but also considers the plastic deformation, which leads to a simple and accurate solution (Chen & Abousleiman, 2012 and Chen et al., 2019). However, the cavity expansion theory suffers from several shortcomings. For example, the influence of penetration rate and pore water pressure is not considered. Yi (2012) used finite element method to analyze soil deformation around penetrometer with different penetration rates. Finite element simulation requires complex constitutive

models to simulate the stress-strain characteristics of sand, and the large distortion of finite element mesh of the soil near the cone-tip does not guarantee legitimate numerical results. The indoor calibration chamber test may present different results due to the size effect than those from the in-situ test (Wesley,1998). Therefore, the model size effect needs to be investigated cautiously in this regard.

In this work, the discrete element method coupled with finite difference method is used to simulate the cone penetration test, which can effectively analyze cone penetrator-soil interaction mechanics while considering the large deformation characteristics of soil near the cone-tip. In order to consider the shape effect of sand particles, the rolling-resistant linear contact model is used in the simulation. The contact parameters were calibrated in accordance with the triaxial drainage testing result. Effects of different contact parameters on soil properties were briefly discussed and pertinent suggestions were given for the choice of model parameters.

2 COUPLED DEM-FDM SIMULATION SCHEME

2.1 *Cone penetration test model*

Discrete element method (DEM) is a numerical method calculating the behavior of a large number of particles by computing the trajectories of each particle with Newton's law of motion (Cundall & Strack,1979). It is widely used for conducting downscaled numerical experiments on virtual sand samples

(Arroyo et al., 2011; Butlanska et al, 2014; Gu et al., 2015). It is advantageous in studying geomechanics by offering both macroscopic and microscopic information of sands compared with traditional numerical methods based on continuum mechanics. While due to the demanding requirement of computational resources, its application on full scale analysis is uninviting. In contrast, finite difference method (FDM) is able to solve the governing equation in a speedy manner while the large deformation of the soil near the cone-tip cannot be handled and the fabric evolution of microstructures can hardly be obtained. Therefore, a DEM and FDM coupling scheme, which can effectively take advantage of the merits of both methods, is appealing for simulating cone penetration testing. In this study, we adopt well recognized software PFC3D for DEM modeling of the near field sand and FLAC3D for FDM modeling of both the cone penetrometer and the far field domain. The coupling of these two is realized via the equilibrium of the interface of the neighboring domains of DEM and FDM.

The schematic of the cone penetration test model is shown in Figure 1a, where the cylindrical ground consists of the inner cylinder and the outer hollow cylinder. The inner cylinder is modeled by DEM containing 79,590 spheres and the hollow cylinder is modeled by FDM containing 50,000 elements. The adopted dimensions of the model are as follows: the diameter of the model domain (D_c) is 752 mm, the height of the soil model (H) is 432 mm, the radius of the inner cylinder (D_1) is 288 mm. As shown in the Figure 1b, the rigid cone penetrometer is modeled by FDM consisting of a frictionless cone rod of diameter (d_c) 35.6 mm, a frictional cone with an inclination of 60° and a frictional sleeve of length (h_c) 32.6 mm. In the simulation, we prescribe a penetrating speed of 0.1 m/s during the entire penetration. In order to ensure that the boundary conditions are consistent with that in the in-situ test, we adopted the boundary conditions suggested by Salgado et al., 1998: the horizontal boundary is prescribed by constant stress, the upper boundary is stress free and the bottom is displacement free.

Figure 2. Grain size distribution.

2.2 DEM parameter calibration

In order to realize the faithful constitutive behavior of sands modeled by the discrete particle assembly, the contact parameters were calibrated by comparing them with the triaxial compression test. Note that we adopt the rolling-resistant linear contact model in the DEM simulation to account for the irregular shape of sand particles. The rolling-resistant linear contact model consists of three parts: linear normal and tangential force-displacement relations and a linear rotational constitutive relation. The particle assembly was generated by the radius expansion method to emulate the particle size distribution of Fontainbleau sand measured in the physical test (Bolton et al., 1999), as shown in Figure 2. First, 16,160 proportionally smaller non-overlapping particles were generated in a 4.5 × 4.5 × 9 mm^3 cuboid, and then multiplied by the radius expansion coefficient to gradually expand to the target particle size. The DEM model and FDM model of the triaxial compression simulation for calibrating DEM physical parameters are shown in the Figure 3. The FDM model consists 50,000 elements and the Mohr-Coulomb model is adopted as the soil constitutive relation with its parameters listed in Table 1. The strain-controlled loading with a constant speed of 10^{-6} m/s is applied in the axial direction and the uniform confining pressure of 100 kPa is applied to the circumferential direction for both PFC3D and FLAC3D models.

In the DEM simulation, the particle assembly was generated to attain the relative density Dr=70% which is comparable to physical samples. Typical ranges of contact law parameters suggested by Gu et al. (2020) were first adopted, e.g. contact stiffness, rolling resistance and contact friction. The contact parameters were further fine-tuned to reconcile the DEM simulation result with that from the FDM simulation, which is deemed to be the true constitutive relation of the soil.

Figure 4 Shows the deviatoric stress-strain relations and volumetric strain-axial strain relations for the triaxial drained test with confining stress of 100 kPa from both DEM and FDM simulations. It can be seen that the
Figure 3. 3D triaxial compression test model for calibrating DEM parameters: (a) PFC3D model and (b) FLAC3D model.

DEM and FDM simulation results (Seif et al., 2010) agree to a satisfactory extent for the dense sample. The calibrated parameters are presented in Table 1.
Table 1. Physical parameters in simulations.

Parameters	Value
Normal and tangential stiffness of cone rod	1.0×10^{10} N/m
Friction coefficient of cone rod	0.2
Normal and tangential stiffnesses of side walls of calibration chamber	1.0×10^{10} N/m
Side wall friction coefficient of calibration chamber	0
Particle stiffness coefficient	6.0×10^{8} N/m^2
Stiffness ratio of particle	0.25 ks/kn
Particle friction coefficient	0.33
Rolling resistance coefficient of particles	0.8
Particle density	2650 kg/m^3
Young's modulus in FDM	60.6 MPa
Internal angle of friction in FDM	37.04
Dilation angle in FDM	6.94

3 NUMERICAL SIMULATION AND RESULT ANALYSIS

In order to improve the efficiency of discrete element simulation, the particle size amplification method was used to reduce the number of particles, and the calibrated parameters for the DEM simulation were adopted to honor the true stress-strain relationship (Yan & Dong, 2011). In this study, the particle expansion ratio was chosen to be 35. The simulation result of the cone penetration calibration chamber test with confining stress of 100 kPa is shown in Figure 5. As shown in the figure, the cone tip resistance as well as the number of particles contacting the cone penetrometer clearly progresses along two stages: growth stage and stable stage. During the initial growth stage, the contact
Figure 4. 3D triaxial compression test result: (a) deviator stress versus axial strain and (b) volumetric strain of the sample versus axial strain.

number of cone tip particles increases continuously in parallel with the cone tip resistance. When the normalized penetration h/d_c depth reaches 2, the cone tip resistance tends to be stable and the average value is about 8.5 MPa, where h is the penetration depth. The results imply that the microscale and macroscale features are highly correlated and the tip resistance could serve as an indicator of the microstructural characteristics of granular soil.

Particle size amplification method increases the simulation efficiency substantially by reducing the number of particles contacting with the cone tip, while the number of contacting particles and the soil near the cone-tip structure may change. In the following, we show the simulation results considering different sizes of the cone penetrometer to validate the efficacy of the particle size amplification method. Figure 6a shows the evolution of the tip resistance with the normalized penetration depth, with two cone penetrometer sizes and the fixed dimension of the coupling model, i.e. d_c/D_{50}=4.89 and 3.81 with D_{50} denoting the mean particle diameter determined from the amplified particle size distribution. It shows that the average tip resistance for d_c/D_{50}=4.89 and 3.81 are 7.45 MPa and 7.23 MPa
Figure 5. Simulation results of cone penetration test with confining stress of 100 kPa.

respectively. The results indicate that the particle size amplification method with a careful selection of the amplification ratio would not hinder the prediction of tip resistance.

To investigate the size effect of the DEM domain, we conducted simulations with different D_1 and constant R_1. The results are shown in Figure 6b. It shows

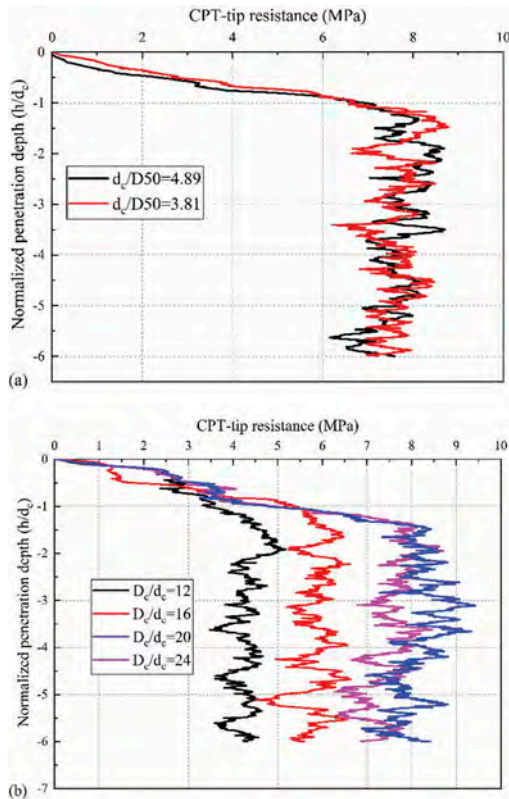

Figure 6. Analysis of the size effect of the model: (a) different cone penetrometer sizes and (b) different coupling model sizes.

that there is a threshold of D_c/d_c under which the tip resistance increases with the size of the DEM domain and beyond which no obvious size effect can be observed.

The soil constitutive behavior depends on the inter particle contact stiffness. To investigate its effect, simulations with two inter particle stiffness were conducted while keeping other parameters the same as in Table 1. Figure 7a shows the variation of radial stress along with the normalized distance r/R, where r is the distance from the center of the cone and R is the radius of the cone. As shown in Figure 7a, the radial stress decreases monotonically to the confining stress, i.e. 100 kPa, as the normalized distance increases. With the increase of the inter particle stiffness, the cone tip resistance increases due to the stiffer behavior of soil.

Figure 7b shows the variation of radial stress with the normalized distance under three different confining stresses 50 kPa, 100 kPa and 200 kPa. As shown in Figure 7b, the radial stress decreases monotonically from the cone neighborhood to the outer boundary with all three confining stresses. It is shown that the differences of the radial stresses under different confining stresses are significant especially at the neighborhood of the cone penetrometer. To reconcile the DEM-FDM simulation with in situ CPT testing, attention should be paid on the confining stress prescribed at the outer boundary.

The relationship between the stable tip resistance and the radial stress of the cone tip at r/R = 2.5 was also investigated and shown in Figure 8. The results show that there is a good linear relationship between the tip resistance and the tip radial stress (r/R = 2.5) under different simulation conditions, which agrees well with the cavity expansion theory (Randolph et al. 1994).

4 DISCUSSION AND OUTLOOK

In this work, we modeled the cone penetrate testing with a DEM-FDM coupling approach. The micro-contact parameters in DEM are calibrated by comparing the triaxial compression simulation results based on DEM and FDM. The size effect of the particle amplification method was analyzed, and the influence of contact stiffness and confining stress was investigated. The main findings of this study can be summarized as follows:

(a) The DEM-FDM coupling method is a promising and efficient simulation method investigating cone penetration mechanics from both macroscopic and microscopic perspectives.
(b) The particle size amplification method is capable of further increasing simulation efficiency substantially without undermining the accuracy of the prediction of cone tip resistance, with a cautious selection of the amplification ratio.
(a)
(b)

Figure 7. Factors influencing radial stress distribution of cone tip: (a) soil modulus, (b) confining pressure.

Figure 8. The relationship between cone tip resistance and cone tip radial stress (r/R = 2.5).

(c) The effects of contact stiffness and confining stress on the stress field in the soil and cone tip resistance are considerable and attention should be paid on them for emulating the in-situ cone penetration testing.

(d) The cone tip resistance and the radial stress around the cone from DEM-FDM simulation manifests a linear relation, which agrees well with the cavity expansion theory.

Data-driven soil profile characterization using statistical methods and artificial intelligence algorithms

R.L. Spacagna
CNR IGAG Area della Ricerca Roma 1, Montelibretti (Roma), Italy

A. Baris, L. Paolella & G. Modoni
University of Cassino and Southern Lazio, Cassino, Italy

ABSTRACT: CPT soil profile interpretation represents a fundamental aspect for subsoil stratigraphic reconstruction of complex geological contexts. In some situations, the soil profile may not exhibit evident boundary changes, making the interpretation more difficult. This crucial aspect plays a key role in the layers boundaries discontinuities identification and the construction of bi-dimensional and three-dimensional geotechnical models. In this paper, CPT and boreholes are used to calibrate and validate a massive and automated site characterization by combining statistical tools and artificial intelligence algorithms (AI). The procedure is applied in the complex stratigraphic context of Terre del Reno (Italy). The proposed data-driven analysis allows to combine the geological and geotechnical knowledge of the subsoil in an efficient and automatic way based on site-specific data, obtaining reliable and indispensable results for the construction of a robust and coherent geotechnical model of the subsoil.

1 INTRODUCTION

One of the subsoil stratigraphic reconstruction challenges is to identify homogeneous soil layers characterized by a different behaviour response. The detection of the strata boundaries represents a crucial aspect in the construction of two-dimensional and three-dimensional geotechnical models. The development of the data-driven analysis and the increasing availability of digitized geo-databases allow to improve the current methodologies to obtain an effective and extensive site characterization, providing a less subjective interpretation of the subsoil data (Phoon *et al*., 2021).

The main studies rely on statistic and probabilistic approaches based on the cone penetration test (CPT) data (Phoon *et al*. 2003, Facciorusso & Uzielli 2004, Uzielli 2008, Wang *et al*. 2013, Paolella *et al.* 2019, Shuku *et al*. 2020). The continuous measurements of soil parameters allow a statistical treatment for the identification of lithological discontinuities and the reconstruction of the stratigraphic profiles (Lo Presti *et al*. 2009). For this purpose, the CPT-based soil behaviour type index (Ic), and the correspondent soil behaviour type (SBT), are used to delineate soil boundaries (Robertson 2016).

This work developed a data-driven methodology for the subsoil stratigraphic reconstruction combining statistical tools and artificial intelligence algorithm (AI). The proposed procedure is applied to the complex

stratigraphic context of Terre del Reno (Italy), extensively affected by seismic liquefaction phenomenon during the May 2012 earthquake sequence (Fioravante *et al*. 2013). From the geodatabase of the Emila Romagna Region, 102 pairs of CPT and boreholes were selected to calibrate and validate the method. The CPT profiles are analyzed, and the homogeneous layers are identified following statistical methods based on the spatial variability analysis of the measured parameters. Each statistically homogeneous layer is associated with the stratigraphic information extrapolated from closer boreholes, according to the Unified Soil Classification System (USCS). From the previous results, an artificial classifier is trained, and the automatic classification procedure of soil profile is tested on a complementary subset of data.

The proposed data-driven analysis combines the geological and geotechnical knowledge of the subsoil in an efficient and automatic way, based on site-specific data, to obtain reliable and indispensable results for the construction of a robust and coherent geotechnical model of the subsoil.

2 METHODOLOGY

The proposed approach aims to define a methodology for the subsoil stratigraphic recognition, applicable at the urban scale. In practice, this operation is based on the interpretation of a considerable amount of data

coming from different sources. The most diffused approach is to combine the borehole logs stratigraphy and Cone Penetration Test results in a deterministic way with a consequent subjectivity of the interpretation of available data.

The increasing availability of site-specific data collected, digitized and stored in the geodatabase allows to improve, even automatically, the consolidated methodologies for interpretation of subsoil data.

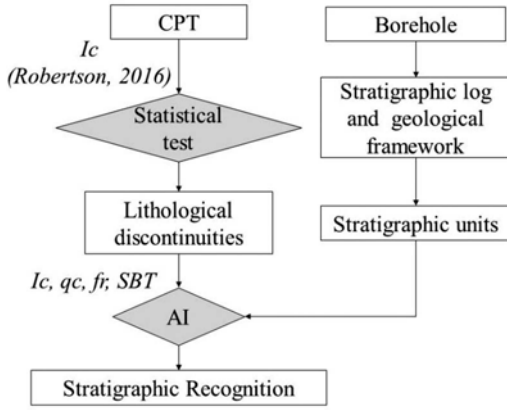
This procedure, summarized in Figure 1, provides a stratigraphic interpretation model applicable to all available surveys in the analyzed area, combining information from different investigation tests. In particular, the proposed methodology identifies the main lithologies from borehole log stratigraphies, the layer discontinuities from the sectioning statistical test of the CPT profiles and the automized stratigraphic classification of each statistically homogeneous layer from AI.


Figure 1. Proposed methodology for the subsoil stratigraphic recognition.

2.1 Definition of stratigraphic units

The definition of the main stratigraphic units detectable in the study area requires a detailed geological, hydrogeological, geomorphological and sedimentological framework.

The stratigraphic reference units for the selected case study are defined by combining the information from the geological framework and the borehole log stratigraphy. The detail of the stratigraphic model, its extension and stratigraphic classification are strictly related to the typology of the performed analysis (i.e. subsidence, liquefaction, design of structures and infrastructures). Therefore, the model (depth and thickness of the strata) and the stratigraphic units are defined according to the analyzed phenomenon (i.e., for a liquefaction risk assessment, the liquefiable layers).

2.2 Soil boundaries discontinuities

The homogeneous soil layers within the CPT profiles are identified based on the soil behaviour type index Ic (Robertson, 2016). The automatic procedure provides an accurate interpretation of the CPT tests considering the spatial correlation of the considered values along with the vertical profile.

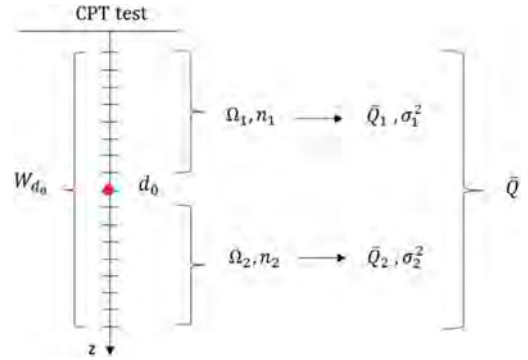
This statistical test verifies the equality of the means and the variance of two subsets of data, according to the procedure shown in Figure 2. The two subsets of data (namely Ω_1 and Ω_2, with size respectively equal to n_1 and n_2, average $\overline{Q_1}$ and $\overline{Q_2}$, and variance $\sigma_1{}^2$ and $\sigma_2{}^2$) are identified along with the vertical CPT profile with a moving window W_{d0} dived by d_0. The T ratio (Equation 1) and the intra-class correlation coefficient ρ_I (Equation 2) are calculated along with the vertical CPT profile.


Figure 2. Definition of the two subsets of relevant parameters along the vertical axis of CPT test (from Spacagna et al, 2015).

$$T = \frac{\overline{Q}_1 - \overline{Q}_2}{\gamma_w} \sqrt{\frac{n_1 n_2}{n_1 + n_2}} \qquad (1)$$

Where:

$$\gamma_w = \frac{n_1}{n_1 + n_2 - 1}\sigma_1^2 + \frac{n_2}{n_1 + n_2 - 1}\sigma_2^2 \qquad (2)$$

$$\sigma_1^2 = \frac{1}{(n_1 - 1)}\sum_{i=1}^{n_1}(Q_i - \overline{Q}_1)^2 \qquad (3)$$

$$\sigma_2^2 = \frac{1}{(n_2 - 1)}\sum_{i=1}^{n_2}(Q_i - \overline{Q}_2)^2 \qquad (4)$$

$$\rho_I = \frac{\gamma_b^2}{\gamma_b^2 + \gamma_w^2} \qquad (5)$$

Where:

$$\gamma_b^2 = \frac{1}{n_1 + n_2 - 1} \sum_{i=1}^{n_1+n_2} (Q_i - \bar{Q})^2 \qquad (6)$$

where $\bar{Q}$ is the average of the data Q_i belonging to the window w_{d0}, with i=1,2, …, (n_1+n_2).

To define the window W_{d0}, the geostatistical approach proposed by Spacagna *et al.* (2015) suggests to calculate the one-dimensional experimental variogram of the variable (Chilès & Delfinet 2012), with a lag equal to the minimum distance of measured point, following the Equation 7.

$$\gamma(h) = \frac{1}{2N(h)} \sum_{i=1}^{N(h)} (z(i) - z(i+h))^2 \qquad (7)$$

where z(i) is the value of the considered variable at a location, z(i+h) is the value of the variable at the distance h, and N(h) is the number of couples of points with a distance equal to h. This spatial correlation of the variable is modelled with a theoretical function. In the present study, the spherical model (Chilès & Delfinet 2012) is adopted to interpolate the spatial correlation (Equation 8).

$$\gamma(h) = \begin{cases} C\left(\frac{3}{2}\frac{h}{a} - \frac{1}{2}\frac{h^3}{a^3}\right) & 0 \leq h \leq a \\ C & h > a \end{cases} \qquad (8)$$
Figure 3. Spherical variogram.

In general, the variogram $\gamma(h)$ is an increasing function with the distance h. The model introduces two parameters. The *sill C* describes the level of spatial variability, and the *range a* represents the maximum distance at which spatial correlation is observed.

The amplitude of w_{d0} used for the statistical test is defined as a ratio of the range a. The T ratio and ρ_I are calculated for each point d_0, implementing two new vertical profiles. The higher values of T ratio and ρ_I correspond to a change of behaviour of the CPT-based parameters Ic.

The critical value of the parameter T ratio (t_c) is evaluated considering the 90% confidence interval of the T ratio distribution and is calculated following Equation 9.

$$t_c = \mu_{T\,ratio} \pm 1,65\,\sigma_{T\,ratio} \qquad (9)$$

where μ_{Tratio} and σ_{Tratio} are respectively mean and standard deviation of the distribution of the T ratio values along the vertical profile. The depth to which T ratio values fall outside the confidence interval represents a change of behaviour along the CPT profile.

The critical value of ρ_{Ic} is calculated following the Equation (10) proposed by Herzagy, Mayne, and Rouhani (1996).

$$\rho_{Ic} = \mu_{\rho_I} + 1,65\,\sigma_{\rho_I} \qquad (10)$$

where $\mu_{\rho I}$ and $\sigma_{\rho I}$ are respectively the mean and standard deviation of the distribution of the ρ_I values along the vertical profile. The depth to which ρ_I values are higher than ρ_{Ic} represents a change of behaviour along the CPT profile.

The transition between two different homogeneous layers is assumed at the d_0 depth points which both critical conditions occur simultaneously.

The described algorithm is implemented with open-source R software (R Core Team, 2021).

2.3 Stratigraphic recognition with AI

In the proposed methodology, the stratigraphic recognition, basically the attribution at each statistically homogeneous layers the correspondent stratigraphic unit, is automatically carried out with artificial intelligence (AI), studying the underlying relation between cone penetration tests information and stratigraphic properties. Reale *et al.* (2018) proposed an automatic classification of fine-grained soils using CPT measurements and Artificial Neural Network. Ching, Wu & Phoon (2020) and Ching *et al.* (2020) proposed a Hierarchical Bayesian Model (HBM) to construct transformation models for soil and rock properties.

The algorithms are trained comparing the outcomes derived from couples of CPT-boreholes considered spatially correlated, providing a complementary description of the subsoil. The CPT-borehole distance has been chosen based on the analysis of the spatial

structure of cone tip resistance in the horizontal direction. A measure of the spatial correlation is the scale of fluctuation, representing the maximum distance over which the points are significantly related (Chilès & Delfinet, 2012).

The calibration procedure is structured as follows: first, the couples of complementary CPT and boreholes are extracted from the geodatabase; once CPT profiles are processed, to each statistically homogeneous layer is associated the stratigraphic unit reported in the complementary borehole; last, the CPT output parameters and their correspondent stratigraphic recognition are used to train, test and validate various algorithms.

The artificial classifier characterized by the highest efficiency is selected and applied to automatically assign the stratigraphic units to the remained sectioned cone penetration test profiles distributed over the studied area.

3 CASE STUDY

The Terre del Reno municipality is located in the southern Po river plain in the Emilia Romagna region (Italy). The area was struck by an intense seismic sequence associated with compression fault ruptures in 2012. The main shock of May 20th 2012 (M_w6.1) produces extensive liquefaction phenomena due to subsoil composition, geologic history and the shallow depth of the groundwater table (Fioravante et al. 2013). The municipality covers an area of 51 km^2, along a former branch of Reno River and is divided into three main districts: Sant'Agostino, San Carlo and Mirabello (Figure 4a).

The San Carlo area is characterized by a complex stratigraphic context due to the depositional history of the Reno river, highlighted by the significant number of liquefactions induced damages (Figure 4b). The calibration of the methodology has been carried out by analyzing the entire available geodatabase on the territory. However, in this work, the stratigraphic recognition is limited to the San Carlo area.

3.1 Definition of stratigraphic units in the municipality of the Terre del Reno

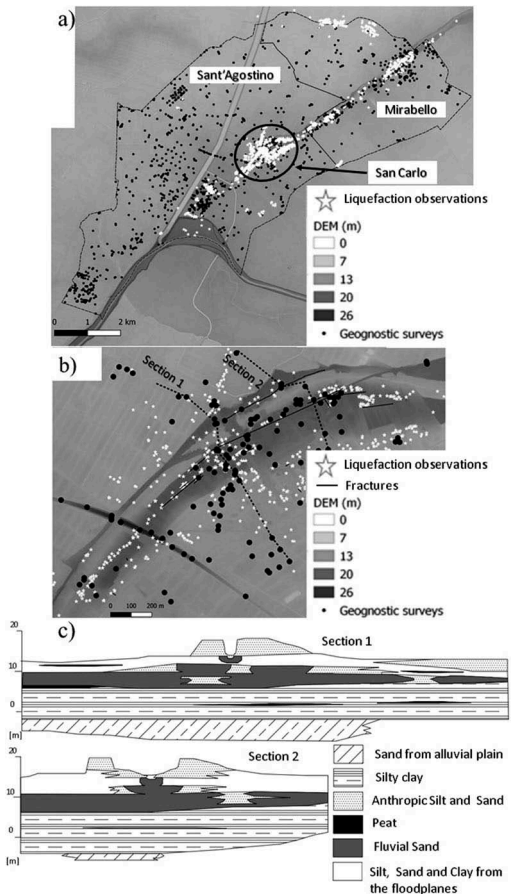
The subsoil of San Carlo is characterized by a relatively recent geologic history, an intensive depositional sequence of the Reno river and a shallow groundwater table (Figure 4c). The depositional activity of the river left superficial layers of loose sand with a thickness of a few meters. In the same period, the population constructed artificial levees mixing sand with silt to regulate the fluvial regime and limit flooding. The urban area is mainly built near those paleo-channel and paleo-levees.


Figure 4. A) Terre del Reno municipality b) San Carlo district, c) Geological sections (adapted from Calabrese et al., 2012).

The deepest layers are constituted of sediments deposited by Apennine and Alpine rivers, interspersed with marine accretion. These alternated processes are ruled by the regression and progression of the Adriatic Sea in the upper Pleistocene-Holocene (Romeo 2012).

The territory of Terre del Reno is covered by around 1700 geognostic surveys, highlighted in Figure 4a. The definition of the stratigraphic units has been carried out analyzing the description reported in 252 boreholes logs distributed all over the municipality. From the geological and sedimentological characterization, four stratigraphic units have been identified in the upper 20 m of the subsoil:

- Unit #1: silt, silty clay, clayey silt;
- Unit #2: sandy silt, silty sand;
- Unit #3: fine and medium clean sand;
- Unit #4: clay, organic clay, organic material.

3.2 CPT profiles processing

The soil boundaries discontinuities recognition has been applied to the district of San Carlo. In the selected area, there is a high density of surveys (Figure 4b). For 369 investigation tests distributed over an area of 3 km², the available boreholes and cone penetration tests reach 82.5%. In particular, the mechanical CPT correspond to 35.5% and the electrical ones to 32% of the total.

The implemented tool provides automatic sectioning of CPT profiles into statistically homogeneous layers.

An example of sectioned CPT profile is shown in Figure 5. From the CPT parameters, the Ic profile is computed. The statistical parameters T_{ratio} and ρ are calculated, and the critical thresholds are estimated. The horizontal dashed lines identify the transition between two different homogeneous layers.
Figure 5. Example of sectioned CPT profile.

For each stratum, the following parameters are computed:

- the Soil Behaviour Type SBT,
- the mean and standard deviation of the Ic values,
- the mean and standard deviation of the friction ratio, FR, defined as ratio between sleeve friction and cone resistance.

3.3 Training and application of the artificial intelligence algorithm

At this stage, information reported in boreholes and sectioned CPT must be cross-correlated to perform an automatic stratigraphic recognition. The calibration of the artificial intelligence algorithm has been performed comparing the outcomes derived from couples of CPT-borehole considered spatially correlated. Due to the complex stratigraphic context in the investigated area of Terre del Reno (Fe), each CPT profile has been considered representative of a circular area having a radius equal to 30 m. This distance has been chosen because the cone tip resistance of the selected site is characterized by

a correlation length equal to Θ = 16.5 m in the horizontal direction and a scale of fluctuation δ = 33 m, representing the maximum distance over which the points are significantly related.

All boreholes located in the defined distance are classified as complementary of the cone penetration tests. The total number of couples CPT-boreholes is equal to 132, but 30 have been deleted due to the poor quality and reliability of the subsoil description. The remaining 102 pairs constitute the starting point for the calibration of the algorithm. The sectioned CPT and the complementary boreholes have been compared.

Besides the output sectioning CPT parameters, at each statically homogeneous layer has been attributed the stratigraphic unit recognized in the complementary boreholes. These parameters are the input values for the calibration of a classifier capable to identify the corresponding stratigraphic unit.

The choice of the algorithm involves the estimation of the efficiency between 32 different artificial classifiers, implemented in the *Classification Learner APP* available in MATLAB R2021b, with a 10 folds cross-validation procedure (Stone 1974). This procedure is suggested to avoid overfitting and to estimate the accuracy obtained within the 10 iterations. Cross-validation divides the dataset into 10 folders of the same size: 9 folders are used to train the classifier while one is used to validate it. This procedure is iterated 10 times, training and testing each folder. The best classifier is a linear discriminant, characterized by an efficiency equal to 81.6%. Linear Discriminant Analysis (LDA) has been proposed by Fischer in 1936. It consists in finding the hyperplane projection that minimizes the interclass variance and maximizes the distance between the projected means of the classes.

In Figure 6a is shown the efficiency of the algorithm to classify the four units, attributing the percentage of success and misclassification. The positive prediction is expressed as Positive Predicted Values (PPV), and the negative classification is expressed as False Discovery Rates (FDR).

Figure 6b consist in a report showing a summary of prediction results of the mutual classification between classes, the grey cells correspond to the PPV and the sum of the remaining elements along the columns is equal to the FDR. For example, the first column summarizes the detail of the layers automatically classified as Unit #1: truly classified in 75.4% of occurrences; Unit #2 has been mistaken with Unit #1 in 15.8% of manifestations; Unit #1 has been attributed to the real Unit #3 in 1.2% and in the remaining 7.6%, Unit #4 has been classified as Unit #1. In particular, the mutual misclassification between sands and clays never occurs. Furthermore, the lower PPV values are associated with Units #1 (silt, silty clay, clayey silt) and #2 (sandy silt, silty sand), located in the upper 10 m of the subsoil and characterized by a complex geological history.

a)

	Predicted Unit			
	1	**2**	**3**	**4**
PPV	75.4%	74.9%	83.2%	92.9%
FDR	24.6%	25.1%	16.8%	7.1%

b)

		Predicted Unit			
		1	**2**	**3**	**4**
True Unit	**1**	**75.4%**	7.3%	1.7%	6.2%
	2	15.8%	**74.9%**	15.1%	0.9%
	3	1.2%	17.4%	**83.2%**	0.0%
	4	7.6%	0.4%	0.0%	**92.9%**

Legenda:
* 1: silt, silty clay, clayey silt;
* 2: sandy silt, silty sand;
* 3: fine and medium clean sand;
* 4: clay, organic clay, organic material.

a)

b)
Figure 7. a) Input parameters and output for the selected LDA algorithm and b) application on the surveys disseminated all over the area.

Once the effectiveness was ascertained, the algorithm (Figure 7a) was applied to the remaining cone penetration tests, obtaining the stratigraphic recognition of the surveys disseminated on the investigated area (Figure 7b).

4 CONCLUSION

This work aims to propose a methodology for subsoil stratigraphic reconstruction based on the most diffused geotechnical survey, combining statistical tools and artificial intelligence algorithms. In particular, the proposed methodology identifies the layer discontinuities from the sectioning statistical test of the CPT profiles, the main lithologies from borehole log stratigraphies, and the automized stratigraphic classification of each statistically homogeneous layer from AI. The procedure has been implemented and validated in the complex geological context of the alluvial plain of Terre del Reno in Italy, characterized by a large geodatabase. The automatized methodology is easily replicable in other contexts for the stratigraphic recognition of the subsoil on a large scale, providing a valid tool for several applications as liquefaction risk analysis at an urban scale on structure and infrastructure (Paolella *et al.* 2021, Baris *et al.* 2021, Modoni et al. 2019) and subsidence study (Spacagna *et al.* 2020, Spacagna & Modoni, 2018). The data-driven analysis provides reliable and indispensable results for the construction of a robust and coherent geotechnical model of the subsoil. The next step concerns the interpolation of the stratigraphic surfaces to obtain a complete reconstruction of the subsoil.

ABSTRACT: The paper shows the geotechnical characterization of a soft clay test site by means of laboratory testing. Such a test site was established in the campus of the Department of Biology of the University of Pisa at about 1.6 km from the Leaning Tower square. The main (but not exhaustive) scope of the present research activity was to compare the propagation velocity of body waves as obtained from various seismic techniques. A preliminary site characterization, based on both laboratory and in situ tests, was carried out. In situ testing consisted of a preliminary CPTu, three boreholes with four high quality Osterberg-type undisturbed sampling, cross-hole, surface seismic reflection test named Multichannel Analysis of Reflection Waves (MARW). Laboratory tests consisted of soil classification (Atterberg Limits and grain size distribution), incremental loading oedometer tests (OE), direct shear tests (DS) and resonant column tests (RC). Moreover, Pagani seismic piezocone and Marchetti seismic dilatometer were used for the assessment of the propagation velocity of body waves.

1 INTRODUCTION

The capability of seismic piezocones (SCPTu) and seismic Marchetti dilatometers (SDMT) in determining the propagation velocity of body waves is the final objective of the present research activity. For such a purpose, a test site was selected in Pisa. This site is in a campus of the University of Pisa, namely the Department of Biology (Figure 1).

Figure 1. Test site layout.

The in-situ characterization consisted of a preliminary CPTu, boreholes (with undisturbed sampling), cross-hole (CH) and surface seismic tests (i.e. SH re-flection test as Multichannel Analysis of Reflection Waves - MARW). A direct stratigraphy was inferred from borehole S1.

The in-situ characterization was carried out by:
- Geoservizi snc (CPTu)
- Geo-Energizer snc (surface seismic test: MARW)
- Servizi Geologici S.a.s. Morbin F. & C. (boreholes S1, S2, S3)
- SolGeo Srl (Cross-hole. Borehole S2 was used as source, the other two as receivers)

The laboratory test results were carried out on four high-quality Osterberg-type samples. In particular, the results of laboratory classification (Atterberg Limits and grain size distribution), incremental loading oedometer tests (OE), direct shear tests (DS) and resonant column tests (RC) are shown. The recommendations of the Italian Geotechnical Society – AGI were mainly followed in performing laboratory tests (AGI, 1994). Anyway, these recommendations mainly conform to the ASTM standards that were preferred in case of discrepancies.

Table 1 shows the identification number of each sample, the sampling depth, as well as types and number of tests that were performed. Some samples were apparently non-homogeneous; therefore, classification and RC tests were carried out by considering different portion of the samples. The water table was located at a depth of three meter from ground level when the samples were retrieved.

Table 1. Laboratory testing program.

Sample	Depth m	Grain Size #	Atterberg #	DS #	OE #	RC #
C1	4.5-5.0	1	1	1	1	1
C2	8.5-9.0	4	4	1	1	2
C3	19.5-20.0	1	1	1	1	1
C4	26.5-27.0	3	3	1	1	2

This paper mainly deals with in situ seismic measurements. Laboratory tests are shown but not discussed or compared with in situ test results, except data coming from RC tests.

2 LABORATORY CHARACTERIZATION

2.1 *Physical characteristics*

Tables 2 and 3 summarize the physical characteristics of the tested samples. In particular, the natural and dry unit weight are reported. As for the unit weight, the mean and the standard deviation are reported. Moreover, the natural water content, the liquid limit and the plasticity index are shown. Percentages of grain size classes and USCS classification (ASTM D2487-17e1, 2017) are eventually reported.

Figure 2 shows the grain size distribution curves. According to the laboratory test results the presence of silt mixtures seems to prevail at various depths.
Figure 2. Grain size distribution curves.

Only at a depth of about 20 m a fat clay was identified from classification tests.

2.2 *Oedometer and direct shear tests*

Tables 4, 5 and 6 summarize the parameters as obtained from incremental loading oedometer tests.

Table 2. Soil classification.

Sample	Depth m	Sand %	Clay %	Pass. #200 %	USCS

Compressibility parameters are shown in Tables 4 and 5, while the hydraulic parameters in Table 6. The results from oedometer tests confirm what already observed as for the soil classification. The sample at the depth of 20 m exhibits a much greater compressibility and a permeability reduced of about two orders of magnitude. The coefficient of primary consolidation was computed by using both Taylor (1948) and Casagrande (1936) methods. Anyway, in the case of specimens containing more silts the interpretation of the settlement-time curve was clearer

with the Taylor method than with the Casagrande approach. Therefore, only the results obtained by the Taylor approach are shown. Obviously, the secondary consolidation coefficient was inferred from the semi-log Casagrande representation as slope of the secondary compression branch of the curve.

In the normally consolidated range, the constrained modulus exhibits the typical linear trend with the increase of the consolidation pressure. Only for the C3 sample a decrease of M until the pre-consolidation pressure was observed. The secondary compression coefficient increases, as expected until the applied pressure is 1.5 – 2.0 times the pre-consolidation pressure. On the other hand, the permeability linearly decreases with the applied pressure in a log scale, as usually. Differences between the clay sample (C3) and the other are evident in terms of both compressibility and hydraulic parameters.

Also, direct shear tests were carried out on the four high-quality Osterberg-type samples. For each sample, three specimens were tested in the direct shear box. The applied consolidation pressures were selected to include the best estimate of the in situ vertical effective stress.

Differences between sample C3 and the others were evident in terms of strength parameters. As a first estimate at peak, sample C3 exhibits a cohesion of about 5 kPa and an angle of shear resistance of about 20° whilst other samples have an apparent cohesion of about 2 kPa and an angle of shear resistance of about 30°. At large displacements the apparent cohesion is almost zero while the angle of shear resistance decreases to about 17° for the C3 sample. For the other samples, the angle of shear resistance remains almost constant. Moreover, except for the C3 sample, the others exhibit a certain curvature of the strength envelope.

2.3 Shear stiffness and damping ratio

RC tests were carried out according to ASTM D4015-15e1 (2015). Figures 3 and 4 respectively show the normalized shear modulus and the damping
Figure 3. Normalized shear modulus vs. shear strain from RC.
Figure 4. Damping ratio vs. shear strain from RC tests.

ratio as inferred from RC tests vs. the log of the shear strain. The reference curves, that have been suggested by Vucetic and Dobry (1991) for non-plastic soils and for soils with a PI of 50%, are also shown.

The influence of the PI on the RC results is confirmed even though a certain discrepancy is seen for high plasticity soils between the experimental results and the suggested curves. The small strain shear modulus typically ranges in between 36 and 40 MPa while the last specimen of the C4 sample gave an initial shear modulus as high as 90 MPa. The specimens were iso-tropically consolidated at the best estimate of the in situ vertical effective stress.

3 IN SITU TESTS

3.1 CPTu and DMT tests

Figures 5, 6 and 7 respectively show, in a standard format, the results of CPTu (ASTM D5778-20, 2020) and DMT tests (ASTM D6635-15, 2015). In particular, Figure 6 shows the modified SBTn (I(B)) profile (Robertson, 2016, 2021). Figure 8 shows the stratigraphic profile as inferred from borehole S1. Boreholes S2 and S3 were both core destruction surveys. As a preliminary comment, the indirect stratigraphic profiles from CPTu and DMT exhibit some differences. This point should be discussed in the light of laboratory test results, which is beyond the scope of this paper.
Figure 5. CPTu test results: (a) tip resistance; (b) sleeve friction; (c) pore pressure.

3.2 Body waves propagation velocities via different techniques

Reflection technique is based on recording time elapsing between the instant an elastic impulse is generated from the surface, reflected from a deep lithological interface and raised back to the surface.

In this sense, reflection exploits seismic impedance contrast between different materials and its advantage is the ability to penetrate underground with accuracy.

MARW is an innovative seismic technique based on 1D simplification of classical reflection survey. Advantages of this technique derive in acquiring a single Common Depth Point (CDP) or Common Shot Gather (CSG). Dataset is subsequently analyzed through a regular processing flow to derive a vertical seismostratigraphy. This method reaches its greatest effectiveness in lithological domains characterized by slopes less than 15°.

Figure 9 represents the acquisition geometry of MARW survey. For this test 96 high sensitivity 4.5 Hz horizontal geophones connected to a 96 channels 24 bit Do.Re.Mi SARA Electronic Instruments Seismograph were employed. The energy source consisted of a 12 Kg sledgehammer transversely hitting (three times to increase S/N ratio) a wooden plate placed in B1 position.
Figure 6. Modified Soil Behaviour Type (SBTn) form CPTu.

A very accurate data processing has been used to increase reflected events visibility: trace normalization, gain recovery (AGC), band pass filter, predictive deconvolution, muting first break, FX deconvolution, NMO correction.

Figure 10 shows from left to right: a) processed CSG before velocity analysis; b) the semblance (which shows velocity values consistent with reflection events); c) time stack trace (repeated four times); d) depth converted stack trace.

waves) and transverse (S waves) propagation times between two or more holes along horizontal trajectories. Travel-times, along with distances between source and receiver points, allow defining seismic wave velocity of investigated soils. The CH tests were carried out using central hole (S2) for positioning of transmitting sources and S1 and S3 holes for simultaneous acquisition by means respective receivers (P and S). Therefore, it was possible to verify the subsoil homogeneity of the survey area. A "Sparker" generator was employed to create compression waves while a "GEOS" transducer produced vertical polarized shear waves (instruments, both source and receivers, used for cross-hole survey was by Solgeo s.r.l.). Record of signals (Figure 11) was made by means of two different types of transducers to receive P and S waves respectively.

Pre-amplified hydrophones were employed to receive P waves and pre-amplified 28 Hz AVG geophones (Amplified Vertical Geophone) for S waves. Acquisitions were carried out with 1 m vertical constant intervals by a 2x16Bit MCHA-GP sampler. Signals were acquired with a 100 kHz frequency sampling for S-waves and 200 kHz for P-waves (record length 100 ms). First arrival times were manually picked through a PC interface. Velocities was simply calculated by operating the distance/times ratio. A preliminary inclinometric survey was carried out to define hole deviation from vertical direction through simultaneous measurement of inclination and

Due to limitations related to acquisition geometry, the accuracy of depth and velocity values is progressively reduced beyond depths of about 60 m.

Alongside the geophones array two in-hole seismic tests (Cross-Hole) were carried out.

Cross-hole geophysical surveys consist of direct measurements, at various depths, of longitudinal (P
Figure 11. Cross-Hole records (S2-S1 left; S2-S3 right).

orientation. All three holes showed contained inclinations ranging between 10 and 20 cm.

Seismic piezocone consisted of a standard cone (10 cm^2 area) measuring tip resistance, sleeve friction, dynamic pore pressure and inclination. The piezocone was pushed by means of a Pagani TG73 – 150 penetrometer. The seismic module of SCPT was equipped with two 3D accelerometers. The relative distance between the accelerometers was 0.5 m. Therefore, two waveforms were recorded for each hit by the data acquisition system. The source consisted of a manual hammer (5 kg) hitting a wooden plate. Test interpretation was carried out by means of the crosscorrelation method and the true interval method.

The SDMT is the combination of the Flat Dilatometer with an add-on seismic module for measuring the shear wave velocity (Marchetti et al., 2008) and optionally also the compression wave velocity. The seismic module is an instrumented steel rod placed just above the DMT blade and equipped with two receivers spaced 0.5 m. When a shear or compression wave is generated at surface, it first arrives to the upper receiver, then, after a delay, to the lower receiver. The wave traces of the two receivers are amplified and digitized at depth and transmitted to the computer at surface. The software processes the signals and evaluates the arrival delay, providing a real time interpretation of the wave velocity. True interval method is used for evaluating the propagation velocity of body waves. Figure 12 compares the body waves propagation
Figure 12. Vs profiles inferred by various techniques.

velocity as inferred from different in situ and laboratory tests. The Figure shows a very satisfactory agreement among the different testing methods. Moreover, laboratory testing well compared to in situ measurements.

4 SUMMARY AND CONCLUSIONS

The paper gives preliminary information about a test site that has been selected for establishing the precision and accuracy of available seismic methods in measuring the propagation velocity of body waves. At this stage we have a preliminary comparison between MARW, CH, SDMT and SCPT. This activity will continue, and we intend to invite other producers of seismic piezocone to participate into this research. As for the S waves the comparison among various techniques is very good. As for the P waves (less important for engineering applications), it is possible to confirm that below the water table (as already observed by various researchers) V_p is almost constant and equal to the propagation velocity in water. On the other hand, only CH test was capable of giving an estimate of V_p.

ABSTRACT: The rapid expansion of offshore wind energy requires accurate and cost-effective site characterisation. The dynamic response of offshore wind turbine structures installed on monopile foundations strongly depends on the stiffness of the subsoil where the small-strain shear modulus governs the behaviour during operational loading. Direct measurement of the small-strain shear modulus with the seismic CPT (S-PCPT) is increasingly performed offshore. However, the additional cost associated with this test leads to incomplete data coverage. In the past, correlations between cone tip resistance and small-strain shear modulus have been developed for onshore conditions. The increasing availability of offshore site data has allowed a unique dataset of over 2000 small-strain shear modulus measurements from S-PCPT to be created for North Sea soil units. The comparison of the small-strain shear modulus inferred from the S-PCPT data to the corresponding cone tip resistance allows recalibration of the existing correlations. This paper proposes a Bayesian approach to update the correlation model for sands proposed in the literature based on the developed dataset for offshore conditions in the North Sea.

1 INTRODUCTION

1.1 *Applications of small-strain shear modulus in geotechnical design*

For offshore wind monopile foundations, the design is mainly driven by the fatigue limit state (FLS) (Maes et al. 2016) and is no longer dominated by the ultimate limit state (ULS) which was traditionally the design driver in offshore Oil & Gas platform geotechnical design. An accurate assessment of the fatigue life of the foundation monopile requires the assessment of non-linear soil response which shows a strong dependence on strain level (Zuccarino et al. 2019).

While dynamic soil properties and strain dependence of the shear modulus have traditionally been researched mostly in the context of earthquake engineering (Idriss and Boulanger 2008), the need for accurate foundation response models for monopile foundations has seen a renewed interest in the characterisation of these properties for marine soils in areas with low seismic activity.

Recent design methods for lateral foundation response of offshore monopiles in stiff clay (Byrne et al 2020) and sand (Burd et al. 2020) make use of the small-strain shear modulus as a governing soil parameter. The improved accuracy of the foundation response models has been demonstrated based on in-situ monitoring data (Stuyts et al. 2020).

1.2 *Offshore measurement of small-strain shear modulus*

Quantifying the small-strain shear modulus (G_{max}) is usually done through in-situ measurements although bender element testing on reconstituted samples can also be performed. Due to the lack of direct access to the seabed, onshore techniques such as cross-hole measurements and surface wave measurements are rarely performed.

Seismic PCPT tests (S-PCPT) are the dominant offshore measurement techniques. Figure 1 shows a sketch of the measurement system. A seismic source at the mudline emits shear waves into the soil which propagate downward with a velocity V_s governed by the mechanical properties of the soil mass. A dual geophone setup is preferred nowadays. The difference in arrival times between the two geophones can be derived by examining the cross-correlation between the two signals. The receiver offset (Δz) divided by the difference in arrival time (Δt) then provides an estimate of the shear wave velocity (V_s). The shear wave velocity can be converted to a small-strain shear modulus when the density of the soil (ρ) is known (Equation 1).

$$G_{max} = \rho \cdot V_s^2 \qquad (1)$$

In recent years, the P-S suspension logging technique has been increasingly used offshore (Masters et al. 2019) but the empirical correlation proposed here is based exclusively on S-PCPT measurements.

Figure 1. Sketch of S-PCPT measurement system.

2 EXISTING G_{MAX} CORRELATIONS

Because the S-PCPT test is relatively more expensive than a conventional PCPT test, shear wave measurements are generally not available at every foundation location. Instead, several authors have sought to correlate shear wave velocity with conventional PCPT measurements to allow derivation of site-specific stiffness parameters. These studies are based on onshore measurement campaigns where PCPT test data are compared to shear wave velocity measurements at locations where both data types are available.

The mostly widely used correlation for uncemented silica sands was developed by Rix & Stokoe (1991) based on calibration chamber measurements and the results of PCPT, S-PCPT and cross-hole tests. Equation 2 shows the dependence of the small-strain shear modulus on the cone tip resistance and the vertical effective stress level.

$$\left(\frac{G_{max}}{q_c}\right)_{ave} = \alpha \left(\frac{q_c}{\sqrt{\sigma'_{vo}}}\right)^{\beta} \tag{2}$$

Figure 2. Geospatial distribution of S-PCPT tests.

where the small-strain shear modulus G_{max}, the cone tip resistance q_c and the vertical effective stress σ'_{vo} are given in kPa. The coefficients $\alpha = 1634$ and $\beta = -0.75$ are suggested by the authors.

Several other empirical correlations exist in the literature (Hegazy and Mayne 2006). Most of these correlations were obtained using regression methods (i.e., least squares fitting) that do not directly quantify the uncertainties of predictions. To overcome this issue, the Bayesian framework can be adopted, as it provides the probability distribution of the model parameters instead of a single best estimate. In addition, the Bayesian framework allows further updating as additional data becomes available during future offshore campaigns.

In this paper, the principle of Bayesian updating of the parameters of the correlation between cone resistance and small-strain shear modulus will be outlined based on the aforementioned model proposed by Rix & Stokoe (1991).

3 NORTH SEA G_{MAX} DATASET

3.1 Data sources

A comprehensive dataset of shear wave velocity and small-strain shear modulus of offshore North Sea soils was assembled in the context of research on monopile response back-analysis. Table 1 shows the data compiled for four areas in the Belgian and Dutch sector of the North Sea. The coordinates of the S-PCPT test locations are shown in Figure 2.

The geology of the Borssele area and the Belgian offshore area shows a layered profile with a surface
Figure 3. Overview of available data on clean sands and the correlation proposed by Rix & Stokoe. The valid range of the correlation is represented by the dashed lines.

layer of holocene/pleistocene sand overlying a tertiary clay formation which dips towards the northeast. In the Hollandse Kust area, mainly cohesionless sediments are found, with channel features leading to lateral variability of the deposits. Finally, the area north of the Wadden Islands has softer soils at the surface, which are classified as peat based on the normalized Robertson chart (Robertson and Cabal 2015). A summary of the available measurement and its classification following the the normalized Robertson chart is shown in Table 1.

This work will focus on clean sands (SBT_n zone 6) since this is the soil type the correlation was initially developed for. In Figure 3 the data are plotted according to the normalisation suggested by Rix & Stokoe (1991). Although the data confirms the general trend suggested by the authors the bias towards conservative estimates is clear and some data fall outside the valid range of this correlation.

4 BAYESIAN UPDATING

4.1 Introduction

Bayesian theory treats uncertainty as degrees of belief and it allows to combine information from multiple sources for the purpose of updating prior knowledge given new information. From a geotechnical point of view, the Bayesian method follows the same logic as the observational method (originally proposed by Terzaghi) and as a result it is a powerful basis for inference (Baecher 2017).

The core of Bayesian methods is the *Bayes' Rule*. It says that a hypothesis (i.e., parameters to be inferred) expressed as probabilities can be modified (i.e., updated) by observational information according to the conditional probability (*likelihood*) of those observations were a certain hypothesis true or not. If a hypothesis is denoted as H, Bayes' Rule can be written in a "friendly form" (Equation 3).

$$P(H|data) \propto P(data|H) \cdot P(H) \qquad (3)$$

where:

- $P(H|data)$ is the *posterior*, the updated probability based on having made certain observations;

- $P(data|H)$ is the *likelihood* of the data;

- $P(H)$ is the *prior*, the probability before seeing the data which reflects prior knowledge.

As more observational data are introduced, uncertainties can be reduced through updating the mean values and decreasing the variance of our hypothesis.

4.2 Probabilistic model

When applied to the derivation of small-strain shear modulus from PCPT measurements, the multiplier α and exponent β in Equation 2 are the principal parameters to be updated by computing posterior distributions using Bayesian inference.

By taking the logarithm of Equation 2, a linear regression model can be used to model the relation between G_{max} and q_c (Equation 4).

$$\log_{10}\left(\frac{G_{max}}{q_c}\right) = \log_{10}(\alpha) + \beta \cdot \log_{10}\left(\frac{q_c}{\sqrt{\sigma'_{vo}}}\right) \qquad (4)$$

where the slope is the coefficient β and $\log_{10}\alpha$ the intercept which will be noted by α'.

The dependent variable $\log_{10}(G_{max}/q_c)$ is denoted by y and the independent variable $\log_{10}(q_c/\sqrt{\sigma'_{vo}})$ by x. Then, the linear regression model can be written in a probabilistic manner as in Equation 5 (Gelman et al. 1995).

$$y \sim \mathcal{N}(\mu = \alpha' + \beta \cdot x, \ \varepsilon) \qquad (5)$$

in other words, the dependent variable y is assumed to follow a normal distribution with a linear trend as mean (μ) and a standard deviation (ε). An error term (ε) is used to model the mismatch between the model and the actual data.

After applying Bayes' rule Equation 5 is the likelihood of the data. Following the Bayesian method, prior distributions need to be assumed for the unknowns parameters, to compute the term $P(H)$ from Equation 3. Standardization was performed on the left- and right-hand side of Equation 4. Standardization consists of subtracting the mean from the data and dividing by the standard deviation. One advantage of standardizing the data is that the same weakly informative priors can always be used without having to think about the scale of the data. A common choice is to assume normal distributions as priors for the intercept and slope and a HalfCauchy prior for the error term.

Figure 5. Computed posterior distribution of the model error represented by the coefficient of variation.

5 PROBABILISTIC RECALIBRATION OF G_{MAX} CORRELATION FOR COHESIONLESS SOILS

The probabilistic models were built using PyMC3, a Python package for Bayesian modelling based on Markov Chain Monte Carlo algorithms (Salvatier et al. 2016).The result of a Bayesian analysis is a posterior distribution, not a single value but a distribution of plausible values given the data and the proposed model and there are many methods for computing the posterior distribution. Here, the posterior was estimated numerically using an algorithm from the Markov Chain Monte Carlo (MCMC) family, known as No-U-Turn Sampler (NUTS) (Hoffman et al. 2014).

The posterior distribution of the inferred parameters α and β can be visualized in Figure 4. The results show that the exponent of -0.75 suggested by Rix & Stokoe applies well to the data. However, the multiplier of 1634 suggested based on the calibration chamber dataset needed to be substantially increased for the North Sea dataset. The statistics of these parameters are summarized in Table 2. The mean and standard deviation are shown as well as the 95% Highest-

Posterior Density (HPD) interval. The 95% HPD is the shortest interval containing the true value of the parameter in question with a probability of 0.95.

Transformation uncertainty which is basically the data scatter about the transformation model can be expressed quantitatively by means of the coefficient of variation (Phoon and Kulhawy 1999). This uncertainty will be noted by CV_M and can be visualised by sampling from the posterior distributions as shown in Figure 5. Transformation uncertainty follows a narrow distribution showing a modal value about 36%.

Finally the inferred model is shown in Figure 6. The average model that fits the data was represented by a black solid line. Note that the most probable value is given by the mode of the posterior. In this case, the mean is a good approximation since the posterior of both coefficients showed a Gaussian shape (Figure 4). This model leads to an improvement in the model bias of 28%. This means that the distribution of the ratio of
Figure 6. Recalibrated correlation model based on North Sea data: average and standard deviation.

predicted to measured G_{max} shifts closer to unity (the original Rix & Stokoe correlation showed a bias of 0.65.

The dashed lines in Figure 6 represent the average standard deviations of the model prediction based on the average CV_M equals to 0.36. The impact of the *statistical uncertainty* of the correlation model is represented by the semitransparent grey band to illustrate the 95% HPD. Both errors, statistical and transformation uncertainties are not constant, increasing when the ratio $q_c/\sqrt{\sigma'_{vo}}$ decreases. Indeed, for shallow layers, less data is available and noise in the data (e.g. due to waves propagating down the cone rod interfering with the shear wave propagating through soil) introduces more scatter in the small-strain shear modulus measurements. It is therefore possible to conclude that the model does not provide accurate predictions when the ratio $q_c/\sqrt{\sigma'_{vo}}$ is lower that 1000 approximately.

6   CONCLUSIONS AND RECOMMENDATIONS

This paper presents the results of Bayesian inference to recalibrate the correlation model between cone resistance and small-strain shear modulus suggested by Rix & Stokoe (1991). This recalibration is based on a dataset of 1749 small-strain modulus measurements with the S-PCPT for North Sea sands.

The results show that the exponent suggested by Rix & Stokoe is largely confirmed by the assembled dataset. However, the multiplier α needs to be substantially increased as the original Rix & Stokoe correlation underestimates the small-strain shear modulus for nearly all cases. The recalibrated model provided in Equation 6.

$$\left(\frac{G_{max}}{q_c}\right)_{ave} = 2241\left(\frac{q_c}{\sqrt{\sigma'_{vo}}}\right)^{-0.747} \quad (6)$$

with a coefficient of variation of the prediction error of 0.36.

The average model is useful in obtaining a best estimate of the small-strain shear modulus. The uncertainty on the estimate of G_{max} can be assessed thanks to the coefficient of variation and by assuming a normal distribution. The provided statistics can be used as a basis for a reliability analysis for e.g. lateral pile response. The effect of the uncertainty on G_{max} on the natural frequency estimate could thus be quantified.

Following the Bayesian updating philosophy, the reported statistics of the model coefficients can be used to build priors distribution for further calibration of the model when new project-specific information becomes available.

Factors influencing CPT$_U$ N$_{kt}$ for marine clay in Singapore reclaimed land

C. Tanaka, M. Angeles & J.Y. Wong

Arup Singapore Pte. Ltd., Singapore

ABSTRACT: Cone penetration tests with porewater pressure measurements (CPT$_U$) are extensively adopted in Singapore due to the presence of soft soils from the young deposits of the Kallang Formation. The most prominent member of this formation is the soft Singapore marine clay, which can be present in thicknesses of up to 50m. Singapore is a relatively small island, and as such, over the past few decades has embarked on numerous reclamation projects to increase land to support their growing economy and population. Therefore, significant data in reclaimed land overlying soft deposits is available, especially in the east of Singapore. This has presented the opportunity to review the factors that influences N$_{kt}$ in the marine clay located within this area. N$_{kt}$ plays a significant role in the evaluation of the undrained shear strength (c$_u$), which is often derived from site-specific calibrations. This paper summarizes the CPT$_U$ results carried out in reclaimed land to the east of Singapore. It discusses the calibration of N$_{kt}$ with other site data, and proposes a range of N$_{kt}$ to be adopted in this location.

1 INTRODUCTION

Reclamation works have been carried out in the east of Singapore in phases, starting with the original reclamation scheme throughout the 1970's and 1980's. Subsequently, further lands were reclaimed for the development of airport infrastructure from the late-1980's till early 2000's, forming the land as it is seen today as shown in Figure 1. Ground improvement works were also conducted to improve the soft marine clay in most of the reclaimed site. A series of site investigation (including CPT$_U$ and boreholes) were carried out on site along the course of the reclamation and ground improvement works to understand the geological conditions and strength of the ground. This paper presents the interpreted undrained shear strength (c$_u$) results from CPT$_U$ carried after all ground improvement works had been completed, post 2014. It compares the cu values obtained at two different locations across the site (Location A and B, Figure 1). It also presents a calibration exercise of N$_{kt}$ while drawing correlations to the site history.

2 SITE HISTORY AND GEOLOGY

The site locations A and B were reclaimed in different phases as part of reclamation works that took place from 1992 to 2005 where 2,000 ha of land were reclaimed by placing 272 million m^3 of granular fill in seawater with a depth up to 15m (Bo et al. 2005). This was done in various ways, including direct dumping, hydraulic filling and sand spreading.

Direct dumping was utilized at deeper waters of 6m to 8m, while hydraulic filling was utilized for shallower depths of 2m to 6m.
Figure 1. Singapore topography maps in 1970s (top left) and 2010s (top right) and Location of site (bottom).

As the reclaimed site was underlain by 50m of soft marine clay, prefabricated vertical drains (PVD) coupled with surcharging were proposed to accelerate consolidation of the underlying deposits during

Table 1. Summary of site works at Locations A and B.

	Location A	Location B
Reclamation Period[1]	Phase 1A: 1992 to 1997	Phase 1B: 1993 to 1999
Reclamation Method[1]	For sites from -5mCD to -10mCD: Direct Dumping from bottom opening barges then hydraulic filling by cutter suction dredgers Others: Hydraulic filling by cutter suction dredgers	Hydraulic filling by cutter suction dredgers
Ground Improvement History	No known post reclamation ground improvement	Post reclamation 1993 to 1999: PVD installed at square grids of 1.5 m/ 1.7 m with surcharging of minimally 18 months[1] Land preparation for future development 2014 to 2018: PVD installed at square grids of 1.0 m/ 1.2 m with surcharging of minimally 6 months

[1]Note: Choa (1995)

reclamation works from 1992 to 2005 (Choa et al. 2001) and post reclamation works from 2014 to 2019. A summary of reclamation and known ground improvement history across the two locations can be found in Table 1.

Extensive site investigations have been carried out post ground improvement for land preparation for future development from 2015 to 2020. More than 2000 CPT$_U$ and 1000 boreholes were conducted on site to understand the post-improvement conditions as shown in Figure 2.

The site investigation show the ground conditions across the site are highly variable due to the multiple reclamation methods. Generally, the site consists of approximately 10m to 15m of thick reclamation fill underlain by 5m to 40m of Kallang Formation, followed by the stiff deposits of the Old Alluvium. The most prominent member of the Kallang formation is the soft marine clay, with thickness varying from 20m and 40 m at Locations A and B, respectively as shown in Figure 3.

Site investigations carried out includes in-situ tests: CPT$_U$ and vane shear tests (VST) and laboratory tests: Triaxial unconsolidated undrained tests (UU) and one dimensional Oedometer tests. These tests are used to determine the undrained shear strength of the ground. From the site investigation, the Marine clay has varying consolidation states as discussed in Chapter 5.
Figure 2. Site investigation plan.
Figure 3. Geological long section.

3 UNDRAINED SHEAR STRENGTH INTERPRETATION OF CPT$_U$

The undrained shear strength (c_u) of the soil from CPT$_U$ is derived using standard correlation (Lunne et al 2002):

$$c_u = (q_t - \sigma_v)/N_{kt} \qquad (1)$$

where:

q_t = corrected cone resistance based on the measured pore pressure; σ_v = total overburden stress; and N_{kt} = empirical cone factor.

The corrected cone resistance (q_t), is calculated from the measured cone resistance (q_c) through the formula

$$q_t = q_c + (1 - a)u_2 \qquad (2)$$

where a = net area ratio of 0.8 to 0.82; and u_2 = pore pressure measured just behind the cone.

Various studies have been conducted to determine the range of N_{kt} values as shown in Table 2. It is observed that a wide range of values have been recommended depending on the varying soil conditions and locations.

Theoretical studies have also related the N_{kt} value to plasticity index (I_p). Singapore Marine Clay properties at this location have been extensively studied by Bo et al (2000), and a N_{kt} correlation is proposed based on plasticity index of the clay where:

$$N_{kt} = 23.8 - 0.263I_p \qquad (3)$$

With a typical I_p of 40% for the marine clay across the site as seen in Figure 4, an N_{kt} value of approximately 14 is recommended.

According to Bo et al. (2000), the N_{kt} will decrease with increasing I_p although studies by Aas et al. (1986) suggest that N_{kt} will increase with increasing I_p; La Rochelle et al. (1988) did not find any correlation between N_{kt} and I_p.

Table 2. N_{kt} recommendations from literatures.

N_{kt} range	Type of Soil	Reference
10 – 15	Normally Consolidated Clay	De Ruiter (1982)
15 – 20	Under-Consolidated Clay	De Ruiter (1982)
15 – 21	Lightly Over-Consolidated Singapore Marine Clay	Dobie (1988)
9 – 17	Clay with PI = 33% – 45%	Lunne et al. (2005)

With the varying range of recommended N_{kt} values, calibration with site-specific undrained shear strength data were utilised for more accurate interpretation of the cone factor. The undrained shear strength data was obtained from the measured uncorrected field VST, Laboratory Triaxial UU test, as well as correlation with one-dimensional oedometer tests pre-consolidation pressure (0.22 P_c').

4 CONSOLIDATION STATE OF CLAY

The consolidation state of the ground is determined by comparing the in-situ and laboratory c_u with the empirical normally consolidated (NC) line with respect to existing ground level. The NC line is derived through the formula by Mesri (1975),

$$c_u = 0.22\sigma_v' \qquad (3)$$

where σ_v' = effective overburden stress with respect to existing ground level.

In general terms, the c_u that falls below the NC line is considered as under-consolidated with respect to existing ground level, while those that lie above are considered over-consolidated with respect to existing ground level.

5 OBSERVATIONS OF N_{KT} VALUES

5.1 Comparison of CPT$_U$ c_u data with VST, UU and Oedometer test data

The undrained shear strength interpreted from various in-situ and laboratory tests for Locations A and B are summarised in Figures 5 and 6, respectively. Interpretations using N_{kt} of 14 and 20 at the two locations are plotted for comparison.

For Location A, N_{kt} value of 14 appears to overestimate the CPT$_U$ c_u data as most of the c_u data from the other tests fall below the CPT$_U$ c_u data as shown in Figure 5a. N_{kt} value of 20 better correlates with the other site investigation data as shown in Figure 5b.

For Location B, N_{kt} value of 20 appears to underestimate the CPT$_U$ c_u data as most of the c_u data from the other tests lies above the CPT$_U$ c_u data as shown in Figure 6a. N_{kt} value of 14 appears to better correlate with the other site investigation data as shown in Figure 6b.

5.2 Comparison of CPT c_u data with NC line

As indicated in Table 1, at Location A, there is not known post reclamation ground improvement
Figure 4. Atterberg limits at locations A and B.

Figure 5a. Location A - c_u plot for N_{kt} = 14.

Figure 5b. Location A - c_u plot for N_{kt} = 20.

works been carried out. Based on Terzaghi consolidation theory, the marine clay is still undergoing consolidation from the reclamation filling carried out to form the site's current ground level. This is in line with interpreted CPT c_u with higher N_{kt} where the CPT c_u data falls below the NC line.

On the other hand, at Location B, two rounds of extensive ground improvement works were carried out. By Terzaghi consolidation theory, the marine clay is expected to be at least in normally consolidated state or over-consolidated. This is in line with interpreted CPT c_u with lower N_{kt} where the CPT c_u data lies above the NC line.
Figure 6a. Location B - c_u plot for $N_{kt} = 14$.
Figure 6b. Location B - c_u plot for $N_{kt} = 20$.

6 CONCLUSION

This paper has presented CPT_U data obtained from two different areas (Location A and B), located within the same site, but with different reclamation and ground improvement histories.

The CPT_U data was used to determine c_u via standard correlations (Lunne,2002). The paper has highlighted that the empirical factor N_{kt} has significant influence in the determination of c_u. Therefore, this paper has presented an N_{kt} calibration exercise by comparing the interpreted c_u from CPT_U with other geotechnical tests, including in-situ vane shear tests, laboratory Triaxial unconsolidated undrained tests and one dimensional Oedometer tests.

The calibration exercise showed that for Location A, which is under-consolidated to existing ground level, an N_{kt} value closer to 20 provides consistency with the c_u obtained from the in-situ and laboratory tests data as well as with its site history. For location B, an N_{kt} value closer to 14 was selected on the same basis.

The N_{kt} values between 14 (Location B) to 20 (Location A) recommend based on a site-specific data calibration is consistent with the general range recommended in other available literature and publications (Lunne,2002).

Based on the N_{kt} variability presented, a site-specific calibration is recommended for derivation of c_u, especially when c_u is critical for the geotechnical design (e.g., assessment of long-term settlements or excavations schemes), and when the site has varying consolidation history, such as the one presented in this paper.

Parameters affecting the CPT resistance of reconstituted sands

Y. Tian & B.M. Lehane
The University of Western Australia, Perth, WA, Australia

ABSTRACT: Despite the popularity of the Cone Penetration Test, uncertainty remains regarding the stress level dependence of q_c in a sand of constant relative density, the effect of the mineralogy and the effect of saturation. This paper provides greater clarity on these effects by presenting results from a large series of drained cone penetration tests performed under controlled conditions in a laboratory pressure chamber. The experiments involve dry and fully saturated silica and carbonate sands placed at a number of relative densities (D_r) and tested at different stress levels and overconsolidation ratios. The observations are compared with existing relationships proposed between q_c and D_r and highlight the approximate nature of such relationships.

1 INTRODUCTION

The relative density (D_r) of coarse-grained soils is usually assessed indirectly from correlations with in-situ test parameters due to the difficulties in obtaining undisturbed samples of these materials. The relationship between CPT cone resistance (q_c) and D_r has been assessed from experiments in laboratory-based pressure chambers that involved CPTs in reconstituted sand samples prepared to a range of D_r values and stress states. The relationships generally employ the following format:

$$D_r = C_1 \ln[q_{c1N}/C_2] \qquad (1a)$$

$$q_{c1N} = [(q_c/p_{atm})/(\sigma'/p_{atm})^n] \qquad (1b)$$

where q_{c1N} = stress normalized cone resistance; C_1 and C_2 are empirical constants, p_{atm} = atmospheric pressure (100 kPa), n = stress level exponent (typically between 0.5 and 0.7) and σ' = effective stress at the level of the cone tip.

The value of σ' adopted is typically the vertical effective stress (σ'_v) in normally consolidated deposits and the mean effective stress (p') in overconsolidated deposits. The use of p' in overconsolidated deposits reflects the dependence of q_c on the in-situ horizontal effective stress (σ'_h) illustrated by Houlsby & Hitchmann (1988). Popular relationships in the form of Equation (1) proposed by Lunne & Christoffersen (1983) and Baldi et al. (1986) respectively are:

$$D_r = 0.34 \ln[q_{c1N}/16] \qquad (2)$$

where $\sigma' = \sigma'_v$ and $n = 0.71$

$$D_r = 0.38 \ln[q_{c1N}/23] \qquad (3)$$

where $\sigma' = $ p' and $n = 0.55$

To allow for shallow penetration effects, which are important at geotechnical centrifuge scale, Lehane et al. (2022) used results from over 70 centrifuge tests in range of normally consolidated silica sands to propose the following relationship:

$$D_r = 0.31 \ln[q_{c1N}/(19 \tanh(az/d_c))] \qquad (4a)$$

where $\sigma' = \sigma'_v$, $n = 0.7$, z=depth, d_c = diameter of the cone penetrometer and a is assessed from an initial approximate estimate of D_r:

$$a = 0.66\exp(-2.5D_r) \qquad (4b)$$

Kulhawy & Mayne (1990) recognized the importance of ageing, overconsolidation ratio (OCR) and sand compressibility and proposed:

$$D_r = \{(q_{c1N}/(305C_F)) \; OCR^{-0.18}C_{age}^{0.5}\}^{0.5} \qquad (5)$$

where $n = 0.5$; C_F = compressibility factor between 0.91 & 1.09 (higher value for more compressible sand) and $C_{age} = 1.2 + 0.05 \log [t/100]$, where t is the time in years.

This paper presents a re-assessment of these correlations using a new series of pressure chamber tests conducted at the University of Western Australia (UWA). These tests were initially performed to test the general applicability of Equation (4) derived from centrifuge CPT data. The test series was subsequently expanded to examine the effect of sand mineralogy (by comparing q_c data in a silica and carbonate sand), sand saturation level (dry and fully saturated) and overconsolidation ratio (hence σ'_h). The test results allow general conclusions to be drawn regarding the relationship between q_c and D_r for reconstituted sands.

2 TEST PROGRAMME

2.1 Test setup

A schematic diagram of the calibration chamber test is shown in Figure 1. The soil sample is created by pluviation of the sand into a cylindrical chamber, which is then loaded vertically to the desired vertical effective stress via a rigid top plate. This plate has circular openings to allow for penetrometer access to the sand. The vertical effective stress is applied by a hydraulic jack and is monitored by a load cell while the cone is driven into the sample at a constant speed by the actuator located on the steel frame. The maximum imposed vertical effective stress imposed in the experiments described here is 75kPa. The walls of the chamber are rigid and a flexible Teflon sheet is bonded to the inner wall to minimize friction.
Figure 1. Schematic of the calibration chamber test.

2.2 Sample preparation

Sand samples are prepared in calibration chambers by pluviation. A sand hopper is fitted on two rails which enables it to move both horizontally and vertically. A constant drop height is maintained during the preparation of uniform sand while the hopper cycles in the horizontal direction. Different relative densities are achieved by varying the horizontal travelling speed, the drop height and the sieve situated at the bottom of the hopper.

Two types of sand are used in this study namely (i) UWA sand, which is a fine silica sand that is sourced commercially and has been tested extensively at the University of Western Australia (UWA) and (ii) Ledge Point carbonate sand, which is obtained from a sand dune near Ledge Point, Western Australia. Properties of the two types of sand are listed in Table 1. A miniature cone with the diameter (d_c) of 7mm is employed for the tests described here. The corresponding d_c/D_{50} ratio is in excess of 20 for both sands, as recommended by Bolton et al. (1999) to avoid particle size effects.

Table 1. Properties of sands used in the tests.

Sand	D_{50} (mm)	Specific gravity	e_{max}	e_{min}	φ'_{cs}
UWA silica sand	0.18	2.67	0.78	0.50	33°
Ledge Point carbonate sand	0.21	2.76	1.17	0.78	35°

* e_{max} and e_{min} are the void ratio limits and φ'_{cs} is the critical state friction angle of the sand

2.3 Test conducted

Over 80 CPTs were conducted in the two sands placed in 12 chambers at a variety of relative densities and consolidated to three vertical effective stress levels (25, 50 and 75kPa). The effects of the degree of saturation (S_r) and overconsolidation ratio (OCR) in silica sand were also examined. A summary of the scope of testing is provided in Table 2, noting that many CPTs were repeated to assess variability and repeatability. Additionally, CPTs were performed to assess if the proximity of the boundary to the penetrometer had an influence on the q_c values measured.

2.4 Boundary effect

Initial trials were conducted to assess if the planned distance of a penetrometer installation location to the chamber boundary (s) influenced the tip resistance.

The steady state q_c values recorded at $\sigma'_v = 50$ kPa in medium dense and dense UWA silica sand at 8, 12 and

Table 2. Summary of the tests conducted.

Sand	D_r	σ'_v (kPa)	S_r	OCR	$q_{c1N,avg}$
UWA	0.1	25, 50, 75	1	1	28
Silica	0.63	25, 50, 75	0	1	118
Sand	0.97	25, 50, 75	0	1-4	283
	0.8	50	1	1	200
Ledge Point	0.06	25, 50, 75	1	1	37
carbonate sand	0.67	25, 50, 75	0	1	163
	0.95	25, 50, 75	0	1	469

27 cone diameters (d_c) from the chamber wall are presented on Figure 2. It is evident that q_c values increased close to the chamber wall at both D_r values when the s/d_c value was less than about 12 and that there is a slightly greater relative effect of the boundary influence in the denser sand. Bolton et al. (1999) found a very similar result in centrifuge CPTs conducted in a circular strongbox, observing no significant increase in q_c due to the proximity of the boundary for silica sand with D_r=81% at s/d_c ratios in excess of 11. All CPT data reported in the following correspond to test results recorded at s/d_c>12.
Figure 2. Influence of normalized proximity to rigid chamber boundary (s/d_c) in medium dense and dense UWA silica sand.

It is of interest to note that q_c values recorded at s/d_c=8 in Ledge Point carbonate sand were identical to those recorded at s/d_c=12 and 27. This reduced boundary influence may arise due to the higher compressibility of the carbonate particles.

3 TEST RESULTS

3.1 Normally consolidated dry silica sand

Typical results obtained during penetration of a 7 mm diameter cone in a pressure chamber are shown in Figure 3(a). These were measured in three separate normally consolidated UWA sand samples with different

D_r values but the same vertical effective stress of 50 kPa. It is seen that the q_c values in dry silica sand increase up to a penetration depth of about $5d_c$ but stabilize thereafter at values of about 2.5 MPa and 8 MPa in the very loose and medium dense silica samples respectively. Evidence from other chamber tests indicated that the slight reduction of q_c with depth seen for these samples is associated with a modest reduction in D_r with depth in these particular samples and is not related to reduced vertical effective stress due to the potential presence of side friction. It should be noted that the very loose sand was water-pluviated and the

(a)

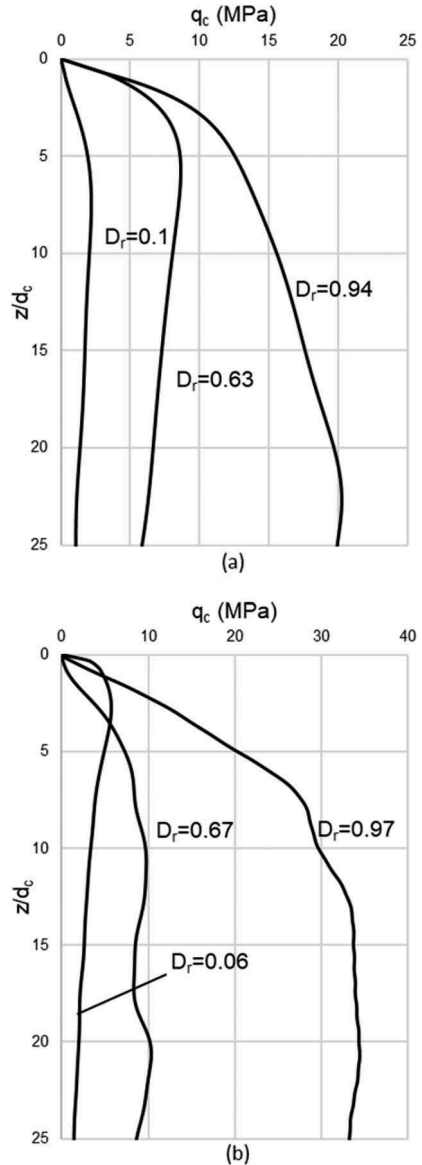
(b)


Figure 3. q_c profiles measured at σ'_v=50 kPa at three relative density values for (a) UWA Silica sand (b) Ledge Point Carbonate sand.
Figure 4. Tip resistance in medium dense UWA silica sand (D_r=0.63) under three stress levels: (a) q_c in MPa, (b) q_c normalized.

reducing trend of q_c with depth in this sample indicates that this process resulted in slightly looser sand at depth.

It is also seen on Figure 3(a) that q_c values in dense silica sand increase with depth and do not tend to a steady state until a penetration depth of about 15-20 d_c. This trend is typical of that shown by other tests indense silica sand. Normalized depths, z/d_c, required to develop steady state conditions in carbonate sand are lower than for silica sand, as seen on Figure 3b. The influence of stress level on the q_c value in a medium dense sample (D_r=0.63) is illustrated on

Figure 4. It is evident that, while the steady state q_c value increases with the vertical effective stress in the sample (σ'_v), q_c is not linearly proportional to σ'_v. This tendency is typical of sands and is reflected by the 'n' exponent in the normalized cone resistance, q_{c1N} (Equation 1b). It is shown on Figure 4(b) that the data from the three stress levels are unified when q_{c1N} is plotted using n=0.7. Data from all 36 CPTs conducted in normally consolidated UWA silica sand were compiled to find a best fit relationship in the form of Equation (1). The following relationship was found to predict measured D_r values to within 10%.

$$D_r = 0.357 \ln[q_{c1N}/21] \qquad (6)$$

where $\sigma' = \sigma'_v$ and $n = 0.7$

Equation (6) is compared with Equation (4) on Figure 5 which was derived independently for the same sand from an extensive series of centrifuge CPTs performed over a larger stress range (from 5 kPa to 330kPa). The plotted centrifuge q_c values correspond to those at the steady state when the hyperbolic tangent term in Equation (4a) is unity. Very good agreement between both data sets is observed, particularly in loose and medium dense sand. The reason for the higher steady state q_c values recorded in dense sand in the centrifuge compared to those in the chamber tests at the same stress levels is under investigation.

Equation (6) is also compared with Equation (2) and (3) in Figure 6, which have previously been proposed for normally consolidated silica sand. Equation (2) has been adjusted to correspond with a stress exponent (n) of 0.7 at the average stress level used in the chamber test of 50kPa to facilitate this comparison. It is evident that agreement is very good between all three equations for D_r <0.7. However, Equation (6) implies greater q_c values in very dense UWA sand, which were also found the centrifuge CPTs.

3.2 Normally consolidated dry carbonate sand

Typical q_c profiles measured in normally consolidated Ledge Point carbonate sand are shown in Figure 3b. A comparison with the the silica sand data on Figure 3a indicates higher q_c values are developed in the carbonate sand at the same density and stress level; this trend reflects higher friction angles of the carbonate particles. The q_c profiles in the carbonate samples also tended to show greater fluctuations or 'peakiness', which is attributed to the samples' greater compressibility. Regression analyses of the calibration chamber data indicated a best fit stress level exponent (n) of 0.7, as for the silica sand and the following best fit relationship:

$$D_r = 0.37 \ln[q_{c1N}/30] \qquad (7)$$
where $\sigma' = \sigma'_v$ and $n = 0.7$

Figure 5. Comparison of q_c relationship with D_r and σ'_v predicted by Equations (4) and (6) for UWA silica sand (for steady state conditions).

Figure 6. Comparison of normalized q_c relationship with D_r predicted by Equations (2), (3) and (6) for normally consolidated silica sand.

Equation (7) is compared on Figure 7 with Equation (6) derived from the calibration chamber data in UWA silica sand. This comparison illustrates the relative magnitudes of q_c values in the two sand types. Equation (5) is also compared with Equation (6) and (7). A stress level of 50 kPa (which was the mean used in the chamber tests) was assumed to enable Equation (5) to be plotted on this figure as this equation employs a stress level exponent of 0.5. In addition, recommended compressibility factors (C_F) of 0.91 and 1.09 were adopted for the silica and carbonate sands respectively. It is evident from the comparison that general agreement is observed between Equation (5) and Equations (6) and (7) both in terms of the trend with D_r and the relative magnitudes of normalised cone resistance.
Figure 7. Comparison of relationships derived for silica and carbonate sand (Equation 6 and 7) with Equation (5) proposed by Kulhawy & Mayne (1990).

3.3 Overconsolidated dry silica sand

Five CPTs were conducted in dense silica sand (D_r =0.97) at σ'_v values of 75 kPa, 50 kPa and 25 kPa after the samples had been pre-loaded to either 100 kPa or 75 kPa. Figure 8a shows the normalized tip resistance calculated using σ'_v and indicates that this normalized value increases with OCR. Figure 8b plots the same data but uses σ'_h to normalize the q_c value for stress level, defined here as:

$$q_{c1N,h} = \left[(q_c/p_{atm}) / (\sigma'_h/p_{atm})^{0.7} \right] \qquad (8)$$

where σ'_h was estimated from the following expression of Mayne & Kulhawy (1982) using the friction angles (ϕ') given in Table 1:

$$\sigma'_h = (1 - sin\varphi_{cs}) OCR^{sin\varphi_{cs}} \sigma'_v \qquad (9)$$

It is seen that the data at all OCRs are unified on Figure 8b, confirming the suitability of employing σ'_h to normalize the cone resistance proposed by Houlsby & Hitchman (1988). It is notable, however, that $q_{c1N,h}$ continues to increase with depth and did not appear to reach a steady state value.

Values of relative density predicted by Equations (3) and (5), which are intended for use in sands at all OCRs, are compared with the measured relative density in Table 3. It is seen that both equations over-estimate D_r and that the degree of over-estimation increases with OCR. Further studies are ongoing at UWA to investigate q_c trends in overconsolidated sands.

3.4 Effect of saturation

The q_c values measured in dry and fully saturated (S_r=0 and 1) silica sand at a relative density of

$$q_{c1N} = (q_c/p_{atm})/(\sigma_v'/p_{atm})^{0.7}$$

$$q_{c1N,h} = (q_c/p_{atm})/(\sigma_h'/p_{atm})^{0.7}$$

Figure 8. Tip resistance in overconsolidated dense silica sand: (a) normalized by vertical effective stress; (b) normalized by horizontal effective stress.

0.8 are compared on Figure 9. This figure also plots q_c profiles measured at cone penetration rates between 0.1mm/s and 1.0mm/s. It is evident that q_c values, given experimental inaccuracies, are essentially identical in all cases. Additional CPTs performed in loose carbonate sand prepared at $S_r=0$ and $S_r=1$ also showed no dependence of q_c on S_r. These findings contrast with centrifuge data reported by Giretti et al. (2018) who found higher q_c values in dry carbonate sand compared with saturated sand and suggest that the higher

values arise due to dry crushed carbonate particles forming a slightly enlarged cone base area on the cone for S_r=0 tests. Jamialkowski et al. (2003) also found slightly lower q_c values in saturated sand, which is not evident on Figure 9 for UWA sand.

4 CONCLUSIONS

Over 80 CPTs were performed in calibration chambers at UWA to study the effect on q_c of stress level, mineralogy, overconsolidation ratio and degree of saturation. Relationships between

stress normalized end resistance (q_{c1N}) and relative density (D_r) are developed for UWA silica sand and Ledge Point carbonate sand. These are shown to be generally consistent with previously published correlations indicating that the relationship between q_{c1N} and D_r is relative insensitive to a sand type of given mineralogy. The testing programme highlighted the need for further studies into the development length of the CPT in dense sands and the cone resistance in overconsolidated dense sand.

Practical experience with cone penetration in frozen soils

N.G. Volkov & I.S. Sokolov
GEOINGSERVICE (Fugro Group), Moscow, Russia

Fugro GeoConsulting, Brussels, Belgium

ABSTRACT: This paper summarizes recent practical experience with CPT investigations at several permafrost sites in Russia. Some of the investigations were performed in unconventional conditions such as with ice cover, in a crawl space, or from a jack-up platform. All CPT measurements used a cone equipped with a temperature sensor to confirm the subzero temperature of frozen soil. Stress relaxation tests were performed in ice-rich permafrost soils to investigate long-term soil strength in both compression and shear. Sampling of frozen soil using direct push techniques was achieved at two sites.

1 INTRODUCTION

Frozen soil has ice content and exhibits rheological behavior, meaning the stress-strain behaviour and mechanical properties change with time. The failure of frozen soil under long-term loading is important for design. The long-term soil strength (the resistance of a soil to failure in response to a long-term load application) is a key parameter in the engineering of frozen ground (Vyalov, 1986). Long-term soil strength can be considered in terms of two main components: the long-term soil strength in compression (σ_c), important for pile end bearing (q_p), and the long-term soil strength in shear (σ_f), important for pile unit side friction (f_p).

Cone penetration testing (CPT) in frozen ground provides valuable data on frozen conditions and soil properties. Both temperature and porewater pressure sensors are required for testing in permafrost (a TCPTU test). Temperature measurement is similar to pore pressure dissipation testing. Penetration is paused and the variation of temperature with time is measured to determine the asymptote. A Stress Relaxation Test (SRT) can be performed at the same time, recording the variation of cone resistance (q_c) and sleeve friction (f_s) with time, for the cone clamped in place. This provides an estimate for the long-term strength in compression (σ_c) and shear (σ_f) (Sokolov, 2020). An SRT test does not increase the time or cost, and data processing can be fully automated for results to be obtained in the field.

2 PRACTICAL EXAMPLES OF SITES WITH CPT IN FROZEN GROUND

Nine cases of TCPTU testing in the Russian Arctic from 2014 to 2021 are listed below. The sites involve a range of permafrost conditions (Figure 1):

1. 2014 – Labytnangy Civil Infrastructure
2. 2015 – Vorkuta Railroad
3. 2016 – Salekhard College
4. 2017 – Ob Gulf, Arctic LNG2
5. 2018 – Ob River, Salekhard Bridge
6. 2019 – Novy Urengoy, Civil Infrastructure
7. 2021 – Kruzenshtern Gas Field, Yamal
8. 2021 – Dikson Area, Kara Sea
9. 2021 – Norilsk river, Talnakh Bridge

The findings from this testing include:

- Frozen sand at -6°C was successfully tested with CPT equipment;
- Up to 62 m of continuous penetration through permafrost was achieved without predrilling;
- Ground ice is generally not found to be critical for cone penetration in permafrost;
- CPT refusal is generally caused by the soil density rather than ice content or soil temperature.

Four of these cases (1-4) were presented at the CPT'18 conference (Volkov et al, 2018). A description for the five sites (5-9) tested between 2018 and 2021 is given below.

2.1 *Ob river, Salekhard bridge*

TCPTU tests were performed at the Salekhard Bridge site located in the Russian Arctic, some
Figure 1. Permafrost sites in Siberia, Russia with CPT investigations (for numbers see description in the text).

160 km upstream from the Ob River estuary (Figure 1, site #5). Three zones at the site of the Ob River bridge are the left bank, the right bank, and the river bed itself. The site is located in a cold region characterized by discontinuous permafrost (Figure 1). The average annual air temperature in the Salekhard area is -5.7°C. The CPT tests were performed during winter January-March 2018 when the Ob River was covered by ice. One CPT was performed to refusal on the right bank and achieved a depth 62 m (with no predrilling). The frozen state of the soil (permafrost) was confirmed by measuring temperature and collecting samples of frozen ground from the adjacent geotechnical borehole. The above is considered to be a record depth for continuous CPT penetration in permafrost.

An interesting observation was made from the CPTs on the left bank. The river formed a talik at this location (an unfrozen soil strata below or near to a river). Due to this talik, part of the soil depth penetrated was frozen and part of it not. This provided an opportunity to compare the same soil horizon in both a frozen and non-frozen state. Although it is generally known that cone resistance in frozen ground is higher compared with the same unfrozen ground, all other conditions being equal, these tests provided a direct quantitative comparison. The cone resistance in the unfrozen sand varied between 8 and 35 MPa, in the frozen sand between 12 and 54 MPa. The refusal depth was similar both in frozen and non-frozen sand and varied between 25 and 30 m.

The CPT data were interpreted to provide soil parameters and associated analysis. For pile design, impact Soil Resistance to Driving (SRD) and Blow Count analyses were completed and axial pile

bearing capacity and uplift capacity were estimated, for locations characterized by both unfrozen and frozen soil conditions. The results compared favourably with subsequent full scale pile tests at the site for both static load capacity and pile drivability.

2.2 *Novy Urengoy, Civil infrastructure*

In the summer of 2019, TCPTU tests with direct push sampling were performed from a crawl space under a civil apartment complex in Novy Urengoy, Western Siberia (Figure 1, site #6).

The structure, supported by piles driven to 10 m below ground level, was experiencing gradual differential settlement due to unknown reasons. It was assumed that settlement was due to insufficient pile bearing capacity. However, the steps taken to increase pile bearing capacity did not stop the settlement. CPT testing was then applied to investigate in more detail the insitu soil conditions between and below the piles. The depth of cone penetration was 30 m, comfortably exceeding the pile length.

Frozen soil was detected at some locations at a depth 11 m (Figure 2). Distinctive peaks of high values in cone resistance and low values in sleeve friction and electric conductivity were interpreted as ice lenses. Some of these ice lenses are highlighted in Figure 2, as an example.

Figure 2. CPT profile in frozen soil at Novy Urengoy.

A direct push probe was then used to collect samples of the frozen soil, using a regular MOSTAP sampler with 35 mm inner diameter (Robertson,

2014). The collected samples confirmed the presence of frozen soil with ice lenses of thickness up to 10 cm (Figure 3). The frozen soil was tested in the laboratory and was found to have a high density that would not compress significantly due to thawing (Table 1). Rather, the thickness of ice lenses were such that significant differential settlement would be expected from gradually melting ground ice.

Figure 3. Frozen soil samples with ice lenses collected by direct push sampler mounted on CPT press at Novy Urengoy.

Table 1. Physical and strength properties of the tested soil.

Parameter	Value		
	Min	max	average
Depth, m	10.5	15.0	-
Soil temperature (T), °C	-0.3	-0.11	-0.20 (8)*
Freezing temperature, °C	-0.15	-0.06	-0.11 (8)
Particle density (ρ_s), g/cm^3	2.60	2.69	2.66 (10)
Density (ρ), g/cm^3	1.98	2.17	2.07 (10)
Dry density (ρ_d), g/cm^3	1.60	1.89	1.75 (10)
Porosity (n), %	29	40	34 (9)
Void ratio (e)	0.42	0.67	0.52 (9)
Water content (W), %	15	24	18 (10)
Liquid limit (W_L), %	20	28	24 (10)
Plastic limit (W_p), %	13	17	15 (10)
Plasticity index (I_p), %	7	11	9 (10)
Liquidity index (I_L)	0.24	0.59	0.39 (10)
Cone resistance (q_c), MPa	4.22	13.52	7.31 (10)
Long-term compression strength (σ_c) MPa	0.08	1.89	0.91 (10)

* (8) – number of tests.

Based on these findings, engineering measures were taken to minimize the heat flow from the building to the ground, including thermal insulation of the basement. A cooling system comprising two-phase thermosyphons was installed to a depth 10 m to cut down any residual heat flow. The geodetic monitoring of the structure since has shown that the differential settlement ceased and the structure has been stable since the cooling system was put into operation.

2.3 Kruzenshtern gas field

Twelve TCPTU tests were performed in the period January-February 2021 on the Sharapov Shar gulf of the Kara Sea (Figure 1, site #7). Ten of the tests reached the designed penetration depth in the range 44 m to 54 m. Early refusal of two other tests were at depths 27 m and 35 m.

The depth of water in the gulf varies between 1 and 4 m. It was unknown if the permafrost would be continuous or discontinuous at the site, and the field investigation was to characterize the ground conditions and presence of permafrost. Only one test encountered permafrost from 9 m depth with a temperature between -0.35 and -1.58°C (Figure 4).

Several peaks of high values in cone resistance and low values in sleeve friction were observed. They were not as clear as the ones at the Novy Urengoy site. However, they were interpreted as ice lenses and some of them are indicated on Figure 4.
Figure 4. CPT profile in frozen soil at Sharapov Shar, Yamal peninsula.

To confirm the presence of permafrost, direct push sampling was applied close to the CPT test

location. The sampler was a regular RANGER with an inner diameter 45 mm. The collected samples confirmed the presence of frozen soil (Figure 5). The cryogenic structure is massive with rare ice layers.

Figure 5. Frozen soil samples with ice lenses collected by direct push sampler mounted on a CPT press at Sharapov Shar.

2.4 *Dikson area, Kara sea*

TCPTU tests were performed in the summer 2021 from a jackup platform nearshore in the area of Dikson, Kara Sea (Figure 1, site #8). Permafrost was not detected although in several locations the clay soil was found to have a temperature in the range 0 to 1°C. The clay was not frozen because of the salinity of the pore water. Conventionally, the measurement of ground temperature nearshore is problematic. To use conventional thermistors, these must be installed in a dry borehole and then monitored with time. In comparison, the TCPTU test is not complex and has a relatively low cost and required time for testing. In addition to the temperature data, a TCPTU test provides valuable data on the variability of temperature and mechanical properties with depth.

2.5 *Norilsk river, Talnakh bridge*

Cone penetration tests with temperature measurements (TCPTU) were performed on the right bank of the Norilsk river, located above the Arctic circle, 15 km from Talnakh city (Figure 1, site #9). The site is located in a cold region characterized by continuous permafrost, with an average annual air temperature in the Norilsk area of -9.6°C. However, the testing revealed a talik at the site formed due to the thermal impact of the Norilsk river.

The TCPTU tests detected ice rich permafrost at the site over a depth range 10 m to 30 m (Figure 6).

The ice rich permafrost was confirmed by geotechnical borehole drilling. The volumetric ice content (I_{tot}) was measured in soil laboratory. The volumetric ice content is the ratio of the volume of ice in a sample to the volume of the whole sample, expressed as a fraction (Everdingen, 2005).

The measured temperature of the ice-rich permafrost varied between -0.1 and -0.6 °C. The top layer of permafrost (10 m to 18 m) comprised clay with organic matter, a stratified cryostructure with high ice content $0.40 < I_{tot} < 0.60$. When thawed, the water content was $W_{tot} = 110\%$ and density $\rho = 1.36$ g/cm^3. The layer below (18m to 30 m) comprised clay with organic matter, a stratified cryostructure and high ice content $0.60 < I_{tot} < 0.90$ (Figure 7). When thawed, the water content was $W_{tot} = 263\%$ and density $\rho = 1.12$ g/cm^3.

Figure 7. Ice-rich permafrost samples collected near Norilsk.

3 STRESS RELAXATION TEST

3.1 *Rheological behavior*

Rheological behavior is inherent for frozen soils. The degree of rheological behavior depends on the physical properties of the frozen soil (ice content, water content, cryogenic structure, etc.). Rheological behavior is characterized by two interrelated parameters: creep and long-term strength (Vyalov, 1986). Long-term soil strength corresponds to a stress level below which no failure takes place within a practically observable period of load application. A stress in excess of the long-term strength results in failure after a certain time. In this paper we consider "practically observable period of load application" as 100 years. If the time period is different, for instance, 50 years, the term is described as the "long-term strength for 50 years".

There are two approaches to evaluate long-term strength (Figure 8). The most common is to measure deformation under an applied constant load to describe creep, i.e. deformation change with time. The second approach measures the stress caused by a constant applied deformation to describe stress relaxation, i.e. stress change with time. The second approach is considered in this paper.

Figure 8. Correlation between Creep and Relaxation in the Rheological testings.

Stress relaxation is the decrease of stress with time in response to constant deformation applied to the soil. Relaxation of stress results from a redistribution of elastic and plastic deformation. All physical bodies possess both elastic and viscous properties. However, the material behavior depends on the correlation between the period of load application (i.e. the observation period) and the relaxation period. If the observation period is shorter than the relaxation period, a body behaves as a Hookean solid. In the alternative case, it behaves like a Newtonian fluid.

The Relaxation period varies significantly for different materials. For instance, limestone 10^{11} sec (thousands of years), glass $10^{1\circ}$ sec (hundreds of years), ice 10^2 sec (hundreds of seconds), water 10^{-11} sec. In the case of water, for instance, when acted on by a force lasting less than 10^{-11} sec it behaves elastically. Rocks experience load over periods of geological time and may develop viscous flow, which can be observed in folding. Ice behaves like an elastic body, failing in its brittle form if struck (or loaded) rapidly, a force applied for less than 10^2 sec (Vyalov, 1986). A long-term load causes ice to flow as a viscous material, as occurs in glaciers. Similar behavior, i.e. brittle failure under a rapid load application and viscous flow due to a long-term load, can be observed in frozen soils.

It is important that the relaxation period does not equal the period of after-effect. The process of relaxation occurs much faster than the process of creep, i.e. relaxation period significantly shorter than period of after-effect, which differs by several orders (10^n). This fact provides a key advantage for the second approach to evaluate the long-term strength which is based on stress relaxation measurements versus the first approach based on creep measurements.

3.2 *Stress relaxation test procedure (SRT)*

Relaxation test approach for soils was first proposed by Vyalov in 1986. It was called an "accelerated method of testing soils for long-term strength, using a dynamometric apparatus". The method description said "if an initial stress is given which is close to the hypothetically instantaneous strength (as determined in advance), the finite value of stress will approach the ultimate long-term strength". The stress should be measured in time.

The stress relaxation curve should then be processed by a fitting method to determine the empirical coefficients for the following equation:

$$\sigma_c = \frac{\beta}{\ln\left(\frac{t_p+1}{T}\right)} \qquad (1)$$

where σ_c = long-term soil strength; t_p = measured time; and β, T are empirical coefficients.

Once the empirical coefficients are determined the long-term strength for a given period of time, for instance 100 years, may be calculated.

The proposed laboratory method was not practically useful at the time due to the low quality of measurement equipment and impossibility to determine the instantaneous strength in advance. Because of these limitations, a pure relaxation test on frozen soils is not common practice.

However, the accelerated method approach can be applied for the conditions when performing in-situ a CPT temperature dissipation test (or pore pressure dissipation test). The only requirement is that the dissipation is performed with the rods clamped (to ensure not movement). In such a case, the deformation is kept constant and the stress relaxation can be measured by the cone (q_c) and sleeve friction (f_s) sensors.

The Stress Relaxation Test (SRT) is described in detail by Sokolov (2020). A key step in the processing was to apply the fitting curve method not for the entire curve, but for the curve starting at some point. This is the point that separates two parts of the curve: the first part corresponds to the relaxation-creep stage while the second part to the relaxation stage. Once this separating point is determined it is possible to back calculate the empirical coefficients β and T for equation (1) and thereby calculate the long-term strength in compression and shear.

3.3 Results

SRT results from site #5 (Figure 1) were verified by comparing with the results of a static pile load test (Volkov, 2019, Sokolov, 2020). The common practice calculates the pile unit end bearing, q_p, from the calculated equivalent average cone resistance, q_{ca}, multiplied by an end bearing coefficient, k_c (Robertson, 2014). This approach did not work well for frozen soils because ice contributes significantly to the cone penetration resistance, but little to the long-term soil strength. Thus in case of ice rich permafrost, the end bearing coefficient, k_c, may be very low compared to common values for non-frozen soils. For instance, based on the numbers provided in Table 2, k_c (which is correlated to the relation between σ_c/q_c), varies from 0.017 to 0.086 and is quite low compared to k_c for non-frozen soils 0.2 to 0.5 (Robertson, 2014).

Table 2.   CPT measured and SRT evaluated results.

Depth, m	T, °C	q_c MPa	σ_c MPa	f_s kPa	σ_s kPa

4   CONCLUSIONS

Practical application of CPT in frozen ground has been illustrated for nine different sites with various degrees of permafrost. The CPT is able to penetrate frozen soils, including frozen sands, ice-rich soils and ice lenses. This application of CPT testing could be significantly enlarged for the current geotechnical activities in the Arctic.

Cone penetration testing provides a lot of data which can be obtained in one push performed within one working day. Perhaps most significant is that a CPT used with a temperature sensor is capable to detect frozen soils by measuring the soil temperature directly. The pore water pressure sensor provides very useful complementary data. For reference, this test has been called by the acronym TCPTU.

In addition, by using a Stress Relaxation Test (SRT) it is possible to estimate the long-term soil strength in both compression (σ_c) and shear (σ_s). The long-term strength results on one of the sites were confirmed by comparison with a static pile load test. The results on σ_c and σ_s derived for other sites also show consistency with the recommended values for pile unit end bearing and pile unit side friction.

Ice content in frozen soil plays a major role and influences strongly key parameters such as long-term strength. TCPTU testing shows great applicability for ice-rich frozen soils both to detect ice and evaluate long-term soil strength in compression and shear. Push sampling methods using the CPT equipment can recover samples for laboratory testing.

A site-specific relationship between CPT data and fines content for fine grained soil in the context of liquefaction analyses

C. Vrettos
Technical University of Kaiserslautern, Germany

ABSTRACT: Fines content is a crucial factor affecting the liquefaction resistance of soils within the frame of the CPT-based cyclic stress ratio approach. In contrast to highly susceptible sands and silty sands, on one hand, and non-liquefiable clays, on the other hand, the proper identification and classification of silts is still an unresolved issue. Several empirical equations have been proposed to correlate fines content with common CPT soil behavior indices. In the frame of a site-specific study comprising pairs of CPT soundings and adjacent exploration borings, gradation characteristics of retrieved soil samples are combined with the respective values of common soil behavior indices inferred from the CPT logs to examine available predictive equations and calibrate a new hyperbolic equation. The investigation confirms the large scatter in the data and the inherent difficulty in establishing a robust correlation.

1 INTRODUCTION

Over the last years, CPT has advanced to the preferred method to assess liquefaction susceptibility in code-based design using the cyclic stress ratio approach. This holds in particular for countries outside the USA and Japan, where the Standard Penetration Test (SPT) does not constitute the primary means of site investigation via soundings. Several codes of practice include CPT-based methods as an equivalent counterpart to SPT-based methods. An example is the current draft of the new edition of the Eurocode EN 1998-5, CEN (2021), that adopted the methodology by Idriss & Boulanger (2008) and its CPT-based update by Boulanger & Idriss (2016).

In this semi-empirical method, as established in the '80s by Seed & Idriss (1983), soils other than sands were characterized with regard to liquefaction susceptibility by the fines content *FC* measured in the laboratory. *FC* is defined according to ASTM D 653-20 as the portion of soil particles finer than 0.075 mm (sieve no. 200). In EN ISO 17892-4:2016 the limit is set at the 0.063 mm sieve. An adjustment for the fines content is made by increasing the measured tip cone resistance by an increment dependent on *FC*.

Alternatives to consider the soil type in the cyclic stress ratio method were proposed by Robertson & Wride (1998) via a soil behavior index derived from CPT data, and by Moss et al. (2006) based on a combination of CPT tip and sleeve resistance by skipping the intermediate step. Despite its deficiencies, the fines content concept presently dominates practice and code-based design.

While in the early years the focus was placed on *FC* values up to 35%, evidence from seismic events and research in the last two decades revealed that fine soils may also show a degradation under high amplitude cyclic loading. It is now distinguished between two types of ultimate limit states: i) sand-like (cyclic liquefaction), and ii) clay like (cyclic softening) behavior, as elucidated among others in the recent review report by the committee of the National Academies of Sciences, Engineering, and Medicine (2016). In this context, fine-grained soils may be classified based on some measure of their consistency in terms of the water content and the Atterberg limits. A plasticity index I_P = 15% is considered as a conservative threshold beyond which the occurrence of liquefaction can be excluded. Such a classification requires collection of several samples, laboratory testing and reliable values of the in-situ water content. Even then, this information will be available only for specific points along the soil depth profile.

An evaluation based on recorded data from CPT soundings linked with a reliable general equation for *FC* constitutes an attractive, widely used alternative. Candidates for the independent variable in such a relationship are the well-established soil behavior type indices, as summarized in the next section. Agaiby & Mayne (2020) compiled several of these equations. The scatter in the data is considerable, in particular for silts, which constitute the crucial soil category in liquefaction hazard assessment.

The necessity to derive a site-specific predictive equation for *FC* in the frame of a critical project motivated the present study. The field investigations

performed, the main results of the accompanying laboratory testing program, the essential analysis steps, and the conclusions drawn are described next. Similar studies with a much larger spatial extent have been conducted for soils in Canterbury, New Zealand, among others by Lees at al. (2015).

2 EQUATIONS FOR THE FINES CONTENT

The vast majority of the suggested equations relate the fines content FC to the soil behavior index I_c proposed by Robertson & Wride (1998) to capture six of the designated zones of the SBTn-chart covering the basic soil types encountered in practice, cf. Table 1. Its current form as proposed by Robertson (2009) is:

$$I_c = \left[(3.47 - \log Q_{tn})^2 + (\log F_r + 1.22)^2 \right]^{0.5} \quad (1)$$

$$n = 0.381 \cdot I_c + 0.05 \cdot \left(\frac{\sigma'_{v0}}{p_a} \right) - 0.15 \leq 1.0 \quad (2)$$

where

$$F_r = \frac{f_s}{q_t - \sigma_{v0}} \cdot 100\% \quad (3)$$

$$Q_{tn} = \left(\frac{q_t - \sigma_{v0}}{p_a} \right) \cdot \left(\frac{p_a}{\sigma'_{v0}} \right)^n \quad (4)$$

where F_r = normalized friction ratio; f_s = sleeve friction; Q_{tn} = normalized cone resistance; q_t = tip resistance corrected for the effects of pore water pressures; n = stress normalization exponent; σ_{v0} = in-situ vertical stress; σ'_{v0} = in-situ vertical effective stress; p_a = atmospheric pressure. Except for very soft fine grained soil, it may be assumed that q_t equals the uncorrected cone resistance q_c (Robertson, 2010).

Table 1. Soil Behavior Type based on I_c.

Zone	Soil Behavior Type	I_c
2	Organic Soils – Clays	>3.6
3	Clay – silt clay to clay	2.95-3.6
4	Silt mixtures – clayey silt to silt clay	2.60-2.95
5	Sand mixtures – silty sand to sandy silt	2.05-2.60
6	Sands – clean sand to silty sand	1.31-2.05
7	Gravely sand to dense sand	<1.31

A threshold I_c = 2.6 is often used to distinguish between clay-like and sand-like soils that are susceptible to liquefaction (Boulanger & Idriss, 2014).

An alternative for the soil behavior index is the modified index I_B introduced by Schneider et al. (2012) and subsequently adopted by Robertson (2016) in his charts to characterize soils:

$$I_B = 100 \cdot \frac{Q_{tn} + 10}{70 + Q_{tn} \cdot F_r} \quad (5)$$

Various equations relating I_c to FC have been suggested in the last decades. Some of them are considered herein in detail. One of the first has been proposed by Robertson & Wride (1998):

$$1.64 < I_c < 2.36 \quad \text{and} \quad R_f < 0.5\% : \ FC = 5\%$$
$$1.26 < I_c < 3.5 : \quad FC = 1.75 \cdot (I_c)^{3.25} - 3.7$$
$$(6)$$

with the friction ratio

$$R_f = \frac{f_s}{q_t} \cdot 100\% \quad (7)$$

Boulanger & Idriss (2016) suggested:

$$FC = 80 \cdot (I_c + C_{FC}) - 137 \quad 0\% < FC < 100\% \quad (8)$$

where C_{FC} is a fitting parameter with a default value equal to 0 and a standard deviation ± 0.29.

The above relationships have been examined in the frame of the extensive regional liquefaction susceptibility study on Christchurch soils by Maurer et al. (2019). Assuming a linear relationship in analogy to equation (8), regression statistics yielded for the mean estimate:

$$FC = 80.645 \cdot I_c - 128.5967 \quad (9)$$

with approximately 68% of the samples having FC within ±16.56% of the mean prediction. For these region-specific conditions and $FC > 10\%$, equation (6) by Robertson & Wride (1998) yields much lower values, i.e. it is too conservative. The many decimal digits in the constants of equation (9) suggest an accuracy that is not attainable.

A large database from different studies has been evaluated by Agaiby & Mayne (2020). The derived relationship reads:

$$FC = 1.3 \cdot (I_c)^{3.77} \quad (10)$$

An equation has also been obtained in terms of the modified index I_B:

$$FC = (293/I_B)^{1.65} \qquad (11)$$

The observed large scatter in the data in all studies lies in the nature of I_c, which was introduced to characterize soils and not to be associated with the susceptibility to liquefaction. A linear or even power law relationship for FC vs. I_c is too simplistic if one considers the complexity of the physics of the problem, the variability of the soil composition even over short distances, the sensitivity of the CPT response as reflected in the strong fluctuation of the recorded data, as well as the uncertainty in capturing the effects of soil plasticity and grain size distribution on the CPT response.

3 SITE-SPECIFIC CORRELATIONS

The investigated site is located in Germany and is characterized by a variable stratigraphy. The top layer with a thickness of approximately 5 m consists of fillings of sand, silt and partially gravel. This is followed by alternating layers of silt, silty sand and gravel, as well as sand-silt mixtures. These soils are underlain by glacial till deposits: debris loam composed of silts and silty sands, and marly till (clays). Below this is sand with different fine-grain and gravel proportions. The encountered sediments are highly variable and hence particularly suited for checking the accuracy of the various predictive equations relating FC to I_c.

Field investigations comprised exploration borings at several locations and CPT soundings adjacent to the boreholes. Disturbed and undisturbed samples have been extracted for further testing.

The laboratory investigations included tests for particle size distribution, Atterberg limits, consistency, compressibility and shear strength.

Soil classification was conducted according to EN ISO 14688-2 in conjunction with DIN 18196. It is very similar to the USCS except for some differences in coding and in including an additional class of intermediate-plasticity for silts and clays.

The primary purpose of the investigation, and accordingly the selection of the sampling depths, was foundation design. Detailed liquefaction assessment was conducted at a later stage, since the region is characterized by low to medium seismicity.

A total of 14 CPT records were evaluated. The tests reached a depth of 20 m. Essential for the accuracy of the prediction is an appropriate geodetic survey in order to assign each sample from the boring to the correct depth along the CPT log. At each CPT location, verification checks have been performed at positions where an unambiguous identification of the soil type was possible. Spikes in the CPT records were carefully inspected, and when an abrupt change in soil type was not justified, an averaging procedure over a few centimeters centered at the location of the sample was applied. As the investigation was not planned to

validate back-analysis procedures for the CPT, the information on the sampling depth of the undisturbed samples tested in the laboratory was not precise enough to allow an exact mapping to the CPT. The accuracy was improved by incorporating the anticipated soil behavior type SBT/SBTn in the selection of the appropriate depth range for the calculation of the FC vs. I_c relationship. Hence, the identification of fines content is more accurate for the undisturbed samples.

Due to the nature of the glacial till sediments, grading for some of the samples spans over silt, sand and gravel with a large uniformity coefficient. In this case and for liquefaction hazard assessment, the adverse influence of low fines content is counterbalanced by the favorable effects of the gravel fraction that provides ample drainage. The SBTn charts presently do not include this soil type, and an interpretation solely according to I_c may be misleading. Moreover, the fill is also characterized by an inhomogeneous composition.
Figure 1. Results at location #13: Borehole log, position and length of extracted soil samples, CPT results, and derived I_c with colors and numbers in brackets indicating the various soil types in the SBT and SBTn charts.

Typical results and the accompanying interpretation of the field investigations at one of the locations are displayed in Figure 1. The delineation, the

coloring, and the material symbols in the borehole logs correspond to the field description of the soil. The CPT log is given in terms of tip cone resistance q_c and friction ratio R_f. The soil type as inferred from the non-normalized SBT-chart by Robertson (2010) is indicated by different colors in the column for R_f. The last column shows the I_c profile as calculated from equations (1) to (4), and also the SBTn soil types in color. SBT- classification is the standard output of the software used, and is considered as a good approximation of the more accurate, normalized SBTn-chart for vertical effective overburden stresses up to 150 kPa (Robertson, 2010; Papamichael & Vrettos, 2018).

Data for all samples are given in Table 2 and include: sounding number (location); sampling depth; indication (U) for an undisturbed sample; material composition in terms of clay (Cl), silt (Si), sand (Sa) and gravel (Gr) content from the laboratory tests; mean value and coefficient of variation (CV) of the soil behavior index I_c and the modified index I_B (CV is the ratio of the standard deviation to the mean); liquid limit w_L and plasticity index I_P. The ground water table was encountered in depths between 5 and 7 m. For the fine-grained soil, the silt

fraction varies between 41 and 80%, the clay fraction between 5 and 43.5%.

In order to establish a relationship between I_c and FC, a single representative value I_c over the nominal depth range of the distinct disturbed/undisturbed samples extracted from the borings is required. The fluctuation of I_c over the sampling depth is considerable, and the following method is used for an automated evaluation. Samples that show for I_c over the respective depth range a coefficient of variation larger than a threshold are dismissed. Comparison of the prediction with the actual soil gradation measured in the laboratory yielded herein a threshold of 8.0. In particular, undisturbed samples extracted from the fill did not meet this criterion. If more data are available, the threshold may be set even lower.

The inherent limitations of the attainable accuracy become evident if one looks at the results for the undisturbed sample taken from the depth of 10.0 to 10.25 m at location #13, cf. Figure 1. While the identification of the soil type is correct, i.e. zone 4 in the SBTn chart matches well the laboratory gradation with 71.7% silt, the derived value I_c ranges between 2.57 and 2.92, which constitutes a significant variation if a reliable prediction of FC is sought.

The plasticity chart of EN ISO 14688-2 with all samples of fine-grained soil is presented in Figure 2. It can be seen that almost all samples classified as silts according to the grading are actually clays with respect to their soil mechanical behavior, as they plot above the A-line in the plasticity chart.

Since both FC and I_P are independent of the actual soil state in terms of consistency, it is of interest to plot the FC versus the plasticity index I_P, as shown in Figure 3. For $FC > 60\%$ there is no correlation between FC and I_P, at least for the soils encountered at the particular site.

Figure 4 Depicts the core of the investigation, i.e. data points of FC versus I_c for the samples fulfilling the coefficient of variation criterion. Figure 5 shows the corresponding data set FC versus I_B. Figure 4 includes the prediction by equations (6), (8) and (10), and Figure 5 that by equation (11).

Figure 4. Fines content FC vs. soil behavior index I_c: data set, and comparison with the various predictive equations.

Figure 2. Sampled soil classified in the plasticity chart of EN ISO 14688-2.
Figure 5. Fines content FC vs. modified index I_B: data set, and comparison with the predictive equations.

Figure 3. Fines content FC vs. plasticity index I_P.

It can be deduced from Figure 4 that for high values of I_c, i.e. for clay-like behavior, equation (6) predicts consistently lower values than actually measured, while equations (8) and (10) are closer to the laboratory results. For low I_c values (sand-like

behavior) though, equation (6) matches the data well. As for the I_B-based relationship in Figure 5, equation (11) is a good approximation.

With regard to the I_c-based estimation of FC, it turns out that none of the three forecast equations considered is suitable for the particular site. Equation (6) is applicable for low I_c and FC values but too conservative for higher FC values. Equation (10), on the other hand, yields higher values for low FC sands (slightly non-conservative), and realistic predictions for medium and high FC values. In order to increase accuracy and avoid the unboundedness of the power-law approximations, the following hyperbolic equation that exhibits a more versatile, "S-like" form is proposed:

$$FC = a \cdot \left(1 - \frac{1}{1 + (I_c/b)^c} \right) \qquad (12)$$

The engineering approximation of the data set in Figure 4 yields:

$$a = 120 \;\; ; \;\; b = 2.62 \;\; ; \;\; c = 8$$

Similarly, the following counterpart is derived for the data in Figure 5:

$$FC = \frac{d}{1 + (I_B/f)^g} \qquad (13)$$

with

$$d = 120 \;\; ; \;\; f = 28 \;\; ; \;\; g = 3.3$$

Equations (12) and (13) focus on silts, which constitute the most critical soil type with the strongest variability in the composition. An accurate prediction is necessary in order to avoid i) the risk of non-conservative design due to an overestimate of fines content, and ii) non-economical design due to a false alert by too low FC estimates. The identification of liquefaction susceptible sands and silty sands of low fines content and low I_c, on the one hand, and of non-liquefiable clayey silts and clays of high I_c, on the other hand, is in general unambiguous.

4 CONCLUSIONS

CPT soundings are nowadays an integral part of modern, high-quality field investigations in earthquake-prone areas. The present study exemplarily shows the application of a state-of-the-art procedure to estimate the fines content of fine soils for subsequent use in liquefaction hazard analyses of a particular site with a strong variability in the subsoil composition. For this type of problem, silts still constitute the type of soil with the most uncertain behavior, and gradation is surely not the most appropriate characteristic to capture it. Targeted field investigations on silts, complemented by laboratory cyclic loading tests, are urgently needed to clarify the related issues.

Numerical modelling of cone penetration tests in spatially variable clays

Ze Zhou Wang, Siang Huat Goh & Xiangxiang Zheng
Department of Civil and Environmental Engineering, National University of Singapore, Singapore

ABSTRACT: In soft clays, a cone factor N_{kt} is typically adopted to correlate net cone tip resistance q_t with undrained shear strength S_u. Many existing numerical studies on the estimation of N_{kt} are performed using analyses in homogeneous soil medium. However, soil properties exhibit spatial variability under real field conditions. In this study, the effects of spatial variability on the interpretation of CPT data were investigated using a finite element analysis technique, namely the Press-Replace method (PRM). This method, which can capture installation effects arising from the penetration of a piezocone, was implemented with the soil domain modelled as anisotropic random fields. Using a pre-determined N_{kt}, statistics of S_u were back-calculated using the q_t profiles obtained from different random field realizations. Comparisons of the back-calculated statistics with the true statistics used to generate the random fields revealed that the true statistics may not be fully recovered from the CPT data.

1 INTRODUCTION

In soft clays, the cone penetration test (CPT) is typically adopted to characterize the undrained shear strength through a cone factor N_{kt} as follows:

$$S_u = \frac{q_c - \sigma_{v0}}{N_{kt}} = \frac{q_t}{N_{kt}} \qquad (1)$$

where σ_{v0} is the total overburden stress, q_c is the cone tip resistance corrected for cone net area ratio, and q_t is the net cone tip resistance. Although the value of N_{kt} is often obtained using laboratory data and site-specific calibration exercises, extensive analytical and numerical studies on the estimation of cone factor values have also been reported in the literature (Yu 2000; Lu et al. 2004).

Many studies are performed based on analyses that assume homogeneity in soil properties. However, it is well known that the properties of natural soils exhibit random variability in both spatial distributions and intensities under real field conditions (Phoon & Kulhawy 1999). Many studies reported that the performance of geotechnical systems can be significantly affected by the presence of spatial variability (Pan et al. 2018; Zhang et al. 2021).

Furthermore, the large deformation caused by the continuous insertion of a piezocone renders conventional small-strainnumerical techniques ineffective, thus adding to the challenges in the numerical analysis of the cone penetration test. Therefore, special procedures, such as the

Arbitrary Lagrangian Eulerian (ALE) (Lu et al. 2004), the Remeshing Interpolation Technique with Small-strain (RITSS) (Zhang et al. 2020) and the Material Point Method (MPM) (Tehrani et al. 2016), have been proposed.

In the literature, numerical simulations of CPT considering both the installation effects and spatial variability have not been widely reported. This paper fused random fields and a simplified numerical procedure, the Press-Replace Method (PRM), for simulating piezocone penetration in spatially variable soils. The PRM is a simplified technique that can be implemented in standard small-strain finite-element programs without the need for additional subroutines. In addition, anisotropic random fields were adopted to realistically express the spatial variability of soil property. With the consideration of both features, the impact of spatial variability on the interpretation of CPT data can be rigorously investigated.

2 METHODOLOGY

The Press-Replace Method (PRM) is a simplified technique to simulate problems associated with continuous penetration of an object into a continuum. The PRM was first used for simulating the load-controlled penetration of a suction anchor in clay (Andersen et al. 2004) and was further used to simulate pile, cone and spudcan penetration (Engin et al. 2015; Tehrani et al. 2016; Wang & Goh 2018).
Figure 1. Illustration of the PRM technique for modelling cone penetration test.

Figure 2. Model setup and relevant modelling details.

Table 1. Key parameter values used in the present study.

Parameter	Value	
	Homogeneous	Heterogeneous
Cone diameter, D	60 mm	60 mm
Cone tip-apex angle, α	60°	60°
Model width, w	0.4 m	0.4 m
Model depth, d	1.0 m	1.0 m
Unit weight, γ_{sat}	18 kN/m³	18 kN/m³
Earth pressure coefficient, K_0	1.0	1.0
Poisson's ratio, v	0.5	0.5
Mean undrained shear strength, S_u	30 kPa	30 kPa
Coefficient of variance, CoV	-	0.3
Horizontal scale of fluctuation, δ_h	-	5.0 m
Vertical scale of fluctuation, δ_v	-	0.5 m
Young's modulus, E	$90S_u$; $300S_u$; $450S_u$; $600S_u$; $900S_u$ kPa	$300S_u$

As its name suggests, the PRM consists of two modelling phases. Figure 1 illustrates the procedures for modelling cone penetration using the method. Essentially, the entire penetration process is separated into many pairs of press-replace phases. Figure 1a illustrates the model setup at the start of an arbitrary stage *i*. In the next step (Figure 1b), a displacement boundary condition is prescribed to simulate the penetration. The prescribed displacement, however, corresponds to only a portion of the total penetration depth. As recommended by Engin et al. (2015), the prescribed displacement corresponds to 1/10 of the diameter or width of the penetration object. After the "press" phase, the "replace" action is performed by switching the soil body that was displaced by the piezocone in the preceding "press" phase to the cone material (Figure 1c), which marks the end of stage *i*. The model setup shown in Figure 1c then forms the initial condition for the next pair of press-replace phase (Figure 1d). These phases are repeated until the desired penetration depth is achieved.

3 MODEL SETUP

The finite-element software Optum G2 was used in this study. In Figure 2, the model consists of a soil domain of 0.4 m in width and 1 m in depth. An axi-symmetric piezocone of 36 mm diameter (*D*) and 60° tip angle was modelled. The penetration started from a pre-embedment depth of 0.03 m, and a -0.0036 m step size (Engin et al. 2015) was adopted.

Interface elements were used to model the inter-actions between the piezocone and soil. Three types of interfaces were adopted. First, the shaft-soil inter-face was modelled as a fully smooth contact (Figure 2c) while fully smooth and fully rough contacts were considered for the cone-soil interface (Figure 2b). Interface extensions (Figure 2b) that are 0.0036 m, i.e. 0.1*D*, in length (Engin et al. 2015), and having the same properties of the neighboring soil, were used to minimize stress oscillations around sharp corners of the cone. The model was discretized using 6490 15-node triangular elements.

The soil was modelled as a single-medium mater-ial using the Tresca model. Table 1 summarizes the key parameter values used in the present study. An S_u of 30 kPa was adopted in the analyses that assumed a homogeneous soil medium, with the Young's modulus E linearly correlated to S_u. Five separate analyses using five E/S_u correlations were carried out, and the results are compared with pub-lished results to validate the PRM method. In the RFEM analyses, a lognormal distribution was used to describe the statistical variability of both S_u and E. The correlation $E = 300S_u$, which is representative of soft clays, was adopted for the RFEM analyses. Other statistics, such as CoV, δ_h and δ_v, adopted in the present study are also representative of natural soft clays (Phoon & Kulhawy 1999).
Figure 3. Comparison of cone factor values with Lim et al. (2018) ($I_r = 150$; $K_0 = 1$).
Figure 4. Comparison of cone factor values with other published results (smooth cone-soil contact).

All random fields were generated using the Karhunen-Loève (KL) expansion (Phoon et al. 2002) and a single exponential autocorrelation function. It is not easy to identify the "correct" function (Spry et al. 1988), but the single exponential autocorrelation function is more commonly used (Phoon & Kulhawy 1999). The K-L expansion was performed using 1000 terms to ensure sufficient accuracy.

4 NUMERICAL MODELLING OF CONE PENETRATION

4.1 Analysis with homogeneous soil properties

This section utilizes published results in the literature to validate the use of the PRM method. Figure 3 compares the results of the present analyses with those reported in Lim et al. (2018) who also adopted the PRM technique. All analyses indicate that the cone factor values reached a plateau at approximately $z/D > 6$, even though Lim et al. (2018) started the penetration at the depth of $z/D = 5$. According to Zhang et al. (2020), a deep penetration mechanism becomes prominent beyond this depth; therefore, a $z/D = 6$ was used in the present analyses to differentiate between a shallow and a deep penetration.
Figure 5. Comparison of cone factor values with other published results (rough cone-soil contact).

Additional analyses, using different values of the rigidity index, $I_r = G/S_u$ (Table 1), were carried out to validate the PRM against other published results. Figure 4 shows the influence of rigidity index on cone factor values for a smooth cone-soil contact. All studies indicate that the cone factors increase approximately linearly with the logarithm of I_r. The discrepancies between different published studies are likely caused by the use of different numerical simulation techniques. Nevertheless, the results obtained using the PRM agree reasonably well with other published results, indicating that the PRM is valid for simulating the large deformation cone penetration process.

Similarly, Figure 5 shows the influence of rigidity index on cone factor values for a rough cone-soil contact. The results obtained using the PRM also agree reasonably well with other published results, which further confirmed the validity of the PRM.

4.2 Random field finite-element analysis (RFEM)

Figure 6a shows an example of a random field for the undrained shear strength. Variations in S_u values were observed mainly in the vertical direction because the vertical scale of fluctuation (δ_v) is much smaller than the horizontal scale of fluctuation (δ_h). Significant fluctuations in the net cone tip resistances with respect to depth, as shown by the solid black line, were observed in Figure 6a. The profile is highly sensitive to the presence of weak and strong soils. For example, at depths of between 0.1 m and 0.2 m, the cone is penetrating through soils whose S_u values are relatively homogeneous, and hence the cone tip profile showed signs of convergence. However, as the piezocone continues to penetrate beyond 0.2m, it will encounter the presence of stronger soils at greater depths, thus causing the net cone tip resistance to pick up quickly. In contrast, the net cone tip resistance from the analysis based on the homogeneous soil medium quickly converged as the deep mechanism was mobilized at $z/D > 6$ (Figure 6b).
Figure 6. An example of random field and the net cone tip resistance profiles ($I_r = 150$).
Figure 7. Comparison of Tresca stress contours ($z/D = 10$; $I_r = 150$).

Figure 7 plots contours of the Tresca stress, $(\sigma_1 - \sigma_3)/2$, where σ_1 and σ_3 are, respectively, the major and minor principal stresses at the instant when the cone tip is at $z/D = 10$, for the analysis in the homogenous soil medium and a selected RFEM realization. Both analyses mobilized a stress bulb that spans from the ground surface to approximately

4D below the cone tip. However, the variation of the stresses within the stress bulb generated by the RFEM analysis is not as smooth as that obtained in the homogeneous soil medium.

Figure 8 shows the comparison of the plastic yield zones obtained from the analysis in the homogenous soil medium and the same selected random realization at a cone penetration of $z/D = 10$. In the homogeneous soil medium, a "butterfly" yield region was obtained that extended horizontally to 5D from the cone tip, which is in good agreement with the 4.7D and 4.65D reported by Lu et al. (2004) and Yu (2000). In contrast, the yield region obtained using the RFEM analysis for this random field realization was smaller and more irregular although the mobilized Tresca stresses were larger in some zones (Figure 7). This is attributed to the fact that the yield region propagated through weaker zones within the soil layer in order to minimize the overall energy dissipation (Zhang et al. 2020).
Figure 8. Comparison of yield regions ($z/D = 10$; $I_r = 150$).

The comparisons shown in Figures 7 & 8 indicate that the analysis in the homogenous soil medium that adopted highly idealized and uniform field conditions could not capture important aspects of realistic soil responses. To better understand the influence of the soil's spatial variability on the cone response, 100 random RFEM analyses were carried out, and the results plotted in Figure 9. For each realization, fluctuations in the computed cone resistance with depth were observed, which are not unlike those recorded from field CPT measurements. Significant difference in the net cone tip resistances computed at penetration depths of $z/D = 10$ or greater were also observed across the 100 realizations. While some realizations yielded net cone tip resistances that are
Figure 9. Net cone tip resistance profiles of 100 random field finite element analyses.

larger than 600 kPa (which is approximately 2 times the value obtained in the homogeneous soil analysis), other realizations can yield values of as low as 150 kPa. These significant differences in the computed net cone tip resistances resulting from the consideration of spatial variability cannot be captured by the analysis predicated on a homogeneous soil medium.

5 BACK-CALCULATION OF UNDRAINED SHEAR STRENGTH

As demonstrated in the preceding section, the presence of spatial variability can alter the failure mechanism and, therefore, the net cone tip resistance significantly. In this regard, the impact of spatial variability on the interpretation of CPT data was further investigated by back-calculating values of undrained shear strength S_u from the net cone tip resistances obtained from the random field finite element analyses (RFEM).

Figure 10 illustrates the procedure to back-calculate S_u, which is similar to that adopted in practice for the interpretation of CPT data in practice. A deterministic PRM analysis was first performed using a homogeneous soil medium with a constant value of S_u (Table 1) to obtain a "calibrated" cone factor, $N_{kt, homogeneous}$. This step simulates the calibration exercise that is typically used in practice to obtain the site-specific cone factor. In the second step, 100 RFEM simulations were performed, each using a heterogeneous soil medium characterized as a random field with a spatially varying undrained shear strength distribution (Table 1). The net cone tip resistances obtained from the RFEM analyses were then divided by the $N_{kt, homogeneous}$ value to arrive at the back-calculated S_u values. Only resistances computed for penetration depths of $z/D > 6$,

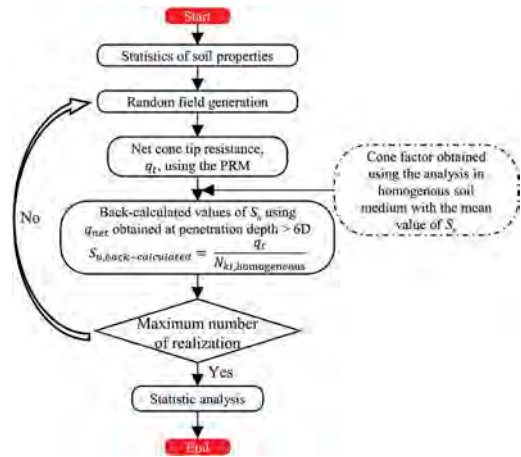
where the deep failure mechanism has become dominant (Figures 3 and 6), were considered for the back-calculation.


Figure 10. Procedures to back-calculate undrained shear strength values using CPT data.

Figure 11 shows the statistical distribution of the back-calculated S_u values. A lognormal distribution, represented by the solid line, was fitted to the histogram. In general, the statistical distribution of the back-calculated S_u values reasonably resembles the benchmark statistics (dashed line). However, as shown in Figure 12, while the mean back-calculated values of S_u (from the 100 RFEM analyses) are largely equal to the true (input) value, the back-calculated CoV values from the RFEM results underestimated the 'true' CoV (prescribed in the RFEM analyses to generate the random fields, see Table 1) by approximately 13%.

The same analyses were also repeated for the case involving a rough cone-soil contact. The results
Figure 11. Statistical distribution of the back-calculated S_u (smooth cone-soil contact; $I_r = 150$).
Figure 12. Convergence of the mean and CoV of the back-calculated S_u (smooth cone-soil contact; I_r = 150).

indicate that, while the mean back-calculated S_u agree with the true statistic, the CoV of the S_u was underestimated by approximately 16%, which is consistent with the results shown in Figure 12.

6 DISCUSSIONS

Figures 11 to 12 suggest that the conventional interpretation of CPT data that uses a "calibrated" cone factor may not fully recover the true statistics of the parameter due to the presence of spatial variability. The back-calculated data can provide a reasonable estimate of the averaged properties of in-situ soils. When only the most probable performance (Peck 1969) is required, the interpreted properties can be reliably utilized. However, when characteristic values (Orr 2007) are required for design purposes, an overestimation of the characteristic value may likely occur, resulting in an optimistic design of the geotechnical system under study. While Zhang et al. (2020) have provided a correction procedure, further research into the impact of spatial variability on the interpretation of CPT data is still warranted.

7 CONCLUSIONS

The continuous penetration of a piezocone into a statistically heterogeneous soil medium was successfully modelled using the Press-Replace Method (PRM). The performance of the PRM was rigorously validated using other published results. Using the PRM and a set of statistics that is representative of natural soft clays, the presence of spatial variability was shown to

significantly alter the failure mechanism and the net cone tip resistances. Undrained shear strength values were then back-calculated following a procedure that resembles the interpretation procedures adopted in practice. The results indicate that, while the interpreted mean S_u value from the RFEM analyses was close to the prescribed (input) value, the value of CoV was underestimated by approximately 13-16%. Further research is needed to provide an improved framework to interpret CPT data.

Some aspects of in situ testing of clay-glacial till mixture redeposited as man-made fills

J. Wierzbicki, K. Stefaniak & S. Wilczyński

B. Brzeziński
Labortest Sp. z o.o. Sp. k., Poznań, Poland

ABSTRACT: The paper presents the results of CPTU and FVT tests carried out in soils, which filled the former brown coal excavation. In their natural state, these lands were pre-consolidated glacial till and clay. Detachment of soil from the original deposit, transport and low-energy redeposition led to the creation of multi-meter-thick non-consolidated embankments, which are now used as a construction subsoil. These embankments consolidate under their own weight, however, unlike typical geological formations, they are characterized by a decreasing influence of consolidation on the strength properties along with depth.

1 INTRODUCTION

The contemporary development of urban areas is related to, inter alia, the location of industrial facilities on the outskirts of cities. Simultaneously, the high cost of land properties within cities make it economically viable to use advanced foundation techniques in case of weak, but cheap, grounds. Therefore, more and more often commercial buildings are located in areas not previously used for construction purposes. One of the most efficient trends in such cases in Poland is the use of land reclaimed after a large scale industrial facilities as brown coal mines. Contemporary an ecological purpose makes it necessary to resign from the simple, but highly devastating from an environmental point of view, use of brown coal as an energy source. Thus, brown coal mines in Poland have been closing for a dozen of years and the rate of these changes will increase in the future. Some of the old brown coal outcrops are being changed into green areas, some of them are used for recreation with a newly built infrastructure, but some of them, especially the ones close to the cities, are going to be used as lands for clean industry facilities.

One of the good examples of such a use of reclaimed land are the areas of brown coal dumps in the vicinity of the city of Konin, in central Poland. The soil that has been dumped is a chaotic mixture of fragments of previously overconsolidated glacial till, sands and clays, very often over 20-meter thick, that consolidate naturally over time. The method of depositing man-made fill, despite the fact that the dumps are made of natural soil, leads to clear differences in their strength and deformation characteristics, as opposed to similar soils deposited as a result of geological processes. In this case, the use of typical geotechnical procedures may cause overestimation of soil strength and stiffness. Due to a complex structure of the man-made fill the in situ tests, as CPTU, seem to be the best solution for geotechnical investigations. Nevertheless, it is worth seeing how the geotechnical properties of overconsolidated soil can be changed because of excavating and low energy redeposition. For this purpose, the results of CPTU and FVT investigations in the reclaimed land were compared with the results of investigations carried out in the areas of natural occurrence of glacial till of the same glaciation in Poland.

2 MAN-MADE FILL TEST SITE

The studies of the embankments of the brown coal mine dump were located on the southern outskirts of the central part of the former Niesłusz outcrop, which is the oldest part of the Konin mining complex (Figure 1).

The primary geological structure of this area consists of the Quaternary sediments dominated by glacial till. Two types can be distinguished: upper moraine, representing the Vistula glaciation, and lower moraine related to the Odra glaciation. In clays, there are numerous intercalcations of sand-gravel and fluvioglacial lenses, as well as varvic clays and erratic boulders (Widera 2001). These sediments lie on the Pliocene and Miocene

formations, among which brown coal accumulated in sedimentation basins is a characteristic element. Clays lay directly above the coal, intercalated with dusty sand, sandy silt or fine-grained quartz sand (Ratajczak & Hycnar 2017).

Figure 1. Location of the test sites.

Brown coal, both in Poland and around the world, is exploited almost exclusively using the opencast method. Exploitation of minerals is related to a number of activities necessary to be performed in the deposit and in its surroundings, which, as a result, lead to the extraction of the mineral. A characteristic element of opencast mining is the removal of the overburden of various thicknesses and compositions, the mining of the mineral and its transport to the destination as well as the transport and tipping of the removed overburden (Nowak & Kozłowski 2009). Almost from the beginning of brown coal mining in the Konin region, this process has been taking place in a system in which the excavated material is transferred to belt conveyors, which are then transported to a gravity stacker that forms an embankment - a dump.

The coal deposits in the Niesłusz outcrop were exploited in the 1950s and the area was reclaimed with little investment: at the site of the dump (where the test site is located), works were undertaken to restore the land for agricultural or forest use and the largest depressions were developed as water reservoirs. The lack of success in restoring the land to agriculture and the close vicinity of a dynamically developing city meant that since the 1990s, these areas have been considered as areas for industrial and commercial development (Gilewska & Otremba 2013) (Figure 2).

Figure 2. Flat surface of the man-made fill at the Niesłusz test site.

The end of brown coal exploitation falls on circa 1961 and agricultural reclamation has been carried out since then, thus it can be assumed that the test site has been subject to consolidation for 60 years under its own weight of deposited material.

The current geological structure of the subsurface zone of the test site is between a few to over a dozen meters of embankments lying on the glacial till (Figure 3).The basic physical properties of the soil are given in Table 1 and the typical grain size distribution is showed in Figure 5.
Figure 3. Typical soil profile at the Niesłusz test site (soil description according to ISO14688-2, gwl – ground water level, w_n – natural moisture, PI – plasticity index).

The ground water found in the subsoil behaves like socalled suspended waters, which can be found at different levels and do not constitute a single piezometric level.

3 GLACIAL TILL TEST SITE

Research in naturally deposited glacial soil was carried out in the area of the Parsęta Lob of the Vistula glaciation, which was formed during the local transgression of the already retreating ice sheet (Figure 1). As a result of this event, two glacial till deposits were deposited: the older, from the previous glaciation phase (the Poznań phase), preconsolidated by the transgressing Parsęta Lob, and the younger, from the melt out phase, normally consolidated or slightly preconsolidated (Pomeranian phase) (Figure 4).

Granulometrically, these sediments are very similar to each other, they are a mixture of sand and gravel in about 50-70%, silt in about 20% and a supplementary part of the till (Figure 5). These soils were created within approx. 4,000 years, several thousand years ago, so the aging processes did not play a decisive role in shaping their geotechnical properties. The basic physical properties of these soils are given in Table 2.

However, the different load history led to a clear differentiation of the geotechnical properties of the

sediments of both phases, which was described, among others, by Wierzbicki et al. (2008). This differentiation is visible, for example, in the natural moisture content (approx. 16% for the clays of the Pomeranian phase and approx. 11% for the clays of the Poznań phase), and especially in the values of undrained shear strength (maximum 290 kPa for clays of the Pomeranian phase and maximum 670 kPa for clays of the Poznań phase) (Wierzbicki 2010).

4 RESULTS

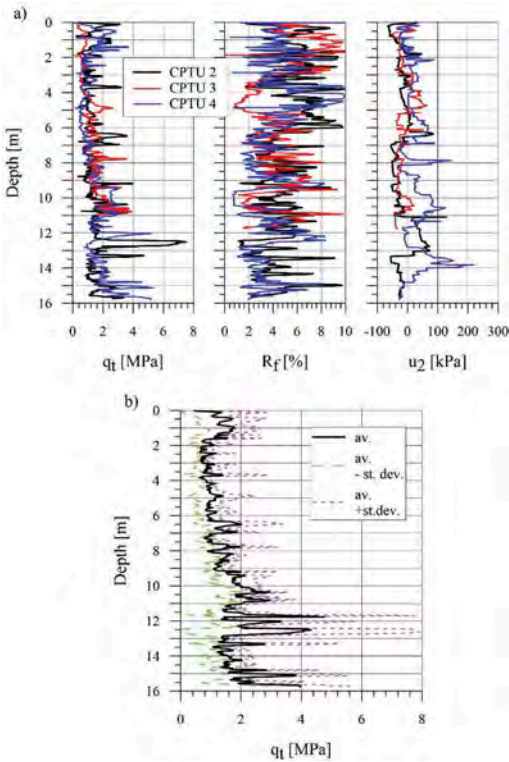
The results of the research carried out on glacial deposits in their natural habitat were presented in detail by Wierzbicki (2010). On this basis, it can be concluded that the typical CPTU profile of the soils of the Vistula glaciation is shown in Figure 6.
Figure 6. Typical CPTU results at glacial till test site (test no. 19) (on the basis of Wierzbicki 2010).


Figure 7. CPTU results at the Niesłusz test site (a) tests no. 2, 3 & 4 and (b) average value of q_t (av.) with plus and minus standard deviation values (av. + st.dev. & av. – st. dev.).

The relatively low and sometimes even negative u_2 values are common in the case of the Vistula glaciation and are caused by a relatively low degree of saturation and low clay content combined with the overconsolidation effect. In case of this land, Wierzbicki (2010) also carried out a series of studies of geotechnical features, which indicate, among others, a different degree of pre-consolidation of individual parts of the profile. On the other hand, the triaxial CIU studies showed that the values of cone factor N_{kt} range from 15 to 23 (in case of sediments with high OCR and high content of gravel fraction).

As far as redeposited sediments are concerned, data from three CPTU soundings located approximately 30 m from each other were used. Boreholes were made in the same places, samples were taken for laboratory tests and FVT soundings were performed. The results of the CPTU tests indicate a general similarity of the results at individual research points (Figure 7). However, this similarity is more visible along of the entire profile rather than locally at individual depths. The results of the FVT test, as well as the CPTU test, indicate a strong local differentiation of the geotechnical features of the subsoil (Figure 8). Again, however, the general trend of strength alterations is increasing along with the depth of deposition (Figure 9). It is worth to notice that no correction for plasticity was used during the c_u(FVT) calculations, due to low plasticity of the investigated soil (PI <20).
Figure 8. Results of FVT at the depth of 4,5 m at the Niesłusz test site (tests no. 2, 3 & 4).

The values of N_{kt} obtained on the basis of the comparison with the results of CIU (natural sediments) and FVT (redeposited sediments), allowed to determine the undrained shear strength $c_u(s_u)$ in accordance with the Equation 1 (Figure 10).

$$c_u(s_u) = \frac{q_n}{N_{kt}} \qquad (1)$$

where: $c_u(s_u)$ = undrained shear strength, q_n = nett cone resistance, N_{kt} = cone factor
Figure 9. The undrained shear strength profiles from FVT at different testing points and the average profile of this parameter (av.) with plus and minus standard deviation values (av. + st.dev. & av. – st. dev.).
Figure 10. The undrained shear strength of glacial till (CPTU 19) and man-made fill (CPTU 2, 3, 4) on the basis of CPTU results (average values (av.) and plus and minus standard deviation values (av. + st.dev. & av. – st. dev.). The N_{kt} value for the ranges between 13 and 17 (depending on the specific soil layer).

5 DISCUSION

In case of redeposited sediments, undrained shear strength $c_u(s_u)$, apart from low values for glacial sediments (Wierzbicki 2010), is also characterized by a clear trend increasing with depth and thus with vertical geostatic stress.

It is worth noting that a similar trend was not observed in naturally deposited land, where the the values of $c_u(s_u)$ are more related to different deposition phases and different pre-consolidation effects *than* only to the increase of depth. The different dependence of the value of $c_u(s_u)$ on the depth of occurrence in both test sites is very clearly visible after the normalization of this parameter by effective vertical stress (Figure 11).

It can be concluded that in case of redeposited sediments, the inclusion of the stress component

excessively influences the normalization, that is, the trend along with the depth is permanently negative across the entire profile. This means that the undrained shear strength of the soil increases slower and slower with increasing depth. Such an effect may be characteristic of underconsolidated deposits. It is particularly worth emphasizing that when the above dependence is presented on a semi-logarithmic scale, we observe variability around 1 in natural sediments, while in sediments redeposited with depth, we still observe a decreasing trend with depth (Figure 12). It is probable that this rule can be universal for all non-compacted man made but for now, it can be proved only in the case of fills which are 16 m thick. Thus, while the dependence of the strength properties in glacial till can be described by a logarithmic function (which is typical in most geotechnical situations), in case of the same granulometric but redeposited soil, it is not appropriate.
Figure 11. Undrained shear strength normalized by vertical stress for glacial till and mam-made fill profiles.
Figure 12. Undrained shear strength normalized by vertical stress in semi-log scale, for glacial till and mam-made fill profiles.

6 SUMMARY

Glacial tills, which in their natural habitat are pre-consolidated soils, lose some of their mechanical properties during excavation and transportation in the form of large fragments and redeposition. They are still soils with sufficiently good geotechnical properties to place building structures directly on them. However, the loss of strength properties is so great that the soils have the profile characteristics corresponding to under-consolidated soils and therefore susceptible to consolidation subsidence. Thus, in case of land deposited within the post outcrops of brown coal mines, the basic problem is not so much reaching the bearing limit state, but the serviceability limit state. Moreover, the research results indicate that the problem of land unconsolidation increases with depth, which makes this situation unique compared to, for example, natural soils (Radaszewski and Wierzbicki 2019).

Cone penetration in a thin medium dense sand layer sandwiched by different clay layers – LDFE analysis

Q. Xie & Y.X. Hu

ABSTRACT: The cone penetration test (CPT) has been the most common site investigation practice for decades. This paper presents the results of large deformation finite element (LDFE) analysis that modeled a CPT into soil comprising a thin medium dense sand layer sandwiched between two clay layers of different undrained shear strengths. An extended critical state Mohr-Coulomb model is utilized to capture the stress-dependent drained behavior of sand, while Tresca failure criterion is adopted for the undrained behavior of clay. Because the sand layer and the surrounding clay layers work as a system that defines the mobilized soil stiffness and soil interface deformation, two soil layer profiles are analyzed to study cone penetration resistance responses, including soft clay on top and stiff clay at bottom, and vice versa. It is found that a peak resistance is registered in the thin sand layer, through the top and bottom clay layers show impact to the peak as well. The impact on the peak resistance from the clay layer ahead (i.e. bottom layer) weights more than the clay layer behind (i.e. top layer). The evolving soil flow mechanisms are revealed to explain the findings.

1 INTRODUCTION

1.1 Historical background

The practice of inserting a rod into soft soil to find embedded stiff layers dates back to the 19th century. However, the first recognizable form of the modern cone penetration test (CPT) was developed in Netherlands in 1934 to predict the ultimate bearing capacity of piles (Barentsen, 1936). The early forms of CPTs comprised a mechanical system of pushing rods to measure the rod tip resistance. In the late 1960s, electric penetrometers came into general usage, enabling resistance to be continuously and automatically recorded (Walker & Yu, 2010). Today the CPT is the most widely used in-situ testing method to investigate soil stratification due to its reliability and repeatability.

1.2 CPT in layered soils

The traditional design charts and formulas to identify soil properties from CPT data were formulated on uniform soils of a single layer (Silva & Bolton, 2004). To directly apply such interpretation method to layered soils can be problematic. This is because the influence zone of a cone can span a distance several cone diameters both behind and ahead of the cone tip (Lunne et al., 2002). When the influence zone crosses layer interfaces, the measured cone resistance represents not only the properties of the local soil around the cone tip, but also the soils in adjacent layers.

The inability to accurately estimate soil properties of individual layers (particularly thin layers) in soil strata has attracted recent attention, with research focused on idealized soil profiles of two or three uniform soil layers in different sequences (e.g. weak soil over strong soil and vice versa, strong layer embedded in soft soils and vice versa). Methodologies included elastic analysis (Vreugdenhil et al., 1994, Yue & Yin, 1999), cavity expansion analysis (Mo et al., 2016), chamber testing (Tehrani et al., 2017), centrifuge testing (Mo et al., 2015) and analysis of field data (Youd & Idriss, 2001, Yost et al., 2019). Moreover, large deformation finite element (LDFE) analysis has been applied for layered clays (Ma et al., 2016, Ma et al., 2017).

For CPT in clay-sand-clay soils, an early analytical solution was obtained by elastic analysis to investigate the "error" between the resistance in a thin embedded stiff layer and the ultimate resistance in an infinitely thick layer of the same stiffness (Vreugdenhil et al., 1994). As suggested by this

study, the "error" was a function of the embedded layer thickness and the stiffness ratio between adjacent layers. The finding was later confirmed by field data (Youd & Idriss, 2001) and examined numerically (Ahmadi & Robertson, 2005). The latter suggested the "error" function only applied to thin and normally consolidated sand layers embedded in soft normally consolidated clays. Thus, caution needs to be taken to apply these formulas for different cases.

In the above studies, the stiffnesses of the top and bottom clays were assumed identical. Thus, the existing solutions may not be suitable for the situation where the top clay stiffness is different from the bottom clay, with a sand layer sandwiched in the middle. This study is set to explore the CPT in these complex soil profiles.

1.3 *Objective*

This study numerically investigates soil responses to cone penetration in a medium dense sand layer sandwiched by two different clay layers. The two soil layer arrangements for the top and bottom clay layers include (i) the top clay being stiffer than the bottom clay, and (ii) the top clay being softer than the bottom clay. The soil flow mechanisms will be revealed and correlated to the features observed in the cone resistance profiles. Additionally, stress history will be analyzed to further explain the cone resistance profiles.

2 METHODOLOGY

2.1 *RITSS method*

Cone penetration is a typical large strain problem in finite element analysis. To overcome mesh distortion in numerical analysis, the remeshing and interpolation technique with small strain (RITSS) method is deployed in this study (Hu & Randolph, 1998a). RITSS method belongs to the arbitrary Lagrangian-Eulerian (ALE) FE methods. It starts with a series of small strain incremental displacement analysis with an initial mesh, followed by updating the co-ordinates of all nodes in the mesh by the displacements calculated in the first steps and then automatically remeshing the whole domain accordingly. On the newly established mesh, the field variables will be interpolated from the old mesh. A new round of small strain analysis will be carried based on the new mesh and the process will be cycled until the desired cone penetration depth is achieved.

The FE based computer program AFENA (Carter & Balaam, 1995) is used in the study with the RITSS method implemented. *H*-adaptive mesh refinement cycles are also implemented in the program to optimize the mesh density and minimize the discretization errors (Hu & Randolph, 1998b).

2.2 *Soil models*

In this study, an extended Critical State Mohr-Coulomb (CSMC) model is utilized to capture the stress-dependent behavior of sand (Li et al., 2013). It introduces the critical state concept into the classical Mohr-Coulomb (MC) model by linking the friction angle and dilation angle with the soil state parameter (i.e. the difference between the current void ratio and the critical state void ratio at current stress level). Elastic parameters (i.e. Young's modulus) are functions of the void ratio and mean effective stress. To fit the large deformation analysis computation, CSMC model balances its complexity with simplicity to avoid numerical difficulties. In contrast to the advanced model for sand, a simple Tresca model is used for clay. There is only one plastic parameter, undrained shear strength (s_u), to determine an unchanged yielding surface. Young's modulus is assumed as proportional to the shear strength (E = $500 \times s_u$), which is within the commonly adopted range (Hossain et al., 2005). Poisson ratio for clay is set at 0.49 for undrained analysis while that of sand is set at 0.3 for drained analysis.

The CSMC model along with the RITSS method for CPT in layered soil has been extensively verified with centrifuge tests data for two types of sand (Xie, 2020). Good agreement has been achieved providing confidence in deploying the model in this study. The sand parameters utilized in this paper are calibrated for Toyoura sand and are provided in Table 1. e_{max} and e_{min} are the maximum and minimum void ratios; ϕ_c is the critical state friction angle; A, m and n are three scaling factors.

Table 1. CSMC model parameters for Toyoura sand.

0.985	0.611	32	0.5	7	0.75

3 NUMERICAL MODELLING

3.1 *Problem definition*

Figure 1 graphically defines the problem. A cone penetrates in clay-sand-clay soil to a depth, d, measured from the cone shoulder to the original elevation of the soil surface. The sand is medium dense (I_D = 60%). The strengths of clay layers vary in two cases: Case A, top clay (s_{ut} = 80 kPa) is stiffer than the bottom clay (s_{ub} = 10 kPa) and Case B, top clay (s_{ut} = 10 kPa) is softer than the bottom clay (s_{ub} = 80 kPa). The reaction force acting on the cone, during continuous penetration, is obtained through the LDFE analysis. The cone shaft and cone face are set as fully smooth as it is normally manufactured with polished stainless steel.
Figure 1. Cone penetration in clay-sand-clay soil.

3.2 Mesh setting

A finite element mesh setting where the cone penetrates in the bottom clay layer is depicted in Figure 2. The numerical model is simplified as 2D-axisymmetric, with the soil domain of equivalent 55D in depth and 55D in radius. The lateral side is set as a roller condition to eliminate soil horizontal movements and the bottom boundary is set as a hinge condition to eliminate both vertical and horizontal movements. The analysis uses six-node triangular elements with three Gauss points. The cone shoulder is initially buried in the soil to avoid numerical difficulties. A mesh refined zone is added adjacent to the cone, which moves with the cone, to improve numerical stability in the area of high strain concentration.
Figure 2. Mesh setting when cone penetrates in bottom clay.

4 RESULTS AND DISCUSSION

4.1 Cone resistance profiles

Figure 3 shows the cone resistance profiles of Cases A and B. There are three zones identified around the embedded sand layer in both cases: (I) blue zone – cone resistance increases linearly and sharply with the cone tip entering the sand layer, starting from the kink point registered above the C-S interface; (II) red zone - another linear increasing stage in resistance, but with lower gradient, leading to the peak resistance in the sand layer; (III) orange zone – cone resistance decreases after the peak, and converges to the ultimate resistance in the bottom clay layer.

To illustrate the evolution of soil failure mechanisms, eight stages are denoted on the resistance profiles in Figure 3. For Case A: Stage A_1 - when the cone resistance is stabilized at its ultimate resistance in the top clay; Stage A_2 - when the resistance decreases after the stabilized resistance is reached; Stage A_3 - when the kink point is formed above the clay-sand interface; Stage A_4 - when cone resistance reaches a turning point with changed gradient; Stage A_5 - when the resistance is increasing at a reduced gradient; Stage A_6 - when the peak resistance is reached in sand; Stage A_7 to A_8- when the resistance decreases gradually till the ultimate resistance in the bottom clay is reached. Correspondingly, eight Stages are chosen for Case B in a similar manner. The normalized penetration depths, d/D, at different stages are listed in Table 2

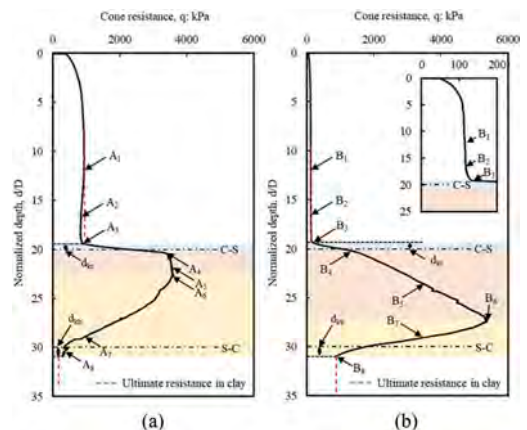
The differences observed between the two profiles are: (i) above the blue zone, the cone resistance shows a slight decrease before reaching the sand layer in Case A, but not in Case B; (ii) in the blue zone, the cone resistance increases more sharply in Case A than in Case B; (iii) in the red zone, the cone resistance reaches a higher peak in Case B than in Case A; (iv) in the orange zone, the cone resistance reduces more sharply in Case B than in Case A. Discussions on these observed features are provided in the following section.


Figure 3. CPT resistance profiles in clay-sand-clay soil: (a) Case A: $s_{ut}/s_{ub} = 8$; (b) Case B: $s_{ut}/s_{ub} = 0.125$ (C-S refers to clay-sand interface while S-C refers to sand-clay interface).

Table 2. Normalized depths at different penetration stages.

Stage No.	Normalized depth (d/D)	
	Case A	Case B
1	12	12
2	16.5	16.5
3	19.3	19.25
4	20.3	20.05
5	22	23.7
6	22.7	27.3
7	29	29
8	30.2	30.85

4.2 Soil flow mechanism

4.2.1 Case A: A sand layer embedded in stiff over soft clays

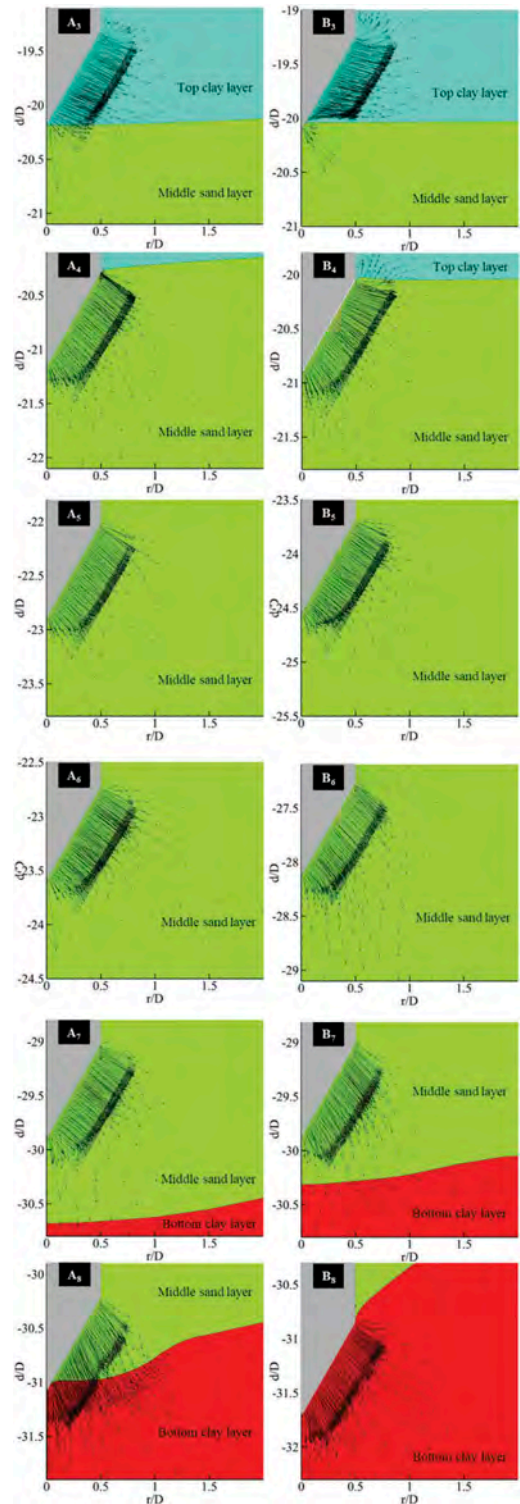
Figures on the left column of Figure 4 depict the flow mechanism for Case A. In the top clay, a cavity expansion failure is formed through Stages A_1 to A_2 until the cone tip touches the sand surface at Stage A_3. The localized failure mode should result in a constant ultimate net cone resistance as the resistance only depends on the local clay stiffness. Therefore, the reduction in resistance at Stage A_2 suggests the cone is impacted by the sand layer ahead of the cone, as soil displacements bend slightly downwards comparing with Stage A_1. From Stage A_3 to A_4, the cone passes through the clay-sand interface as grouped in the blue zone in Figure 3(a). Because the magnitude of mobilized stress in sand is much higher than that in clay, the resistance increases sharply over these stages, resulting in a kink registered at Stage A_3. Soil movement is disconnected by


Figure 4. Soil flow mechanisms in Cases A (left) and B (right).

the layer interface: cone squeezes the top clay sideways while pushing the sand downwards. From Stage A_4, the cone shoulder detaches from the sagged interface, which marks the full cone being buried in the sand layer, and the resistance development enters a new stage as shown by the red zone in Figure 3(a). The cavity expansion merges again at Stage A_5, implying the cone senses little impact from surrounding clays except the overburden pressure. Moving to Stage A_6, the soil displacements bend downwards. This implies that the cone is sensing of the bottom soft clay, thus the cone resistance starts to reduce. From Stages A_7 to A_8, soil movements keep bending downward as the cone approaching the bottom clay. The mobilized sand keeps reducing until the resistance reaches the stable value in the bottom clay. At Stage A_8, less than 1D of sand is mobilized and the soil movement is largely attracted to the bottom clay. This reduced mobilization in sand causes the resistance to decrease in the yellow zone in Figure 3(a). The S-C interface sags extensively by ~1D, compared to 0.18D for the C-S interface at Stage A_3. A kink is formed far from the original elevation of the interface (e.g. $d_{kb} > 1D$).

4.2.2 Case B: A sand layer embedded in soft over stiff clays

The soil flow mechanisms for Case B are depicted in the right column of Figure 4. Many features observed in Case A can also be noted in Case B, including: (1) cavity expansion in the top clay before the cone tip touches sand (Stage B_1 to B_2); (2) cavity expansion in sand before the cone senses the bottom clay (Stage B_5); (3) the downwards bending soil displacement due to the attraction of the bottom clay (Stage B_6 to B_8). The similarities in the flow mechanisms between Cases A and Case B can explain the similar observations in the resistance profiles, while the differences between the cases are discussed below.

4.2.3 Further discussion on the profile differences

Difference (i): above the blue zone, cone resistance reduction in top clay only appears in Case A. This can be explained by the stress-dependent sand stiffness with the impacts from the surrounding clays. Figure 5 depicts the soil mean stress contours for Cases A and B. In CSMC model, sand stiffness (E_s) is a function of mean effective stress and void ratio. Extracted for Point E in Figure 5 (measured 1D from the central line and 1D below the cone surface) from the output files: E_s = 20.8 MPa at Stage A_2, and 10.5 MPa at Stage B_2. The stiffness of top clay (E_c) is 40 MPa in Case A and 5 MPa in Case B. Therefore, the sand layer is mobilized as a soft layer below the cone at Stage A_2, resulting the cone resistance reduction above the blue zone in Case A. This phenomenon remains until the cone penetrates into the sand layer.

Difference (ii): in the blue zone, cone resistance profile exhibits sharper increase in Case A than in
Figure 5. Mean stress contours at (a) Stage A_1, (b) Stage B_1, (c) Stage A_2, (d) Stage B_2 (MS refers the mean stress).

Case B. This may be due to the influence of the top clay layer to the mobilized sand layer. In Case A, the top clay is stiffer than that in Case B, which mobilizes higher stress in sand layer, hence a stiffer mobilized sand layer. The sand stiffness promotes a sharper increase in the cone resistance.

Difference (iii): in the red zone, the cone resistance in Case B increases with a higher gradient and lasts longer than those in Case A, and it results in a higher peak. This may be due to the influence of the bottom clay. In Case B, the bottom soil is stiffer. The stiffer bottom clay reduces the sand layer sagging and promotes higher peak resistance.

Difference (iv): in the orange zone, the cone resistance reduces more sharply in Case B than in Case A. This can also be explained by the stress-dependent behavior of sand with the impacts from surrounding clays. As discussed before, the mobilized stiffness of sand depends on its in-situ mean effective stress. Soil stiffness determines the length of sensing distance to the new layer ahead. The observation is consistent to that by Lunne et al. (2002) where a cone senses a new layer earlier in a stiff layer than in a soft layer. Thus, in Case A, the sand layer is stiffer than the bottom clay, hence the cone can sense the bottom soft clay earlier and the reduction in resistance is gradual. On the contrary, in Case B, the bottom clay is stiffer, hence the cone senses the bottom clay later and the reduction in resistance is more dramatic.

Therefore, it was observed that the top clay has more influence on the cone resistance profile in the blue zone and the zone above. The bottom clay has more influence on the cone resistance profile in the red zone and orange zone. As the peak resistance is developed in the red zone, the bottom clay has more

influence on the cone peak resistance. The peak resistance in Case A is about 2/3 of that in Case B, as the bottom clay is softer in Case A than in Case B.

5 CONCLUSION

The paper studies CPT in a thin medium dense sand layer sandwiched by two different clay layers. Two Cases of soil profiles are established, such as stiff over soft clay and vice versa. By deploying the CSMC model, the stress-dependent behaviors of sand are well captured to reveal a systematic soil responses of cone penetration into clay-sand-clay soils.

The study shows that the top clay has more influence on the cone resistance profile in the top layer and the blue zone. The bottom clay layer has more influence on the cone resistance profile in the red zone and the orange zone (refer to Figure 3 for coloring zones). A softer bottom clay in Case A induces more bending of the sand layer. A stiffer bottom clay in Case B induces higher cone peak resistance in the sand layer.

Further studies are needed to investigate more triple-layer profiles to provide guidance in CPT data interpretations.

Study on SPT N-values and relative density through various soundings in full-scale chamber test ground

H. Yabe, K. Harada, T. Ito & E. Watanabe
Geotechnical Division, Fudo Tetra Corporation, Chuo-ku, Tokyo, Japan

ABSTRACT: In Japan, the evaluation of ground strength, such as the liquefaction resistance, is often carried out through the *N*-value of the standard penetration test (SPT), and it is used in various designs. Other soundings are also used, including the cone penetration test (CPT) and the Swedish weight sounding (SWS) that is comparatively simpler when compared with SPT, and conversion formulae to *N*-value have also been proposed by various researchers. In this paper, the various soundings described above (SPT, CPT, and SWS) were carried out in a sandy ground, where the density was controlled and measured by Radio Isotope (RI) method. Then, the correlation between the SPT *N*-value and the relative density *Dr* was examined. Based on the results, the *N-Dr* correlation was examined using the results of various soundings in a full-scale chamber test where the ground density was controlled. The results confirmed the applicability of the correlation formulae, with good correlation confirmed not only between *Dr* and SPT *N*-value, but also with the *N*-value estimated from each sounding.

1 INTRODUCTION

Japan has long been prone to ground disasters due to earthquakes and heavy rain, and recent events indicate that it is more prone to these hazards than ever. Countermeasure works have generally been implemented to prevent ground disasters. Ground surveys are essential when determining the necessity and the scale of countermeasure works and confirming the effectiveness after their implementation. The methods frequently used for such ground surveys include in-situ investigations (soundings) through the standard penetration test (SPT). The SPT *N*-values obtained have been used in the design of various facilities. For example, in the case of the sand compaction pile method used as a countermeasure against liquefaction, SPT *N*-value is used to determine if the implementation of the countermeasure works is necessary and to confirm the level of improvement after their execution. Also, considering that the design is carried out considering the relative density (*Dr*) estimated from the SPT *N*-values obtained, the appropriateness of SPT *N*-values and their evaluation (*Dr*-conversion) are important.

In addition to SPT, other soundings used include the cone penetration test (CPT) and the Swedish weight sounding test (SWS). Because there are cases where CPT and SWS can be implemented relatively easier than SPT, formulae to obtain the SPT *N*-value and *Dr* from the results of CPT and SWS have been developed.

The authors carried out the above-mentioned soundings in an artificially constructed sandy ground to conduct full-scale tests on ground improvement methods. The correlation between SPT *N*-values and *Dr* was examined by comparing: (1) the SPT *N*-values with the normalized *N*-values estimated from the CPT/SWS penetration resistance values; and (2) the estimated *Dr* obtained using available conversion formulae with the measured *Dr* during the construction of the full-scale test ground. This paper reports on comparative studies carried out for two cases of ground with different target relative densities.

2 OUTLINE OF FULL-SCALE TEST GROUND

The full-scale test ground is shown in Figure 1. The test ground covered an area measuring 12.2 m × 23.4 m and a depth of 7.5 m, enabling the use of actual construction machines.

As shown in the figure, the full-scale test ground had a deck slab made of concrete and was surrounded by side walls made of steel sheet piles such that a saturated ground could be reproduced. The test ground was saturated after backfilling with sand. For this purpose, vertical pipes were installed at several locations on the sidewalls with a 50 cm thick crushed stone layer at the bottom. Water was injected and distributed through the pipes and the crushed stone layer to saturate the full-scale test ground from the bottom.

The pit sand produced in Namegata (Japan) was used to backfill the test ground. The physical properties of the pit sand are shown in Table 1 and Figure 2. Table 1 also shows the physical properties of Toyoura sand, a Japanese standard sand, for comparison.
Figure 1. Photos of the full-scale chamber.

Table 1. Physical properties of the backfilling material and Toyoura sand.

Material	Fc (%)	ρ_s (g/cm^3)	e_{max}	e_{min}	e_{min}*	U_c
Toyoura Sand※	0.0	2.65	0.985	0.611	0.674	1.51

3 DENSITY CONTROL DURING CONSTRUCTION OF FULL-SCALE TEST GROUND AND SOUNDING TEST RESULTS

3.1 Density control method

The full-scale test ground was constructed for each of the two cases through backfilling with sand material layer by layer, with each 0.3 m thick layer spread and compacted to the required density. More specifically, the first layer was spread to level the ground. The remaining three layers were compacted by

a roller and other equipment to ensure trafficability for the heavy machines to be used on the test ground.

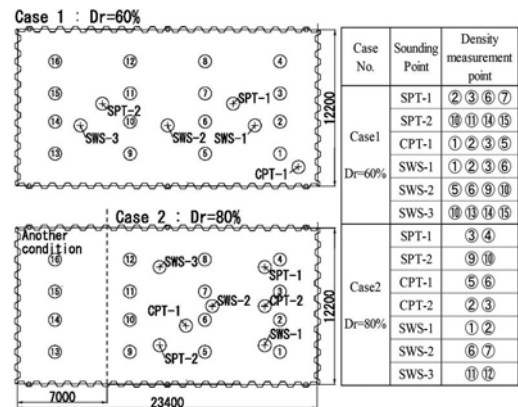
The density of the full-scale test ground was controlled by measuring the relative density of each layer at 16 locations through the RI (Radio Isotope) method. Then, after completing the construction of the full-scale test ground, various soundings were conducted. Figure 3 shows the locations where the density measurement and various soundings were conducted. In the figure, the locations of the density measurement are indicated by numbers, and the sounding locations are indicated by letters (such as SPT, CPT, and SWS). Also, in Case 1, the full-scale ground was constructed with $Dr = 60\%$ while in Case 2, the ground has $Dr = 80\%$.


Figure 3. Relationship between the locations of density measurement and soundings within the chamber.

3.2 SPT, CPT, and SWS sounding results

Figure 4 shows the measured profiles of the penetration resistance values (SPT N-values, q_c-values, and N_{SW} values) for each sounding. Comparing the measured results for the same type of sounding conducted more than once (except for CPT in Case 1), a similar trend can be observed regardless of the measurement location. In Case 1, the values of the penetration resistance for each sounding do not change much with depth. However, in Case 2, the penetration resistance values for each sounding increases with depth, and the overall values are larger than those of Case 1 (which has lower relative density).

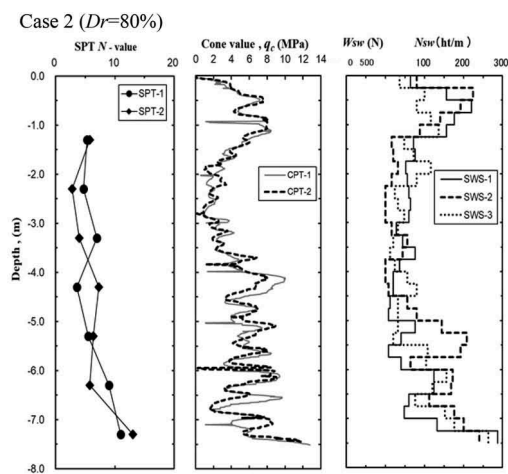
Figure 5 shows the RI value profiles measured in the vicinity of the sounding points. Two to four points in the vicinity of the sounding were selected based on Figure 3, and the average of the RI values is shown.

In Case 1 (target relative density $Dr = 60\%$), the overall variation of the measurement results was large, and there were places where the measurement results exceeded the control target density. However, the overall average of the measurement results, with dry density $\rho_d = 1.45\text{-}1.50$ g/cm^3 and relative density

Case 1 (*Dr*=60%)

Case 1 (*Dr*=60%)

Case 2 (*Dr*=80%)

Case 2 (*Dr*=80%)


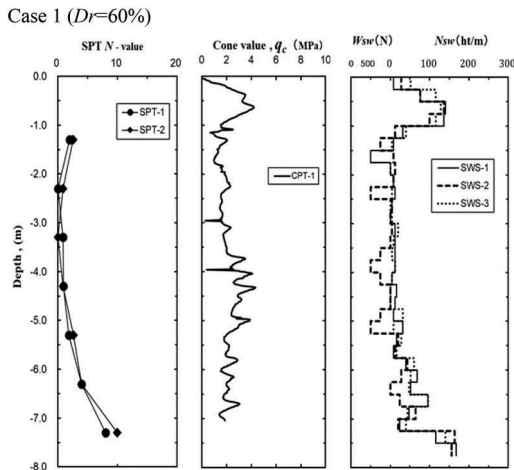


Figure 4. Results of soundings for each case.

Figure 5. Results of density measurement corresponding to each sounding.

Dr = 55-70%, was within the acceptable range when compared with the target values.

In Case 2 (target relative density *Dr* = 80%), similar variation in the measurement results was observed, with most of the values exceeding the target value. The overall average relative density was in the range of 85-100%, which was greater than the target value of 80%.

Comparing the profiles shown in Figures 4 and 5, there was variation in the measured *RI* values at various points around the sounding locations. However, the overall average *RI* values generally showed a similar trend to the sounding results.

4 DISCUSSION ON THE CORRELATION BETWEEN THE SOUNDING RESULTS

Table 2 shows the correlations available in the literature between *Dr* and penetration resistance as well as the relations between SPT *N*-values and CPT/SWS

values obtained in natural or artificial grounds. The conversion formulae to obtain *Dr* are derived from the relation between the penetration resistance and relative density in the range of void ratios reported in the available studies shown in Figure 6.

Figure 7 shows the procedure to estimate *Dr* from the CPT/SWS penetration resistance and SPT *N*-values. What follows below is a discussion on the consistency between the sounding results in the sand layers of the full-scale test ground constructed with controlled density and those from studies in natural ground.

4.1 *Comparison between SPT N-value and normalized N-value*

Figure 8 shows the comparisons between the SPT *N*-value and the normalized *N*-value calculated from the penetration resistance of CPT and SWS using the conversion formulae shown in Table 2 for the relevant cases. According to the figure, the SPT *N*-values

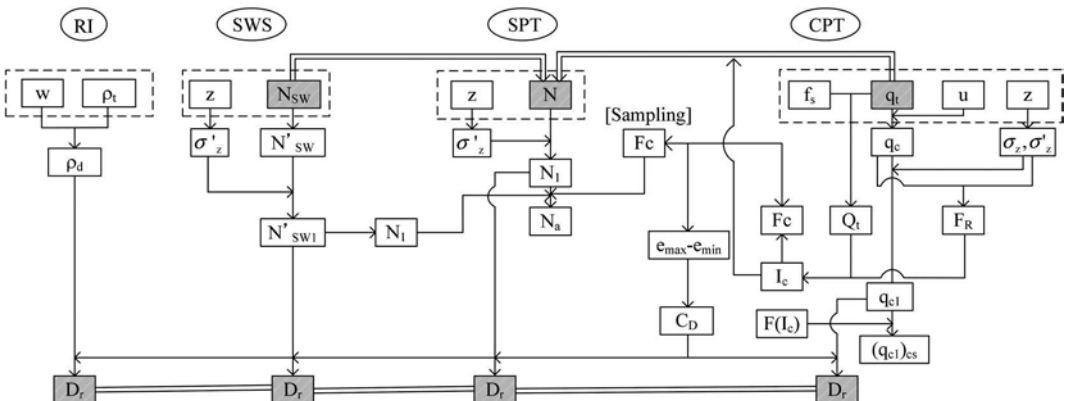

Figure 7. Correlations among each sounding test.

and the normalized *N*-values have distribution profiles which are similar to each other. Also, according to Figure 9, which shows the correlation between the SPT *N*-values and the normalized *N*-values (estimated from the penetration resistance of CPT and SWS using the conversion formulae), the SPT *N*-values correlate well with the normalized *N*-values.

4.2 Comparison of RI-measured Dr and sounding-estimated Dr

Figure 10 shows the comparisons between the *Dr* estimated from the relevant soundings (SPT, CPT, and SWS) and the *Dr* measured through the RI method for each respective case. The *Dr* obtained through the soundings was calculated from the average values of the respective cases. The *RI* values were the average of the measurements at the locations near the sounding locations.

From the figure, the *Dr* measured through the RI method is generally larger than the *Dr* estimated from the results of respective soundings. Also, the *Dr* based on CPT and SWS is close to the *Dr* measured through the RI method, but the *Dr* estimated from SPT largely differs from the *Dr* measured by the RI method. Similar tendencies can be found in Figure 11.

The reasons for these observed trends are considered to be threefold. The first reason is the difference between the full-scale test ground and an actual ground. The test ground was constructed by stacking sand layers each with thickness of 30 cm and saturated immediately before conducting the soundings. In contrast, the actual ground has complex strength distribution due to the stress history developed during a long accumulation period and aging effects. Thus, it is considered that the *Dr* measured in the full-scale test ground with younger age differs from

Figure 9. Comparison between measured and estimated *N*-value.

Figure 11. Comparison between measured and estimated relative density.

Figure 12. Relationship between cyclic strength and relative density of Namegata sand and of Toyoura sand.

the Dr calculated by the conversion formulae developed for natural ground.

The second reason is the difference in penetration mechanisms. The SPT, which dynamically applies loads by dropping a hammer into the ground, tends to have a wider variation in relative density than the CPT and SWS, which statically apply loads to the ground. It is also possible that the degree of saturation of the test ground affected the Dr.

The third reason is the difference in the concepts of the minimum void ratio, e_{min}, used to calculate the relative density. There are cases where the minimum void ratios obtained through compaction tests ($e_{min}*$) are smaller (denser) than the e_{min} based on its original definition (specified in standard). It is considered that there is a large difference between the measured and estimated Dr values because the conversion formulae listed in Table 2 are based on the conventional Dr, while the relative density from the RI method represents compacted state. Note that there is a significant difference between e_{min} and $e_{min}*$ for the backfilling sand, as shown in Table 1.

Figure 12 compares the relationship between the cyclic strength and relative density for Namegata sand and for Toyoura sand. As shown in the figure, the cyclic strength of Toyoura sand increases rapidly at relative density of 80%, while that of Namegata sand increases slowly. In other words, the actual minimum void ratio of the backfilling sand is smaller than that from the standard test, and the relative density is considered to be overestimated.

5 SUMMARY

The various soundings in the full-scale test ground confirmed that the existing correlation formulae could be approximately applied to the correlation between control values and the Dr converted from the results of various soundings. We will continue our comparative study between the measured density in the test ground and the density obtained through the correlation formulae to further verify the accuracy of the correlation formulae.

Correcting measured CPT tip resistance for multiple thin-layer effects

K.M. Yost, J. Cooper, R.A. Green, E.R. Martin & A. Yerro
Virginia Tech, Blacksburg, VA, USA

ABSTRACT: Multiple interbedded fine-grained layers in a sand deposit have a "smoothing" effect on the measured tip resistance (q_c) from the cone penetrometer test (CPT). This can result in an underestimation of the predicted liquefaction resistance of the sand layers. Herein, the efficacies of two multiple-thin-layer correction procedures are evaluated using published calibration chamber test data. The results highlight limitations of the assessed procedures for profiles with layers less than 40 mm thick. A new approach to estimate the "true" q_c (i.e., values that would be measured in a stratum absent of multiple thin-layer effects) from measured q_c is explored. The proposed numerical optimization algorithm searches for "true" soil profiles with a finite number of layers. We compare two versions of the algorithm that numerically optimize different functions, one of which uses a logarithm to refine fine-scale details, but which requires longer calculation times to yield improved corrected q_c profiles.

1 INTRODUCTION

Cone penetrometer test (CPT) data (i.e., tip resistance, q_c, and sleeve friction, f_s) are typically reported at 1 to 2 cm depth increments. However, data measured at a given depth are not representative only of the soil at that discrete depth, but are actually averaged or "blurred" values of the "true" values that fall within a zone of influence above and below the cone tip. For example, this zone of influence can include soils that are as far away as 10 to 30 times the cone diameter (d_{cone}) ahead of the cone tip (Ahmadi and Robertson 2005). Thus, the presence of multiple interbedded fine-grained layers in a sand deposit can result in a significant underestimation of the predicted liquefaction resistance of the sand layers. This phenomenon is referred to as multiple thin-layer effects.

Several methods have been proposed to correct CPT data for multiple thin-layer effects. These procedures seek to use the measured CPT data in an interlayered soil profile and estimate the "true" CPT data that would be measured in the profile absent of multiple thin-layer effects (i.e., a true representation of the CPT data at a discrete depth in the profile). In general, approaches to correct for multiple thin-layer effects can be split into two categories: forward procedures and inverse procedures. In both cases, all procedures proposed thus far focus on correcting q_c, not f_s (though some provide methods to retroactively adjust f_s based on the corrected q_c; complexities in correcting f_s are briefly discussed in Section 4 of this paper).

Forward procedures, like the ones proposed by Youd et al. (2001), Ahmadi and Robertson (2005), de Greef and Lengkeek (2018), and others, apply a series of corrections directly to the measured q_c (q^m) to obtain a "corrected" q_c (q^{corr}) that is a best estimate of the "true" q_c (i.e., q_c that would be measured in the profile absent of multiple thin-layer effects, q^t). Inverse procedures (e.g., Boulanger and DeJong 2018; Cooper et al. 2022) start by making a guess of q^t (q^{inv}) and then apply an artificial blurring model (representative of the blurring effect of the cone in layered soils) to q^{inv} to obtain a "simulated" q^m ($q^{m,sim}$). Then, $q^{m,sim}$ is compared to the actual q^m. If the misfit between $q^{m,sim}$ and q^m is too large, an update is automatically applied to provide a new, improved q^{inv} guess. The procedure iterates until the misfit is acceptable, at which point the last guessed q^{inv} is considered to be a best estimate of q^t.

To develop and validate multiple-thin-layer correction procedures (forward or inverse), one must know both q^m and q^t for a given layered soil profile. Typically, we only know q^m. CPT calibration chamber tests or numerical simulations can be used to obtain both q^m and q^t. In the following sections, the efficacy of existing forward and inverse procedures for correcting multiple thin-layer effects is assessed directly using calibration chamber data. Then, an alternate inverse procedure is proposed and assessed using the same calibration chamber data. Finally, a brief discussion of limitations and areas for future procedure improvement is provided.

2 ASSESSING EXISTING PROCEDURE EFFICACY

2.1 Overview of Deltares calibration chamber tests

A series of CPT calibration chamber tests performed at Deltares by de Lange (2018) were used to assess the efficacy of existing multiple-thin-layer correction procedures. Several soil profiles were considered in these tests, including layered sand-clay profiles and reference (single layer) sand profiles. The CPTs performed in the reference sand profiles were used to estimate q^t for the sand layers in the sand-clay models, where the reference sand profiles had similar relative densities (D_R) and overburden pressures (σ'_v) to the sand layers in the layered sand-clay models. No reference clay profiles were constructed, however, q^t for the clay could be estimated from one of the sand-clay models that had clay layers that were thick enough (200 mm, or $8d_{cone}$, thick) for q^t to fully develop. Details of how the tests were performed and information about the soils used to create the profiles are excluded for brevity and can be found in de Lange (2018).
Figure 1. Thin-layer correction factor (K_H) values derived from the de Lange (2018) calibration chamber tests (shown as points) were used to define K_H curves for several normalized thin-layer thicknesses (H/d_{cone}) for the Deltares procedure (Yost et al. 2021a).

2.2 Overview of Deltares forward procedure

Trends observed by de Lange (2018) using the CPT calibration chamber dataset were used to develop a forward multiple-thin-layer correction procedure, the details of which are discussed thoroughly in Yost et al. (2021a). This procedure, termed the Deltares [DEL] procedure, consists of two parts: (1) identification of layer interfaces based on peaks and troughs in q^m, and (2) computation and application of

a correction factor K_H (a function of: layer thickness, H; d_{cone}; and normalized ratio between minimum and maximum q^m in a layer, q_{ratio}) that increases tip resistance in thin dense layers. In short, the DEL procedure requires an input of q^m and outputs a corrected tip resistance (q^{corr}) that is an estimate of q^t. K_H factors developed for the DEL procedure are provided in Figure 1.

2.3 Overview of BD18 inverse procedure

The Boulanger and DeJong (2018) [BD18] inverse multiple-thin-layer correction procedure proposes that q^m is equal to q^t convolved with a depth-dependent spatial filter, w_c:

$$q^m(z) = q^t(z) * w_c(z) \tag{1}$$

where $*$ represents a convolution, and q^m, q^t, and w_c are all functions of depth (z). The spatial filter w_c is a discretization of a continuous function that represents the influence of soil above and below the cone tip on q_c at a particular depth. The BD18 procedure uses an iterative splitting optimization technique to solve the misfit function defined by:

$$q^{inv} = \mathrm{argmin}_{q^t} \| q^m - q^t * w_c \|_2 \tag{2}$$

The BD18 procedure includes two steps to smooth the results to prevent them from becoming unstable: *first*, a smoothing step performed after each iteration of the inversion that computes a moving average of q^{inv} over a pre-defined smoothing window, and *second*, a low-pass spatial filtering step performed once the optimization procedure has converged to a solution. After the optimization procedure is performed, a separate interface correction procedure is applied in which sharp transitions in q^{inv} (which presumably correspond to layer interfaces) are identified. A constant value of q^{inv} (either the maximum or minimum q^{inv} identified in the transition zone) is then applied to the entire transition zone within a layer, effectively setting a single q^{inv} value for each identified soil layer.

A modified version of this procedure, termed BD18MOD, was also explored in this study. For this variant of the procedure, the recommended smoothing and filtering steps that ensure convergence of the solution were adjusted. Specifically, the smoothing window was reduced to a maximum of three q^m data points (the default smoothing window is max[3, ceiling($0.866d_{cone}/\Delta z$)], where Δz is the depth interval at which the data were collected), and the low pass spatial filtering step applied after the inversion was eliminated. We found that this improved the performance of the procedure in identifying very thin layers, but also destabilized the solution, resulting in non-convergence for some scenarios.
Figure 2. Results from application of multiple-thin-layer correction procedures to de Lange (2018) calibration chamber data for: (a) Soil Model 4 with 40-mm-thick clay layers; and (b) Soil Model 8 with 20-mm-thick-clay layers (Yost et al. 2021a).

2.4 *Assessment of procedures using calibration chamber dataset*

Direct assessments of the efficacies of the DEL forward procedure, and the BD18 and BD18MOD inverse procedures were performed using the calibration chamber data from de Lange (2018). Note that this is a biased comparison of the efficacies of the procedures, since the DEL procedure was developed and calibrated using this dataset. Regardless, the DEL and BD18/BD18MOD procedures were applied to the q^m for the layered sand-clay soil profiles reported by de Lange (2018). The resulting q^{corr} (from the DEL procedure), q^{inv} (from the BD18 procedure), and q^{invmod} (from the BD18MOD procedure) were compared with the q^t determined from the reference sand profiles. Select results from this exercise are shown in Figure 2.

As shown in Figure 2a, the DEL procedure was effective at identifying the interbedded sand layers and outputting a q^{corr} that is a good estimate of q^t for those layers. Conversely, the BD18 procedure does not identify the interbedded layers, and actually estimates a q^{inv} slightly less than the q^m (and significantly less than q^t) in the interbedded sand layers. The q^{inv} values estimated using the BD18MOD procedure in the interbedded sand layers are a better estimate of q^t, but the layer interfaces are not well defined. The performance of these procedures was similar for all soil profiles in this dataset that contained layers that were 40 mm (or $1.6d_{cone}$) thick.

For the soil profiles in the dataset with interbedded layers less than 40 mm thick, the efficacy of all procedures was poor, as exemplified in Figure 2b. None of the procedures were successful at

identifying all of the 20-mm-thick layers in this profile or providing a good estimate of q^t for those layers, although the DEL procedure did a slightly better job at identifying the layer interfaces compared to the BD18 and BD18MOD procedures.

Several other useful observations were made during this exercise. None of the procedures performed well on the reference sand (single layer) soil models (i.e., all procedures erroneously identified and attempted to correct for thin, interbedded layers that were not present). In general, the BD18MOD procedure performed better than the BD18 procedure on this dataset, however, the modifications to the smoothing steps tended to de-stabilize the solution (e.g., see phantom peak and trough between 0.4 and 0.55 m in Figure 2b). Complete results from this analysis are provided in Yost et al. (2021a).

3 PROPOSED ALTERNATIVE INVERSE PROCEDURE

Because none of the procedures discussed in the previous section were shown to be especially effective at resolving multiple thin-layer effects for profiles with thin layers less than 40 mm thick, an alternative procedure is desired. The inverse approach proposed by Boulanger and DeJong (2018) is attractive because it is fully automated and incorporates an actual description of the physics behind multiple thin-layer effects (i.e., through the blurring model described by the convolution of q^t with the spatial filter w_c). Building on this approach, we pose the inverse problem in a new way by assuming that q^t is

a piecewise constant function, and forcing guesses of q^t (i.e., q^{inv}) to be a piecewise constant function. Thus, the procedure searches for a finite number of layers in a soil profile, each having a thickness and constant q^{inv}. This approach differs from the BD18 approach, which solves for an independent q^{inv} value at every depth, and then subsequently applies a procedure to impose a constant q^{inv} within each identified layer. Reducing the number of degrees of freedom in the problem and eliminating the interface correction step results in a more computationally efficient procedure.

The inverse problem is posed to minimize the misfit function that describes the difference between the actual measured tip resistance profile (q^m) and the simulated measured tip resistance profile ($q^{m,sim}$), which is created by applying an artificial blurring filter to the q^{inv} guess. We restrict q^{inv} to be a piecewise constant function defined by N layers, each paired with a q^{inv} value. Therefore, each proposed q^{inv} profile is described by a material property vector, m, that has $2N$ components (i.e., thickness and q^{inv} for N layers), where N can be adjusted throughout the optimization. For any assumed m, we can extract the q^{inv} values represented by the piecewise function at every depth of where CPT data were measured. The q^{inv} profile resulting from this reconstruction process is denoted by q^{inv} (m). The q^{inv} profile with the minimized misfit is likely to be a good estimate of the q^t profile, but numerical optimization algorithms may yield different answers depending on the choice of the misfit function. Written as an equation, this algorithm optimizes:

$$m^{inv} = \arg\min_{m \in R^{2N}} \left\| q^m - q^{m,sim}\left(q^{inv}(m)\right) \right\|_2 \quad (3)$$

This is not the only way to pose the optimization problem. For applications where both large-scale and fine-scale features contribute to the misfit, a logarithmic misfit function can be more appropriate and is thus proposed as an alternative to Equation 3:

$$m^{inv} = \arg\min_{m \in R^{2N}} \log\left(\left\| q^m - q^{m,sim}\left(q^{inv}(m)\right) \right\|_2 \right) \quad (4)$$

This procedure, including both forms of the misfit function, is detailed in Cooper et al. (2022) [Cea22] and is summarized in Figure 3.

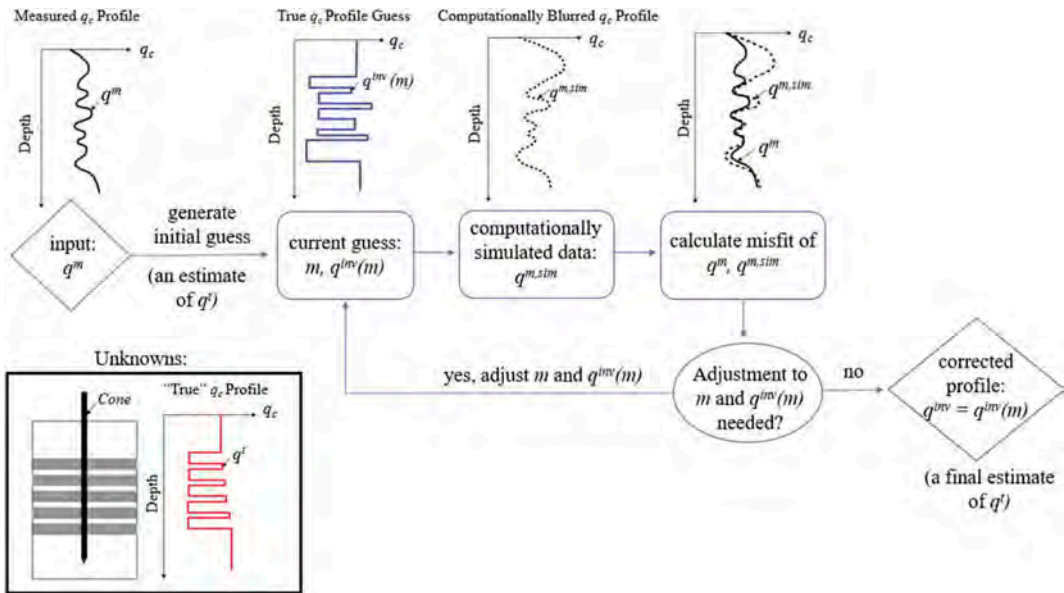
In addition to posing the optimization problem, it is necessary to select a numerical optimization algorithm to iteratively update the q^{inv} guess. Cooper et al. (2022) utilizes a Particle Swarm Optimization (PSO) algorithm that identifies minima of the selected misfit function. PSO was selected because it is able to test many widely varying guesses of m, overcoming the challenges often associated with global versus local minima. Consequently, small adjustments to layer thicknesses or assumed q^{inv} only marginally affect $q^m - q^{m,sim}$. To optimize the PSO algorithm, two additional computational procedures are proposed. An add-one-in (AOI) algorithm is utilized to automatically add new layers between existing layers to assess whether the addition of that layer reduces the misfit function of the


Figure 3. Cea22 inverse approach to correct for multiple-thin-layer effects in CPT tip resistance (modified from Cooper et al. 2022).

proposed profile. A leave-one-out (LOO) algorithm is utilized to remove insignificant layers from the guessed values of q^{inv} that are not physically realistic and contribute to unnecessary additional degrees of freedom.

A key component of this procedure is the application of an artificial blurring filter to the guessed value of q^{inv}. The Cea22 procedure adopts the same framework to describe this blurring as proposed by BD18 (i.e., Equation 1). However, they propose a blurring filter that is a scaled and truncated chi-squared distribution, selected for its asymmetry, smoothness, and relatively good match with the de Lange (2018) calibration chamber data:

$$q^{m,sim}(z) = (q^{m,sim}(q^t))(z) = \qquad (5)$$

$$= \int_{-\infty}^{\infty} q^t(\Delta z)p(z - \Delta z)d\Delta z$$

where $\int_{-\infty}^{\infty} p(z)dz = 1$ and $p(z) \geq 0$ for all z. In practice, this integral is only calculated over a finite interval. This blurring function was chosen because it is simple to implement and only requires the use of a matrix convolution function ("conv" in MATLAB). This blurring function results in $q^{m,sim}$ values that represent a weighted combinations of the q^t values of the surrounding soil layers at a given depth. Although this method can quickly compute $q^{m,sim}$ for any q^{inv} guess, it is a simplification of true physics and could be improved upon in future work. This is exemplified by the difference between the actual observed q^m in the layered soil profile (shown in solid black) and the q^m derived from applying the blurring filter to the known q^t (shown in solid blue) in Figure 4, and is discussed further in Section 4.

The Cea22 procedure was applied to the de Lange (2018) calibration chamber data using the q^m derived from applying the blurring filter to q^t (i.e., the blue solid line in Figure 4), in lieu of using the actual measured q^m. It was found that the algorithm with the logarithmic misfit function (i.e., Equation 4) was more effective than the standard misfit function (i.e., Equation 3) at refining the very thin layers in the calibration chamber test soil profiles; see Figure 4. The q^{inv} resulting from the standard misfit function missed several thin layers in q^t, while the q^{inv} resulting from the logarithmic misfit detects each of the thin layers in the layered zone.

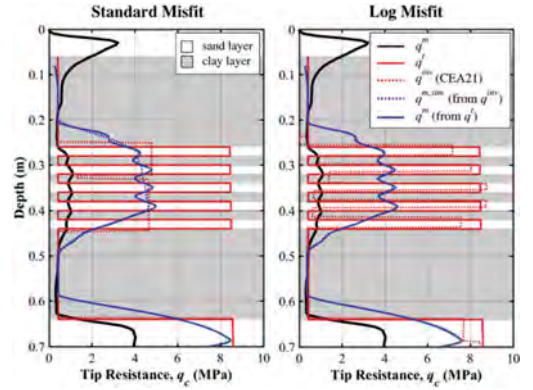
Both algorithms (standard and logarithmic misfit) had $q^{m,sim}$ closely matching q^m derived from application of the assumed blurring filter to the known q^t, indicating that the increase in computational rigor provided by the logarithmic misfit algorithm was required to achieve the detailed match between q^{inv} and q^t for this profile. Results were similar for other profiles in the de Lange (2018) dataset and are examined in more detail in Cooper et al. (2022).


Figure 4. Comparison between Cea22 inverse procedure using the standard misfit function and the logarithmic function on data from Soil Model 9 CPT 3 from de Lange (2018) (modified from Cooper et al. 2022).

4 DISCUSSION AND CONCLUSIONS

Multiple thin-layer effects in CPT data can be addressed using forward or inverse procedures. In this paper, a new forward method (DEL procedure) and a new inverse method (Cea22 procedure) are compared to the existing inverse procedure proposed by Boulanger and DeJong (2018) [BD18] using a set of calibration chamber data collected by de Lange (2018). It is shown that neither the DEL nor the BD18 procedure are effective in correcting for multiple thin-layer effects in profiles with soil layers less than 40 mm thick, with the DEL procedure yielding slightly better results than the BD18 procedure. Because this type of profile is of particular interest for liquefaction assessment, it is desirable to improve on these procedures.

The Cea22 procedure poses the inverse problem that was first proposed by Boulanger and DeJong (2018), but in a new way - searching for a finite number of soil layers each with a thickness and constant q^t. Application of this procedure indicates that this new formulation is better able to identify thin, interbedded layers than the DEL, BD18, or BD18MOD procedures. Furthermore, the restriction on number of degrees of freedom is computationally efficient. It was shown that the logarithmic misfit function is more effective at identifying very thin layers than the standard misfit function. There are tradeoffs in using the standard versus logarithmic misfit function, namely, use of the logarithmic misfit function is significantly more computationally expensive (i.e., 5 to 10 minutes runtime for CPT soundings with several hundred data points, compared to 1 to 2 minutes for the standard misfit function). However, the use of the logarithmic misfit function is anticipated to be worth the extra computational time for highly stratified soil profiles.

Inverse procedures like the BD18 and Cea22 procedure require an artificial "blurring" that mimics

multiple thin-layer effects in CPT data. Thus far, simple blurring models have been adopted. For example, the Cea22 procedure uses a convolution of a point spread function derived from the Chi squared probability density function. As shown in Figure 4, this method does not capture well the true complexity of the physics involved with cone penetration through layered profiles and can be improved upon. If the q^t is known for a profile, a q^m derived from applying the blurring filter to q^t can be used as input to the multiple-thin-layer correction procedure to assess the efficacy of the procedure itself, without assessing the accuracy of the blurring filter. This is the approach taken in this paper to assess the Cea22 procedure. Developing a more accurate blurring filter is the focus of ongoing work.

A persistent challenge in developing and validating multiple-thin-layer correction procedures is the lack of available q^m and q^t pairs for a given layered soil profile. These data can only come from calibration chamber tests (e.g., de Lange 2018) or from numerical simulations. Towards this end, numerical simulations of CPT in layered profiles, like those from Yost et al. (2021b), can supplement the limited available calibration chamber data and be used to develop and calibrate these methods. Numerical simulations should be calibrated and validated with laboratory calibration chamber data if possible.

Finally, all the procedures discussed in this paper focus on developing methods to correct CPT q_c for multiple thin-layer effects. However, CPT f_s is perhaps even more subject to multiple thin-layer effects owing to the large size of the sleeve friction sensor (typically ~110 to 134 mm in length). As a result, the friction sleeve will likely be in contact with multiple soil layers at once in a highly interlayered profile. Additionally, resolving the f_s for a given layer is further hampered by soil from overlying layers being dragged down into underlying layers as the cone advances, which has been observed both experimentally (i.e., de Lange 2018) and numerically (i.e., Yost et al. 2021b). Since f_s is required to compute normalized soil behavior type index (I_c) for liquefaction triggering calculations, it is critical that future work addresses multiple thin-layer effects on f_s.

ABSTRACT: The coefficient of consolidation (c_h), an important soil property, is often estimated from the piezocone penetration test (CPTU) data. However, the number of interpreted c_h data is usually limited especially in the horizontal direction because the CPTU is usually performed vertically and the dissipation test is time-consuming. In the present study, a novel method is proposed for the interpolation of c_h data in a 2D vertical cross-section. Firstly, the original c_h is interpolated by CPTU dissipation data. Then, the c_h values are interpreted based on the dissipation data at every location including the untested locations using random field theory. Finally, real case is illustrated to prove the applicability of the proposed method. It is shown that the proposed method can reasonably interpolate the c_h at untested locations. Overall, the new method can spatially interpolate the c_h from limited CPTU dissipation data and significantly save the test time.

1 INTRODUCTION

The coefficient of consolidation (c_h), an important geotechnical parameter that reflects the consolidation property of clays, is often used to estimate the seepage characteristics and consolidation settlement of clays (Burns and Mayne, 2002; Duan et al., 2018; Zhao et al., 2021a). It can be interpreted by either laboratory-based oedometer tests or in-situ tests. Due to the drawbacks of oedometer tests being time-consuming, high cost, and disturbance of soil sample, determining c_h by in-situ tests has received extensive attention (Krage et al., 2015). Among various in-situ test methods, the piezocone penetration test (CPTU) has been widely

used to determine c_h in the field since it is fast, repeatable, and economical (Cai et al., 2011; Lunne et al., 1997; Robertson et al., 1992; Zhao et al., 2021b).

The basic principle for estimating c_h by CPTU is as follows: The excess pore pressure (Δu) can be generated around the cone during the penetration process. The penetration process will be halted when a predetermined depth is reached, then the dissipation of the penetration-induced excess pore pressure around the cone will be recorded at a certain time interval and plotted as the excess pore pressure dissipation curve. As a result, the time corresponding to 50% dissipation of the excess pore pressure (t_{50}) can be recorded and used to interpret c_h for lightly over-consolidated to

normally consolidated clays (Chu et al., 2002; Sully et al., 1999). For heavily over-consolidated clays, the excess pore pressure rises initially, and then gradually dissipates until it becomes zero due to the dilatory response (Burns and Mayne, 2002; Lunne et al., 1997; Wu et al., 2021; Zhao et al., 2021a). To address this problem, Chai et al. (2014) proposed an empirical equation to correct the value of t_{50} determined from non-monotonic dissipation curves using an uncoupled plane strain radial consolidation analysis. Then, the corrected t_{50} was used in existing interpretation models.

However, the CPTU dissipation test in super soft soils and marina soils with low permeability can be time-consuming. In these cases, a single cone sounding can take over a day. Moreover, CPTU is only applicable to one-dimensional (1D) analysis, i.e., along the depth. In engineering practice, however, two- or three-dimensional (2D or 3D) geotechnical analysis is often performed in which 2D or 3D information on subsurface soil stratification and zonation is needed (Chen et al., 2016a; Duan et al., 2021; Wang et al., 2020). It is impractical to perform a large number of CPTU dissipation tests over a whole site. Fortunately, random field theory-based spatial interpolation method can provide 2D geotechnical analysis efficiently. For example, Chen et al. (2016a) used random field theory to spatially assess liquefaction-induced settlements. The visualization of the spatial map of c_h can provide useful information for guiding the design and construction of ground or subgrade treatment (Zhao et al., 2021a). Therefore, the development of a simple spatial map is appealing and expected in engineering practice.

In the present study, a novel method was proposed for the interpolation of c_h data in a 2D vertical cross-section using random field theory. Firstly, the original CPTU dissipation data was interpolated in the 2D vertical cross-section. Then, the c_h values were interpreted based on the dissipation data at every location in the 2D vertical cross-section including the untested locations. Finally, real CPTU dissipation data was illustrated to prove the applicability of the proposed method.

2 CPTU-BASED INTERPRETATION MODEL

In the past few decades, many CPTU-based theoretical and empirical interpretation models were proposed for the estimation of c_h (Baligh and Levadoux, 1986; Burns and Mayne, 2002; Cai et al., 2011; Krage et al., 2015; Robertson et al., 1992; Sully et al., 1999; Teh and Houlsby, 1991; Torstensson, 1977). One representative model proposed by Teh and Houlsby (1991) is considered in this study.

This model considers the effect of rigidity index (I_r) based on large strain path analysis and finite difference analysis:

$$c_h = \frac{T^* \sqrt{I_r}}{t_{50}} \cdot r^2 \qquad (1)$$

where T^* is a modified dimensionless time factor, which is taken as 0.245 in this paper; t_{50} is the time corresponding to 50% dissipation of excess pore pressure (s); r is the radius of the CPTU cone (17.85mm).

The key to interpret c_h is to determine the time t_{50} corresponding to 50% dissipation of excess pore pressure. For non-monotonic dissipation curves, the time should be corrected. Chai et al. (2014) proposed an empirical equation to correct the value of t_{50} determined from non-monotonic dissipation curves using an uncoupled plane strain radial consolidation analysis. Then, the corrected time was used in Eq. (1). The proposed empirical equation is as follows:

$$t_{50m} = \frac{t_{50}}{1 + 18.5\left(\frac{t_{u\max}}{t_{50}}\right)^{0.67}\left(\frac{I_r}{200}\right)^{0.3}} \qquad (2)$$

where t_{50m} is the corrected time for 50% excess pore pressure dissipation (s); $t_{u\max}$ is the time elapsed for reaching the maximum measured excess pore pressure (s).

3 RANDOM FIELD THEORY

To perform 2D analysis over the entire area of interest, random field theory is introduced in this section. The main steps are as follows (Chen et al., 2016b): 1) evaluation of c_h at individual testing locations; 2) statistical and spatial characterization of the index; 3) random field realization and Monte Carlo (MC) simulation to generate 2D c_h maps.

3.1 *Spatial correlation*

The semivariogram is used to describe the spatial correlation of the predicted P_L value, which can be obtained based on the half variance of two random variables separated by a distance h:

$$\gamma(\boldsymbol{h}) = \frac{1}{2}\mathrm{Var}[Z(\boldsymbol{u}) - Z(\boldsymbol{u} + \boldsymbol{h})] \qquad (3)$$

where $Z(\boldsymbol{u})$ is a Gaussian random variable at location $\boldsymbol{u}$. There are several semivariogram theoretical models, including the linear, spherical, exponential, and Gaussian models.

Then, the semivariogram is related to the spatial correlation $\rho(\boldsymbol{h})$ by:

$$\rho(\boldsymbol{h}) = 1 - \gamma(\boldsymbol{h}) \qquad (4)$$

The vector distance h can account for both separation distance and orientation as:

$$h = \sqrt{\left(\frac{h_x}{a_x}\right)^2 + \left(\frac{h_y}{b_y}\right)^2} \qquad (5)$$

where h_x, h_y are the scalar components of the vector h along the field's principal axes; scalar quantities a_x, a_y specify how quickly spatial dependence decreases along those axes. The ratio of $a_x/b_y = 1$ represents the correlation decreases with distance equally in all directions.

3.2 *Sequential simulation process*

To generate random field realizations of the variables of interest, a conditional sequential Gaussian simulation method is implemented, which has been extensively used by mining scientists and geostatisticians for natural resource evaluations and spatial prediction of geohazards. It is worth noting that a multiscale extension of this conditional sequential Gaussian simulation method has been developed in recent studies (Wang et al., 2017). The procedure can be illustrated by:

$$(Z_n|Z_p = z) \sim N\left(\Sigma_{np} \cdot \Sigma_{pp}^{-1} \cdot z, \ \ \sigma_n^2 - \Sigma_{np} \cdot \Sigma_{pp}^{-1} \cdot \Sigma_{pn}\right)$$

(6)

where Z_n is the next realization to be simulated; Z_p is the vector or of all known and previously simulated points.

Once Z_n is simulated, it becomes a known data point in the vector of Z_p to be conditioned upon by all subsequent data locations. This process is repeated to other unknown points until all locations in the field have been simulated.

Random field models incorporate the spatial dependence of the measured parameter through the covariance matrix. The covariance of values at two separated locations could be expressed as:

$$\Sigma = \text{COV}\left[Z_i, Z_j\right] = \rho_{Z_i,Z_j} \cdot \sigma_{Z_i} \cdot \sigma_{Z_j}$$

(7)

where ρ_{Z_i,Z_j} is the spatial correlation (calculated by Eq. (4)) between the random variables Z_i and Z_j with standard deviations of σ_{Z_i} and σ_{Z_j}, respectively.

Once the empirical semivariogram $\gamma(h)$ is characterized, it will be plugged into the covariance matrix Eqs. (4) and (7). Thus, the unknown value Z_n at location n could be drawn using Eq. (6). The generated value is then assigned to location n and treated as known data. This process is repeated until all the unsampled locations are assigned with values. Detailed process of random field modeling may be found in Chen et al. (2016a, b).

4 ILLUSTRATIVE EXAMPLE

4.1 *Interpretation of dissipation tests*

The CPTU test site is located in the Yangtze River tunnel of Jiangyin, Jingjiang City, Jiangsu Province, China. The geological formation in this area belongs to the floodplain geomorphic unit of the Yangtze River, and the depth of the groundwater level is 1.5m below the ground surface. Figure 1 shows the profiles of the CPTU site.
Figure 1. Layout of CPTU dissipation tests at the Yangtze River tunnel of Jiangyin, Jingjiang City, Jiangsu Province, China.

At this test site, a total of 4 CPTU boreholes were performed. The CPTU equipment is shown in Figure 2. The dissipation test was performed using a multifunctional, digital, and vehicle-mounted CPTU system produced by Vertek-Hogentogler (Randolph, OH), USA (Cai et al., 2011). The parammeters of the CPTU probe are as follows: cone apex angle of 60°, a cone bottom diameter of 35.7 mm, a cross-sectional area of 10 cm^2, a sleeve surface area of 150 cm^2, the pore pressure is measured at the u_2 position, penetration rate is 20 mm/s. During the penetration process, the Δu can be measured at regular intervals. Then, the dissipation of Δu over time was recorded until the pore pressure reaches the equilibrium hydrostatic pressure. After that, the penetration was continued further to the next desired depth and the above steps were repeated. Finally, a total of 14 dissipation tests were performed in this site.
Figure 2. CPTU test equipment.

High-quality soil samples were also taken at different depths, corresponding to the depths of dissipation tests, using a stationary piston sampler. The diameter of the stationary piston sampler is 76 mm. The soil sample at the end of the tube was extruded for waxing and sealing at both ends after withdrawing the stationary piston sampler from the borehole. The collected soil samples were temporarily stored near the site before being transported back to the laboratory. In this study, unconfined compression tests and the K_o-consolidated undrained triaxial tests (CK_oU) were performed on undistorted samples to estimate undrained shear strength (s_u) and shear modulus (G) of the soils. Then, the I_r can be calculated by $I_r = G/s_u$. Other important soil parameters such as unit weight (γ) and overconsolidation ratio (OCR) were also obtained from laboratory tests, as listed in Table 1.

It can be noted that the OCR is in the range of 1.18-1.29, indicating the clays at the test site are usually lightly over-consolidated.

The key to interpret c_h is to determine the time t_{50} corresponding to 50% dissipation of excess pore pressure. The excess pore water dissipation curves are shown in Figure 3.

Table 1. Typical soil properties in the CPTU soundings.

Sounding	γ (kN/m^3)	s_u (kPa)	E_s (MPa)	OCR
CPTU1	17.5	18.34	3.58	1.22
CPTU2	17.6	17.85	3.26	1.21
CPTU3	17.4	20.16	3.81	1.29
CPTU4	17.3	19.13	3.50	1.18

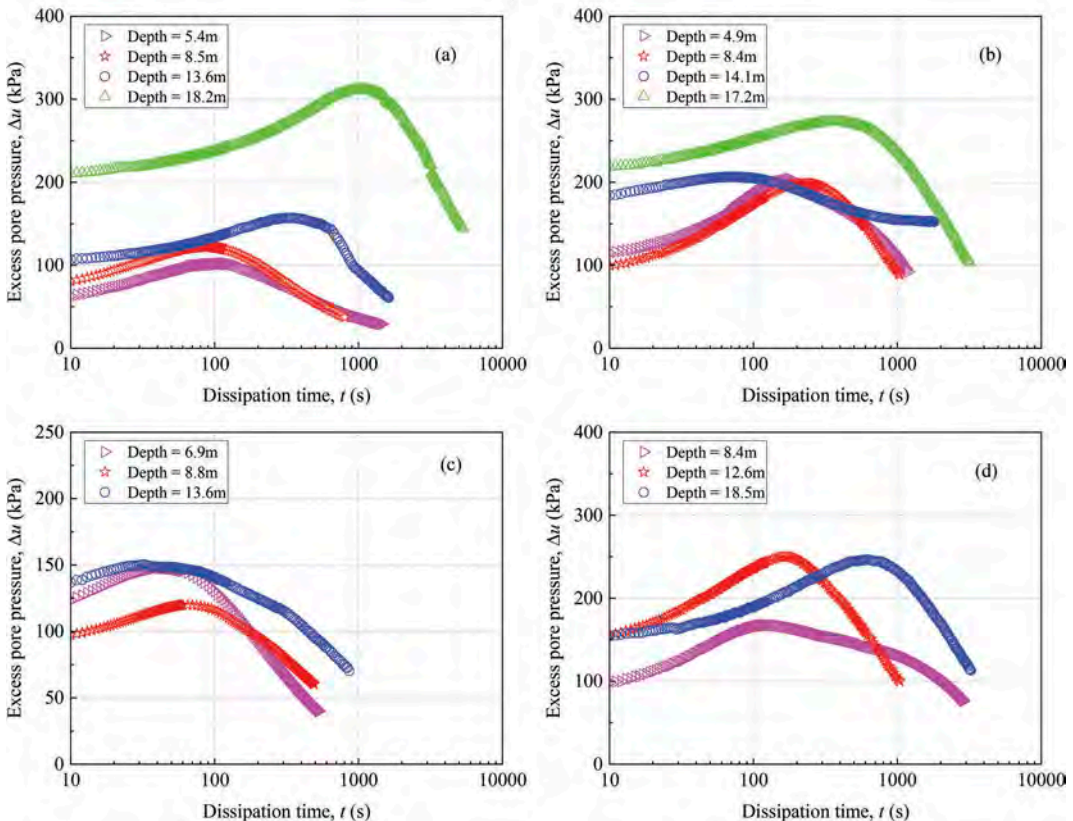
It can be noted from Figure 3 that the dissipation curves are non-monotonic dissipation curves, that is, the excess pore pressure rises initially and then gradually dissipates until it is zero. The non-monotonic dissipation curves are mainly caused by (a) shear-induced dilatancy of over-consolidated clays or dense sandy soils around the cone and (b) possible unloading effects of the soil elements moving from the vicinity of the face to the shoulder of the cone, which can cause a large gradient in pore pressure going from the cone to the shaft (Zhao et al., 2021a). Therefore, the c_h should be interpreted using Eqs. (1) and (2). The results are listed in Table 2. It can be noted that the c_h varies significantly in the spatial, it is therefore to be interpolated spatially using random field theory.


Figure 3. Dissipation curves at soundings (a) CPTU1; (b) CPTU2; (c) CPTU3; (d) CPTU4.

Table 2. Interpretation results of dissipation tests.

Sounding	No.	Depth (m)	I_r	t_{umax} (s)	t_{50} (s)	t_{50m} (s)	c_h (mm²/s)
CPTU1	1	5.4	160	107	513	73	13.577
	2	8.5	90	98	392	58	12.754

	10	8.8	110	55	420	75	9.670
	11	13.6	120	53	707	182	4.593
CPTU4	12	8.4	125	120	2520	73	13.577
	13	12.6	135	180	640	80	11.378
	14	18.5	125	580	2390	331	2.637
Mean					1156	168	8.825
SD					943	151	4.657
COV					0.816	0.894	0.528

4.2 Spatial interpolation

The length of the area is 20 m, whereas the depth of the area is 20 m. Of the 14 dissipation tests, 12 dissipation tests are used to develop the hazard map of liquefaction-induced lateral spread based on random field theory, while the other 2 dissipation tests (i.e., No. 6 and 11) are used for the validation.

As suggested by Chen et al. (2016a), the lognormal distribution is used to fit the distribution of c_h. Then, the fitted lognormal distribution is adopted to characterize the semivariogram and then generate random fields in the sequential Gaussian simulation. In the present study, the typical exponential semivariogram has been used to fit the empirical semivariogram. The grid size of the random field in this site is set as 0.1 m. A parametric analysis of MC simulation number ranging from 1,000 to 10,000 has been performed, as shown in Figure 4. It is shown that 1,000 MC simulations are enough as COV of the c_h values tends to be stable with the MCS number goes beyond 1,000.

The spatial map of c_h is shown in Figure 5. The c_h can be characterized and visualized. The c_h values at dissipation tests No. 6 and 11 are about 11.586 mm²/s and 6.325 mm²/s, respectively. It is evident that the c_h values at dissipation tests No. 6 and 11 interpolated based on random field theory are similar to the validation values, and can be viewed as the smoothed representation of the actual data. This proves the reliability of the random field theory in spatial interpolation.

The proposed method can be used to spatially interpolate any fields in the future. It can generate c_h values at untested sites and reflect the actual values in the field, which are often not available in the engineering practice. Therefore, the proposed method can significantly save the test time especially in super soft soils and marine soils.
Figure 4. Variations of COV of c_h as the number of Monte Carlo simulations increases.
Figure 5. Spatial map of mean values of c_h in the testing site.

5 CONCLUSIONS

In this study, the random field theory was incorporated in the interpretation model of c_h, which can be used for areal interpolation and uncertainty quantification. It can provide the spatial map of c_h over a field using limited CPTU data. The spatial map can provide useful information on the need of project-specific geotechnical investigation.

The proposed method can interpolate c_h values at untested sites and reflect the actual values in the field, which are often not available in the engineering practice. Therefore, the proposed method can significantly save the test time especially in super soft soils and marine soils.

Evaluation of the geotechnical behavior of mining tailings through CPTU tests in the soil improvement process for the decharacterization of upstream heightened dams

J.L. Albino
Universidade Federal de São Carlos – UFSCAR, Brazil

T.A.T. Souza J. & L.S. Machado
Universidade Federal de Viçosa – UFV, Brazil

ABSTRACT: In order to assess the pore pressure conditions, to verify the drained behavior or not of a reservoir of a tailings dam raised upstream, and to observe the evolution of the resistence of the material, CPTU surveys were carried out before and after the execution of works for the implementation of vertical geodrains in the reservoir of this dam. After the comparative tests, it was possible to indicate the safety gains of the structures resulting from the execution of the works.

Keywords: CPTU test, upstream tailing dam, pore pressure dissipation, geodrains, liquefaction

1 INTRODUCTION

The decharacterization of dams heightened by the upstream method is a legal obligation in the national territory (Brazil). This obligation is a reaction the last dam failures in Brazil, in which the failures of the Fundão Dam in 2015 and the B1 Dam in 2019 were mainly caused by the liquefaction of the tailings. Mine tailings disposed hydraulically in dams tend to have a contractile behavior, mainly due to the initial void rate and material saturation. To carry out the decharacterization, the concern of liquefaction is also present, and it is necessary to control the possible triggers.

In this environment, companies must rethink not only their traditional approaches to mining operations, but also the development of technologies and studies of tailings deposal.

Laboratory evaluations allow testing materials in a controlled manner, under the desired conditions. However, a limitation of these analyzes is the extraction of undisturbed samples, especially those in depth and in regions of low resistance. This is because, in the sampler crimping process, the sample is disturbed, making the test results divergent from the field condition.

On the other hand, measures to assess the *in situ* tailings behavior can significantly contribute to the identification of the undrained behavior of the soil and the susceptibility to liquefaction. Tests such as CPTU, for example, are able to assess the *in situ* conditions of the material, the development of effective stress and pore pressure along the depth.

Therefore, CPTU tests were carried out prior to the elaboration of the project to de-characterize an upstream heightened dam work located in the iron quadrangle. Since the behavior of the material was observed as susceptible to liquefaction, interventions were carried out downstream of the dam in order to turn the material initially with undrained behavior into drained behavior. These interventions were carried out with the use of vertical geodrains to accelerate the densification process, and mainly, in the dissipation of pore pressure.

The vertical geodrains contains a HDPE (High Density Polyethylene) core forming small channels. The core is wrapped in non-woven geotextile, which acts as a filter. Thus, the water captured by the drain is conducted through the small channels of the HDPE core to the surface of the land, where it is drained by the upper drainage layer, placed on the surface of the land.

After the interventions, a second battery of CPTU tests was carried out. Through these investigations, it was possible to evidence the dissipation of the pore pressure in the dam and in the tailings, causing the material to behave in a drained way. Such findings were significant for the decharacterization of the dam to be carried out safely.
Figure 1. Pore pressure of CPTU 2017 before construction.

1.1 CPTU test

Currently, one of the main forms of sounding for simplified identification of soil properties is the CPTU. The characterization of intermediate sedimentary soils, especially silty sands, non-plastic silts, silty clays and fine-grained tailings are often complicated due to the difficulty of sampling these materials. Thus, CPTU tests can be used to determine the stratigraphic profiles, *in situ* conditions of the material and to estimate the material's geotechnical parameters. [1, 2]

With the CPTU crimping, automatic information is collected on tip resistance (q_c), resistance by lateral friction (f_s) and pore pressure at different points of the cone (u_1, u_2 e u_3). [3]

Because of the characteristic geometry of the cone, the record is disturbed by atmospheric pressure and by the difference in pore pressure value collected at different points (u_1, u_2 e u_3). Thus, it is necessary to correct the values obtained when carrying out the drilling according to the boundary conditions. Therefore, the main values that can be generated at first with the CPTU are the standardized resistance of the tip Q_{tn}, the normalized friction ratio F_r, the friction ratio with R_f and the parameter of pore pressure as B_q. [1, 4]. The

ways of calculating these values are presented below, equations (1) to (7):

$$Q_{tn} = [(q_t - \sigma_{vo}) / \sigma_{atm}] \; x \; (\sigma_{atm}/\sigma'_{vo})^n \qquad (1)$$

$$F_r = [f_s / q_t - \sigma_{vo})] \; x \; 100\% \qquad (2)$$

$$R_f = f_s / q_c \; x \; 100\% \qquad (3)$$

$$B_q = (u_2 - u_0) / (q_t - \sigma_{vo}) \qquad (4)$$

$$q_t = q_c + (1 - a) \; x \; u_2 \qquad (5)$$

$$n = 0.381 \; x \; I_c + 0.05 \; x \; (\sigma'_{vo}/\sigma_{atm}) \qquad (6)$$

$$I_c = \left\{ [3.47 \; x \; log(Q_{tn})]^2 + [1.22 + log(F_r)]^2 \right\}^{0.5} \qquad (7)$$
Figure 2. CPTU 2017 dissipation test (13.0 meters) before construction.

We can define the elements of the formulas written above, with q_t being the corrected true tip resistance, σ_v being the total vertical stress at depth, σ'_{vo} the vertical effective stress ($\sigma'_{vo} = \sigma_{vo} - u_0$), f_s a lateral friction resistance, q_c the penetration resistance of the tip, α being the ratio of the cone areas (A_N / A_T), u_2 is the measured pore pressure, u_0 is the equilibrium pore pressure.

1.2 Assessment of soil behavior

From the parameters obtained above, along with the CPTU drilling depth, several geotechnical characteristics of the soil can be identified.

794
Figure 3. CPTU 2017 Cone tip resistance before construction.

Figure 4. Pressure pore of CPTU 2020 after construction.

With the CPTU test, it is possible to evaluate, through correlations, the following soil characteristics: stratigraphy, geotechnical profile, density coefficient (C_h e C_v), relative density (D_r), undrained resistance (S_u), sand effective friction angle (φ'), stress history (pre-consolidation stress, OCR), permeability coefficient (k), maximum shear modulus (G_o), deformability coefficient (m_v), modulus of deformability or Young's (E), effective friction angle (φ'), confined or oedometric modulus of deformation (M), sensitivity (S_t), permeability coefficients (k_h and k_v) and evaluation of susceptibility to liquefaction of a soil. [2, 8]

Another very important point is that with the records of cone tip resistance, lateral friction resistance and pore pressure, the CPTU interpretation is applied for the stratigraphic determination of the soil based on the behavior type graphs of the soil (SBTn). This proposal was presented by Robertson (1990) where plots of two abacuses are made ($Qt \times Fr$ (%) e $Qt \times Bq$), where the Q_t is the normalized of cone tip resistance (8) [5, 6, 7]:

$$Q_t = (q_t - \sigma_{vo}) / (\sigma_{vo} - u_0) \qquad (8)$$

For this study, the pore pressure acting on the tailings will be evaluated in order to identify its reduction after the implementation of vertical geodrains in a dam's reservoir. In addition, the behavior of the material regarding the dissipation test will also be evaluated in order to assess the change from undrained to drained behavior of the tailings.

1.3 Dissipation test

The dissipation test consists of interrupting CPTU penetration and observing the pore pressure over time.

Data is logged and must occur to a minimum dissipation of 50%.

Pressures are plotted as a function of the square root of time. The graphical technique suggested by Robertson and Campanella (1989) provides a value for t_{50}, which corresponds to the time to consolidation of 50% [9].

The value of the consolidation coefficient in the radial or horizontal direction C_h was then calculated by Houlsby and Teh's (1988) theory using the following equation (9) [10]:

795
Figure 5. CPTU 2020 dissipation test (15.5 meters) after the works.

$$C_h = T \ x \ r^2 x \ Ir^{0.5}/t_{50} \qquad (9)$$

Where T is the time factor given by the theory of Houlsby and Teh (1988) corresponding to the pore pressure, r piezocone radius, Ir is the stiffness index, equal to the shear modulus G divided by the undrained strength of the clay (S_u) and t_{50} the time corresponding to 50% consolidation.

Furthermore, the pore pressure dissipation during a CPTU dissipation test is controlled by the consolidation coefficient in the horizontal direction (C_h) which is influenced by a combination of soil permeability (k_h) and compressibility (M), like defined by the following equation (10):

$$k_h = \ C_h \ x \ \gamma w \ / \ M \qquad (10)$$

Where M is the restricted modulus and γw is the unit weight of water, in compatible units.

2 RESULTS

Initially, with the performance of CPTU tests in 2017, before the geodrain implantation works, the presence of pore pressure was observed at a critical depth for the structure's safety assessments. In this condition, it was noticed that up to a depth of 6.5 m of drilling depth, there were pore pressures close to 230 kPa, thus indicating that the tailings deposited in these quotas presented an undrained behavior. Below we have Figure 1 with the representation of the result of pore pressure observed.

Furthermore, with the performance of the dissipation tests, it was observed that at the deepest point of dissipation (13.0 meters) a permeability value was found in the house of 2.56 x 10^{-9} m/s, classifying it in this way as waterproof material. The dissipation test will be shown below, Figure 2.

Finally, another point observed is due to the resistance of the material collected with the execution of the CPTU. For this first moment, low cone tip resistance was observed up to 6.5 m deep. The result will be shown below, Figure 3.

With the implementation of vertical geodrains in order to reduce the pore pressures acting in the critical region of the dam and provide the drained behavior and increase the local resistance of the material, new tests were carried out to verify what was foreseen in the project, the reduction of the pore pressure and the guarantee of the behavior drained by the tailings.

After performing the pore pressure tests, it was initially identified a considerable variation of the acting pore pressure up to 6.5 meters in depth. In
Figure 6. CPTU 2017 Cone tip resistance after the works.
Figure 7. Comparison between the 2017 and 2020 CPTU in the critical region of pore pressure.

Figure 8. Comparison between the 2017 and 2020 CPTU in the critical region of cone tip strength.

this condition, the behavior of the tailings presented an average pore pressure of 50 kPa and in some points a reduction of up to 200 kPa of pressure was observed. This situation can be seen in Figure 4 below.

In addition to the gains observed during the pore pressure measurement, considerable gains were also observed during the tailing's dissipation test. As can be seen in Figure 5, below, with the dissipation at the deepest point in the CPTU probe, 15.5 meters, it was identified that the permeability of the material increased to the house of 1.53×10^{-7}, thus improving the drainage capacity of the tailings around one hundred times. In this condition, the tailings started to be classified as low permeability soil.

Finally, another point is due to the resistance gain observed for the material up to 6.5 m, where the cone tip resistance initially found values close to 0.0 kPa and after the execution of the works, peaks close to 15.0 kPa were observed. This graph of the new CPTU assay is shown in Figure 6, below.

3 CONCLUSION

As can be seen throughout the results presented, before the works were carried out, there were conditions of high pore pressures in the initial portion of the test. With the execution of the works, there was a considerable reduction in the critical pore pressure condition, improvement in the tailing's drainage capacity an increase in the cone tip resistance of the CPTU in this material.

A comparative graph of the pore pressure reduction in the critical region will be presented below, Figure 7.

Finally, as already mentioned, for the critical layer, up to 6.5 m, a considerable increase in material strength was also observed. A comparative graph of the increase in cone tip strength in the critical region will be presented below, Figure 8.

Therefore, carrying out the CPTU test was of great value in proving critical conditions in the field and in verifying the effectiveness of the work performed.

ABSTRACT: Until now the vibratory pile driving method is not widely used because there is no reliable approach for drivability analysis. One of the main issues with the current drivability analysis methods are the inability to accurately predict the cyclic soil behavior during vibratory pile driving. In this research, the cyclic soil behavior was evaluated using a new in-situ soil investigation method, the vibratory cone penetration test (VCPT). VCPT penetrates the ground, while inducing controlled vertical cyclic strains, and measuring cone resistance, sleeve friction, and pore water pressure. Nine static CPTs and 15 VCPTs were performed at a constant frequency with three different amplitudes. The resulted cone resistance-displacement cycles were compared with the state-of-the-art soil-pile interaction models. The reduction in soil strength against vibratory loading was found to be amplitude-dependent; and it was observed that a cavity formed between the cone and soil during the upward movement of the cone for high displacement amplitudes.

1 INTRODUCTION

The notion of using vibratory pile driving to install the foundations for offshore wind turbines is increasing, because this driving technique produces less noise, causes less damage to the pile, and has a higher installation speed than impact pile driving technique (Holeyman and Whenham, 2017). The main problem of this technique is the lack of a well-established method for drivability analysis. The current drivability analysis of vibratory pile driving derives from soil-pile interaction models modified from impact pile drive analyses (Jonker, 1987, Wong et al., 1992, van Baars, 2004, Viking, 2006, Holeyman and Whenham, 2017, Lee et al., 2012). The vibratory pile driving models utilize empirical parameters, having been derived from conventional (quasi static) soil investigation methods, such as CPT and SPT, to predict the cyclic soil response during vibratory pile driving (Wong et al., 1992). The load application of the conventional soil investigation methods differs from that of vibratory pile driving. Therefore, the current soil-pile interaction models are likely unable to assess (1) degradation processes along the pile shaft and pile toe and (2) the effect of different amplitudes of vibratory pile driving on cyclic soil behavior (Jonker, 1987, Holeyman and Whenham, 2017).

The vibratory cone penetration test (VCPT) is an in-situ soil investigation method, which penetrates the ground while inducing cyclic loads (Sasaki and Koga, 1982). The first VCPT tool utilized horizontal vibration as it was developed to investigate the liquefaction potential due to earthquake loading. More recently, VCPTs induced vertical (down-hole) vibrations (Wise et al., 1999, McGillivray et al., 2000, Mayne, 2000). The vertical cyclic motion of VCPT may be considered to resemble the motion of vibratory pile driving (Al-Sammarraie et al., 2018, Stähler et al., 2018, Viking, 2006). The measured cone resistance and displacement at the tip of the VCPT allow for evaluating the stress-displacement cycles of loading and unloading of the vibrational penetration (Al-Sammarraie et al., 2018). From these cycles, the stiffness during each individual loading and unloading cycle may be obtained (Wong et al., 1992, Lee et al., 2012). When cyclic penetration exceeds a certain amplitude threshold, the resistance at the toe decreases to zero during the upward movement and the begin of the downward movement of the penetrating object. This loss in resistance is called cavitation and is described in terms of a "cavity" even

though it is unlikely that a total empty space is formed (Massarsch and Westerberg, 1996, Rodger and Littlejohn, 1980, Viking, 2006). The degree of cavitation during vibratory pile driving is defined as the length of upward and downward movement of the penetrating object without soil contact (Massarsch and Westerberg, 1996, Massarsch et al., 2017, Vogel-sang et al., 2017, Dierssen, 1994). The cavitation and the loading and unloading stiffness during vibratory penetration have recently been investigated by utilizing the so-called Vibro-Penetration Test VPT, which is a soil investigation test that uses a vertical harmonic excitation force to drive a rod with a conical tip into the ground (Cudmani and Manthey, 2019). The VPT has a fixed relationship between frequency and potential maximum force and is furthermore influenced by the soil reaction while VCPT allows for independent variation of penetration speed, frequency and amplitude. Until now, the VCPT method was not applied to study the loading and unloading stiffness as well as the cavitation that may occur during vibratory pile driving. The influence of the displacement amplitude on the soil resistance and the loading and unloading stiffness is also still unknown.

In this study, the influence of displacement amplitudes on the degradation of cone resistance was investigated. It was explored to what extent the stiffness during loading and unloading cycles and the cavitation changed with displacement amplitudes. Finally, the obtained cyclic soil resistance were utilized to parametrize the current pile-soil interaction models developed by Dierssen (1994), Wong et al. (1992), and Jonker (1987), the results are quantified and discussed.

2 METHODOLOGY

2.1 VCPT device

The VCPT comprises a 100 kN hydraulic cylinder, a clamp, a valve unit, a displacement sensor, and a real time controller (Figure 1).

The hydraulic cylinder was used to push the rods and the cone into the ground having been controlled
Figure 1. Vibratory cone penetration test device.

by the external displacement sensor. The displacement amplitude of VCPT, measured from the displacement sensor, is referred to as "VCPT amplitude" hereafter. The actual displacement of the cone was obtained from a three-axis acceleration sensor, which was located in the cone. This acceleration sensor had a sampling rate of 500 Hz.

2.2 Geological and geotechnical setting

The study area is located in Cuxhaven, Northern Germany. The soil deposits in the area consist mainly of very dense sand. The stratigraphy and the physical properties of the sand deposits were determined from a drill core in the vicinity of the test field (Figure 2). The stratigraphic characterization followed (Sindowski, 1965, Ehlers et al., 1984, Geo-Engineering, 2014) (Figure 3), grain size analyses were carried out according to DIN 18123 (2011), and the unit weight was provided from (Geo-Engineering, 2014).

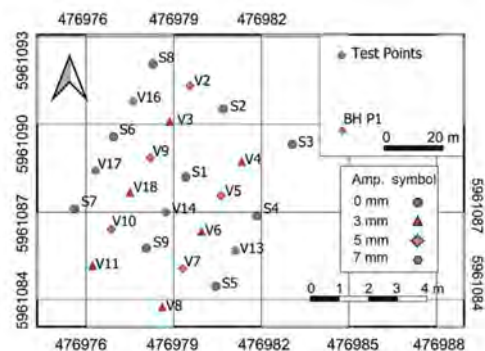
The deposits are of Pleistocene age and consist of a 4-m-thick Middle Saalian unit composed of fine- to medium-grained sands, and an underlying 7-m-thick Older Saalian unit composed of compacted heterogenic stratified sand deposits, with a till layer in between (Figure 3). The 60-cm-thick Drenthe till layer, composed of grains from clay to gravel size. The soil behavior types were calculated following Robertson (2009) from CPT S7 (Figure 2). Most of the sand deposits are soil behavior type 6 (sand like). Only the till layer is soil behavior type 3 and 4 (clay-like, silt-like). The sand deposits have relative densities between dense to very dense following the CPT correlation of Baldi et al. (1986).


Figure 2. Maps of the layout of test points and the location of the core. The coordinate system used to create the maps was UTM zone N32.

2.3 Experimental layout

A cone with an area of 5 cm^2 was used to perform nine static CPTs (SCPTs hereafter) and 15 vibratory CPTs (VCPTs hereafter) in a systematic grid. In Figure 2, the letter "S" refers to SCPTs and "V"

refers to VCPT. The spacing between tests was chosen to be 1.4 m, being equivalent to 55 times cone diameter. The spacing was chosen to be larger than the minimum recommended distance between CPTs (Al-Sammarraie et al., 2020, DIN EN ISO 22476-1, 2012, BS 1377-9, 1990). The SCPTs were performed before the VCPTs.

The VCPTs were performed at a constant frequency of f=20 Hz and at three different VCPT amplitudes of 3, 5, and 7 mm (Figure 2). The CPT locations were determined by a DGPS system with a horizontal resolution of ±2 cm. A theodolite with an accuracy of ±0.3 cm was used to ensure a common height reference at the start and the end of each CPT.
Figure 3. Stratigraphy and soil properties of test site (a) core; (b) grain size distribution (Geo-Engineering, 2014); (c) bulk unit weight (Geo-Engineering, 2014); (d) soil be-havior types (SBT); (e) friction ratio; (f) corrected tip resistance; and (g) relative density derived after Baldi et al. (1986).

2.4 Evaluation of SCPTs and VCPTs datasets

The data of SCPT and VCPT were evaluated following four steps: (1) correlation, (2) cyclic behavior analyses, (3) statistics, and (4) degradation factors. Detailed explanation of the four steps is included in Al-Sammarraie (2020).

2.4.1 Correlation

The peak values of each individual cycle of the entire VCPT datasets were selected. The resulting VCPT datasets were defined as peak vibratory cone resistance, $vq_{c,p}$, peak sleeve friction, $vf_{s,p}$, and peak pore water pressure, vu_p. The vibratory cone resistance datasets that included the full information about each cycle is hereafter referred to as cone resistance cycles, $vq_{c,cy}$.

In order to minimize the effect of local heterogeneities and changes in the depth of specific soil layers at small horizontal distance, all SCPT and VCPT datasets were correlated and shifted to a common depth. The cone resistance dataset of SCPT S7 was selected to be the "reference dataset" and all other SCPT and VCPT datasets were shifted to it (Figure 2) (Al-Sammarraie, 2020). After the depth shift, the depths of the SCPT and peak VCPT datasets were resampled to a common vertical depth scale with an increment of 0.5 mm.

2.4.2 Cyclic behavior analysis

In this step, the loading stiffness, K_b, and unloading stiffness, K_e, and the upward displacement with cavitation, d_{cav}, were quantified. Since the acceleration and cone resistance data were affected by noise, The cycles of cone resistance cycles, $vq_{c,cy}$, and raw acceleration, a, were stacked and averaged in order to reduce the noise level (Al-Sammarraie et al., 2018). Every second cycle of the correlated and shifted datasets of vibratory cone resistance and raw acceleration was selected and processed until the final depth of penetration of 12 m, while avoiding averaging between different of individual push-strokes. All data points of the selected cycle were added to the equivalent points of the neighboring cycles above and below and then divided by the number of cycles. This approach is similar to a moving average where the points are overlaid in phase. For cone resistance cycles and raw acceleration cycles each point is the average of 41 points. The moving average windows corresponded to a vertical length of 4 cm. The stacking and averaging process resulted in stacked cone resistance cycles, $vq_{c,cy,st}$, and stacked acceleration, a_{st}.
Figure 4. Fit function to determine loading stiffness, unloading stiffness and upward displacement with cavitation.

The stacked acceleration data, a_{st} was integrated twice to obtain the cyclic displacement, d_{cy}. The

constants of integration – depth and average velocity – were obtained from the displacement sensor.

The cone resistance-displacement cycles were used to determine the loading and unloading stiffnesses as well as the upward displacement with cavitation (Figure 4). This was done by using a fit function that consists of four connected linear sections to fit the cone resistance-displacement cycle (Figure 4). The loading stiffness K_b was then calculated from the slope of the second section (from point 1 to 2) and the unloading stiffness K_e from the third section (from point 2 to 3). The upward displacement with cavitation, d_{cav}, was defined as the length of the fourth section (from point 3 to 4). These steps resulted in datasets of loading stiffness, K_b, unloading stiffness, K_e, and upward displacement with cavitation, d_{cav}.

2.4.3 Statistics

The objective of the statistics step was to calculate representative datasets for different tests in the systematic grid (Figure 1). The datasets of the SCPT and VCPT that had the same VCPT amplitude, were averaged using Eq 1. The datasets of the loading/unloading stiffness and the cavitation were also averaged with respect to their corresponding VCPT using Eq 1.

$$X_r = \frac{\sum_{i=1}^{n} X_i}{n} \qquad (1)$$

Where X_r is the representative dataset; X_i is an individual dataset; n is the total number of CPTs with the same amplitude; and i running from 1 to n.

2.4.4 Degradation factors

The degradation factors of representative cone resistance and sleeve friction was determined from Eqs. 2 and 3, in order to investigate whether or not the changes in VCPT amplitude affected the cone resistance and sleeve friction.

$$\beta_{q_c} = \frac{vq_{c,p,r}}{q_{c,r}} \qquad (2)$$

Where βq_c is the degradation factor of representative cone resistance (Jonker, 1987); $vq_{c,p,r}$ is the representative peak vibratory cone resistance; and $q_{c,r}$ is the representative static cone resistance.

$$\beta_{f_s} = \frac{vf_{s,p,r}}{f_{s,r}} \qquad (3)$$

Where βf_s is the degradation factor of representative sleeve friction; $vf_{s,p,r}$ is the representative peak vibratory sleeve friction; and $f_{s,r}$ is the representative static sleeve friction. Degradation factors with values near

zero represent high reduction, whereas values close to one represent small reduction in the representative cone resistances and sleeve frictions due to VCPT.

2.5 Pile-soil interaction models

2.5.1 Karlsruhe model

In the Karlsruhe model, four steps of the cyclic penetration are identified to describe the cyclic soil resistance-displacement behavior during vibratory penetration (Figure 5) (Dierssen, 1994, Cudmani and Manthey, 2019). The straight line between points 1 and 2 is expressed by:

$$q_T = K_b(depth - depth_1) \qquad (4)$$

Where q_T is the resistance force at the toe; K_b is the loading stiffness of the soil.

When the pile moves upward the straight line between points 2 and 3 is expressed by:

$$q_T = q_{T,2} - K_e(depth - depth_2) \qquad (5)$$

Where q_T is the resistance force at the toe; $q_{T,2}$ is the resistance at the toe at point 2; K_e is the unloading stiffness of the soil.
Figure 5. Description of the four phases of cyclic penetration (Dierssen, 1994).

When cyclic amplitude is large enough the resistance at the pile toe will reach zero and a cavity is formed, represented by the straight line between points 3 and 4 (Figure 5). At step between points 4 and 1′, the pile moves downward while the stress at the toe remains zero because of the cavity.

The loading, K_b, and unloading stiffness, K_e, are empirical parameters, however in this study, they were obtained from the cone resistance-displacement cycle and were used as input for the fit (Figure 4). For step between points 4 and 1′, the loading stiffness was restricted between values of 5-10 MPa/m, in order to account for the effect of cavity.

2.5.2 The model of Wong et al.

The cyclic penetration in this model is modeled with two equations in two parts one for the loading and one for the unloading part (Figure 6).

The first part is the loading part, which is described by (Wong et al., 1992):

$$q_l = \left[\frac{K_b w}{\left(1 + \left|\frac{K_b w}{q_0}\right|^{n_q}\right)^{\frac{1}{n_q}}} \right] F_q \left(1 - e^{-mw}\right) \qquad (6)$$

And the unloading part is described in Eq.7:

$$q_u = q_c - \left[\frac{K_e(w_c - w_p)}{\left(1 + \left|\frac{K_e(w_c - w_p)}{q_0}\right|^{n_q}\right)^{\frac{1}{n_q}}} \right] F_q \left(1 - e^{-m(w_c - w_p)}\right) \qquad (7)$$
Figure 6. Loading and unloading parts and the explanation of depths of model of Wong (Wong et al., 1992): (a) Loading (b) Unloading.

Where, q_l and q_u are the loading and unloading resistance at the pile toe respectively; q_c is the unit toe resistance at the previous reversal; K_b and K_e are the loading and unloading stiffness respectively; w, w_p, and w_c, are the displacements as noted in Figure 6; q_0 is a reference value of toe resistance; F_q is the fitting factor; m is the constant which controls the magnitude of the amplitude.

The parameters K_b, K_e, q_0, and n_q used in this model were obtained by fitting the model to the cone resistance-displacement cycles obtained from VCPT (Figure 4).

3 RESULTS

The peak vibratory cone resistances of the sand deposits were nearly always below the static cone resistance (Figure 7b). The reduction in the peak vibratory cone resistances to the static cone resistance increased with VCPT amplitude.

During VCPT, the sleeve friction was reduced with increasing amplitude until it reaches 0 MPa at

VCPT amplitude of 5 mm indicating total loss in shear stress between the sleeve and soil (Figure 7d).

The degradation factors of cone resistance decreased with increasing VCPT amplitude in the sand deposits (Figure 7c). In the silty till layer however, the degradation factors of cone resistance were close to one, indicating no effect of VCPT. The βq_c determined for different amplitudes were compared to the β-factor obtained from Jonker (1987) (Figure 7c). The degradation factor proposed by Jonker is 0.25 for sand and 0.4 for clay (the latter being considered to have similar soil properties to the silty till layer) and it is not related to changes of amplitudes.

The degradation in sleeve friction was highly affected by the VCPT amplitude in the sand deposits (Figure 7e). The silty till layer exhibited no degradation in sleeve friction during VCPT.

The representative loading and unloading stiffness values and the upward displacement with cavitation were plotted along the depth (Figure 8). In general, both loading and unloading stiffness values decreased with VCPT amplitude (Figure 8c-d). All stiffness values were very low in the silty till layer. The upward displacement with cavitation for amplitudes 5 and 7 mm exhibited approximately similar values (Figures 8e). The upward displacement with cavitation at a lower amplitude of 3 mm were lower.
Figure 7. Degradation factors of representative cone resistance and sleeve friction for different VCPT amplitudes.
Figure 8. Loading and unloading stiffnesses and the upward displacement with cavitation plotted along the depth of penetration.

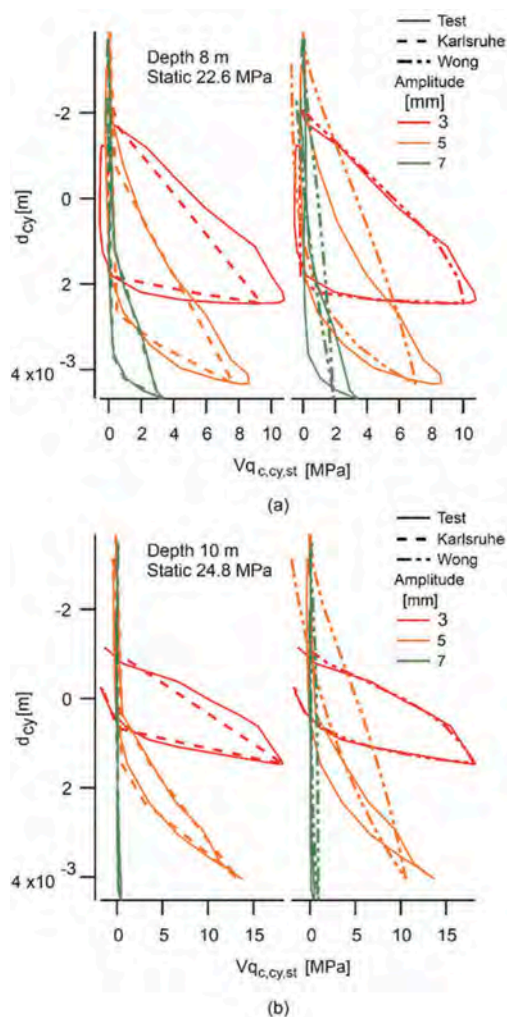
The Individual cone resistance-displacement cycles measured by VCPT at different depths were plotted and compared with the corresponding Karlsruhe and Wong fits (Figure 9). The results of Karlsruhe model agree with the cone resistance-displacement cycles for 5, and 7 mm amplitudes at depth of 8 and 10 m. For the 3 mm amplitude, the Karlsruhe model showed limitations to fully capture loading part of the resistance-displacement cycle. On the other hand the Wong model seemed to fully match the cycles at 3 mm amplitude, however larger difficulties were found when trying to to capture the cyclic behaviour at 5 and 7 mm amplitudes.


Figure 9. Stacked cyclic cone resistance – displacement behavior for the three applied amplitudes and the corresponding Karlsruhe and Wong fits at depths of a: 8 m; b: 10 m.

4 DISCUSSION

The increase in degradation of cone resistance and sleeve friction with VCPT amplitudes (Figure 7), provided practical evidence that the degradation in soil resistance during vibratory pile driving depends on the amplitude of vibration. This conclusion agrees with previous studies about assessment of vibratory-drivability in sand, in which it was assumed that one of the important factors affecting degradation factor for piles, β, is vibration amplitude (Jonker, 1987, van Baars, 2004).

The degradation in cone resistance during VCPT may be related to the cavitation (Dierssen, 1994). During the upward movement of the cone, the unloaded soil may lose its strength, collapses and starts to flow into the cavity, which might be filled with liquified material. However, because there is only a short time interval until the reversal to the downward movement, the liquified material might have still not fully solidified (Dierssens, 1994). This process may result in remolding and/or loosening of the soil below the cone (Massarsch et al., 2017). Therefore, a reduction in cone resistance occurs when the cone gets again in contact with the soil during the downward movement.

The increase in degradation of loading and unloading stiffness with increasing amplitudes (Figure 8c-d), agrees with the degradation of the secant Young's modulus with increasing strain in triaxial tests on Ticino Sand (Yamashita et al., 2000).

The dependency of the observed cyclic behaviour on the cyclic amplitude, raises questions regarding the fruitfulness of current soil-pile interaction models to try to estimate soil cyclic resistance from the static cone resistance (Holeyman and Whenham, 2017a). Nevertheless, Wong et al. (1992) modelled the cyclic soil behaviour by including cyclic degradation of the pile-soil interface, and the loading and unloading phases during vibratory driving. However, the model utilizes empirically implemented parameters for very specific soil-pile systems, with no account for the effect of the cyclic amplitude (Eqs. 6 and 7) (Wong et al., 1992, Lee et al., 2012). Furthermore, the model does not account for the cavitation part of the cone resistance-displacement cycles which reliably occurs at higher displacement amplitudes (Figure 8e). This explains the inability of the model to capture the cone resistance-displacement cycles with amplitudes of 5 and 7 mm (Figure 9). The Karlsruhe model on the other hand accounts for cavitation part of the vibratory cycles during pile driving. Therefore, it could well match the cone resistance-displacement cycles with higher amplitudes of 5 and 7 mm (Figure 9). Although the measured cone resistance-displacement cycle differed slightly in the shape with rounder edges compared to Karlsruhe model; the ability of the Karlsruhe model to capture the cyclic soil response to the different values of the applied cyclic amplitudes (Figure 9), proved the effectiveness of utilizing the cyclic soil parameters obtained from VCPT.

5 CONCLUSION

In this study, VCPTs were performed to investigate the cyclic soil behavior in-situ. It was found that:

1- The degradation in vibratory cone resistance and sleeve friction increased with VCPT amplitudes. The degradation is suspected to be related to increase in cavitation.
2- The degradation in the loading and unloading stiffness increased with increasing VCPT amplitudes.
3- The parameters of the cyclic soil resistance obtained from VCPT could successfully be used in the current pile-soil interaction models.

ABSTRACT: Following the 2012 Emilia-Romagna earthquake, widespread liquefaction of silty sands was observed, providing the opportunity to gain a better understanding of the influence of fines content on liquefaction hazard and mitigation works. This paper presents the results of a thorough geotechnical investigation performed as part of a full-scale liquefaction experiment involving controlled blast tests in Bondeno, a small village that suffered liquefaction in 2012. Piezocone (CPTU) and seismic dilatometer (SDMT) tests were performed in natural and improved soils after Rammed Aggregate Pier® (RAP) treatment to provide accurate soil characterization and to evaluate the effectiveness of liquefaction mitigation. CPTU and SDMT results revealed a good agreement in the geotechnical characterization of the site, detecting homogenous soil properties in both the natural and treated soils and estimating CPTU-DMT coupled parameters in sandy layers (e.g. overconsolidation ratio, at-rest earth pressure coefficient), that are usually not determinable by the use of a single type of in situ test. In particular, the combined use of CPTU-DMT data provided verification of the increase in the lateral stress produced by the RAP installation. Data analyses revealed that the RAPs were an effective ground improvement technique despite the high percent of fines ($\approx$ 25-35%).

1 INTRODUCTION

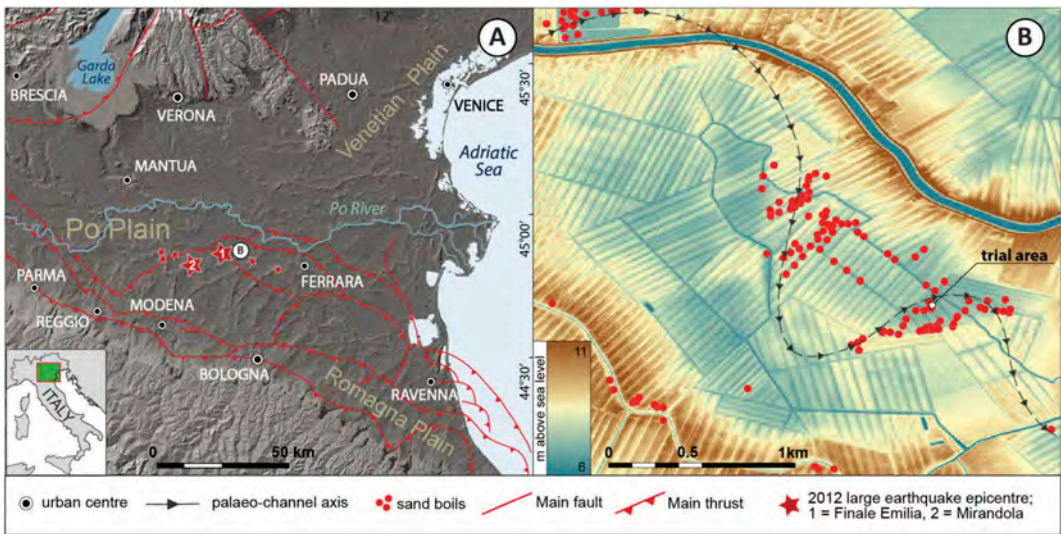
Several ground improvement solutions are available to mitigate the liquefaction hazard posed by clean sands; namely, increasing the soil resistance by densification or reducing the earthquake-induced excess pore pressures through drainage or reducing the shear strains through reinforcement. Vibratory compaction methods are a common and effective form of densification for cohesionless soils (Castro 1969), as proven by extensive research (e.g. Mitchell 1981, Vautherin et al. 2017, Amoroso et al. 2018). However, their effectiveness decreases as the fines content and plasticity increase (Mitchell 1981). Therefore, other ground improvement techniques, such as vibratory replacement, are often preferred in silty sands or sandy silts to protect the soil against liquefaction by increasing soil density, providing drainage for excess pore water pressures, and increasing the stiffness and shear resistance of the soil (Priebe 1998).


Figure 1. (a) Location of the Bondeno Test Site and of 2012 main shocks; (b) geomorphological features from LIDAR map (modified after Amoroso et al. 2020): greenish color indicates lower elevation above the sea level, while brownish color refers to higher elevation.

Examples of this type of reinforcement include Stone Columns (SC), Soil Mixed Columns (SMC), and Rammed Aggregate Piers (RAP). This last approach appears to be a promising solution in sandy silts and silty sands to increase not only the density, but also the lateral stress and shear stiffness, which is often neglected and poorly understood (Smith & Wissmann 2018, Amoroso et al. 2020).

The at-rest earth pressure coefficient (K_0) is a key parameter that should be considered with reference to liquefaction mitigation works (Schmertmann 1985, Salgado et al. 1997, Harada et al. 2010).

In this respect, in situ tests have an essential role to play in estimating the horizontal stress in granular soils before and after treatment. As argued by Massarsch et al. (2019), using cone penetration test (CPT) and flat dilatometer test (DMT) results could produce improved estimates of K_0. Moreover, Baldi et al. (1986) and later Hossain & Andrus (2016) proposed a combined CPT-DMT K_0-interpretation to take into account both the resistance and stress history of the soil, while the use of a CPT-only approach would have been overly affected by arching of stresses around the penetrating sleeve.

The coupling of CPT and DMT tests with downhole geophysics (i.e. seismic piezocone SCPTU and seismic dilatometer SDMT) provides a more efficient approach to the task of geotechnical site characterization, offering clear opportunities for the economical and optimal collection of the data (Mayne et al. 2009). Therefore, direct push technologies are more relevant for understanding the changes in soil properties following ground improvement (e.g. Jendeby 1992, Amoroso et al. 2018).

This investigation presents in situ test results from a thorough geotechnical campaign performed before

and after Rammed Aggregate Pier (RAP) treatment of a silty sand site in Bondeno (Italy), a small village strongly affected by liquefaction following the 2012 Emilia-Romagna earthquake. The overall details of the research activities can be found in Amoroso et al. (2020) while details regarding the performance of the RAP group following a blast test are provided by Rollins et al. (2021) and regarding the liquefaction assessment and ground improvement are listed in Amoroso et al. (2022).

2 THE BONDENO TEST SITE (BTS)

2.1 Geological and geomorphological setting

The Bondeno Test Site (BTS) is located in the southeastern portion of the Quaternary alluvial Po Plain, one of the largest and most populous plains in Europe. The area was affected in 2012 by an intense seismic activity linked to the tectonic evolution of the fault-fold structures (Figure 1a) that form the front of the Apennine chain buried below the plain (e.g. Toscani et al. 2009).

The earthquake sequence induced widespread site effects, including liquefaction manifestations, soil fracturing and lateral spreading (Emergeo Working Group 2013). At BTS the liquefaction hazard is concentrated in a subsurface sand deposit of a Holocene Po meander (Figure 1b). Figure 1b shows the higher elevations (brownish zones) indicating fluvial ridges bounding the lower, relatively flat interfluvial depression (greenish zones). The meandering course of the paleochannel is built up within the interfluvial depression and supports the identification of the paleochannel axis together with the location of sand boils. The
Figure 2. CPTU and SDMT interpreted results in natural (NS) and treated (TS) soils: (a) q_t, I_c, D_R, φ' from CPTU; (b) I_D, K_D, M, V_S from SDMT (modified after Amoroso et al. 2022).

meander base is frequently cut into upper Pleistocene coarse sand, accumulated during syn-glacial times. The meander unit geometry has been reconstructed through the analysis of remote sensing data (satellite images and LIDAR) and correlation of underground geotechnical investigations (Amoroso et al. 2020). This meander sand body is partially buried by finer grained levee sediment of historic age.

2.2 *Site investigations*

To assess the effectiveness of the RAP treatment at the BTS, in situ tests were performed before and after pier installations, according to the phases reported below:

- Phase I consisted of site investigations performed before the treatment (pre-RAP) and before the blast (pre-blast). Boreholes with SPTs and disturbed soil sampling, CPTUs, and SDMTs were executed up to a maximum depth of 20 m in two relatively small circular areas (10 m-diameter and 20 m-spacing) associated with the blast experiment, one for testing the natural soil (Natural Panel, NP) and one for testing the improved soil (Improved Panel, IP). This paper includes only CPTUs and SDMTs performed in the IP;
- Phase II included site investigations carried out approximately one month after the pier installation (post-RAP) and before the blast (pre-blast) within the IP. The treatment consisted of a 4 × 4 quadrangular grid (2 m center-to-center spacing) of RAP columns, each 9.5 m long and with a final

diameter of 0.5 m (area replacement ratio equal to 5%). Details on the construction methodology are reported in Saftner et al. (2018). Each CPTU, Medusa DMT (automated dilatometer test, Marchetti et al. 2019) and SDMT test was performed up to a maximum depth of 15 m at the exact center of four RAPs.

Further details on the site investigations performed within the full-scale liquefaction experiment through controlled blast tests are reported in Amoroso et al. (2022).

3 SITE CHARACTERIZATION

3.1 *Natural soil*

The stratigraphic arrangement of the subsoil beneath the test site area was deduced by the combined interpretation of borehole logs, SPTs, CPTUs, Medusa DMTs and SDMTs carried out before the RAP installation, as reported by Amoroso et al. (2020). Apart from a 0.8 m thick topsoil layer (CH, according to Unified Soil Classification System, USCS ASTM D2487-11 2011), the following well-defined stratigraphic units, also reflecting their sedimentological framework, could be identified:

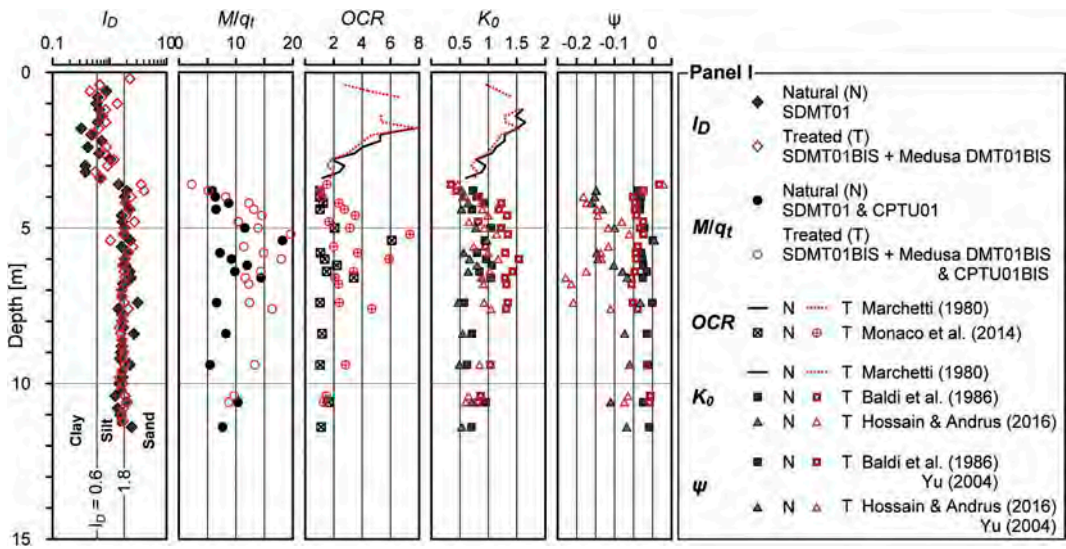
- a layer of clays and silts (CL), from 0.8 to approximately 3.3-3.4 m in depth;
- a predominantly silty sand unit, approximately 9 m thick, attributable to Holocene alluvial deposits of a Po river paleochannel. Samples


Figure 3. CPTU-DMT combined interpreted results in natural (NS) and treated (TS) soils: I_D, M/q_t, OCR, K_0, ψ (modified after Amoroso et al. 2022).

recovered from this unit can generally be classified as SM, having a *FC* typically in the range of 25-35%. Thin layers of coarser sediments have been occasionally found;

- a thin layer of sandy silt (ML), from 11.8-12.6 to 13.0-13.4 m in depth (interfluvial deposits);
- sands-silty sands (SP-SM) of the late Pleistocene epoch (namely, glacial braided Po River deposits), detected below 13.0-13.4 m in depth.

Figure 2 provides plots of representative piezocone and seismic dilatometer profiles carried out in the pre-RAP phase and located in the treated panel, respectively CPTU01 and SDMT01 (black lines). In particular, the CPTU profiles are shown in terms of the corrected cone resistance (q_t), soil behavior type index (I_c, Robertson 2009), relative density (D_R, Jamilokowski et al. 2001), and friction angle (φ', Kulhawy & Mayne 1990), while the SDMT results are reported in terms of the soil material index (I_D), horizontal stress index (K_D), constrained modulus (M), and shear wave velocity V_S), according to Marchetti (1980) and Marchetti et al. (2001) correlations.

The comparative analysis of the CPTU and SDMT parameters reveals a substantial agreement between the measurements collected in the IP, thus indicating negligible horizontal spatial variability in the stratigraphic conditions of the test site.

3.2 *Improved soil*

Figure 2 also provides a comparison between field soil properties before and after RAP installation in the IP, in terms of both CPTU and SDMT profiles (green lines).

With regard to the piezocone profiles (Figure 2), the increase in the q_t values after column construction

appears to be particularly noticeable (q_t = 13.10 ± 1.76 MPa versus 9.54 ± 1.37 MPa before installation) from 6 to 8.5 m in depth, but relatively moderate from 3.5 to 6 m. Negligible changes in the q_t profile can be observed in the silty sands below the base of the piers. Obviously, these changes in q_t affect the computed estimates of the geotechnical parameters reported in Figure 2, i.e. D_R and ϕ'.

The effect of RAP installation is evidently reflected by the increase in K_D (on average 48-53%), and even more in the higher M from SDMT (80-87%), at depths between 4 and 9 m (Figure 2b). The corresponding average increase in q_t is 30-35% (and in D_R is approximately 10% and is limited to a depth between 6 and 8.5 m). These results point to a significant increase in horizontal stress and stiffness resulting from pier installation, in agreement with previous observations (Saftner et al. 2018). In fact, the horizontal stress strongly influences both K_D and M estimated from DMT using the Marchetti (1980) correlation, which incorporates K_D.

The observed results are in line with previous comparisons of pre- vs. post- CPTs and DMTs executed for monitoring ground improvement (e.g. Jendeby 1992), since the RAP installation produced an average increase in M from DMT after treatment approximately 2.5 times the corresponding increase in cone penetration resistance q_c. The decrease in K_D observed in the upper crust may be due in part to the construction of an overlying working platform, but also to RAP installation under low confining stress and to seasonal variations in water content caused by fluctuation of the GWT from 1.5 m (February 2018) to 0.5 m (March 2018). No improvement was detected in the silty sands below the toe of piers, unlike RAP case histories in clean sands studied in New Zealand (e.g. Vautherin et al. 2017).

The combined interpretation of CPTU and DMT data provided information on stress history and the state parameter in sand, in both the natural and treated soils as shown in Figure 3. Filtering the data for $I_D \geq 1.8$ and $I_c \leq 2.6$, in the sand layers the ratio M/q_t (with M estimated from DMT) is shown in Figure 3. The average values of M/q_t are about 7-10 in natural soil and 13-14 in treated soil. These values are in line with the available experience from field observations before and after compaction of sand fills, reported by Marchetti et al. (2001) and Marchetti & Monaco (2018), which show an increase in the ratio M from DMT/q_c from $\approx$ 5-10 before compaction to $\approx$ 12-24 after compaction. The finding that compaction increases both M from DMT and q_c, but M at a faster rate, suggested the potential use of the ratio M from DMT/q_c, as a broad indicator of "equivalent" OCR in sands.

The in situ earth pressure coefficient K_0 was estimated using correlations proposed by Baldi et al. (1986), based on both DMT and CPT data, and by Hossain & Andrus (2016), which require as an additional input also OCR (in this case evaluated by Monaco et al. 2014). In the upper silty clay layer OCR and K_0 were estimated from DMT (Marchetti 1980).

The OCRs of about 1-2 estimated in the natural soil, excluding the shallow "crust", indicate that the deposit is normally consolidated or slightly overconsolidated, with $K_0 \approx 0.5$-0.7. As a result of the RAP installation, the "equivalent" OCR increased to about 3-3.5 and K_0 to about 0.9-1. The values of K_0 estimated according to Hossain & Andrus (2016) are lower than those estimated according to Baldi et al. (1986). The increase of M/q_t, OCR and K_0 after treatment was more pronounced at depths between 7 and 9 m.

An approximate estimate of the in situ state parameter ψ in sand from DMT was obtained according to Yu (2004), with K_0 determined by both Baldi et al. (1986) and Hossain and Andrus (2016) methods. Figure 3 shows that the input K_0 has a large influence on the calculated values of ψ, with an apparent contradiction versus the expected trend. In fact, the higher K_0 (i.e. higher OCR) estimated according to Baldi et al. (1986) should involve lower negative values of ψ compared to those obtained using K_0 from Hossain & Andrus (2016), while the opposite is observed in Figure 3. On the other hand, the reduction of ψ after treatment found using both K_0 methods is consistent with the corresponding increase of OCR and K_0 before and after treatment.

A more complete overview on the ground improvement effectiveness at BTS using in situ tests is reported in Amoroso et al. (2022).

4 CONCLUSIONS

At BTS a comprehensive comparative study based on CPTU and SDMT testing was carried out in a liquefaction-prone silty sand site improved by a group of Rammed Aggregate Piers and subjected to controlled blasting.

CPTU and SDMT tests revealed good agreement in the geotechnical characterization of the site, detecting homogenous soil properties in both the natural and improved panels. Use of both CPTU and DMT provided better estimates of soil properties in sandy layers (e.g. OCR, K_0), that are usually not determinable using a single type of in situ tests.

The comparison of the in situ tests performed pre-blast in natural and treated soils highlighted the effectiveness of the RAP treatment between 4 and 9 m depth in silty sands. The increase in the DMT parameters following treatment were more pronounced relative to those obtained from CPTU data (i.e. K_D increase $\approx$ 48-53%, M increase $\approx$ 80-87%, q_t increase $\approx$ 30-35%), thus suggesting a higher sensitivity of DMT to the increase of horizontal stress. On the contrary, V_S measurements showed a very low sensitivity to the ground improvement Moreover, the combined use of CPTU and DMT tests showed a significant increase of M/q_t and K_0 after treatment, supporting the use of the piers to increase the lateral soil stress and to mitigate liquefaction.

ABSTRACT: A joint academia-industry project, the Pile Soil Analysis (PISA) project, resulted in an empirical method for assessing the monotonic lateral loading response of large diameter monopiles. The method predicts four soil reactions, namely the distributed load and the distributed moment along the pile shaft, the pile base shear and the pile base moment. The method considers pile load test data and 3D numerical modelling. A 1D framework allows prediction of the four soil reactions. In this paper, a CPT-based approach is proposed to derive the four soil reaction components for use in a 1D model for conceptual design of monopiles in sand subject to monotonic lateral loading. The approach relies on results from 3D finite element analyses that were performed considering soil conditions for a sand site used in the PISA project (Dunkirk site). The results are compared to pile load test data from the PISA project, showing good agreement, particularly for load levels related to the serviceability limit state.

1 INTRODUCTION

Monopiles are commonly used as foundations for offshore wind turbine generators (WTGs). The current trend in the ever-growing offshore wind energy sector is for WTGs to becoming bigger which evidently leads to requirements for monopiles with large diameters up to 10 m to support the superstructure. It is expected that the ratio of embedded length to diameter, *L/D* (or slenderness ratio) of monopile foundations for the 10 MW+ next-generation wind turbines could be in the range between 2 and 6 (Panagoulias et al., 2018). Such structures are categorised as intermediate foundations according to ISO (2016).

An industry standard approach for assessing monopile lateral response was a *p-y* method for long slender piles, adjusted to large diameter monopiles. The *p-y* method is based on the Winkler assumption according to which the soil surrounding the pile is modelled as a set of uncoupled, non-linear, elastoplastic springs which define the lateral pressure (*p*) applied to the pile at a given depth, as a function of the lateral displacement (*y*). The method, however, does not capture the physics of the monopile behaviour accurately.

A joint academia-industry project, the Pile Soil Analysis (PISA) project, resulted in an empirical method for assessing the monotonic lateral loading response of large diameter monopiles. The method is based on conventional models for caisson design, predicting four soil reactions, namely the distributed load and the distributed moment along the pile shaft, the pile base shear and the pile base moment (Figure 1). The PISA schematisation excludes torsional foundation loading (Burd et al., 2020). The empirical method considers pile load test (PLT) data and 3D numerical modelling. A 1D framework allows prediction of the four soil reactions and requires, for sands, profiling of three soil parameters, namely the relative density, the vertical effective stress and the shear modulus at small strain.

In this paper, a CPT-based approach is proposed to derive the four soil reaction components for use in a 1D model for conceptual design of monopiles in sand subject to monotonic lateral loading. The approach relies on results from 3D finite element (FE) analyses that were performed considering soil conditions for a sand site used in the PISA project (Dunkirk site). The results are compared to PLT data from the

PISA project, showing good agreement, particularly for load levels related to the serviceability limit state (SLS).

2 DATABASE

Several piles driven into dense sand at the Dunkirk site were tested during the PISA project in order to investigate the effect of different design aspects such as pile geometry, load ratio, unloading/reloading behaviour and creep. In this paper, the results from three PLTs on medium diameter piles, $D = 762$ mm (i.e. DM3, DM7 and DM4; see Table 1) were compared to results from 3D FE analyses. This allowed, using the FE-derived resistance components, development of a CPT-based method.

Table 1. Geometry of PISA piles considered in this study (Taborda et al., 2020).

Pile	Diameter (m)	Length (m)	Slenderness ratio (-)	Wall Thickness (mm)
DM3	0.762	6.1	8.0	25
DM4	0.762	4.0	5.3	14
DM7	0.762	2.3	3.0	10

3 FINITE ELEMENT MODEL

3.1 General

The commercial software packages Plaxis 3D and Plaxis Monopile Design Tool, MoDeTo (Plaxis BV, 2018), were used to perform the FE analyses and extract the soil reaction curves. Through the latter, the monopile was modelled and then the FE analysis was performed in Plaxis 3D. Finally, each of the four

soil reaction curves were extracted via MoDeTo at different load steps and pile depths.

3.2 Soil model

The Dunkirk test site was characterised using a range of in situ tests and advanced laboratory testing (Zdravković et al., 2020). Several CPTs were performed next to the test pile locations and other key locations. Figure 2 presents the average cone resistance at the site. The general soil stratigraphy is shown in Table 2. The water table is found approximately at 5.4 m below ground level.

The Hardening Soil small strain model (HSsmall) was used as soil constitutive model. The model was calibrated against available soil data from the Dunkirk site, including CPTs, seismic CPTs and laboratory tests such as triaxial tests with bender element measurements. The calibration process included study of several CPT-based and empirical parameter formulations from the literature (e.g. Robertson and Cabal, 2015; Brinkgreve et al., 2010), investigation of parameter interdependency and performance of single element test predictions.

The focus of the CPT-based approach was accurate representation of the SLS, according to which the allowance for the total permanent tower axis tilt rotation is 0.5° (DNVGL, 2016). By analysing the data obtained from the PISA project, this limit is reached at approximately 30% to 50% of the maximum horizontal load applied to the monopiles during pile load testing; hence only that portion of the horizontal load-deformation curve was considered for the HSsmall calibration process.

Table 3 shows an overview of the soil parameter values for the calibrated HSsmall soil model.
Figure 2. Cone resistance profile at the Dunkirk site (Zdravković et al., 2020).

Figure 3 illustrates the comparative results between the measured horizontal load-displacement responses from the PLTs and the predicted responses from the performed 3D FE analyses. A fairly good match is observed at the initial part of the curves, rendering the prediction of the stiffness response, which was of primary interest, satisfactory.

Additional (fictional) piles were considered in order to expand the database and check the influence of pile geometry on each of the four soil reaction components. Table 4 shows an overview of the additional piles considered for the sensitivity analyses.

4 SOIL REACTION CURVES

4.1 *Distributed lateral load (p-y)*

The relationship between p and y along the pile shaft has been widely studied. In recent years several formulations for *p-y* curves have been developed by taking into consideration the cone penetration test and considering the link between cone resistance (q_c) and in situ horizontal effective stress of the soil (Houlsby and Hitchman, 1988). An overview of some of those formulations together with their corresponding authors is shown below:

Table 2. Soil stratigraphy at the Dunkirk site (Zdravković et al., 2020).

Depth (m)	Material	Description
0 - 3	Hydraulic fill	Sand dredged from offshore Flandrian deposits
3 - 30	Flandrian sand	Marine sand deposited during three local transgressions
> 30	Ypresienne clay	Eocene marine clay located beneath the southern North Sea

Table 3. Summary of soil parameters for HSsmall model.

Depth [m]	0-3	3-5.4	5.4-9	9-12.2	12.2-15
γ' [kN/m^3]	19.1	20.8	11.0	11.8	9.8
$E_{50,ref}$ [MPa] ($=E_{oed,ref}$)	250	223	174	202	87

Table 4. Geometry of additional (fictional) piles considered in the study.

Pile	Diameter (m)	Length (m)	Slenderness ratio (-)	Wall Thickness (mm)
DM3A	1.0	6.1	6.1	25
DM3B	1.2	6.1	5.1	25
DM3D	2.0	6.1	3.1	25
DM7B	0.762	3.0	3.9	10
DM7D	0.762	4.7	6.1	10
DM7E	0.762	3.8	5.0	10
PL1	0.762	15.0	19.7	20
PL2	0.5	15.0	30.0	25
PL3	0.6	21.0	35.0	30

$$p = \min\left(2D(\gamma'z)^{0.33} q_c^{0.67} \left(\frac{y}{D}\right)^{0.50}, Dq_c \right) \quad (1)$$

$$p = 2.84D(\gamma'D)\left(\frac{q_c}{\gamma' \cdot D}\right)^{0.72}\left(\frac{y}{D}\right)^{0.64} \quad (2)$$

$$p = 3.6D(\gamma'D)\left(\frac{q_c}{\gamma' \cdot D}\right)^{0.72}\left(\frac{y}{D}\right)^{0.66} \quad (3)$$

$$p = \begin{cases} 4.5G_{max}\, y, \text{ for } \frac{y}{D} \leq 0.0001 \\ p_u\, f(y), \text{ for } \frac{y}{D} > 0.01 \end{cases} \quad (4)$$

where Equation 1 is by Novello (1999), Equation 2 is by Dyson & Randolph (2001), Equation 3 is by Li et al. (2014), Equation 4 is by Suryasentana & Lehane (2016), D = pile diameter, γ' = effective unit weight of soil, z = depth, G_{max} = small strain shear modulus, p_u = ultimate lateral soil resistance (for more details refer to Suryasentana & Lehane, 2016) and $f(y)$ = exponential function that depends on lateral displacement (for more details refer to Suryasentana & Lehane, 2016).

Equations 1 to 4 were used to derive p-y curves which were then inserted in a 1D Timoshenko beam model for modelling of the pile-soil lateral behaviour. Long slender (fictional) piles $(L/D \geq \sim 20)$ were considered so that the influence of the other three soil reaction components (distributed moment, base shear and base moment) to the overall response is negligible (see Table 4; piles PL1, PL2 and PL3). The results obtained from the 1D model were thereafter compared with results from 3D FE analyses and it was found that Equation 2 (Dyson and Randolph, 2001) was providing the better match and was thus selected to define the p-y component for this study.

4.2 Distributed moment (m-ψ)

The distributed moment (m) is caused by the vertical shear stresses along the pile shaft due to pile rotation (ψ). It is considered that m is linked to p, which is acting as a normal force along the shaft, through consideration of the pile-soil interface friction angle (δ) and the pile geometry (L and D). A fitting parameter, $F_{m\psi}$, was adopted in order to investigate the relationship between the aforementioned parameters for the range of pile geometries considered.

$$F_{m\psi} = p \cdot D \cdot \tan\delta \qquad (5)$$

where δ = pile-soil interface friction angle taken as $2/3\varphi'$.

By considering the maximum value of the distributed moment at every slice along the pile shaft obtained from the 3D analysis, m_{max}, the influence of L/D on the ratio $m_{max}/F_{m\psi}$ was investigated (Figure 4) and a formulation for determination of m is proposed (Equation 6). The relatively low R^2 value is attributed to the small dataset and the fact that the proposed linear trend might be less suitable as L/D increases.

$$m = 0.07 \cdot p \cdot D \cdot \tan(\delta) \cdot \left(\frac{L}{D}\right)^{0.7} \qquad (6)$$

The distributed load and distributed moment are soil reactions along the pile shaft, thus the pile was divided into slices and both soil reactions were computed per slice. By considering geometric continuity
Figure 4. Distributed moment ratio as function of the slenderness ratio L/D.

of the rigid pile, the rotation can be obtained from the horizontal displacements. Figure 5 shows the distributed moment for various slices along the shaft of pile DM4, obtained both from the 3D FEA and the proposed CPT-based formulation (Equation 6).
Figure 5. Pile DM4 distributed moment along each slice. Solid lines correspond to the results from 3D FE models and dashed lines correspond to the results from the proposed CPT-based formulation.

4.3 Horizontal base force (H_B)

Due to the applied force at the pile head, the base of the pile tends to move in the opposite direction, generating a horizontal base force (H_B). H_B was linked to the base displacement, v_b, via a fitting parameter, F_{HB}, which is a function of the q_c at the pile base and the pile geometry (Equation 7). Figure 6 shows the relationship between F_{HB} and the ultimate horizontal base force, $H_{B,ult}$, for all piles in the considered database.

$$F_{Hb} = \frac{q_c \cdot D^2}{(L/D)^{0.36}} \qquad (7)$$
Figure 6. Fitting parameter F_{HB} versus the ultimate horizontal base force, $H_{B,ult}$.

Curve fitting with results from the Plaxis 3D models of the database resulted in the following bi-linear relationship:

$$
H_B = \begin{cases} \dfrac{0.00235q_c}{\left(\frac{L}{D}\right)^{0.36}} \left(\dfrac{\pi D^2}{4}\right)\left(\dfrac{v_b}{0.0005D}\right), \ for \frac{v_b}{D} \leq 0.0005 \\[3ex] \dfrac{0.00235q_c}{\left(\frac{L}{D}\right)^{0.36}} \left(\dfrac{\pi D^2}{4}\right), \ for \frac{v_b}{D} > 0.0005 \end{cases}
$$

$$(8)$$

Figure 7. Pile base horizontal reactions. Solid lines correspond to the results from 3D FE models and dashed lines correspond to the results from the proposed CPT-based formulation.

Figure 7 shows the pile base horizontal reactions obtained from the 3D FEA in comparison to the reactions from the proposed CPT-based formulation (Equation 8) for a selection of piles from the database.

4.4 *Base moment (M_B)*

The base moment is caused by rotation of the pile toe. Similarly to the base horizontal force, the base moment relationship contains a first linear portion followed by a plateau. Curve fitting with results

from the Plaxis 3D models of the database resulted in the following bi-linear relationship:

$$
M_B = \begin{cases} \dfrac{0.00171q_cD}{\left(\frac{L}{D}\right)^{0.52}} \left(\dfrac{\pi D^2}{4}\right)\left(\dfrac{\psi_b}{0.0007D}\right), \ for \frac{\psi_b}{D} \leq 0.0007 \left[\frac{rad}{m}\right] \\[3ex] \dfrac{0.00171q_cD}{\left(\frac{L}{D}\right)^{0.52}} \left(\dfrac{\pi D^2}{4}\right), \ for \frac{\psi_b}{D} > 0.0007 \left[\frac{rad}{m}\right] \end{cases}
$$

$$(9)$$

Figure 8 shows the pile base moment reactions obtained from the 3D FE models and the proposed CPT-based formulation (Equation 9) for a selection of piles from the database.

Figure 8. Pile base moment reactions. Solid lines correspond to the results from 3D FE models and dashed lines correspond to the results from the proposed CPT-based formulation.

5 PILE LATERAL RESPONSE

The four soil reaction components, as computed with the use of the proposed equations, were entered in a 1D Timoshenko beam model for modelling of the general monopile response under lateral loading. Results for the piles of Table 1 are shown in Figures 9 and 10. The predictions of the CPT-based method show in general good agreement with the PLTs and the 3D FE analyses for the initial part of the load-displacement curve, i.e. until approximately half the ultimate lateral load (Figure 9). The initial stiffness response of the monopiles is, therefore, fairly captured. Figure 10 depicts the pile deflections below ground level at different loads, all with magnitude lower than half of the ultimate lateral load. Again, a satisfactory agreement between the results of the CPT-based method, the 3D FE analyses and the PLTs is observed.

Figure 9 shows that after a certain level of ground level displacement, the response obtained from the proposed CPT-based method is stiffer than the response obtained from the 3D FE analyses and the PLTs. Therefore, a cut-off point needs to be defined beyond which the proposed
Figure 9. Comparison of ground level load-displacement for three piles tested during the PISA project. Solid lines represent the results of the pile load tests; thinly dashed lines represent the results of the 3D FE calculations; thickly dashed lines represent the results of the CPT-based method.
Figure 10. Comparison of deflection at and below ground level for three piles tested during the PISA project. Solid lines represent the results of the pile load tests; thinly dashed lines represent the results of the 3D FE calculations; thickly dashed lines represent the results of the CPT-based method. Values within brackets denote the applied load in kN.

method is less accurate. This point was defined by analysing, for all piles of the database, the difference in stiffness magnitude between the 3D FE analyses and the CPT-based method, at ground level and at all load levels. Consequently, it is recommended that the proposed CPT-based method is used for predictions of monopile lateral

response in which the displacements at ground level are not larger than 2% to 3% of the pile outer diameter. This level of deformation generally corresponds with the serviceability limit state of monopiles used in the offshore wind industry.

6 DISCUSSION AND CONCLUSIONS

The paper presents a CPT-based method for predicting the response of laterally loaded monopiles in a sand setting. In order to verify application of the method to full-scale monopiles and until further experience is gained with the use of this method, a FE analysis, considering typical soil conditions of the investigated site and expected pile geometry, is recommended as a minimum.

The method allows for performing monotonic conceptual design calculations for monopile foundations supporting WTGs in a time-efficient manner, requiring only CPT data. Total computing time can be reduced by up to 90 % with respect to performing 3D FE analyses.

The proposed soil reaction formulations were calibrated against soil data from the PISA sand site in Dunkirk and consider a specific limit state, i.e. the SLS. Therefore, applicability of the method to marine sites with significantly different soil conditions (e.g. in terms of strength, stiffness, sand type) than the ones at Dunkirk and/ or for different limit states should be carefully checked. In these occasions, FE analyses are required prior to implementation of the approach shown in this paper to develop a site-specific CPT-based method. Alternatively, the PISA 'numerical-based method' can be employed (Byrne et al., 2017).

The curve fitting process considered the individual soil reactions from the 3D FE analyses and not the actual PLTs, since modelling of each individual soil reaction component based on measured PLT data has been shown to be problematic (Foursoff, 2018).

The proposed CPT-based method provides a representation of the global monopile response under monotonic lateral loading, although the individual soil reactions at a local level can differ considerably between the FE analyses and the CPT-based formulations. The latter can be attributed to factors such as imperfect curve fitting and inherent limitations of the 1D model which cannot accurately represent all mechanisms of soil-pile interaction at a local level.

The CPT-based method should be employed in its entirety, i.e., individual soil reaction components should not be excluded from the analysis or used independently.

Automatic interpretation and statistical evaluation of soil conditions for preliminary design of offshore foundations using the cone penetration test

L. Berenguer Todo Bom & M. Kanitz
Ramboll, Hamburg, Germany

ABSTRACT: The increasing need for renewable energy has led to a substantial growth of the offshore wind industry. To meet the need of the demanding timelines of the industry, while maintaining a thorough and robust design of the offshore foundations, automation is key in supporting rapid and accurate geotechnical screening of any investigated site. The preliminary design of foundations for offshore wind turbines is a crucial step to determine the feasibility of the planned structures to build an offshore wind park at the site. Therefore, an initial estimate of the ground conditions, in terms of both soil stratigraphy as well as soil strength and stiffness properties are necessary. This contribution presents a MATLAB-based tool which performs an automatic interpretation and statistical evaluation of soil conditions based on solely cone penetration testing (CPT) data. The tool derives a preliminary ground model by assembly of similar soil type and strength and stiffness parameters are determined through available CPT correlations. A depth-dependent statistical evaluation of the strength and stiffness parameters for each soil layer in the respective soil profile is computed. The output profiles can be adopted directly for the preliminary design of offshore foundations such as jacket pin-piles, suction bucket or monopiles using the PISA rule-based method.

1 GENERAL

1.1 Introduction

The increasing demand in the contribution of renewable wind power to the national energy grids of most countries in the world continues to accelerate at a rapid pace. Due to the increasing size of these structures to improve efficiency and increase energy production, the offshore environment with steadier wind speeds than on land has become very attractive for these types of investments.

The design cycles of offshore wind turbine foundation typically consist of 3 phases. An initial phase termed 'concept', followed by 'Front-end engineering design' (FEED) and ending in the 'detailed' stage. The geotechnical investigation campaigns are typically undertaken during the concept and FEED stages of development, where cone penetration tests (CPT) are undertaken at representative and all planned foundation locations, respectively. Whilst non-binding, important decisions concerning the foundation type and sometimes geometrical and installation methodologies are made early in the design process. Improving the methodologies and processes involved in the preliminary design of the foundations, resorting to the significant information provided by the CPT in situ testing is the main goal of this contribution.

2 BACKGROUND

2.1 Offshore foundation design practice

The most common foundation types in the offshore wind industry are the monopile and jacket structures. The monopile consists of a single tubular steel element supporting the wind turbine generator (WTG). A jacket structure consists of a welded tubular space frame with vertical or battered legs and bracing system, which is then in turn commonly fixed to the seabed by pile elements, among other foundation options.

The preliminary design of these foundations typically resorts to the methods defined in the API RP 2GEO (2014) and DNVGL-RP-C212 (2017) standards. More recent developments, namely the CPT-based methods for the calculation of axial capacity, Jardine et al. (2015) and Lehane et al. (2005), and the PISA working group publications, Byrne et al. (2020), are currently adopted already during early stages of design for jacket piles and monopiles, respectively.

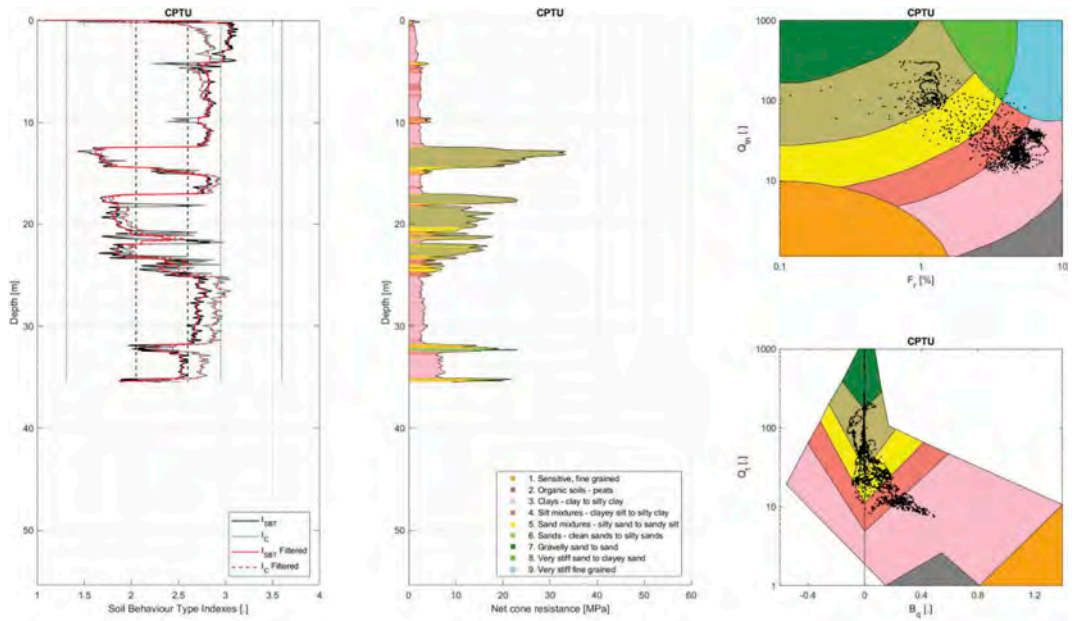
The definition of a ground model and derivation of geotechnical properties is a necessary initial step for these design approaches. The following sections describe in detail an automatic procedure to undertake it supported on the CPT data.


Figure 1. Soil classification based on *Ic* (left), based on the Robertson textural chart (middle) and Robertson chart (right).

2.2 *CPT classification charts and ground model definition*

CPT measurements can be used to determine the soil stratigraphy and the soil type. For this purpose, classification charts can be used that link the CPT measurements to the soil type. Robertson (1990) proposed two charts based on either the normalized cone penetration resistance with variable stress exponent Q_{tn} and the pore pressure ratio B_q or based on Q_{tn} and the normalized friction ratio F_r. These charts are subdivided into 9 regions ranging from sensitive fine grained over sand to very stiff fine-grained soil. The normalized Soil Behavior Type Index, I_c, based on Robertson and Wride (1998) is a parameter for mechanical behavior classification of the soil and defined in Equation 1.

$$I_c = \left((3.47 - \log Q_{tn})^2 + (\log F_r + 1.22)^2 \right)^{0.5} \quad (1)$$

It defines the soil as either sand (for $1.31 < I_c < 2.05$), sand/silt mixtures (for $2.05 < I_c < 2.6$), clay/silt mixtures (for $2.6 < I_c < 2.95$) or clay ($2.95 < I_c < 3.6$). Robertson (2010) additionally proposed a non-normalized Soil Behavior Type Index I_{SBT} that is based on basic CPT measurement values:

$$I_{SBT} = ((3.47 - \log q_c/p_a)^2 + (\log R_f + 1.22)^2)^{0.5} \quad (2)$$

2.3 *Correlations for strength and stiffness soil parameters*

For coarse-grained soils (sands), the dry density and the friction angle are evaluated based on CPT correlations. For sands, the CPT correlations according to Robertson & Campanella (1983), Equation 3, as well as Meyerhof & Hanna (1979), Equation 4, are well-established to derive the internal friction angle φ':

$$\varphi' = \tan^{-1}\left(0.1 + 0.38 \cdot \log q_t/\sigma'_{v0}\right) \quad (3)$$

$$\varphi' = 26.8 + 4.5 \log q_c \quad (4)$$

with q_t= corrected cone resistance [MPa] and σ'_{v0} = vertical effective stress [MPa].

For fine-grained soils, the undrained shear strength C_u can be evaluated based on CPT measurements by the cone factor N_{kt} through:

$$C_u = q_{net}/N_{kt}, q_{net} = q_t - \sigma_{vo} \quad (5)$$

The shear wave velocity in sands can be derived with the CPT correlation after Baldi et al. (1989) with the cone resistance q_c [MPa] and σ'_{v0} [MPa]:

$$v_s = 277 \, q_c^{0.13} \sigma'_{v0}{}^{0.27} \quad (6)$$

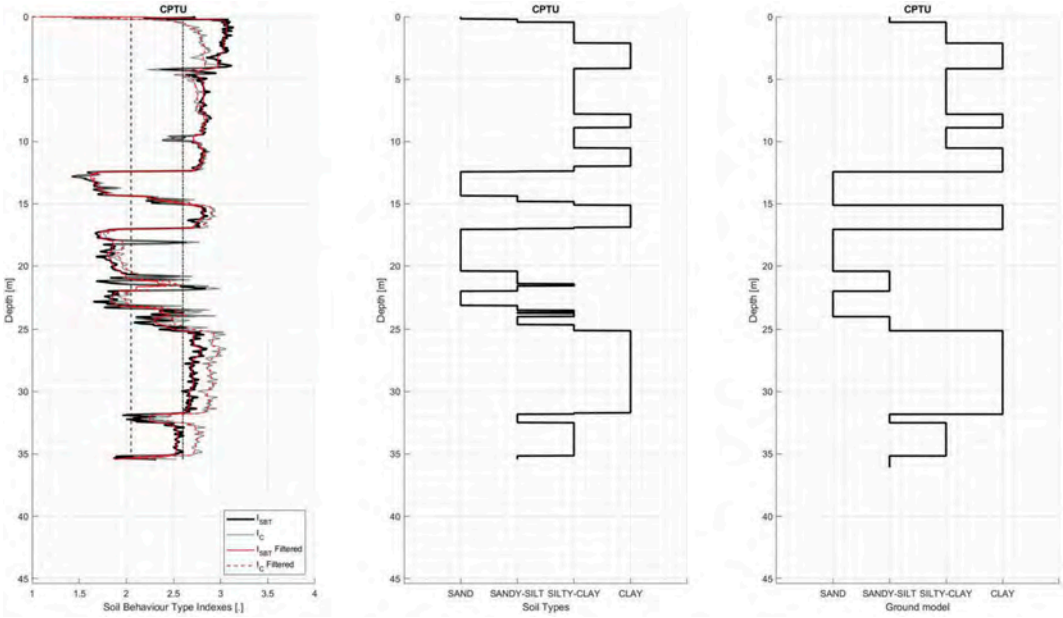
For the CPT correlation of the small strain shear modulus, G_0, in sands, the correlation after Rix and Stokoe (1991) can be used via q_c [kPa] and σ'_{v0} [kPa]:


Figure 2. Identified soil types based on I_c (right), preliminary ground model (middle), simplified ground model (right).

$$G_0 = 1.634 \, q_c^{0.25} \sigma'_{v0}{}^{0.375} \qquad (7)$$

For clays, the shear wave velocity is derived with the CPT correlation after Mayne and Rix (1995) through Equation 8 with q_c in [kPa].

$$v_s = 1.65 \, q_c^{0.627} \qquad (8)$$

Finally, the small strain shear modulus in sands is based on the CPT correlation proposed by Mayne and Rix (1993) with q_c in [kPa]:

$$G_0 = 2.78 \, q_c^{1.335} \qquad (9)$$

3 CPT INTERPRETATION

For a preliminary assessment of the design of the offshore wind turbine foundations, the CPT measurements at the turbine locations are analyzed. To derive the soil information, including strength and stiffness values, the cone tip resistance q_c, the sleeve friction f_s and the excess pore water pressure u_2 are required in depth. The following sections explain the necessary steps to derive a soil profile including the required soil parameters for the foundation design from the CPT measurements.

3.1 Preliminary ground model

As a first step, the soil type is determined based on either the soil textural chart, Robertson (1990) or the

soil behavior type index I_c, Robertson & Wride (1998). Figure 1 shows the derived normalized soil behavior type index I_c and I_{SBT} (left), the net cone resistance over depth including a description of the soil type based on the textural chart (middle) and the textural chart type plots for a CPT measurement (right), for a given turbine location.

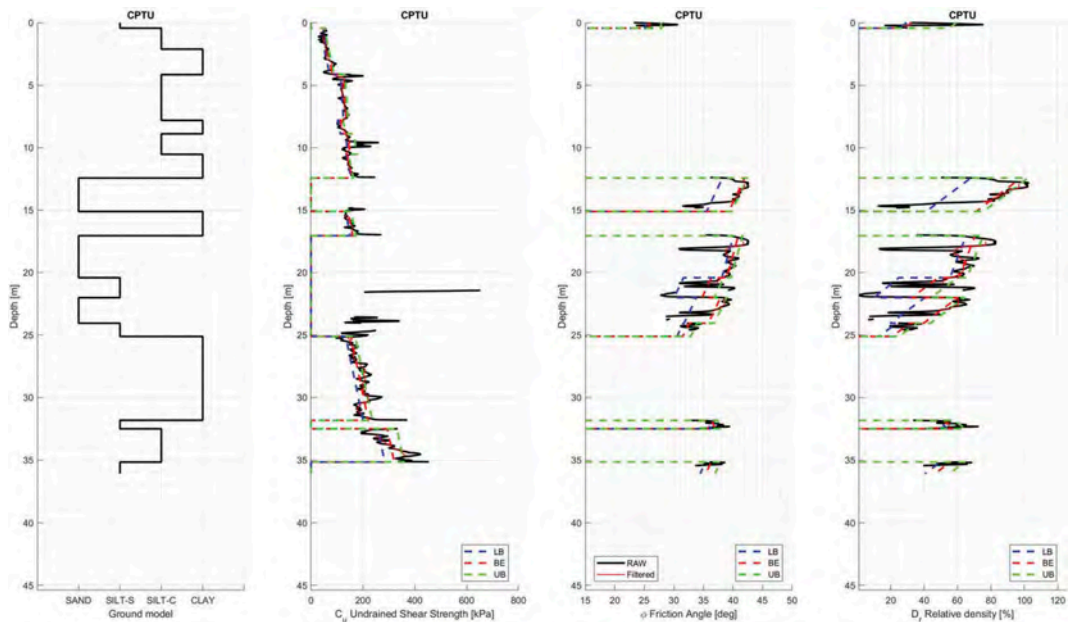
Since CPT measurements can vary substantially due to repushes or small rocks at the cone tip, the soil behavior type index is filtered with a moving median function to smooth these variations. Through this investigation and presentation, the soil types present at the site are identified and an initial assessment can be made regarding the design of the foundations. In Figure 1, the location is characterized by clay layers with high thickness and embedded sand layers of medium to high thickness. Some minor stratification of the soil can also be observed in a depth of 20 m to 25 m. The textural chart additionally indicates that the location is mostly comprised of fine soils since most data points plots into section 3 (clay to silty clay) and 4 (clayey silt to silty clay). The comparison between I_c and the textural chart shows a good agreement in terms of soil classification. For preliminary ground models a low level of soil variability and stratification is preferred prior to additional soil information being available. The aim of the ground model is to identify soil units that can be characterized for the entire offshore wind farm site. Thin layers tend to do not influence the foundation design. To improve the efficiency of the analysis of the foundation design, a ground model is automatically created, neglecting thin soil layers to derive a general ground model.


Figure 3. Derived ground model (right) with relevant soil parameters for design including lower bound, best estimate and upper bound values.

Figure 2 presents the output of this automatic procedure which details the ground model derived. On the left side of the figure, the Soil Behavior Type indexes over depth are shown as in Figure 2. In the middle, the detailed ground model is shown which is derived directly from I_c, still including thin layers.

By defining a threshold thickness of the soil layers to be acceptable in the ground model, the simplified ground model is derived (Figure 2 right). The soil layering procedure is based on a moving median approach of around 50 cm in both directions. In this analysis, the limit thickness of a soil layer is set to 0.55 m.

3.2 *Determination of relevant soil parameters*

Following the ground model definition, the derivation of the soil parameters relevant to the foundation design is undertaken. The CPT measurements are analyzed to derive the strength and stiffness parameter of the determined soil units. In the preliminary stage of the design process, typically, laboratory tests results of the soil are not yet available. Well-established correlations for the relevant soil parameters are hence employed to derive a first estimate of the soil properties from the in-situ CPT measurements. For all soil types, the submerged unit weight γ' and the small strain shear modulus G_0 are derived. The soil type determines which correlation (see Sec. 2.3) is used to derive G_0. For clay and silty clay soils, the undrained shear strength c_u is determined while for sand and silty sands, the internal friction angle φ' and the relative density D_r are calculated. For φ', the minimum

value obtained between Equation (3) and Equation (4) is adopted. The relative density is determined based on the correlation of Jamiolkowski et al. (2003). Figure 3 presents the correlated strength parameters over depth for the investigated soil profile, all of which are obtained automatically following the ground model definition.

3.3 *Statistical methodology for parameter derivation*

Since soil parameters can vary significantly, a statistical assessment of their distribution in depth is preferred. The local scatter present in CPT measurements should not be taken directly as input values for parameter derivation but rather statistically quantified. Figure 3 shows the soil parameters over depth for the investigated CPT profile. For the design of offshore wind turbine foundations, the statistical derivation of a lower bound (LB), upper bound (UB) and best estimate (BE) of the soil parameters, defined as the 25th, 75th and the minimum between the mean and the median, respectively, is required. Therefore, a depth-dependent statistical evaluation considering a linear variation of the soil parameter within each layer is performed for every soil unit in the preliminary ground model. These percentiles are typical assumptions in offshore foundation designs for a normal distribution of the parameters. The statistical evaluation of the mean determines if a soil parameter is constant or varying in depth as can be seen in Figure 3.

4 DESIGN APPROACHES

Different approaches can be used for the design of offshore wind turbine foundations based on design phase, client or regional specifications and the foundation type. For monopiles, the lateral bearing capacity is design-driving while for jacket-pile foundations, the axial bearing capacity is more relevant.

4.1 Monopile design approaches

For monopiles, the most used approaches are based on the API RP 2GEO (2014) or the PISA rule-based methodology proposed by Byrne et al. (2020) and Burd et al. (2020).

4.1.1 Enhanced API approach

The soil interaction curves described in the API RP 2GEO (2014) and DNVGL-RP-C212 (2017) standards do not include the local distributed moment component. This component was re-introduced by the PISA working group, Byrne et al. (2020), due to its relevance in the lateral component of resistance and therefore, in the design of large diameter pile foundations. The incorporation of the soil resistance component is usually achieved by either performing Finite Element Analyses (FEA) or adopting the PISA rule-based formulations. For the preliminary design of pile foundations, however, FEA are not usually performed and the database supporting the correlations proposed by the PISA rule-based methodology is empirically verified only for three onshore sites in northern Europe. To bridge this gap in the adequacy of the correlations to other regions of the world, and avoid conservativism in preliminary designs, a simple calculation of this component can be adopted. Considering a simple geometrical assumption, the distributed moment component can be determined from the T-z curves defined in DNVGL-RP-C212 (2017). The distributed moment component is defined in Byrne et al. (2020) as shown in Equation 10.

$$m = \frac{-1}{4} \int_{0}^{2\pi} t_z D^2 \cos\phi \, d\phi \qquad (10)$$

The variable t_z represents the vertical shear stresses on the pile shaft, D the pile diameter and the angle ϕ is defined in the Figure 4. Assuming uniformly distributed vertical shear stresses on the pile shaft the distributed moment's component can be easily calculated. The rotation variable ψ can be simply determined by considering that the shear strain in each pile element to be negligible which results in $\theta = \psi$, since the ratio of shear stress to the pile's shear modulus, pile cross section and shear factor is assumed infinitesimal. Hence the rotation variable ψ can be simply defined from the z component of the T-z curves as shown in Equation 11.
Figure 4. Pile geometrical definitions, as according to Byrne et al. (2020).

$$\psi = tan^{-1}\left(\frac{2 \cdot z}{D}\right) \qquad (11)$$

4.1.2 PISA rule-based methodology

In the PISA methodology, the lateral resistance of the monopile is determined considering the lateral soil reaction (P-y), the distributed moment along the pile shaft (m- ψ), the base shear reaction (S-y) and the base moment (M_B-ψ). The soil reaction curves are determined by a normalized analytical function that is described by the ultimate resistance, ultimate displacement, curvature of the reaction function and initial stiffness. Details of the analytical function, and correlations from soil parameters described in the previous sections to obtain the normalized parameters, can be found in Burd et al. (2020) and Byrne et al. (2020). These four parameters are either taken from the rule-based sets provided in Burd et al. (2020) and Byrne et al. (2020) or, more adequately, calibrated based on advanced 3D FE models.

4.2 Jacket piles design approach

The design of the jacket piles follows the guidelines presented in API RP 2GEO (2014). For the axial bearing capacity, the shaft friction resistance (T-z) and the tip resistance (Q-w) are determined. The T-z curves describe the relationship between mobilized soil-pile shear transfer and local pile deflection at any depth while the mobilized end bearing resistance and axial tip deflection is described by the Q-w curves. The soil parameters defined using the automated procedure described allow for an advanced preliminary design of this foundation type.

5 EXAMPLE MONOPILE MODEL

The derived ground model and geotechnical parameters can be used in the different design approaches to obtain a monopile design. In Figure 5, the results obtained from laterally loading a monopile with an outer diameter of 8.4m, wall thickness of 80mm and an embedment length of 32m in the analyzed soil profile, are shown. A lever arm of 38m of the horizontal load was considered based on the wind and wave loading conditions.
Figure 5. Global monopile lateral stiffness curves - FEA, PISA rule-based, API and enhanced API.

As additional background information, the derived load-displacement curve from advanced Finite Element Analyses (FEA), undertaken in the detailed design stage, is also plotted.

The results shown corroborate the conservativism associated with the API methodology and the significant improvement seen in both the PISA rule-based approach and the enhanced API. Moreover, the simplified calculation of the distributed moment curves option falls within the expected range of lateral monopile stiffness behavior observed in the more established approaches.

6 CONCLUSIONS

An automatic procedure to derive geotechnical ground models and parameters based on the CPT data has been described. The employed soil classification charts and parameter correlations are state of the art and the most adequate per region of the world and soil type can be adopted. Finally, a simplified approach to derive the distributed moment lateral contribution from the axial resistance curves is included. An exemplary monopile design is shown and the lateral load displacement curves plotted for different design methodologies.

ABSTRACT: To reduce the harmful noise for marine life, generated during impact driving of offshore foundations, vibratory driving was presented as an alternative. Vibratory driving produces less noise and allows faster installation in sandy soil. This technique is cost-efficient for offshore pile installations and causes less pile fatigue than impact driving. One of the main issues with vibratory driving is the lack of a reliable driveability analysis. This is due to uncertainties in understanding of cyclic soil response during vibratory driving and the effect of different vibratory driving parameters on the soil response. In this study Vibratory Cone Penetration Test (VCPT) is used to assess the cyclic soil response during vibratory penetration. VCPT penetrates the soil while inducing cyclic loads and measures cone resistance. VCPTs were conducted in a calibration chamber to investigate the reduction of the cyclic cone resistance due to variation in frequency for the same penetration path. The VCPT results are discussed in terms of acceleration, energy, reduction ratio, which are considered as primary parameters in the different driveability analyses methods. The effect of cavitation during upward movement of the cone is investigated and discussed.

1 INTRODUCTION

With the increasing demand for renewable energy, there is an increased need to deploy offshore wind turbines around the world. Most wind turbines are constructed on pile foundations which are commonly installed by impact driving (Fischer et al. 2013). However, such construction activities adversely impact marine life due to underwater high-pressure noise generated during impact driving (Dahl et al. 2015). Alternative installation options such as vibratory pile driving, widely used in onshore engineering, have been gaining attention in offshore wind farm projects. This is because vibratory pile driving generates less noise in the water, causes less structural fatigue to the piles, enables fast installation in sandy soil, and allows easy pile handling (Tsouvalas 2020). It suffers from drawbacks such as, inefficiency in fine grained soil (Massarsch et al. 2017), and the lack reliable driveability model. It has also been proved that the bearing capacity of vibrated piles is less than that of impact driven ones (Holeyman and Whenham 2017); (O'Neill et al. 1990). The main issue with the current driveability models is the lack of understanding of the effect of dynamic pile driving parameters on the degradation of cyclic soil resistance.

Different methods have been developed to predict the degradation of the cyclic soil resistance by vibratory pile driving. The most prevalent ones are the β value introduced by Jonker (1987) and the acceleration-based Vibdrive model using a quasi static approach (Holeyman 1993). In the former, the degradation factors were obtained from observations of full-scale vibratory pile installation in different soil types. In the latter, the effect of dynamic pile driving parameters on the degradation of cyclic soil resistance is considered implicitly by providing an empirical liquefaction factor. Until now there is no clear understanding of the effect of different dynamic pile driving parameters on the degradation of cyclic soil resistance.

Various studies have identified different key parameters influencing the degradation of soil resistance due to vibratory driving. Acceleration, frequency, displacement amplitude, energy and soil type dependent β value have been proposed as key parameters (Barkan 1962); (Rodger and Littlejohn 1980); (Jonker 1987); (O'Neill and Vipulanandan 1989); (O'Neill et al. 1990); (Wang 1994); (Viking 2002); (Cudmani and Manthey 2019). For one vibratory driver-pile combination, all these parameters are interlinked or fixed. There is no key parameter agreed upon by the past studies that dominates the degradation of soil resistance. Until now no systematic study has been made to isolate the dynamic and quasi static effects of vibratory pile driving.

There are different suggestions explaining the degradation of cyclic soil resistance during vibratory pile driving. In the work of Dierssen (1994) a total

loss of stress between the soil and the penetrating object was observed during the upward movement of the pile. This zone of total loss of stress is called cavity and the process is called cavitation. The soil is presumed to flow in this cavity and to be disturbed during this process. This disturbance is postulated to be responsible for the degradation of the cyclic soil resistance. Acceleration is also an important parameter that affect the degradation of cyclic soil resistance. This was proven in study by Barkan (1962) where steel balls placed on a unconfined dry sand bed started to penetrate when the acceleration of the whole bed exceeded a value near to the acceleration of gravity, this process is called fluidization (Barkan 1962). Furthermore, if the excess pore water pressure generated by cyclic loading reaches the value of the total stress, liquefaction and thus total loss of shear strength occurs (Kramer 1996). Therefore, liquefaction is another possible cause for the degradation of cyclic soil resistance during vibratory penetration.

The effect of various vibratory pile driving parameters can be investigated with VCPTs. The penetration of the cone is controlled by amplitude, frequency and average penetration velocity and these parameters can be varied independently. These parameters are also directly linked to the acceleration. The soil behavior itself is linked to cavitation, cyclic stress amplitude, confining stress, number of cycles and drainage. In this study the influence of dynamic parameters was isolated from quasi static influence by performing tests with different frequencies and proportionally changed average penetration velocities, leading to identical penetration paths in the depth vs average depth plane (Figure 1, 2). A change in frequency changes the dynamic parameters like acceleration and time for drainage, while leaving quasi static parameters like deformation per cycle unchanged (Figure 1).
Figure 2. Illustration of VCPT penetration modes of 3 mm amplitude with varying frequency and average penetration velocity; depth vs. average depth plane. Orange stars represent the penetration after 4 cycles. Compare to Figure 1.

When the vibration amplitude of different penetration modes are the same and if the frequency and average penetration velocity for each of these penetration modes vary with the same factor, then they have the same penetration path in the depth vs. average depth plane. This is best seen in Figure 1 and 2, where the four stars marked in the time domain (Figure 1) fall in the same spot in the average depth domain (Figure 2). In fact all the points of the three penetration modes fall directly on each other in the average depth domain. If the soil reacts only quasi statically then, the resistance and other soil behavior would be the same for all three penetration modes. The differences among the three penetration modes are then the dynamic effects. This study systematically quantifies the influence of currently proposed key parameters on vibratory penetration.

Mini Vibratory Cone Penetration Tests (VCPT) were carried out in the Marum Calibration Chamber (MARCC). The VCPT, has a cone which penetrates the sample while applying vertical cyclic loading and measures the cone resistance. It was used for in-situ soil investigation to obtain dynamic soil parameters (Al-Sammarraie 2020). However, laboratory investigations eliminate the effect of inherent soil variability encountered during field investigations. Hence, this investigation is carried out in the MARCC to investigate the fundamental soil behavior.

2 METHODOLOGY

2.1 Properties of Cuxhaven Sand

The Cuxhaven Sand for the experiment comes from a sand pit in Altenwalde, Cuxhaven, Northern Germany. Cuxhaven Sand has similar properties as North Sea sand with cone resistances greater than 60

Figure 1. Illustration of VCPT penetration modes of 3 mm amplitude with varying frequency and average penetration velocity, depth vs. time. Orange stars represent the penetration after 4 cycles. Compare to Figure 2.

MPa in situ (Naumann et al. 2013). It is a Pleistocence glaciofluvial sand deposited in the Saalian glacial (Stähler 2020). It is uniform, well sorted, fine to medium quartz sand with less than 5% of fines (Fleischer et al. 2016). The properties of the sand is given in Table 1.

Table 1. Parameters of Cuxhaven Sand.

Property of the sand	Value
Uniformity coefficient (C_u)	3.09
Median diameter (D_{50})	0.25 mm
Minimum void ratio (e_{min})	0.48
Maximum void ratio e_{max}	0.82
Specific gravity (G_s)	2.644
Quartz content	>95%
Figure 3. MARUM Calibration Chamber (MARCC).

2.2 Calibration chamber

In MARCC, the sample is fitted inside the chamber with a sinter plate on top and a water-filled cushion at the bottom (Fleischer et al. 2016). The soil sample is laterally contained in a latex membrane with a pressure-controlled cell water around it. The pore pressure is connected to the sample through small tubes located below a geotextile at the bottom of the sample and the sinter plate on top. The axial strain is computed by the volumetric changes in the water filled cushion. The axial, cell and pore pressures are controlled using three syringe pumps. The lateral strain is obtained from three lateral circumferential displacement sensors installed around the sample at height of 0.15 m, 0.25 m, 0.35 m from the top (Figure 3). The lateral stress caused by an infinite soil medium that would be around in the field is simulated in the chamber by applying Boundary Condition 5

(BC5) (Huang and Hsu 2005). Expansion is induced during CPT penetration and the stress increase with BC5 is equivalent to the reaction of a infinite half-space of the same material. The soil stiffness for this increase is based on the polynomial function obtained in lateral compression test performed prior to penetration of the cone (Kluger et al. 2021). The soil is finally penetrated with a small cone (Table 2).

Table 2. Specification of the cone in VCPT.

Cone diameter	Sampling Rate	Sample to cone ratio
12 mm	1 kHz	25

2.2.1 Sample preparation

The sample is prepared by air pluviation with a hand-held device similar to the one described in the work of Baldi et al. (1982). The sand is pluviated at a constant falling height of 0.60 m in a sample mould. The flow rate of the pluviation is adjusted by varying the aperture size of the hand-held device. The constant drop height with the chosen flow rate led to a dense sample of Cuxhaven Sand. After pluviation of the sample, a vacuum of -50 kPa is applied through the pore pressure tubes to keep the sample stable before removing the surrounding mould.

2.2.2 Saturation

The sample is saturated by increasing the vacuum at the rate of 10 kPa/steps until nearly full vacuum of ca. -100 kPa is reached. The effective stress is held constant at ca. 50 kPa by changing cell pressure and pore pressure simultaneously. Deaired deionized water is added to the sample from the pore pressure tubing at the bottom of the sample at a constant flow rate of 500 cm^3/minute until the sample is saturated. Then the pore pressure and the cell pressure are increased again in 10 kPa steps holding the effective stress of ca. 50 kPa constant. Later, after the application of 300 kPa back pressure a saturation test is performed and all tests had degree of saturation of 95% i.e., Skempton's B value of 0.95 was achieved (D7181 2020).

2.3 Lateral compression test

The lateral compression test determines the unique stress - strain relationship for the application of BC5 during the penetration. In this test, the cell water pressure is increased until lateral strain ε_h of 0.08% is reached, while keeping the axial strain fixed and maintaining a constant pore pressure. The resulted stress-strain curve is fitted by a unique fifth order polynomial function to compute the compensating pressure for the strain in BC5 (Huang and Hsu 2005). At the end of test the lateral stress is reversed back to initial stress. The influence of lateral compression test on the cone resistance was found negligible (Stähler 2020).

2.3.1 Consolidation

The consolidation stress is is chosen to be equivalent to at depth of 10 m; therefore, the sample was anisotropically loaded to an effective vertical stress σ'_v of 100 kPa, horizontal effective stress σ'_h of 45 kPa. This corresponds to a lateral earth pressure of 0.45 (Fleischer et al. 2016). The sample was allowed to consolidate for a minimum of 90 minutes.

Table 3. VCPT with varying dynamic pile driving parameters investigated in MARCC.

Experiment	Name	Frequency (Hz)	Velocity (mm/s)	Amplitude (mm)
Push 1	V1	5	10	3
	V2	2.5	5	3
	V3	1	2	3
Push 2	V4	10	20	3
	V5	0.5	1	3
	V6	0.25	0.5	3
	V7	0.125	0.25	3
Push 3	S1	-	20	-

2.3.2 Vibro Penetration

The tests are performed at a constant amplitude of 3 mm with different frequencies and proportional varied average penetration velocities (Table 3). The total penetration depth is 0.42 m and a steady state penetration is expected between 0.18 m and 0.32 m from the top of the sample (Kluger et al. 2021). In two experiments, two VCPT Pushes were conducted. Each Push had 3-4 tests in the same penetration. Tests V1 to V4 were performed in Push 1 in the the first experiment, and tests V5 to V7 were performed in Push 2 in the second experiment (Table 3). At frequency greater than 10 Hz, the applied displacement amplitude of 3 mm was not completely achieved. Initially the cone penetrated for 0.18 m in the sample to reach steady state conditions with the same penetration mode. Then the frequency and average penetration velocity were changed approximately after every additional 50 mm. It was observed that after each driving parameter change, the steady state cyclic soil response was achieved in the first cycle. For comparison, a static CPT with BC5 is also conducted in a third experiment.

2.4 Data analysis

The maximum cone resistance of each cycle is the maximum cyclic cone resistance $q_{c,cyc,max}$. For every test, a dataset of cone resistance and displacement which consist of 50 to 80 steady state cycles are chosen. Two consecutive cycles were then overlayed 25 - 40 times with the following two consecutive cycles (Figure 4). This resulted in 25 - 40

independently measured points with the same phase for each point of two full sinusoidal cycles. The overlayed double cycles were then averaged yielding the mean cyclic cone resistance $q_{c,cyc,mean}$ and the mean displacement d (Figure 4).

2.5 Pile-soil interaction models

In order to compare the effect of dynamic parameters on the cyclic cone resistance $q_{c,cyc}$, following prediction models are evaluated.
Figure 4. Stacking of 25 double cycles of cone resistance and displacement from V1 (5 Hz). The shaded colour along the mean curves represents 25 overlayed double cycles.

2.5.1 Jonker's model

Jonker estimated the cyclic cone resistance $q_{c,cyc}$ from static q_c by using the β value. This is an empirical value estimated from the past project experiences of different soil types (Jonker 1987). For comparison with the experimental results of the current study, a β value of 0.15 is used from Jonker's recommendation as a "representative value" of a clean sand.

$$q_{c,j} = \beta q_{c,static} \qquad (1)$$

where, $q_{c,j}$ is the cyclic resistance based on β value [kPa], β is the empirical degradation value for cyclic cone resistance, static q_c is the static cone resistance [kPa]

2.5.2 Energy based model

The total energy dissipated for each penetration cycle was computed from the force - displacement curves (Cudmani and Manthey 2019) (Figure 5).
Figure 5. Energy for each cyclic cone resistance - displacement cycle of VCPT. The shaded part represents energy dissipated for each cycle in Karlsruhe model. Modified after Cudmani and Manthey (2019).
Figure 6. Static q_c vs penetration depth, $q_{c,cyc,max}$ vs penetration depth for test V1 - V7 (represented by penetrating frequency).

3 RESULTS

The maximum cyclic cone resistance $q_{c,cyc,max}$ profiles for each Push seem to be continuous even when the vibro penetration mode is changed (Figure 6). On the other hand, the vibratory penetrations as well as the static penetration are not in perfectly constant steady state conditions but undulate in a resistance range between 2 - 4 MPa. A gradual reduction in $q_{c,cyc,max}$ are observed along the bottom boundary predominantly in Push 2 (Figure 6). When

comparing the static q_c with maximum cyclic cone resistance $q_{c,cyc,max}$, there is 25 - 50% reduction in the $q_{c,cyc,max}$ for all the vibratory CPTs (Figure 6). The Jonker's model underestimates the cyclic cone resistance value $q_{c,j}$ (Figure 6).

At the steady state, the $q_{c,cyc,max}$ of the mean cyclic cone resistance value from different vibrational modes exhibited minimal changes with changing frequency (Figure 7). The energy dissipated during the penetration of each cycle was roughly proportional to the $q_{c,cyc,max}$ (Figure 7). However, the energy for tests with penetration modes of 5 and 10 Hz were low even though the $q_{c,cyc,max}$ is in comparison high.
Figure 7. Maximum cyclic cone resistance at various driving frequency, Energy calculated using (Cudmani and Manthey 2019) for various driving frequency.

The reduction of cone resistance in comparison to the static penetration is also seen when looking at the full details of the penetration cycles (Figure 8). The mean cone resistance - displacement cycle is similar to Karlsruhe model, but more roundish and not exactly reaching zero (Dierssen 1994) (Figure 5, 8). During downward motion, the cone resistance rises linearly until it reaches $q_{c,cyc,max}$. In the current study, it is observed that the magnitude of cyclic cone resistance degradation remains almost unchanged even at much lower frequencies and way longer time intervals of upward motion of cone and cavitation.

From the cone resistance - displacement cycles, the upward displacement with cavitation could be observed for all the performed VCPTs. The upward displacement with cavitation ranged from 3.9 to 4.2 mm for all VCPTs. Both in the lowest frequency of 0.125 Hz, where 8 s are needed for the cone to reverse to downward motion and in the highest frequency of 10 Hz where only 0.1 s is spent for the start of downward motion, it was observed that the upward displacement with cavitation were nearly identical (Figure 8). When comparing the first and second cycles of cone resistance - displacement curve of each
Figure 8. Mean cone resistance - displacement cycles for different vibrational modes of VCPT.

VCPT, it is clear that the cone penetrated approximately 2 mm in virgin soil in the second cycle. However, the value of $q_{c,cyc,max}$ of this cycle was still well below the static cone resistance (Figure 8).

4 DISCUSSION

The lower value of $q_{c,cyc,max}$ compared to static q_c might be attributed to cavitation as proposed by Dierssen (1994) (Figure 6). But Dierssen (1994) attributed the loss of contact from the soil mainly to the short time span for the cone to go up and to reverse for downward motion, which might indicate that the cavitation is a dynamic process. In this study however, no difference was found in the upward displacement with cavitation for 0.1 s and 8 s reversal time of the cone, therefore there seem to be no dynamic effect in the cavitation for the tested penetration modes and material. The similar values of upward displacement with cavitation might lead to approximately similar degree of remolding and loosening of the soil for all VCPTs which might be reflected in the similar reduction in the cyclic cone resistance. A relation between length of upward displacement with cavitation and reduction in the cyclic cone resistance could not be established since this length was almost constant and experiments with a lot more different penetration modes would be necessary to establish such a relation.

A classical reduction in cyclic cone resistance due to liquefaction was not expected from the beginning, because a recent field study suggested that there was no development of pore water pressure when performing vibratory CPTu (Al-Sammarraie 2020); (Wong et al. 1992); (O'Neill and Vipulanandan 1989). The non frequency i.e., time dependent reduction of $q_{c,cyc,max}$ supports the notion that liquefaction is not the main cause of cyclic cone resistance degradation

in Cuxhaven Sand, since the pore pressure would have ample time to drain at lower frequencies.

The gradual reduction in the $q_{c,cyc,max}$ for the VCPTs performed in Push 2, could be an effect of soft bottom boundary of the chamber. The influence of bottom boundary in MARCC was observed in the static CPTs (Kluger et al. 2021). However, since this gradual reduction in $q_{c,cyc,max}$ was not observed in the Push 1, the explanation of bottom boundary could be disregarded (Figure 6). The more plausible explanation for this reduction is the heterogeneity in the sand fabric and relative density that occur due to imperfect execution of the air pluviation method (Lagioia et al. 2006).

The underestimation of $q_{c,j}$ represented in Figure 6 calculated from β value is almost certainly caused by the oversimplification of the multi-variate degradation of cyclic soil resistance due to dynamic loading (Viking 2002). The proposed β values are based on data from real vibratory driver-pile combinations with amplitudes probably in the range of 6 mm, which is larger than the amplitude of 3 mm used in this study.

The proportionality between energy and $q_{c,cyc,max}$ is most likely because the general shape of the cone resistance - displacement cycle is very similar for all the VCPTs in this study. Therefore the area below the curve is proportional to the maximum value of cone resistance. If the upward displacement with cavitation would differ a lot, this proportionality would break down. The slightly lower energy dissipation at the high driving frequency, i.e., 5 Hz and 10 Hz is probably due to the inability of the system to achieve complete displacement amplitude of 3 mm (Figure 7). The dissipated energy might be an important parameter to predict the degradation of the cone resistance since both are constant and ca. proportional in this study. However,like for the cavitation, since both values are constant more data with different boundary conditions is needed to prove it. It can be concluded that the upward displacement with cavitation does not depend on frequency and average penetration velocity and that the energy is constant for same penetration path regardless of the frequency, for tested penetration modes, soil type and state.

The dynamic parameters have surprisingly little effect on the degradation of the cyclic soil resistance in this study (Figure 7), however there seem to be a complex quasi static behavior of the soil for frequencies between 0.125 and 10 Hz and corresponding maximum accelerations between 0.00185 and 11.8 m/s^2 With higher frequencies the dynamic effects will almost certainly appear, but its significance for the vibratory driving of monopiles with driving frequency of 20 Hz is unclear and would need futher experiments, for which it is planned to upgrade the MARCC system. The observed quasi static effects are probably very important for vibratory driving of big monopiles and classic liquefaction and acceleration driven fluidization may not be the only process allowing for penetration with little resistance during vibratory driving.

5 CONCLUSION

A static CPT and several VCPTs were performed in MARCC in Cuxhaven Sand to investigate the influence of dynamic pile driving parameters on cone resistance. The degradation in the cyclic cone resistance is most likely related to the soil disturbance which might be caused during the loss of contact during the upward motion of the cone tip, a process named cavitation. The dynamic pile driving parameters, acceleration and drainage time have little to no influence on degradation of the cone resistance for tested penetration modes. Jonker's β value underestimates the cyclic cone resistance for 3 mm amplitude. The energy dissipation provides a proportional estimate of cyclic cone resistance but since both parameters were constant no conclusive relation could be determined. The penetration path in the depth vs average depth plane should be used more to discern the processes leading to the degradation in the cyclic soil resistance, to finally come to reliable driveability predictions.

Application of a new q_c averaging approach for end bearing of driven piles in sand

E.J. Bittar, Y. Tian & B.M. Lehane
The University of Western Australia, Perth, Australia

ABSTRACT: CPT-based methods to estimate axial pile capacity generally relate the pile base resistance with a q_c value averaged in the vicinity of the pile tip ($q_{c,avg}$) and hence implicitly acknowledge the greater zone of influence of a full scale pile compared to a cone. To account for layered deposits (e.g. loose over dense sand), most common designs methods average the cone tip resistance over 1.5 diameters (D) above and below the cone tip or use the Dutch methodology where the averaging is conducted over a zone of $0.7D$ to $4D$ below the pile tip and $6D$ to $8D$ above the pile tip. This paper examines an alternative averaging approach based on an algorithm which allows estimation of the steady state end bearing resistance of penetrometer with the same diameter as a pile (q_p). End bearing stresses determined at a base displacement of 10% of the pile diameter ($q_{b0.1}$) in a database of instrumented static load tests on driven piles are compared with the corresponding q_p values. It is shown that the $q_{b0.1}/q_p$ ratio varies with the effective area ratio of driven piles and is independent of the pile diameter. The best-fit equation of the database of end bearing measurements provide a rational and improved means of determining end bearing of driven piles.

1 INTRODUCTION

1.1 *CPT and pile end bearing resistance*

Cone Penetration Test (CPT) data are widely used directly in the design of deep foundations. The similarities between a cone and a closed-ended displacement pile in terms of their geometry and installation mode provide the basis for direct correlations.

The steady-state penetration resistance for a 36 mm diameter cone (q_c) and that of a field scale displacement pile (q_b) can be expected to be theoretically equivalent in a homogeneous soil. However, natural soils comprise layers with different properties and thicknesses leading to a scale effect. This scale effect arises because of the greater sensing and development distances of the larger diameter pile. The steady-state end resistance profile of a pile (q_p) is therefore a 'smoothened' or filtered variant of the actual CPT q_c profile (Bittar et al., 2020a).

CPT design methods for driven piles generally assume that the base resistance at a pile base settlement of 10% of the diameter ($q_{b0.1}$) is directly proportional to the cone tip resistance q_c. The constant of proportionality (α or k_c) is less than one due to effects of partial mobilization (i.e. a settlement of 10% of the diameter, D, is not sufficient to attain steady state conditions) and due to effects of partial embedment (as the pile has not penetrated far enough to generate a steady state resistance).

The need for use of an appropriate average q_c value ($q_{c,avg}$) for estimation of pile end bearing is acknowledged in current CPT methods. Most of the CPT-based methods use the LCPC method (Bustamante & Gianeselli, 1982) where $q_{c,avg}$ is the average q_c value in the zone $1.5D$ above and below the pile tip ($q_{c,1.5D}$). However, there is a concern that the zone of influence in the LCPC method ($\pm 1.5D$ from the pile tip) is too small. Lehane (2019), for example, describes a case history where this averaging approach over-predicted the capacity of a closed-ended pile driven a distance of $2.5D$ into a sand stratum underlying a soft estuarine clay.

This paper examines an alternative q_c averaging approach based on an algorithm, devised by Boulanger & DeJong (2018), which allows estimation of the steady state end bearing resistance of a penetrometer with the same diameter as a pile (q_p). Laboratory and field experiments are described that assess the applicability of this approach. $q_{b0.1}$ values measured in a database of instrumented static load tests on driven piles are then compared with the corresponding q_p values with a view to determining a more rational means of estimating the end bearing of driven piles that allows for scale effects.

1.2 *Alternative averaging technique*

Boulanger & DeJong (2018) proposed a procedure to account for multiple thin-layer effects by considering

cone penetration as an inverse problem, assuming that the measured q_c is equal to the "true" q_c (q^t) convolved with a depth-dependent spatial filter (Yost et al., 2021). The filter is depicted in Figure 1 (where z' is the distance from the cone tip normalized by the penetrometer/pile diameter) and encapsulates experimental observations via filter parameters to represent the dependency on layers in the vicinity of the cone tip on (i) the z' value, (ii) the relative strengths (or q^t values) of adjacent layers and (iii) whether the cone is above or below a given layer (i.e. negative or positive z' value).

Bittar et al., (2020a) present experimental observations showing that the procedure can provide a reasonable estimate of the steady state end resistance of a full-scale pile (q_p) value. Further comparisons with experimental observations in the laboratory and field are presented here before examining the application of the approach for estimating the end bearing resistance of driven piles in sand.
Figure 1. Normalized cone penetration filter versus normalized depth from the cone tip with lines for $q_{tz}'/q_{tz}'=0 =$ 0.01, 0.1, 1, 10, and 100 (Boulanger & DeJong, 2018).

2 EXPERIMENTAL ASSESSMENT OF BOULANGER & DEJONG (2018)

2.1 *Laboratory penetrometer testing*

A number of penetration tests were conducted in a cylindrical 400 mm diameter, 400mm high steel pressure chamber. Full details of the test set-up and chamber are provided in Tian & Lehane (2022).

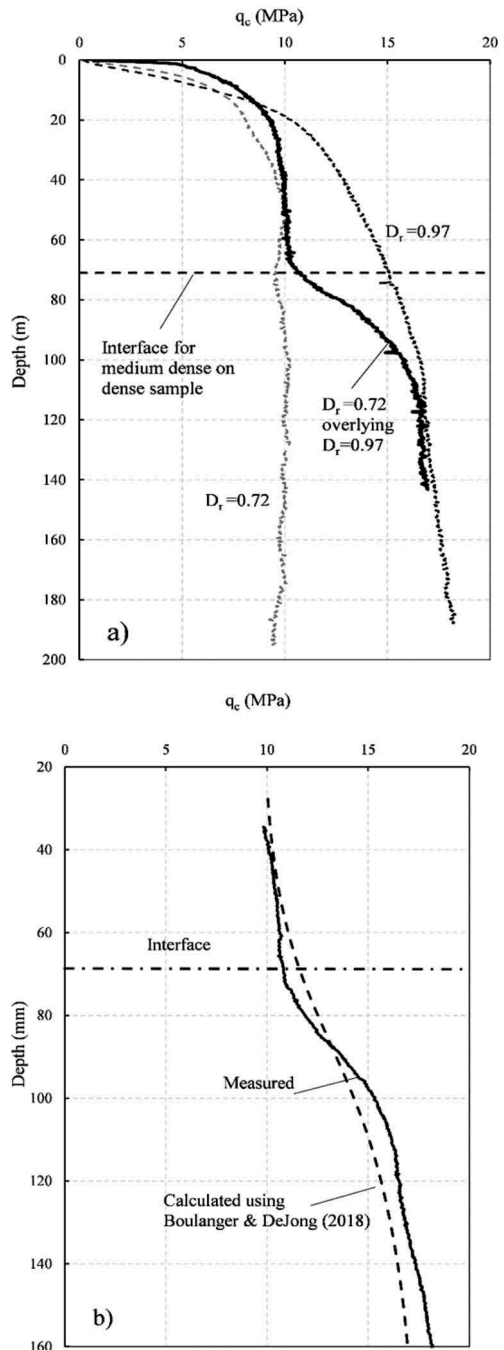
An illustration of the effects of development length and layering on the penetration resistance measured by a 7mm diameter cone is shown on Figure 2. The penetrometer resistances in the medium dense and dense sands (with respective relative densities, D_r, of 72% and 97%) attain a steady state after a penetration of about $6D$ in sand with D_r =72% and about $15D$ in that with D_r=97%; the tendency for greater development distances in denser sand has been observed by Ahmadi & Robertson,


Figure 2. (a) CPT resistance in uniform and layered profiles, (b) measured and predicted CPT resistance in sample with dense sand underlying medium dense sand. Note cone diameter =7mm and vertical effective stress=50 kPa.

(2005), Tehrani et al., (2017) and others. Figure 2a also plots the penetration resistance in a layered profile with medium dense sand overlying dense sand. It

is seen that the penetrometer senses the dense sand at a distance of about $1D$ above the interface between the two layers and then requires a penetration of about 8D before reaching the steady state resistance of the dense layer.

The calculated penetration resistance, assuming steady state q_c values of 10 MPa and 18 MPa in the medium dense and dense sand respectively is compared with the measured response on Figure 2b. These calculations were performed using the default parameters proposed by Boulanger & DeJong (2018) and lead to reasonable, although certainly not perfect, predictions.

2.2 Field scale penetrometer testing

Penetrometer tests were carried out at the University of Western Australia (UWA) Shenton Park Field Station. This site, which comprises a 6m deep deposit of Aeolian sand, has been used for a range of studies with details reported in Bittar et al. (2020b), Lehane et al. (2004), and elsewhere. The penetrometer tests plotted on Figure 3 at this site were conducted using a standard 35.7mm diameter cone and a 65mm diameter closed-ended pile. Both devices were pushed at the standard rate of 20mm/s and correction for shaft friction on the pile to allow derivation of end bearing from a head load cell was determined with a high level of confidence using results from fully

instrumented jacked piles reported by Lim & Lehane (2014).

The end resistance corresponding to the 35.7mm cone was converted to a true penetration resistance (q^t) using the Boulanger & DeJong (2018) default parameters (noting q^t is equivalent to the end resistance measured with an infinitesimally small cone). This q^t profile was then used as input to calculate the penetration resistance of the 60mm diameter pile.

The calculated and measured profiles of end resistance are plotted on Figure 3. This comparison shows that the Boulanger & DeJong (2018) calculation for the 60mm diameter pile is a reasonable approximation to the measured profile, albeit over-estimating resistance by up to 10% at around 0.8m depth. However, as seen on Figure 3, the calculated resistance is a substantial improvement on the standard approach of averaging q_c values within 1.5D of the penetrometer tip.

The comparisons made on Figures 2 and 3 provide evidence in general support of the Boulanger & DeJong (2018) algorithm for prediction of penetrometer resistance in layered sands. The value of q_p determined using this approach is equivalent to the bearing resistance of a pile with the same diameter as a penetrometer and is considered a rational means of determining an average q_c value in the vicinity of a pile tip ($q_{c,avg}$).
Figure 3. Measured and predicted resistance at the site: cone tip resistance, $q_{c,1.5D}$, Boulanger & DeJong method and 65mm pile tip resistance.

3 DATABASE ANALYSIS

The feasibility of employing q_p as a measure of the average q_c value near a pile tip ($q_{c,avg}$) for estimating $q_{b0.1}$ is examined here using databases of end bearing capacity measurements ($q_{b0.1}$) for closed and open ended driven piles. These databases, which are summarised in Tables 1 and 2, are an extension of those presented by Xu et al. (2008) and were used in the development of the 'Unified' CPT-based method for axial pile capacity calculation of driven piles in sand (Lehane et al., 2020).

3.1 Closed-ended driven piles

The Boulanger and DeJong (2018) algorithm was employed to determine q_p for each database pile using the published default values of the algorithm (as employed for Figure 2 and 3). These q_p values are assumed equivalent to $q_{c,avg}$ values where they are compared on Figure 3 with $q_{b0.1}$ values measured for the closed-ended pile database. A proportional relationship is observed for closed-ended piles, where:

$$q_{b0.1}/q_{c,avg} = q_{b0.1}/q_p = 0.5 \qquad (1)$$

The coefficient of variation for ratios of measured $q_{b0.1}$ values to those calculated using Equation (1) is

Figure 5. $Q_{b0.1}/q_p$ variation with effective area ratio for open-ended piles.

0.22. Figure 3 also compares measured $q_{b0.1}$ values with average q_c values taken equal to $q_{c,1.5D}$ Greater scatter in the proportional relationship is seen and there is a clear tendency for the $q_{b0.1}/q_{c,1.5D}$ ratio to reduce with increasing pile diameter.

3.2 Open-ended driven piles

The mode of penetration of a pipe pile can be fully plugged, partially plugged or fully coring. The degree of sand displacement near the base can be described by the final filling ratio (*FFR*), which is taken to be the average incremental filling ratio (*IFR*) over the final 3 diameters of installation. The effective area ratio of a given open-ended pile (i.e. the ratio of the displacement induced to that of a fully plugged pile) is then given as (where D_i is the internal pile diameter):

$$A_{re} = 1 - FFR(D_i/D)^2 \qquad (2)$$

When *FFR* data were not reported for the database piles, the value of the *FFR* was estimated using the following equation proposed by Lehane et al. (2020), where d_{cpt}=35.7mm

$$FFR = \tanh\left[0.3\left(D_i/d_{cpt}\right)^{0.5}\right] \qquad (3)$$

The equivalent pile diameter causing the same level of displacement is then obtained as:

$$D_{eq} = D[A_{re}]^{0.5} \qquad (4)$$

Values of $q_p=q_{c,avg}$ were calculated for each open-ended pile in the database using the Boulanger and DeJong algorithm and a pile diameter of

D_{eq}. A consistent linear increase in $q_{b0.1}/q_p$ with A_{re} is apparent on Figure 5 with an extrapolated $q_{b0.1}/q_p$ ratio at $A_{re} = 1$ corresponding to the best estimate for closed-ended piles on Figure 4. The best-fit linear fit to the database is:

$$q_{b0.1}/q_p = 0.12 + 0.38A_{re} \qquad (5a)$$

$$A_{re} = 1 \text{ for closed} - \text{ended/plugged pile} \qquad (5b)$$

This best-fit line is seen to represent all the data with good accuracy except for the case with the very low A_{re} value of 0.01 which is believed to be affected by the proximity of a low strength clay near the pile base (Randolph, 2003). Further analyses showed that Equation (5) is much better performing that an equivalent relationship using $q_{c1.5D}$ (see data points on Figure 5) and also has no bias with respect to pile diameter and relative density of the sand.

4 CONCLUSIONS

This paper demonstrates that the Boulanger & DeJong (2018) algorithm provides a reasonable means of predicting pile/penetrometer end resistance in layered stratigraphy. This algorithm is then used to deduce steady state end bearing resistances for penetrometers with the same diameter or equivalent diameter of piles. This steady state resistance (q_p) is shown to be directly proportional to the measured end bearing of a database of driven piles at a displacements of 10% of their diameter ($q_{b0.1}$). A simple equation which includes an effective area ratio term as well as q_p is proposed (Equation 5) and is considered to provide a more rational and reliable means of assessing pile base resistance in sand.

ABSTRACT: Screw piles are widely used in onshore engineering applications and have recently been considered as an alternative foundation solution for offshore wind turbines (OWTs) supported on jacket structures. The high loads required to support such structures demand a considerable up-scaling of the screw pile geometry typically used onshore. Driven piles followed a similar upscaling process for their use in offshore structures and the CPT tip resistance (q_c) value is now commonly used directly in design methods for both onshore and offshore driven piles. This paper evaluates the performance of a new CPT-based design method (UWA-SP -21) to predict the axial capacity of screw piles in tension and compression. To achieve this, a database of single helix load tested screw piles sand is collated and used for assessment of the method. The development of this CPT design approach reflects the process that was following for driven piles. UWA-SP21 has been developed through studies of onshore piles. The findings from this study can in the future be extrapolated appropriately to the larger pile sizes required offshore, in the same way that driven pile design has evolved.

1 INTRODUCTION

Screw (or helical) piles have been increasingly used to support a variety of structures such as pipelines, transmission towers, bridges and commercial buildings. Screw piles are steel tubes with one or more helical elements fabricated on the shaft that are screwed into the ground through the application of torque and thrust (vertical force) (Richards et al. 2019). This pile configuration increases the axial base resistance, allows a rapid, quiet and low-vibration installation, and enables reusability. These advantages have increased interest in their use as an alternative foundation solution for offshore wind turbines (OWTs) supported on jacket structures. However, given the much larger scale required to meet the axial load requirements of OWTs compared to current onshore applications, concerns have been raised regarding the large installation torque necessary for their installation (Sharif et al., 2020; Bittar et al., 2021).

The total axial resistance of a single helix pile, Q_{ult}, is usually considered as a combination of the helix bearing resistance (Q_h) and shaft resistance developed along the pile shaft (Q_s). In tension, two failure mechanisms are commonly assessed depending on the helix embedded depth (H) or embedment ratio (H/D_h), where H is the helix embedded depth and D_h the helix diameter. These failure mechanisms are known as the 'shallow' failure (cylindrical, conical, circular) and the 'deep' failure. The compression capacity is dominated by a localized 'deep' failure mechanism of the helix.

The axial capacity of screw piles is often estimated using conventional bearing capacity theory or 'semi-empirical methods' derived from anchor test results from the laboratory or the field (Mitsch & Clemence, 1985). These so-called 'theoretical methods' are limited as they require estimation of appropriate soil strength parameters and the capacity estimates are very sensitive to the adopted strength parameters. In situ test data are rarely used directly in the assessment of axial capacity (Fateh et al. 2017).

In practice, an estimate of the screw pile capacity is obtained during construction via an empirical relationship with the torque measured at the end of installation. Tsuha & Aoki (2010), Spagnoli et al. (2020), and others, assume that the torsional resistance measured during installation is related directly to a pile's axial capacity. This is because the normal forces generated on the helix that lead to its frictional and hence torque resistance are a measure of the axial resistance associated with a localized failure. The torsional resistance is also needed as a check to assess if the helix has sufficient structural strength under the application of axial load (Spagnoli & Gavin 2015).

The prediction of the installation torque for typical onshore piles is often based on one of three methods (Davidson et al. 2020), namely (i) correlation of field measured torque with anticipated or measured pile capacity (Hoyt & Clemence, 1989;

Perko, 2009); (ii) modification of empirical pile capacity design methods (Ghaly & Hanna 1991; Tsuha & Aoki, 2010; Sakr, 2015) and (iii) direct correlation with the cone penetration test (CPT) end resistance (Gavin et al. 2013; Spagnoli et al. 2016; Al-Baghdadi et al. 2017; Davidson et al. 2018a).

Although CPT-based capacity design methods for screw piles have received little attention until recently, such methods are now commonly used in the design of driven offshore piles in sand. The 22nd edition of the American Petroleum Institute (API) recommendations presents driven pile design methods, including the conventional (API) approach and four CPT-based methods. Lehane et al. (2005) performed an assessment of the reliability of the CPT methods and noted considerable improvement in their predictive performance compared with the traditional API main text approach. The commentary of the API design guidelines states that CPT methods are "fundamentally better and show statistically closer predictions of pile load test results" than the API main text approach and are preferred to the main text approach (Igoe et al. 2014).

Given the experience with offshore driven piles and the potential use of screw piles offshore, it is surprising that studies on the use of CPT q_c to design screw piles were rare until the recent studies listed above. Bittar et al. (2022) recently presented the development of one such CPT approach (UWA-SP-21) for prediction of screw pile axial capacity and the torque required for installation. This paper examines the performance of UWA-SP-21 against a database of full scale field tests involving various single-helix screw pile geometries in a range of different sands.

2 CPT METHOD FORMULATIONS FOR AXIAL CAPACITY

Informed by tests on instrumented screw piles, Bittar et al. (2022) proposed a direct application using empirical factors (β_c and α_h) applied to the CPT end resistance (q_c) for the estimation of axial capacity at a displacement of 10% of the pile diameter (Q_{ult}). The proposed formulation for ultimate capacity is:

$$Q_{ult} = {}_1^n \Sigma Q_{hi} + Q_s \qquad (1a)$$

$$Q_{hi} = \alpha_{hi} q_{ci} \pi D_h^2 / 4 \qquad (1b)$$

$$Q_s = (\pi d_s L_s) q_{c,avg} / \beta_c \qquad (1c)$$

where Q_{hi} is the axial capacity of a single helix (i) separated by more than three helix diameters (D_h) from an adjacent helix, Q_s is the axial capacity of the pile shaft, d_s is the diameter of the pile shaft, L_s is the length of the pile shaft, q_{ci} is the cone resistance at the level of the helix, $q_{c,avg}$ is average cone resistance along the pile shaft.

The method assumes that a deep localized failure mechanism applies (i.e. Figure 1b), which is expected for $H/D_h > 3$, and draws on parallel methods for the similar situation of non-displacement piles. Recommended empirical factors for α_{hi} are 0.2 for compression and 0.15 for tension. These factors are closely comparable to factors observed for footings and at the base of bored piles at a displacement of 10% of the foundation diameter (e.g. Lehane 2012) and emerge, as discussed by Lehane (2019), because of the local hemispherical expansion type mechanism of footings at this level of displacement and the proportional relationship between q_c and cavity expansion limit pressure. For evaluation of shaft capacity (Q_s), Bittar et al. (2022) proposed a β_c value of 230, which is close to the β_c value proposed for non-displacement piles by Doan & Lehane (2021). The contribution of Q_s to Q_{ult} is relatively small.

It is of interest to compare equation (1) with other formulations. For example, Gavin, et al., (2013) proposed a similar relationship but employ an α_{hi} factor of 0.065 and assume that the unit shaft friction of the shaft helix is 60% of the CPT friction sleeve value. This method was adopted by Spagnoli (2017) to evaluate torque predictions and it has to be noted that it was developed for uplift capacity only.

Perko (2009) and Tappeden (2004) amongst others use of the LCPC-1982 (LCPC) method proposed by Bustamante and Gianeselli (1982) for the calculation of screw pile capacity. It should be noted, however, that this method was established for predicting the axial capacity of conventional piles, and the applicability of the method to screw piles is questionable.

The predictive ability of the Gavin et al. (2013) and LCPC-1982 methods is examined along with that of UWA-SP-21 (i.e. Equation 1) in the following.

3 INSTALLATION TORQUE PREDICTION

The determination of Q_{ult} for helical piles in industry is typically based on an empirical relationship with torque via a dimensional torque factor, K_t (Li & Deng 2019). Hoyt & Clemence (1989) assume a direct proportional relationship between Q_{ult} and T as:

$$Q_{ult}(kN) = K_t(m^{-1}) \times T(kNm) \qquad (2)$$

However, the dimensionality of the K_t factor means that the value is likely to change as piles are upscaled from onshore to offshore applications. The same authors propose a formulation for K_t that depends on the pile shaft diameter, d_s. Perko (2009) proposed the following equation which relates K_t with the shaft diameter of screw piles (d_s):

$$K_t\left(m^{-1}\right) = \frac{2.49}{\left[d_s(m)\right]^{0.92}} \qquad (3)$$

Perko (2009) collected data of Q_{ult} and T for single helix screw piles data and correlated these by a linear regression (Figure 1) – which is a minor simplification of Equation 3, altering the power applied to d_s to unity. The data were from tests performed on piles with helix diameters up to 350 mm (for which $K_t \geq 6.54$, Eqn 3) and lengths up to 8 m (Spagnoli 2017). However, the torque measurements in most of this database were less than 30 kNm and the Q_{ult} vs T relationship is highly scattered in this region. As a consequence, Spagnoli (2017) suggests no unique Q_t - T correlation exist.
Figure 1. Torque vs. uplift capacity for previously-published case studies of single-helix piles (modified from Perko 2009).

4 DATABASE OF LOAD TESTS ON SCREW PILES IN SAND

A database of static load tests on screw piles was compiled by the authors. This database comprises 18 pile tests with 7 tests in tension and 11 in compression; the shafts of all piles were open ended. Many of the cases were derived from tests performed by Screw Pile Australia Pty Ltd while others were sourced from the literature. All the piles included in the database contain CPT results in the vicinity of the test piles.

All CPT data were digitized at depth intervals of 0.1 m. Pile capacity was defined as the load at a pile head displacement of 10% of the helix diameter ($0.1D_h$). The buoyant weight of piles tested in tension was deducted from the maximum head load to determine the tension capacity. The documented cases provided by Screw Pile Australia included piles that were typically loaded to a displacement of about 5% of D_h. The measured load displacement curves were therefore extrapolated using Chin's method (Chin 1970) to determine the ultimate capacity, defined at $0.1D_h$

(which was typically 15 to 20% higher than the measured load at a displacement of $0.05D_h$.

It is noteworthy that existing guidance on the installation of screw piles suggests that installation should be performed in a pitch-matched manner (Perko 2009) i.e. one full rotation to advance the helix by a depth equal to the helix pitch (p). No specific information regarding the advancement ratio of the database piles is available although it is expected that the ratio is somewhat less than unity as operators often allow the auger to pull itself into the ground without the assistance of additional axial thrust. Characteristics of the screw pile database are provided in Table 1.

5 METHOD PREDICTIVE PERFORMANCE

The ratio of capacities calculated using UWA-SP-21 to measured capacities (Q_m/Q_c) was evaluated and the predictive performance was expressed in terms of the mean (μ) and coefficient of variation (CoV) of the Q_m/Q_c ratios. For comparison purposes, the same approach was adopted to evaluate the CPT-method suggested by Gavin et al. (2013) and the LCPC approach mentioned previously. Measured and calculated capacities and the associated statistics are provided in Tables 2 and 3. It is observed that:

- The UWA-SP-21 method (Bittar et al. 2022) provides the lowest CoV and an average value close to unity both in compression and in tension.
- The LCPC method significantly over-predicts the capacity of screw piles in compression (μ=0.42) and tension (μ=0.38). This arises as the multiple on q_c in the LCPC method varies 0.3 and 0.5 while the corresponding multiple UWA-SP-21 is between 0.15 and 0.2.
- The high average value of the Gavin et al. (2013) approach (μ=1.37) indicates that the method underpredicts the uplift capacity of screw piles. The CoV of Q_m/Q_c for this method is also significantly higher than that of UWA-SP-21.

UWA-SP-21 is evidently the best performing method with an excellent CoV value for Q_m/Q_c of only about 10%. The method does, however, overpredict the capacity of the database piles on average by 8% in tension and 10% in compression.

6 TORQUE PREDICTION ASSESSMENT

Table 4 lists the torques measured at the end of installation of the database piles (T_m). These were measured using a pressure gauge on a hydraulic system. The accuracy of this gauge is dependent on the rotational speed applied and the hydraulic differential pressure across the gear motor. An accuracy of ±20% is expected using this system. It is important for operators to know in advance what magnitude of torque is required to give confidence that the installed pile will

develop a certain axial capacity. It is therefore of nterest to assess if there is a relationship between end of installation torque and axial capacity (as described in equations 2 and 3) and, furthermore, if the UWA-SP-21 method can allow a reasonable estimation of final installation torque using Equation (3).

The relevant data for this assessment are provided in Table 4 where the final installation torques are calculated using Equation (3) either (i) from the measured load test capacity, $Q_{ult,m}$ or (ii) from the ultimate capacity calculated using UWA-SP-21, $Q_{ult,c}$.

The average ratio of measured to calculated torque was 1.06 when applying Equation (3) to the measured tension capacity and was 1.03 when applying the same equation to the tension capacity calculated using UWA-SP-21. The coefficient of variation of measured to calculated torque using both approaches was about 22%, which supports the validity of a direct relationship between capacity and torque as proposed by Perko (Equation 3) - at least for the range of screw pile geometries covered by the database.

Figure 2 compares the measured uplift capacities with the final measured installation torque from the piles in the database (Table 1 and 4). The regression analysis shows great consistency when compared with the results found by Perko (2009) in Figure 1.
Figure 2. Measured torque vs. uplift capacity for single-helix piles in the presented database.

7 CONCLUSIONS

A database comprising 18 static load tests on single helix screw piles is presented. These piles had helix diameters ranging from 0.3m to 0.6m and lengths between 2.5m and 8m. It is demonstrated that the UWA-SP-21 CPT method (Bittar et al. 2022) provided pre-dictions of the axial compression and tension capacity of these piles that were generally within about 12% of the measured capacities.

Table 4. Measured and calculated final installation torque for each pile in the database.

					Avg	**1.06**	**1.03**
					CoV	**0.21**	**0.22**

T_m = measured torque; T_c = calculated torque using Equation 3, Perko (2009)
T_c from $Q_{t,m}$ = torque calculated from the measured $Q_{ult,m}$
T_c from $Q_{ult,c}$ = torque calculated from $Q_{ult,c}$, the capacity calculated via Bittar et. al. (2022), see Equations 1-2.

This promising predictive performance is a substantial improvement on existing approaches and arises from the simple relationship between spread footing bearing stress and CPT q_c at a displacement ratio of 10%. A combination of this method and the relationship between final installation torque and tension capacity proposed by Perko (2009) enables assessment of the torque required for installation of single helix piles to an accuracy of about 25%.

This method has the potential for scaling up to the dimensions of offshore piles, following the same research direction that has led to CPT-based methods now being favoured for predicting the capacity of driven tubular piles. This research will support the adoption of screw piles as an alternative foundation solution for offshore wind turbine jacket structures.

CPT-based liquefaction ejecta evaluation procedure

Jonathan D. Bray & Daniel Hutabarat
University of California, Berkeley

ABSTRACT: A CPT-based procedure to estimate the severity of liquefaction ejecta is presented. It employs a liquefaction ejecta demand parameter (L_D) that captures the amount of upward seepage pressure that can produce artesian flow due to elevated excess hydraulic head and a crust layer resistance parameter (C_R) that captures the strength and thickness of the nonliquefiable crust layer. L_D tends to increase systematically as ejecta severity increases at the thick, clean sand sites, and low L_D values are estimated at stratified soil sites that did not produce ejecta. C_R captures the differing performances of sites with and without a competent crust layer overlying a thick liquefiable layer with a high L_D value. The proposed $L_D - C_R$ liquefaction ejecta severity chart separates cases with severe or extreme ejecta, which have high L_D and low C_R values, from cases with minor or no ejecta, which have low L_D and high C_R values.

1 INTRODUCTION

Ejecta-induced ground failure contributed nearly 90% of the liquefaction land damage in the residential area of Christchurch, New Zealand during the 2010-2011 Canterbury earthquake sequence (van Ballegooy et al. 2014). The severity of land damage increased as more liquefied sediment was ejected. Ground-failure indices, such as Liquefaction Potential Index (LPI, Iwasaki et al. 1978) and Liquefaction Severity Number (LSN, van Ballegooy et al. 2014), often overestimated the severity of sediment ejecta produced at level-ground stratified silty soil sites in Christchurch (e.g., Maurer et al. 2014).

Hutabarat and Bray (2021a,b) performed nonlinear dynamic effective stress analysis (ESA) to find that the location of liquefaction triggering, soil layer stratification, and vertical hydraulic conductivity (k_v) profile govern the post-shaking ejecta mechanism and system response of sites that contain liquefiable layers that either produce sediment ejecta or not. The insights obtained from performing ESA are noteworthy; however, it may be infeasible to perform ESA for projects when subsurface data are limited. Cone penetration test (CPT)-based simplified procedures for evaluating liquefaction triggering have proved reliable for evaluating liquefaction triggering. A CPT-based procedure for estimating the severity of ejecta-induced ground failure for level-ground conditions is presented in this paper. The procedure quantifies two governing factors: liquefaction ejecta demand (L_D) and crust layer resistance (C_R). The L_D parameter considers the excess hydraulic head (h_{exc}) and artesian water pressure that can develop at a site, and the C_R parameter considers the thickness of the nonliquefiable crust layer and its

equivalent shear strength which suppress manifestations of liquefaction. These parameters are used to estimate the amount of ejecta likely to occur.

2 LIQUEFACTION EJECTA SEVERITY

LPI estimates the severity of liquefaction ground damage using a linear depth-weighted integration of the factor of safety against liquefaction (FS_L) to a depth of 20 m as

$$LPI = \int_0^{20\ m} F(FS_L)\ (10 - 0.5z)\ dz \qquad (1)$$

where $F(FS_L) = 1 - FS_L$ for $FS_L < 1.0$; $F(FS_L) = 0$ for $FS_L \geq 1.0$, and z is the depth below ground surface (m). LPI ranges from 0 to 100, where a higher value indicates more severe liquefaction-induced ground failure. LPI's performance has been evaluated extensively (e.g., Maurer et al. 2014). LSN estimates the severity of liquefaction ground damage as

$$LSN = 1000 \int \frac{\varepsilon_v}{z} dz \qquad (2)$$

where z = depth > 0 and ε_v = post-liquefaction volumetric strain estimated using Zhang et al. (2002). LSN utilizes a power-law depth-weighting function to emphasize the relative importance of shallow liquefied layers to cause severe ground failure. Additionally, Towhata et al. (2016) developed a liquefaction severity chart by comparing the LPI

values and thickness of the crust (H_1) values for cases with and without liquefaction-induced damage. Like Ishihara (1985), Towhata et al. (2016) compare liquefaction demand and crust resistance, but instead of using the thickness of the liquefiable layer (H_2), they use LPI to represent liquefaction demand.

The poor performance of these liquefaction indices in stratified silty soil sites in Christchurch is affected primarily by the limitations of simplified liquefaction triggering procedures in capturing their response (e.g., Beyzaei et al. 2018 and Cubrinovski et al. 2019). Sediment ejecta is a post-shaking hydraulic phenomenon resulting from the migration and redistribution of excess-pore-water-pressure (u_e) generated during earthquake shaking. The dissipation process of residual u_e can trigger high-gradient upward seepage that induces hydraulic fracturing in the upper crust layer. With a sufficiently high hydraulic gradient, artesian flow can be produced that exploits cracks in the crust layer to eject liquefied sediment onto the ground surface. Ejecta production is governed largely by the post-shaking upward seepage developed in the soil profile (Hutabarat and Bray 2021a,b). The amount of excess hydraulic head ($h_{exc} = u_e / \gamma_w$, where γ_w is the unit weight of water), soil's hydraulic conductivity (k_v), and the degree of soil layer stratification are key factors that largely determine the hydraulic gradient (i) and volume of upward seepage in the liquefiable layer.

ESA results indicate the h_{exc} developed at shallow depths in sites without sediment ejecta remains low during and after shaking. Low-k_v layers within a highly stratified deposit impede upward seepage so the generated h_{exc} is insufficient to produce artesian flow. Although liquefaction is triggered in isolated layers of loose sand at deeper depths, upward seepage is impeded by an overlying low-k_v layer. Liquefaction triggering in a deeper layer can also reduce the seismic demand so that liquefaction is not triggered at shallow depths. Conversely, Hutabarat and Bray (2021a,b) showed that ejecta amount largely depends on the thickness of the liquefiable high-k_v soil layer and homogeneity of the k_v-profile at sites with significant ejecta. The simulations indicated the high-hydraulic gradient upward seepage that flows within a thick, continuous, high-k_v deposit can trigger post-shaking secondary liquefaction within the sand layer directly beneath the crust. A thick, continuous, and high-k_v sand site requires more time to return to its initial hydrostatic state; thus, it can produce more ejecta. Partially stratified sites with thin and less permeable sand layers produce less upward seepage which in turn produces no or minor-to-moderate ejecta (Hutabarat and Bray 2021b).

3 CHRISTCHURCH LIQUEFACTION CASE HISTORIES

Researchers from the Univ. of Canterbury, Univ. of California at Berkeley, Univ. of Texas at Austin, and Tonkin+Taylor investigated liquefiable sites in Christchurch with underestimations or overestimations (e.g., Cubrinovski et al. 2019). Of these sites, 44 well-investigated free-field level-ground sites were selected to represent various soil profiles, ground shaking intensities, and observed ejecta amounts. Their performance during the four Canterbury earthquakes: 2010 M_w7.1 Darfield, 2011 M_w 6.2 February, 2011 M_w6.0 June, and 2011 M_w 5.9 December events were considered. The 44 sites were classified as either thick, clean sand sites or partially-to-highly stratified silty soil sites to evaluate the effect of this attribute. Details of the sites are described in Hutabarat and Bray (2021b).

Figure 1 shows representative thick sand sites and stratified silty soil sites. The Robertson (2016) modified soil behavior type index (I_B) zones are used to classify the sand-like ($I_B > 32$), intermediate ($22 < I_B < 32$), and clay-like ($I_B < 22$) soil responses of the layers. Thick sand sites (Figure 1a-b) contain at least 4.5 m thick of continuous sand-like and high-k_v soils within the depth of the groundwater level (GWL) to 15 m. Stratified soil sites (Figure 1c-d) contain partially-to-highly stratified deposits of sand, intermediate, and clay soil layers where there is no continuous sand layer thicker than 4.5 m within the GWL to 15 m depth. The parameter z_{AB} highlighted in the figures is the thickness of the sand-like soil layer that may contribute to ejecta production if liquefaction is triggered measured from the top depth of z_A to the bottom depth of z_B. The parameter z_{AB} is measured from directly below the nonliquefiable crust layer to the bottom of the first continuous sand-like soil layer.

CPT-based liquefaction triggering back-analyses of all cases were performed using the Boulanger and Idriss (2016) "BI-16" procedure. The analyses considering LPI and LSN used the probability of liquefaction (P_L) of 15% to be consistent with their criteria. The liquefaction triggering calculations were performed using the median peak ground acceleration (PGA) values and a fines-content correction (C_{FC}) factor of 0.13 for Christchurch soil (Hutabarat and Bray 2022). The GWL for each site was estimated based on nearby well records and V_p measurements. Only the FS_L of soil with the Robertson (2009) SBT Index (I_c) < 2.60 is computed to calculate LPI and LSN for each case using Eqs. 1 and 2.

The distributions of LPI and LSN for each case within the two site groups categorized by ejecta severity are presented in Figure 2 with box-and-whisker plots (Tukey 1977) to evaluate their performance in estimating ejecta amounts at thick sand sites and partially-to-highly stratified soil sites. The box height represents the range of the first (Q_1) to third (Q_3) quartile of the distribution and the horizontal orange line in the box is the median value. The whiskers extend 1.5 times the interquartile range (IQR = Q_3 -Q_1) and data points beyond the whiskers are outliners. LPI and LSN show a flat trend of increasing ejecta amounts with increasing median values for thick sand sites (Figure 2a). There is an overlap in the
Figure 1. Examples of thick sand (a-b) and stratified soil (c-d) profiles of q_{c1Ncs}, I_B, and observed ejecta severity (given below site name in the sequence of the DAR, CHC, JUN, and DEC earthquakes where N = None; Mi = Minor; Mo = Moderate; S = Severe; E = Extreme).
Figure 2. Box-and-whisker plots of liquefaction ejecta demand parameters grouped based on observed ejecta severity for: (a) 96 case histories with thick sand deposits and (b) 80 case histories with stratified deposits.

boxes representing the middle 50% of their distributions. There are numerous No ejecta cases above the top whisker with values higher than the Minor and Moderate top whisker. Also, LPI and LSN are not reliable for highly stratified soil sites as shown in Figure 2b. Several stratified sites have high index values but did not produce ejecta. Similar results are obtained if the input parameters are varied. The performance of the new liquefaction demand parameter (L_D) shown in Figure 2 is discussed next.

4 LIQUEFACTION DEMAND PARAMETER

Figure 3 illustrates the conceptual framework employed in the CPT-based procedure to estimate

ejecta severity. Ejecta results from high-gradient upward seepage developed in hydraulically continuous liquefied soil layers beneath the crust. For highly stratified sites, the liquefiable soil layer directly beneath the crust does not develop sufficiently high-gradient upward seepage, either because liquefaction is not triggered from reduced seismic demand due to liquefaction at depth or an underlying low-k_v soil layer impedes the upward water flow during the advection process. The intensity of the seepage is higher if a thicker liquefied layer develops h_{exc} higher than the critical head to produce artesian flow and it is composed of a high-k_v soil (Hutabarat and Bray 2021b).
Figure 3. (a) Sediment ejecta mechanisms in a typical thick sand site and (b) Artesian Flow Potential concept.

During shaking, the elevated u_e increases the total hydraulic head. Tokimatsu and Yoshimi (1983) proposed this relationship to estimate the pore pressure ratio (r_u) as the function of FS_L:

$$r_u = 0.5 + \frac{\sin^{-1}\left(2\ FS_L^{\left[\frac{1}{\alpha\beta}\right]} - 1\right)}{\pi}\ ; \text{for } 1.0 \leq FS_L < 3.0 \tag{3}$$

where they proposed to use α = 1.0. The β parameter is set to -0.2, which gives $1/(\alpha\ \beta)$ = -5.0. The inverse sine term must be calculated in radians, and r_u = 1.0 for FS_L = 1.0. The FS_L in Eq. 3 is computed using the BI-16 liquefaction triggering procedure. Once r_u is computed, the h_{exc} at each depth is estimated using

$$h_{exc} = \frac{r_u \sigma'_{vo}}{\gamma_w} \tag{4}$$

where σ'_{vo} = initial effective vertical stress and γ_w = unit weight of water (9.81 kN/m³).

Liquefaction ejecta demand from upward seepage is estimated by the head difference between a specified depth and the ground surface. A thicker H_1 creates a longer travel path for water to flow, which reduces the seepage gradient and thus increases the resistance parameter. Additionally, a stronger crust provides more resistance against ejecta being produced than a weak crust.

To produce ejecta, the h_{exc} in liquefied layer must exceed a critical value h_A which is the required h_{exc} at a depth z to produce artesian flow above the ground surface to exploit cracks in the crust layer and produce a flow that transports the liquefied soil to the ground surface. The Artesian Flow Potential (AFP) concept of Hutabarat and Bray (2021a) assumes the h_A value required to cause artesian flow at a depth z is equal to z which is represented by the h_A line with slope 1H:1V down from the ground surface. AFP equals the red area in Figure 3b between the profile of h_{exc} and the h_A line when $h_{exc} > h_A$. More ejecta are produced at sites with higher AFP values that remain high after shaking.

A soil layer's k_v directly influences the upward flow of water in a soil column that can induce post-shaking secondary liquefaction at shallow depths. The water flowing upward from a deep liquefied layer can increase the h_{exc} in a shallow layer if the intermediate soil layers have high k_v values. Conversely, a low-k_v intermediate depth soil layer with sufficient thickness can restrict the upward flow of water from deep liquefiable layers. To capture this effect a normalized-k_v weighting factor is employed where a low permeability layer lowers ejecta potential and a high permeability layer increases ejecta potential. The Robertson and Cabal (2015) CPT correlation is adopted to estimate k_v using CPT data:

$$k_v(\text{m/s}) = 10^{(0.952 - 3.04 I_c)}; \text{ when } 1.0 < I_c < 3.27 \quad (5)$$

A normalized k_v factor is used as the weighting function where the k_v value of clean sand calculated for $I_c = 1.8$ is selected as the baseline hydraulic conductivity. Nearly all Moderate, Severe, and Extreme ejecta cases investigated in this study contain a thick deposit of clean sand with $I_c \leq 1.8$. Soil layers where h_{exc} exceeds h_A with low I_c values and thus high k_v values are multiplied by factors greater than one, and soil layers with high I_c values and thus low k_v values are multiplied by factors less than one.

The liquefaction ejecta demand parameter (L_D) is estimated as

$$L_D(\text{kN/m}) = \gamma_w \int_{z_A}^{z_B} \frac{k_v}{k_{cs}} (h_{exc} - h_A) dz \begin{cases} \text{when } h_{exc} \geq h_A \\ 0, \text{ otherwise} \end{cases} \quad (6)$$

where z_A = depth from the ground surface to the top of the shallowest soil layer below the GWL with $I_c <$

2.6 that is at least 250-mm thick; z_B = depth from the ground surface to the top of the shallowest soil layer between the depths of z_A and 15 m with $I_c \geq 2.6$ that is at least 250-mm thick. The depth z_B will be 15 m if there is no soil layer (at least 250-mm thick) with $I_c \geq 2.6$ below z_A. L_D is calculated in these steps:

1. Estimate z_A, and z_B based on the I_c profile.
2. Compute FS_L at each depth.
3. Compute r_u at each depth interval using Eq. 3.
4. Compute h_{exc} at each depth using Eq. 4.
5. Compute normalized-k_v weighting factor (k_v/k_{cs}) at each depth using Eq. 5 to calculate k_v.
6. Compute L_D using Eq. 6 where h_A is defined by the 1V:1H line shown in Figure 3b.

Figure 2 shows the distribution of the computed L_D value for each case history with its observed severity of ejecta. The results indicate:

- L_D has a lower variation than LSN and LPI as reflected by its shorter box-and-whisker box for the No ejecta cases shown in Figure 2a for the thick sand sites. Also, 87% of these cases have $L_D < 5$.
- There is some overlap of the L_D boxes of the Minor and Moderate cases shown in Figure 2a, but the median values of L_D increase systematically as the severity of ejecta increases. Some Minor-to-Moderate cases have $L_D < 5$, which overlaps with the None cases, which is likely due to the bias in the liquefaction triggering calculation.
- The Minor and Moderate L_D boxes do not overlap the Severe L_D box, and the Severe L_D box does not overlap the Extreme L_D box. More than 75% of the Severe ejecta cases have $L_D > 15$.
- L_D resolves the overestimation problem of the other liquefaction ground damage indices for the highly stratified sites (Figure 2b). The range of the None cases is smaller than the Minor and Moderate cases. The use of z_{AB} which considers the impedance of upward seepage by a low-k_v profile is primarily responsible for this improvement.

5 CRUST RESISTANCE PARAMETER

The crust layer resistance parameter (C_R) captures the strength and thickness of the nonliquefiable crust layer. It captures the differing performances of sites with and without a competent crust layer overlying a thick liquefiable layer with a high L_D value. The crust resistance parameter (C_R) is estimated as

$$C_R(\text{kN/m}) = \int_{0\,m}^{H_1} s_u \, dz \begin{cases} s_u = K_o \, \sigma'_{vo} \tan(\phi_{cs}), & \text{if } I_B > 22 \\ s_u = \frac{(q_t - \sigma_{vo})}{N_{kt}}, & \text{if } I_B \leq 22 \end{cases}$$

$$(7)$$

where H_I (m) = thickness of the layer above z_A until the ground surface; s_u (kN/m^2) = shear strength of the crust layers estimated using the CPT data; K_o = coefficient of lateral pressure, which is assumed to be 0.5; ϕ_{cs} is the critical state friction angle which is assumed to be 33 degrees; and N_{kt} = 15 in the tip resistance (q_t) correlation used for clay. A soil with $I_B > 22$ will have a lower $s_{u\text{-}eq}$ than a crust layer composed of clay defined by $I_B < 22$, because the vertical effective stress is low at shallow depth. Thus, s_u represents the strength (and integrity) of the crust.

6 EJECTA SEVERITY EVALUATION PROCEDURE

The Christchurch case history data are plotted on the L_D-C_R charts shown in Figure 4 with zones for classifying ejecta severity potential. The horizontal boundary line for each zone is determined qualitatively using the Q_I-Q_3 ranges of the box-and-whisker plot shown in Figure 2. The boundaries of the ejecta zones were adjusted for larger C_R values to bring in its effect. The classification boundaries were selected qualitatively to separate data to minimize bias and misclassifications. The bilinear boundary lines shown in Figure 4 are defined by three [C_R, L_D] data points that separate adjacent zones as:

- None-to-Minor: [0, 2.5] [100, 2.5] & [250, 25]
- Minor-to-Moderate: [0, 6] [90, 6] & [250, 70]
- Moderate-to-Severe: [0, 15] [85, 15] & [250, 150]
- Severe-to-Extreme: [0,85] [75, 85] & [200, 250]

Examination of the data plotted on the Liquefaction Severity Charts shown in Figure 4 indicates:

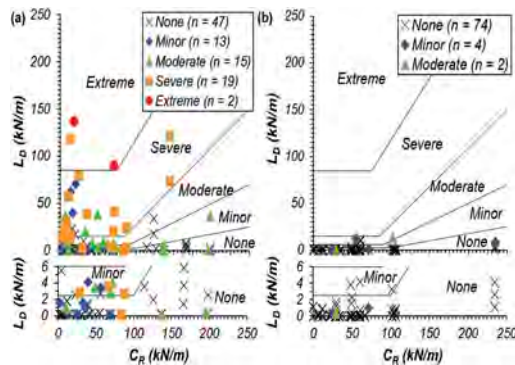
- The 2 Extreme ejecta cases with $L_D > 85$ and C_R < 75 are located at the top left part of the chart in the Extreme zone.


Figure 4. Ejecta severity using Liquefaction Demand (L_D) and Crust Resistance (C_R) parameters at: (a) thick sand sites and (b) stratified soil sites. The inserts show data for $L_D < 6$ kN/m.

- The Severe ejecta cases generally have lower L_D values and higher C_R values than the Extreme cases. C_R helps distinguish the severity of ejecta by shifting a data point left or right.
- C_R with L_D helps distinguish Moderate ejecta cases from Severe ejecta cases at thick sand sites; whereas it is difficult to distinguish Minor ejecta cases from Moderate and None cases.
- The No ejecta cases generally have $L_D < 2.5$ so C_R does not aid significantly in distinguishing these sites from cases with ejecta.

The L_D – C_R charts (Figure 4) generally estimates ejecta severity well for the 176 case histories investigated by Hutabarat and Bray (2022). The chart resolves the overestimation problem of other indices at highly stratified soil sites (Figure 4b). The improvement is largely because L_D captures the important role of low-k_v layers in impeding upward seepage, which prevents ejecta production at stratified soil sites.

Table 1. Severity criteria used in this study.

Category	Area within 20 m covered by ejecta (%)	Best-estimate ejecta-induced settlement (mm)*
None	0	0
Minor	< 5	< 50
Moderate	5 - 20	50 - 100
Severe	20 - 50	100 - 300
Extreme	> 50	> 300

* Based on settlement measured at sites with localized ejecta.
Figure 5 . Liquefaction-induced ejecta severity chart.

7 CONCLUSIONS

The L_D – C_R chart shown in Figure 5 provides a straightforward means to assess the severity of ejecta at a level-ground, free-field site. The proposed

chart captures two key attributes of the problem: liquefaction ejecta demand through L_D and crust resistance through C_R. Additionally, an estimate of ejecta-induced 1D free-field ground settlement is provided using the values of Table 1 based on the liquefaction severity category zone in the $L_D - C_R$ chart shown in Figure 5. Although the $L_D - C_R$ chart proved useful in evaluating ejecta potential, the chart's accuracy is hindered by the limitations of the simplified liquefaction triggering procedure used to perform the liquefaction assessment.

As discussed previously, the $L_D - C_R$ chart may produce misestimations for some cases. Often dynamic ESA can resolve these cases of overestimation or underestimation. Overall, the proposed chart with a parameter that captures liquefaction ejecta demand (L_D) and a parameter that captures crust resistance (C_R) provides reasonable estimates of ejecta severity. L_D captures the influence of depth (represented by the h_A line) and the hydraulic conductivity contrast (represented by the k_v/k_{cs} weighting factor), and C_R captures the resistance of the crust to discern when the crust might prevent ejecta formation.

Estimating k_v is challenging, and hence, estimating k_v/k_{cs} in Eq. 6 is challenging. To achieve results consistent with this study, the Robertson & Cabal (2015) CPT correlation should be used to estimate k_v. The k_v/k_{cs} weighting factor captures the post-shaking upward seepage mechanism where a high-k_v deposit tends to produce a higher rate of upward seepage that can more readily erode the crust layer. The normalized-k_v weighting factor incorporated in L_D enables it to capture important features of liquefaction induced upward seepage which are not captured by other ground failure indices.

The $L_D - C_R$ chart attempts to assess reliably the highly complex phenomenon of ejecta production in a practical manner. Investigation of additional liquefaction field case histories that produced different amounts of ejecta is warranted to refine the proposed chart. Limitations include the proposed procedure cannot capture the system site response during earthquake shaking. Additionally, the $FS_L - r_u$ relationship used in the calculation is for fine-clean sand, but it is used to estimate r_u for silty soils. Lastly, the upward seepage pressure is computed based on the unit weight of water, though the fluidized sediment will be heavier than water; however, it is difficult to estimate its value accurately, and the unit weight of water is used to keep the method straightforward. Estimating z_B is important as a thicker z_{AB} may result in an unrealistically higher L_D.

ABSTRACT: The estimation of building settlements founded in saturated sandy and silty soils is a relevant part of foundation design. Settlement calculation methodologies are still based on SPT and plate-load tests. SPT results can have significant dispersion and soil stiffness estimations are obtained from correlations without a physical meaning and valid only for particular soils and geology conditions. Moreover, plate-load tests are normally limited to shallow depths. CPT and DMT can obtain reliable results in engineering units. These tests are operator independent and the equipment is truly standard worldwide. Results obtained using CPT and DMT equipment for an urban renovation project with buildings founded on saturated sands and silts in Concepción city in Chile, are presented. These results allow estimations of static and liquefaction-induced settlements obtained from calculation methods developed for CPT and DMT.

1 INTRODUCTION

Bearing capacity and settlements are key components in the analysis and design of foundations. Bearing capacity of shallow foundations is usually calculated adopting the Terzaghi procedure which has been extended for different conditions (geometry, loading). However, in silty sands the design becomes controlled in most of the cases by the allowable settlement and not by bearing capacity. Therefore, estimations of settlements are crucial in almost every project. Settlement estimation involves usually the determination of the soil stiffness by means of an operational deformation modulus related to the design load range, which can be obtained from laboratory tests such as triaxial tests. Alternatively, in situ tests can be carried out instead or to complement the information from laboratory. In situ testing can have benefits in terms of measuring directly in the soil without the hassles of extracting, transporting, storing and the preparation of samples. A traditional in situ test carried out in projects is the standard penetration test SPT. However, there are concerns about its reliability and result interpretation for soil stiffness due to poor reproducibility and lack of continuity (Robertson, 2012). In situ load plate test can provide a scaled footing load-displacement response. However, its applicability is limited to surface or shallow depths.

Cone penetration test CPT is versatile and reliable since results can be faster and continuously obtained without major operator influence as with SPT (Lunne et al., 1997). A CPT based method to estimate static settlements of shallow foundations in sand requires the soil modulus of deformation E_s, which is normally obtained from the cone tip resistance.

The flat dilatometer test DMT is another in situ test which has had a particular success in the estimation of settlements of shallow foundations (Schmertmann, 1986; Schnaid, 2009; Marchetti, 2015). The settlement estimation is mainly based on the determination of the 1D dilatometer modulus M_{DMT}. Schmertmann (1986) has shown 16 case histories for different structures on sand, silt, clay, peat and mixtures of these soils where the use of M_{DMT} led to an average and standard deviation values of the estimated/measured settlement ratio s_e/s_m of 1.18 and 0.36 respectively, with s_e/s_m varying from 0.71 to 2.23 for measured settlements between 3 mm and 2.85 m. If only sand and silt and their mixtures were considered (9 cases), s_e/s_m average and standard deviation are 1.10 (0.73 – 1.34) and 0.21 for settlements between 3 and 58 mm. Moreover, other researchers have collected more cases with favourable performance of the DMT (Hayes, 1986; Monaco et al., 2006; Failmezger et al., 2015). For that reason, settlement studies based on CPT have often been benchmarked against results from the DMT (Kaggawa et al., 1996; Lehane and Fahey, 2004).

This work focuses on the Aurora de Chile urban recovery project located at the Bío Bío north

riverbank in the city of Concepción, Chile, which started in 2016. The project considered the construction of 8 four-storey buildings of with 128 flats and 78 two-storey houses. As part of the geotechnical site investigation, one DMT and two CPT tests were carried out. This offers the opportunity for the comparison of settlement estimations based on results from CPT and DMT. The soils found in the project area correspond to fluvial deposits mainly of sands and silts and a mixture of them. Static settlements are determined from CPT and DMT results considering 1D deformation modulus for each soil layer and different vertical load increments. Liquefaction-induced settlement analysis based on the Ishihara (1996) chart and the liquefaction potential are performed. The latter follows the modified Seed and Idriss (1971) simplified method for CPT (Youd and Idriss, 2001) and DMT (Monaco et al. 2005; Marchetti et al. 2013).

2 STATIC SETTLEMENT ESTIMATION

Static settlement can be calculated based on a 1D compression modulus also referred to as oedometric or constrained modulus M which is commonly obtained from consolidation tests. This modulus M corresponds to the slope of a straight line between two points in the 1D effective vertical stress - vertical strain curve, which is therefore valid for that stress increment applied by a structure.

2.1 *CPT-based settlement prediction*

The CPT test consists in the continuous penetration through the soil of a standard steel bar with a conical tip at a constant rate of 20 mm/s. An electronically instrumented cone with load cells allows the measurement of the cone tip resistance q_c and sleeve friction resistance f_s. The use of a piezocone also allows the continuous measurement of the pore water pressure u. The CPT equipment and test procedures are standardized (ASTM D5778, 2020; EN ISO 22476-1, 2012). The CPT results can provide a detailed record for the evaluation of the ground stratigraphy and geotechnical properties (Lunne et al., 1997; Robertson, 2009a). Settlement estimations for footings in sand can be carried out by methods that use the drained elastic modulus E. 1D constrained modulus M are generally used for the estimation of long term consolidation settlements. However, for stresses below the preconsolidation stress, it can be assumed that M is approximately constant and possible to correlate with the net cone resistance $(q_t - \sigma_{v0})$ by means of DMT-CPT relationships represented in the Q_{tn}-F_r chart (Robertson, 2009a, 2009b).

$$M = \alpha_M(q_t - \sigma_{v0}) \quad (1)$$

where q_t is the corrected tip resistance, σ_{v0} is the in situ vertical stress and α_M is a modulus factor:

If

$$I_c > 2.2 \; : \alpha_M = Q_{tn} \text{ for } Q_{tn} \leq 14 \quad (2a)$$

$$\alpha_M = 14 \text{ for } Q_{tn} > 14 \quad (2b)$$

If

$$I_c < 2.2 \; : \alpha_M = 0.03\left[10^{(0.55I_c+1.68)}\right] \quad (3)$$

where I_c is a soil behaviour type SBT index that can represent the SBT zones in the Q_{tn}-F_r chart, Q_{tn} is the normalized tip resistance and F_r is the friction ratio. I_c represents the radius of a concentric circle:

$$I_c = \left[(3.47 - \log Q_{tn})^2 + (\log F_r + 1.22)^2\right]^{0.5} \quad (4)$$

$$Q_{tn} = \left[(q_t - \sigma_{v0})/p_a\right](p_a/\sigma'_{v0})\text{n} \quad (5)$$

$$F_r = \left[f_s/(q_t - \sigma_{v0})\right] \times 100\% \quad (6)$$

where n is an exponent which varies according to the soil type (Robertson, 2009a). α_M increases from soft soils to dense granular soils with a division around the middle for $I_c = 2.2$. Expression (9) is used to calculate static settlements, where M is obtained with (1) to (6).

2.2 *DMT-based settlement prediction*

The flat dilatometer test DMT provides subsurface information through two horizontal pressure readings in a circular membrane. The DMT is recognized for being a suitable test to acquire information related to the stiffness of the soil. Moreover, it is also sensitive to the soil stress history, therefore, it can provide reasonable estimations of parameters such as the coefficient of lateral earth pressure K_0, over-consolidation ratio OCR and 1D constrained modulus M (Marchetti et al., 2001; Schnaid, 2009; Marchetti, 2015). M can be estimated according to the following expression:

$$M_{DMT} = E_D R_M(K_D, I_D) \quad (7)$$

where E_D is the dilatometer modulus, determined by the elasticity theory for the 60 mm diameter membrane displacing 1.1 mm.

$$E_D = 34.7(p_1 - p_0) \quad (8)$$

where p_0 and p_1 are the corrected lift-off and full expansion pressures, respectively. R_M is a correction factor applied to E_D, which is a function of the horizontal stress index K_D and the material index I_D; therefore, it is calculated according to the soil type. Static settlements are calculated using the following 1D relationship:

$$S_{\text{DMT}} = \sum \frac{\Delta\sigma_v}{M_{\text{DMT}}} \Delta z \qquad (9)$$

where $\Delta\sigma_v$ is the stress increment applied by buildings or embankments in the middle of a layer of thickness Δz, which can be adjusted using the theory of Boussinesq for deep layers.

3 IN SITU TESTING RESULTS

Figure 1 shows the q_t and f_s variation with depth as well as the soil behaviour type SBT interpretation for the CPT profiles. The CPT1 (Figure 1a) and CPT2 (Figure 1b) tests reached 22 and 17.5 m, respectively. The groundwater was detected at approximately 5.5 m depth from the ground level. In general, sand layers from fluvial deposits are detected with maximum thicknesses of 10 m mixed with silt and clay lenses with thicknesses that vary between 0.8 to 1.5 m.

The DMT test reached a depth of 10 m and the variation of I_D and K_D with depth are shown in Figure 2. The stratigraphy is comparable to the CPT1 profile, both coinciding in the presence of a soft layer of clay approximately 1.5 m thick at 4 m depth. It is worth noting that when $K_D = 2$ soils are normally consolidated.

In Figure 3 some of the soil parameters that are calculated based on the measurements from both test equipment are compared. Similarities can be seen between DMT and CPT1 for the profiles of unit weight γ and friction angle ϕ', where ϕ' is around 35° in the first 4 m and 40° below 6 m. In Figure 4, the 1D compression modulus M shows low values in the first 3 m, and in the clay layer even lower values between 2 and 6 MPa according to the DMT and between 2 and 12 MPa according to CPT1.

Below 6 m, M increases with much larger values with better agreement between CPT and DMT for values in the order of 180 and 200 MPa. Figure 4 also shows the $M_{\text{DMT}}/M_{\text{CPT1}}$ ratio, where it can be observed that CPT1 tend to overestimate M respect to DMT.

4 STATIC SETTLEMENT CALCULATIONS

Settlements are calculated with the method previously explained in 2.1 and 2.2 considering a 2 m wide square footing and founded 2 m below ground level. An increasing sequence of vertical load is considered as the stress increment $\Delta\sigma_v$.

Figure 5. Shallow foundation static settlement estimated from DMT and CPT test results.

5 LIQUEFACTION ANALYSIS

5.1 *Liquefaction occurrence*

Chile is a highly seismic country and in particular Concepción is a region where several mega-thrust earthquakes ($M_w \geq 8.0$) have occurred (in year 1570, 1657, 1730, 1751, 1835, 1939, 1960 and 2010). Moreover, the Aurora de Chile project site is next to Bío Bío River, the largest of Chile in terms of width and water flow volume. For that reason, it is important to assess the liquefaction potential of the saturated sandy ground and the associated settlements.

The procedure to assess liquefaction potential is mainly based on the simplified method by Seed and Idriss (1971) developed initially for SPT, from which the cyclic stress ratio CSR imposed by the earthquake can be estimated.

$$\text{CSR} = 0.65(a_{max}/g)(\sigma_{v0}/\sigma'_{v0})r_d \qquad (10)$$

where r_d is a stress reduction coefficient which account for the reduction of a_{max} with depth in absence of liquefaction. The expression used of r_d is too big to include it here (see (3) in Youd and Idriss, 2001).

For CPT data, a modified, although similar empirical procedure presented by Youd and Idriss (2001) has been adopted, where q_t is normalized and transformed to:

$$q_{t1Ncs} = K_c(q_t/p_a)/(p_a/\sigma'_{v0})^n \qquad (11)$$

where K_c is a grain characteristic factor that is a function of I_c and in this form a clean sand value q_{t1Ncs} is obtained, from which the cyclic resistance ratio CRR can be determined (Robertson and Wride, 1998).

$$CRR_{7.5} = 0.833(q_{t1Ncs}/1000) + 0.05 \text{ if } q_{t1Ncs} < 50$$
$$CRR_{7.5} = 93(q_{t1Ncs}/1000)^3 + 0.08 \text{ if } 50 \leq q_{t1Ncs} < 160$$
$$(12)$$

$$K_c = 1.0 \text{ for } I_c \leq 1.64$$
$$K_c = -0.403I_c^4 + 5.581I_c^3 - 21.63I_c^2 + 33.75I_c - 17.88$$
$$\text{for } I_c > 1.64$$
$$(13)$$

Subsequently, a liquefaction factor of safety FS_L can be obtained as:

$$FS_L = (CRR_{7.5}/CSR)MSF\,K_\sigma \qquad ((14))$$

where MSF is a magnitude scale factor to account for earthquakes different from $M_w = 7.5$.

$$MSF = 10^{2.24}/M_w^{2.56} \qquad (15)$$

which results in MSF = 0.66 for M_w = 8.8. A correction factor for confining stresses higher than 100 kPa is determined as:

$$K_\sigma = (\sigma'_{v0}/p_a)^{f-1} \qquad (16)$$

where f is a factor related to the site conditions such as relative density DR, ageing and overconsolidation ratio OCR. In these analyses f has been assumed either 0.65 for DR > 60% or 0.75 for DR ≤ 60%.

For DMT, FS_L is also calculated using (14) with the same components as for CPT, except $CRR_{7.5}$ which is determined with the following expression (Monaco et al., 2005):

$$CRR_{7.5} = 0.0107K_D^3 - 0.0741K_D^2 + 0.2169K_D - 0.1306 \qquad (17)$$

The liquefaction analyses assume M_w = 8.8 earthquake and a maximum acceleration a_{max} = 0.4g, which are actually the values recorded in the centre of Concepción during the 2010 earthquake and normally adopted in practice.

Figure 6 shows the variation with depth of the liquefaction factor of safety FS_L determined from the CPT and DMT results. The groundwater level is assumed to be at 2 m as an unfavourable condition during winter when the river water level is very high. A vertical line for FS_L = 1 separates where liquefaction is likely or not to occur. It can be observed that between 2 m and 3.5 or 4 m (where starts the clay layer) FS_L < 1 for CPT and DMT results, hence,

liquefaction is highly likely to occur there. It is worth mentioning that liquefaction has been reported along the Bío Bío river promenade during the 2010 earthquake (Verdugo et al., 2010). Liquefaction is not expected in the clay layer as shown for CPT2 and DMT. However, FS_L < 1 for CPT1 due to the very low values of the clay tip resistance. It is important to bear in mind that liquefaction does not occur in clay.

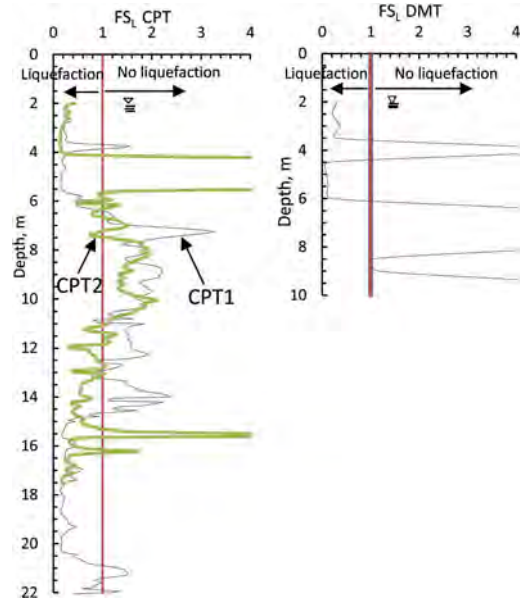
Below the clay layer liquefaction may still take place down to 7.5 m according to the CPT results.


Figure 6. Liquefaction factor of safety obtained from CPT and DMT tests.

Between 7.5 and 11 m FS_L > 1 for CPT results, although for DMT between 8.5 and 9 m, FS_L = 1.0 - 1.2, which is somewhat close to CPT2 results. This zone of no liquefaction may stop propagation of liquefaction occurring below. Indeed, below 11 m FS_L < 1.0 and according to CPT1 a layer of 6 m thick may liquefy.

5.2 Liquefaction-induced settlements

The estimation of free-field settlements caused by earthquake-induced liquefaction is carried out usually based on the soil incremental volumetric strain ε_{vol} Dissipation of excess pore pressure densifies the soil which may result in important volume changes leading to settlements. A chart proposed to estimate ε_{vol} as a function of FS_L and N_1 from the SPT or alternatively q_c or DR can be used (Ishihara and Yoshimine, 1992; Ishihara, 1996). From CPT and DMT data this chart was

directly used for $\varepsilon_{vol} = f(FS_L, q_t)$ and $\varepsilon_{vol} = f(FS_L, DR)$, respectively. The DR expressions used are a best fit to the DR-K_D plot by Reyna and Chameau (1991) for normally consolidated sands and the DR-K_D-OCR plot by Lee et al. (2011) for over-consolidated sands:

$$DR = 50.66\ln K_D + 7.95$$
$$DR = a \ln K_D + b \tag{18}$$

Figure 7a shows the variation with depth of the increments of ε_{vol} for each layer analysed from CPT
Figure 7. For CPT and DMT: a) incremental volumetric strain with depth and b) accumulated vertical displacement with depth.

and DMT data. It can be observed that in the first 2 m and below 15 m there are high values of ε_{vol}. The three curves are relatively close to each other denoting similar variation trends of ε_{vol}. Figure 7b shows the accumulated integration of ε_{vol} with depth which is the accumulated vertical displacement at each depth. It is clear to observe that DMT data lead to smaller settlements s_L compared with CPT data. s_L increase rate is higher in the first 4 m and then stabilises and increases again around 11 m and 15 m for CPT2 and CPT1, respectively. For the first 10 m, s_L is estimated to be around 100 mm for DMT, whereas for CPT1 $s_L \approx 150$ mm and $s_L \approx 130$ mm for CPT2. If the liquefied soil below 10 m manages to dissipate the excess pore pressure, s_L values may increase even more to values of 300 mm at 17.5 m (CPT2) and up to 550 mm at 22 m (CPT1).

It has been found that free-field liquefaction-induced settlement can become different from that occurring underneath buildings founded on shallow foundations (Bertalot, 2011). The overburden pressure imposed by a building applies large confining stresses in the soil which tend to modify settlements. Overburden increases settlements because of higher loads, but only until a certain value of bearing pressure owing to the reduction of excess pore pressure ratio with confinement (Bertalot et al., 2013). A chart has been developed to estimate building settlements s_L based on data that include the Concepción 2010 earthquake (Bertalot et al., 2013). s_L is determined based on the thickness of liquefied soil D_L, building width B and building bearing pressure q. For $B = 15$ m, $q = 50$ kPa, $s_L/D_L = 0.1$ and considering $D_L = 2$, 5 and 7 m results in $s_L = 200$, 500 and 700 mm, which are larger than those from free-field.

6 CONCLUSIONS

CPT and DMT tests were carried out in fluvial silty sands in Concepción Chile. A general good agreement was found among the results of soil profile interpretation, constrained modulus and resistance parameters. Static settlements estimated through the 1D M_{DMT} were approximately twice larger than those estimated with CPT data. Free-field liquefaction-induced settlements resulted in much larger than that from static analyses, from 100 mm (DMT) up to 150 mm (CPT) for the first 10 m. Including the confining stress imposed by a building increases even more the liquefaction-induced settlements.

Numerical modeling of static load test in drilled shaft using CPTu results

ABSTRACT: The projects with deep foundations use information from field tests (e.g. CPTu and static load test) to predict an ultimate capacity. The static load test verifies foundation design parameters and installation method. However, this test establishes the real behavior of the drilled shaft under specific conditions and the possibility of experimenting in different conditions becomes extremely expensive and unfeasible. Therefore, the numerical modeling of the static load test becomes important because the initial soil profile and dimensions of the drilled shaft could be changed. This article presents the comparison of the load–displacement curves by numerical modeling in fine soils with that load–displacement curve through a static load test in a drilled shaft built in Cochabamba, Bolivia.

1   INTRODUCTION

The objective of a load test is to verify that the pile prototype in real conditions of the underground has enough bearing capacity. However, this test establishes the real behavior of the pile in singular conditions, and the possibility of testing in different settings make them extremely expensive and infeasible.

The necessity of developing mathematical models to predict the behavior of a pile under different conditions is evident. The implementation of a numerically model of load test allows to explore different settings demanding a little effort during its execution. These models require detailed study of the field conditions in a load test to be modeled.

The project "Nudo Viario Beijing" in the city of Cochabamba (Bolivia) is a project of great magnitude that its infrastructure required the execution of load tests (e.g., CPTu and static load tests). The present document analyzes the numerical model for the load test of a pile through the interpretation of results obtained from the field test using FB-Multipier v.5.5 software.

2   GEOTECHNICAL MODEL

The geotechnical model based on the CPTu results analyzes the water table, the soil classification, the soil unit weight, the friction angle, and the undrained shear strength. This data is needed for the model.

2.1   *Water table*

The CPTu did not find any water table (the pore pressure transducer has been damaged at the beginning of the test), however; it was evidenced that it was 2 meters below the surface, because an excavation has been carried out to that depth.

2.2   *Soil classification*

Figure 1 shows the evaluation of the CPTu test results using the I_{SBT} behavior index proposed by Robertson (2010). The characterization of the soil based on the fines content proposed by F. Yi (2014) allowed an identical characterization to that obtained utilizing the soil type behavior indexes (I_{SBT}), moreover, being known the percentage of fines content present in the layer, it allowed a precise definition of the type of soil.

There are 15 strata in the underground profile, 8 of them of clay and 7 of silt.

2.3   *Unit weight*

Within the evaluation process of the unit weight from the CPTu results, it was applied the equations proposed by Mayne (2012); Robertson & Cabal (2010). Figure 2 indicates the estimation of the unit weight values.
Figure 1. I$_{SBT}$ behavior index proposed by Robertson (2010).

2.4 Undrained shear strength

Figure 3 indicates the variation of the undrained shear strength results depending on the depth. The equation proposed by Mayne & Kemper (1988) to evaluate the undrained shear strength is based on the Nkt factor:

$$s_u = \frac{q_t - \sigma_{vo}}{N_{kt}} \qquad (1)$$

where q_t is the resistance to the corrected tip σ_{vo} is initial vertical total stress N_{kt} is a factor that varies between 10 to 20 (Ameratunga et al., 2016). The results of Nkt = 12.76 have been used.

2.5 Geotechnical model based on the results of the CPTu test

In summary, Figure 4 shows the geotechnical model based on the CPTu results for the numerical model.

The principal geotechnical parameters are indicated. The unit weight and undrained shear strength have been defined in low, medium, and high values for each clay strata. For silt strata, it was defined the friction angle with constant values between 30° and 36°.

2.6 Selection of geotechnical parameters

The unit weight and undrained shear strength data in a soil stratum vary in depth, which value is representative? The comparison between these parameters has been made (low, medium, or high values)
Figure 2. Unit weight estimation from CPTu results. (Mejia, 2016).

3 LOAD TEST

The static compression load test was performed on the top of the drilled shaft based on ASTM D1143–07. Figure 5 shows the results obtained reaching up to 4347 kN with a registered maximum displacement of 17,89 mm (1,50% strain based on the drilled shaft diameter).

4 SOIL–STRUCTURE INTERACTION IN FB–MULTIPIER SOFTWARE

Due to the fact that the models for the soil and piles are not lineal, FB–Multipier carries out an iterative solution process through a secant method for solving the non-linear equations. The software uses a Newton–Raphson iteration scheme where in each iteration the stiffnesses of the soil and piles are used to form the stiffness matrix and calculate the deformations. These deformations were used then to find the internal loads in each discretization of the piles.
Figure 3. Undrained shear strength estimation (Mejia, 2016).

4.1 Numerical model in FB–Multipier software

In order to get the geotechnical model of the underground, it has been carried out the numerical model of a compression load test of a drilled shaft in the FB – Multipier software. The principal parameters used are the unit weight and the undrained shear strength since these values influence the t–z and q–z curves which are based on the research made by Reese & O'Neill (1988) and Wang & Reese (1993) for drilled shafts.
Figure 4. Geotechnical model based on the CPTu test results.

4.1.1 Global data
In the FB–Multipier v.5.5 software, the numerical models based on the conceptual geotechnical model

have been carried out in a drilled shaft simulating the compression load test for stages.

4.1.2 Pile data

The drilled shaft considered in this study is of diameter 1,20 m, length 22 m, and made of concrete with a resistance of 41,37 MPa. The drilled shaft has been built with 24 steel bars of 25 mm. All of these parameters have been included in the FB-Multipier software.

4.1.3 Soil parameters

The soil´s parameters were defined according to the geotechnical model. It is indicated the phreatic level and each stratum was defined with the unit weight and undrained shear strength data.
Figure 5. Load test results (Camacho & Gomez, 2016).

4.1.4 Deformations in the model

According to the results of the static load test, it has been input the displacements in the head of the drilled shaft.

Two stages of displacements were input. First, displacements between 0,20 mm to 6,95 mm with a step of 0,15 mm, and secondly, displacements between 6,95 mm to 20,15 mm with a step of 0,30 mm. Ninety load states were obtained with these displacements.

4.2 Results of the numerical model

In Table 1, the numerical model has been labeled with the names described for each case. For example, for a low undrained shear strength and a high unit weight, it has been called CPT01 curve.

The results of the sensitivity study of the geotechnical parameters that influence the t-z and q-z curves are presented in Figure 6.

The general result of the geotechnical parameters shows a proportional direct relationship between the parameters and the peak load. The higher the undrained shear strength and unit weight, the higher the peak load. Three groups of curves have stood out due to undrained shear strength, being the geotechnical parameter that defines a difference in peak loads in a range of 3000 kN. The unit weight, on the other hand, varies the peak loads in a range of 300 kN. The curves with the highest correlation to the static load test curve are the CPT02, CPT05, and CPT08. According to Table 1, all the strata have a medium undrained shear strength and each curve represents a low (CPT02), medium (CPT05), and high (CPT08) unit weight in all strata.

Table 1. Curves' names.

Unit weight	Undrained shear strength		
	Low	Medium	High
Low	CPT07	CPT08	CPT09
Medium	CPT04	CPT05	CPT06
High	CPT01	CPT02	CPT03

5 RESULT ANALYSIS

The analysis has been done from a geotechnical model with low, medium, and high values of unit weight and undrained shear strength. A model has been developed in the FB-Multipier software obtaining 9 load-displacement curves that have been compared with the executed static load test curve. From this group of 9 curves, it has been chosen 1 curve which best represents the load test in a numerical model.

5.1 Conceptual geotechnical model analysis

The CPTu test indicates a geotechnical profile as intercalation of fine-grained saturated soils, predominantly lean clays with sand (8 strata) with intercalations of sandy silt strata (7 strata).

The low, medium, and high values of the unit weight have been obtained with the correlation of the CPTu proposed by Robertson & Cabal (2010).

5.2 Load–displacement curves

From the FB–Multipier software it has been obtained load–displacement curves. The static load test curve
Figure 6. Load test and numerical models results based on the CPTu test.
Figure 7. Load – Displacement curves from CPTu test.

plot is a group of points joined by lines. It has been observed a relationship and curvy trend between a load of 635,17 kN to 4.045,71 kN, whereas the lastest load and displacement data indicates an abrupt drop in drilled shaft capacity.

Therefore, it has been chosen to correlate the curves obtained from the numerical models with the points of the load test between 635,17 kN to 4.045,71 kN. The correlation indicator is r2 calculated with the displacement obtained by the load.

5.3 Modeling

Figure 7 indicates 3 load–displacement curves (FB–Multipier) that correlate with the load test. The correlation indicator r2 varies between 0,86 to 0,95.

6 CONCLUSIONS

The geotechnical model extends from the surface to a depth of 25,50 m. where the lean clay strata with sand (75%) interspersed with sandy silt strata (25%) resulting in a slightly plastic over consolidated profile with a low expansion and variable consistency. The water table is ubicated 2 meters below the surface (Figure 4).

In the static load test, the load–displacement curve has been developed until reaching the maximum load of 4.346,64 kN and the maximum deformation of 17,89 mm was obtained in stage 12 of peak load. In the unload stage, 3,46 mm has been recovered until the end of the test.

The load test has been modeled in different scenarios from the interpretation of field test results (e.g., CPTu and static load test). It has been observed that the strength parameters that influence the t-z and q-z curves are the unit weight and the undrained cohesion. Thus, the sensitivity analysis of these two combined parameters was carried out resulting in 9 resistance states.

The load–displacement curves were obtained with the FB-Multipier software that performs the soil–pile interaction through the t-z and q-z curves. An axial displacement has been induced in the drilled shaft head (simulating the static load test) to obtain the resultant force at the same point. Ninety cases of load states have been determined and then a load–displacement curve has been plotted.

The load–displacement curves were analyzed for each geotechnical model. In addition, it has been chosen to correlate the curves obtained from the numerical models with the points of the load test between 635,17 kN to 4.045,71 kN. The correlation indicator is r2, calculated with the displacement obtained by the load.

The correlation indicator r2 has varied between 0,86 and 0,95 based on the CPTu field test.

The load–displacement curve with the correlator r2 close to 1 has been graphically observed determining that the numerical model CPT08 is appropriate to be used.

ABSTRACT: characterization of the spatial variability of geotechnical properties of river embankment soils is important for the enhanced modelling and assessment of embankment stability. In practice, available data is usually limited. This study presents the results of a quantitative statistical analysis of the spatial variability of cone tip resistance from the results of 16 closely spaced SCPT carried out near a recent breach in a levee on the Panaro river in northern Italy. Two geotechnical homogeneous soil units are preliminary identified in the levee to ensure the meaningfulness of the analysis in terms of soil type. For each unit, the horizontal and vertical spatial variability and spatial correlation structures of cone tip resistance are investigated by a two-step procedure involving the calculation of empirical semivariograms and the subsequent fitting of semivariogram models. Horizontal and vertical scales of fluctuation are estimated based on fitted semivariogram model parameters.

1 INTRODUCTION

Levee and dike collapses cause considerable financial and social losses in many countries, especially in highly developed areas. Therefore, risk assessment of river embankment stability is receiving increasing attention worldwide. The quantitative estimation of the vulnerability of embankments, which is necessary for the risk assessment process, can be pursued in the form of fragility curves from the outputs of slope stability analyses. A key parameter in slope stability analyses is soil strength, which varies spatially within soil volume due to factors such as compositional heterogeneity, level of compaction, degree of saturation, cementations, and presence of ancient breech-repairing materials.

A levee failure occurred along the Panaro River in Northern Italy on 6th December 2020. The failure was caused by a combination of concurrent causes including soil heterogeneity, relict animal burrows, presence of ancient brick elements in the embankment body, as well as of rhizomes of Arundo Donax.

To corroborate the interpretation of such collapse, an extensive geotechnical and geophysical campaign was conducted, including a series of 16 closely spaced SCPT. CPT measurements have extensively proved to be well-suited for assessing inherent soil variability because a large volume of near-continuous data can be collected in a cost-effective way, the test has good repeatability, the equipment is highly standardized, and the procedure is well defined and almost independent of operator skill. The investigations revealed that the levee embankment is made of sand-silt mixtures in different proportions. While friction angle varies within a limited range (30-33 degrees), cohesion, which depends primarily on compaction level, soil suction and cementation, varies significantly even within a limited area.

This paper describes the procedures and results of a quantitative investigation into the vertical and horizontal spatial variability of cone tip resistance performed on the unsaturated silty sand of the river levee embankment. Section 2 describes the results of the geotechnical site investigation campaign along with a preliminary descriptive statistical analysis. CPT results are pre-processed to identify homogeneous soil units (Sec. 3) in which spatial soil variability is modelled through the application of geostatistical techniques (Sec. 4). Results of the geostatistical modelling process are assessed and discussed in Sec. 5

2 DESCRIPTION OF GEOTECHNICAL CAMPAIGN

The geotechnical campaign conducted in the area of the breach consisted in 12 CPTU, 2 SCPTU, 2 DMT, 2 boreholes, 7 ERT. A total of 11 undisturbed samples were collected for laboratory testing. To investigate in greater depth the spatial variability of soil strength, a short stretch of levee embankment, located approximately 150m west of the breach, was investigated through 16 seismic CPT soundings at a constant horizontal spacing of 2.5 m.

Cone tip resistance q_c and sleeve friction f_s were measured at vertical intervals of 1cm and the shear wave velocity V_s was measured at vertical intervals of 25cm with the true interval method. These tests reached a maximum depth of 5.5m. Figure 1a-b plots the complete set of results of the SCPT campaign. A smoothing procedure based on a moving average with a 40cm-wide window is applied to each SCPT vertical to remove small-scale noise.

Although the tests are very closely spaced and the boreholes show that the material is classifiable consistently as a mixture of sand and silt, simple visual inspection of Figure 1a-b reveals significant horizontal inter-sounding variations in the measured properties at the same depth, and intra-sounding, depth-wise variability in the vertical direction. While vertical variability can be expected due to in-situ stress effects and to stratigraphic layering, horizontal variability is more significant than could be foreseen given the close spacing of the soundings and the limited extension of the area. To quantify this variability, descriptive second-moment sample statistics were calculated depth-wise for q_c, f_s, and V_s; more specifically: mean (μ), standard deviation (σ), and coefficient of variation (COV=σ/μ), given by the ratio of the standard deviation to the mean. Figure 1c-e plots the depth-wise mean and COV of q_c, f_s, and Vs. The grey shaded area represents the values within one sample standard deviation from the sample mean.

The depth-wise COV of tip resistance and sleeve friction varies between 0.15 and 0.6, with an average of 0.37 for q_c and 0.49 for f_s. This indicates that the horizontal variability of the deposit is relatively high, according to the "rule of thumb" provided by Harr (1987), by which coefficients of variation below 10% are considered to be "low", between 15% and 30% "moderate", and greater than 30%, "high". The COV of shear wave velocity varies between 0.11 and 0.78 with an average of 0.22; indicating that the overall level of horizontal variability of this parameter is moderate.

From a geotechnical perspective, it is important to parameterize not only the degree of horizontal and vertical scatter in data measurements, but also the spatial correlation structure, i.e., whether the spatial variation of mechanical behavior as described by SCPT occurs abruptly or with continuity. The above descriptive statistical analysis is not suited to fully describe variability as it cannot provide information regarding spatial variability patterns. Moreover, the descriptive analysis does not account for the possible presence of different stratigraphic units which could display distinct geotechnical properties. In the following we focus on the variability of the tip resistance.
Figure 1 (a) q_c and V_s measured in the 16 SCPT; (b) f_s measured in the 16 SCPT; (c-e) average values and COV in horizontal direction of q_c, f_s and V_s respectively.

3 IDENTIFICATION OF HOMOGENEOUS SOIL UNITS

Sample statistics and spatial variability parameters aimed at characterizing specific soil types are only meaningful if conducted on soil volumes which are sufficiently homogeneous for geotechnical purposes. A moving-window procedure proposed by Uzielli et al. (2008) is employed to identify Homogeneous Soil Units (HSUs) statistically. The normalized tip resistance Q_{tn}, normalized friction ratio F_r and soil behaviour type index I_c are computed from field measurements according to Robertson (2009).

$$Q_{tn} = \frac{q_c - \sigma_{v0}}{p_a} * \left(\frac{p_a}{\sigma'_{v0}}\right)^n \tag{1}$$

$$F_r = \frac{f_s}{q_c - \sigma_{v0}} * 100 \tag{2}$$

$$I_{cn} = \left((3,47 - \log Q_{tn})^2 + (1,22 + \log F_r)^2\right)^{0,5} \tag{3}$$

where

$$n = 0,381 I_c + \frac{0,05\sigma'_{v0}}{p_a} - 0,15 \tag{4}$$

The vertical effective stress is estimated considering soil suction (s) by applying the Bishop effective stress principle

$$\sigma'_{v0} = \sigma_{v0} + sS_r \tag{5}$$

S_r is the degree of saturation computed from soil suction assuming the Van Genuchten soil water retention model (Eq. 6) with typical parameters for these soils derived from the laboratory tests, i.e., p_0 =5kPa, λ=0.3, $S_{sat} = 1$, $S_{res} = 0.16$.

$$S_r = S_{res} + (S_{sat} - S_{res})\left(1 + \left(\frac{s}{p_0}\right)^{\frac{1}{1-\lambda}}\right)^{-\lambda} \tag{6}$$

A linear suction distribution is assumed above water level, which is 10m-deep in this site.

For each investigated depth, average values of Q_{tn}, F_r and I_{cn} are computed over the horizontal direction and used to identify the homogeneous soil units (HSU), see Figure 2a. The procedure is based on the evaluation of the coefficient of variation (COV) of the data within a 40cm-wide moving window. Each position of the moving window defines two semi-windows of equal height above and below a centre point. The COV shows a peak at the interface between different homogeneous soil units. Q_{tn}, F_r and I_{cn} show an increase of COV

between 1.8m and 2.3m as well as between 5.0 and 5.3m, which correspond to the transition zone between different HSU (Figure 2b). Q_{tn} is used for the identification of HSU because it is the parameter that best captures soil compaction effects. Indeed, it is clear from the borehole that the embankment is built with silty sand but compacted at different densities. The threshold value for COV is set to 0.15.

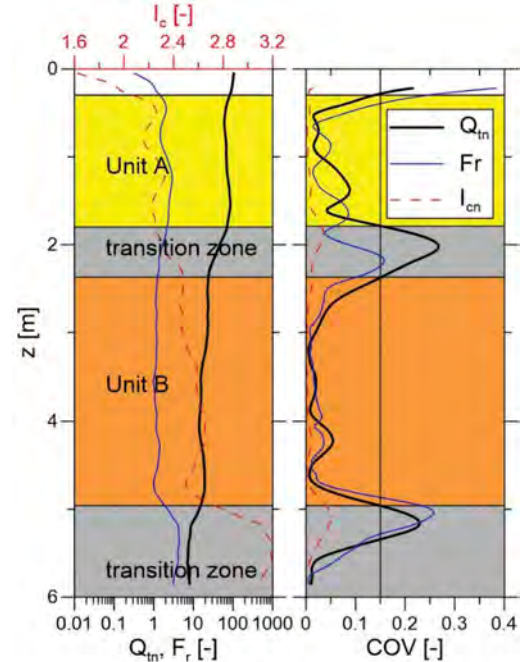
With this procedure it is possible to identify two HSUs: Unit A (between the depths of 0.30m and 1.80m) and Unit B (between 2.35m and 5.00m).


Figure 2. Identification of HSU.

4 MODELLING OF SPATIAL VARIABILITY

The spatial correlation structure of tip resistance is investigated using a geostatistical approach by means of semivariograms. Given the well-known anisotropy in geotechnical properties stemming from in-situ stress effects and other site-specific factors, horizontal and vertical variability are addressed separately. The adoption of specific geostatistical techniques and models relies heavily on the hypothesis of data stationarity, which denotes the invariance of a data set's statistics to spatial location. Stationarity can be achieved through a number of data transformation techniques. Here, data decomposition is implemented, by which the "total" spatial variability of a spatially ordered measured geotechnical property $[q(z_1 \ldots z_n)]$

in a sufficiently physically homogeneous soil unit is broken down into a trend function $[t(z_1 \ldots z_n)]$ and a set of residuals about the trend $[r(z_1 \ldots z_n)]$. In the one-dimensional case, for instance, taking depth (z) as the single spatial coordinate, decomposition is expressed by the following additive relation

$$q(z) = t(z) + r(z) \qquad (7)$$

Stationarity of the residuals is verified with the Mann-Kendall test (Kendall, 1938, 1955). This non-parametric statistical test involves the calculation of the test statistic τ. Low values of τ indicate a low significance of spatial correlation (and, thus, a more probable stationarity of data), while τ values close to $+1$ or -1 indicate positive or negative correlation respectively.

The spatial correlation structure of residuals is investigated through a sequential process involving: (1) the calculation of empirical semivariograms; (2) the fitting of semivariogram models; and (3) the estimation of the scale of fluctuation from semivariogram model parameters. The scale of fluctuation (δ) describes the distance over which the parameters of a soil are significantly correlated. A low scale of fluctuation attests to less gradual spatial variability. The scale of fluctuation can be calculated from the values of the characteristic parameters of the semivariogram models (a: range; c_0: nugget; c: sill) which are fitted to empirical semivariograms. Table 1 summarizes the semivariogram models used in this study and the model-specific functions used to calculate the scale of fluctuation (Elkateb et al. 2003). In the model equations given in Table 1, h is the lag distance, i.e., the distance between observations.

Table 1. Semivariogram models and analytical expressions for the scale of fluctuation (Onyejekwe et al. 2016).

Model	Equation	δ
Gaussian (GAU)	$c\left(1 - \exp\left(-\frac{h}{a}\right)\right) + c_0$	$\sqrt{\pi}a$
Spherical (SPH)	$\begin{cases} c\left(\frac{3h}{2a} - \frac{h^3}{2a^3}\right) + c_0 \text{ for } h \leq a \\ c + c_0 \text{ for } h > a \end{cases}$	$0.75a$
Exponential (EXP)	$c\left(1 - \exp\left(-\frac{h^2}{a^2}\right)\right) + c_0$	$2a$

4.1 Horizontal spatial variability

Horizontal spatial variability is investigated by slicing each homogeneous soil unit into 30cm-thick sub-units and conducting two-dimensional geostatistical modelling on each sub-unit. A total of 15 sub-units were obtained. The central value of the vertical

depth interval and the average tip resistance in of each sub-unit are considered as reference values for geostatistical modelling purposes. A linear trend in horizontal direction is determined for each reference depth $(q_{c,trend}(x) = a_1 x + a_0)$ and the residuals are calculated through data decomposition. Application of the Mann-Kendall test assessed the stationarity of the residuals of linear detrending for all sub-units.

The empirical semivariograms of the residuals for all sub-units are plotted in Figure 3. These are fitted with the Gaussian (GAU), Spherical (SPH) and Exponential (EXP) semivariogram models summarized in Table 1. Though semivariogram model fitting is performed automatically, best-fit models were subsequently scrutinized critically to assess their adequateness. The GAU and SPH model are those providing the best fits overall. An example of the best-fit model for the depth of 3.53m is shown in Figure 4.

Figure 5 plots the scale of fluctuation for each reference depth for the selected semivariogram models. GAU and SPH model provide similar values of δ, while higher values are obtained with the EXP model. The horizontal scale of fluctuation (Table 2) ranges between 3.7 and 21.1m. Average values of 6.8m, 7.4m and 11.5m are obtained for the GAU, SHP and EXP models, respectively. These average scale of fluctuations are lower than reported in other studies (e.g. (Cami *et al.*, 2020)), but it must be considered that they highly depend not only on the database but also on the reduced horizontal spacing between soundings, which allows full exploitation of the typically existing nested correlation structure as discussed in Cami *et al.* (2020).
Figure 3. Empirical semivariogram in horizontal direction.
Figure 4. Best fitting semivariogram model for the reference depth of 3.53m.
Figure 5. Horizontal scales of fluctuation by reference depth obtained from semivariogram model fitting.

4.2 *Vertical spatial variability*

Vertical spatial variability is investigated by soil unit and sounding. A cubic trend model $(q_{c,trend}(z) = a_3z^3 + a_2z^2 + a_1z + a_0)$ is applied to each instance and the residuals are calculated. The Mann-Kendall test is performed to assess stationarity. The empirical semivariograms for all soil units and SCPT soundings are shown in Figure 6. These are fitted with the semivariogram models summarized in Table 1, yielding the vertical scales of fluctuation given in Table 3 and plotted in Figure 7.

The EXP model predicts the largest values of scale of fluctuation, followed by the SHP and GAU models. In Unit A, δ varies between 0.1m and 0.6m, thus generally lower than in Unit B, where calculated values range between 0.2m and 0.9m. These values are consistent with the results of previous studies, e.g. (Cami *et al.*, 2020).

5 DISCUSSION AND CONCLUSIONS

The vertical and horizontal spatial variability in cone tip resistance of the unsaturated silty sand forming a levee is investigated through statistical and geostatistical modelling of the results of 16 closely spaced SCPT soundings. Results of the descriptive second-moment statistical analysis attest to a high degree of scatter in measured data, presumably due to the effect of partial soil saturation and other site-specific phenomena.

To supplement the outputs of the statistical analysis and to overcome its limitations with respect to the quantitative characterization of the spatial correlation structure of mechanical resistance to cone penetration, geostatistical modelling of the spatial correlation structure was conducted both in the horizontal and vertical directions for two depth intervals referring to highly homogenous soil units.

The horizontal correlation structure, parameterized by the horizontal scale of fluctuation, proved to be stronger (i.e., with cone resistance varying significantly over smaller horizontal distances) than typically assessed in existing literature. This result could be reconducted to both the high quality of the dataset (the small horizontal spacing between consecutive soundings allows the appreciation of nested correlation structures) and to the specific site effects which result in the surprisingly high degree of inter-sounding variability. Results of vertical spatial correlation modelling are fully in line with previous studies, thus attesting to the general correctness in the modelling approach.

The results obtained in the study confirm the particular site conditions which lead to the significant horizontal inter-sounding variability observed through the geotechnical testing campaign. While the complexity of the physical phenomena which lead to such variability require further and more extensive investigation, the quantitative assessment of the spatial correlation structure and its anisotropy attest to the importance of statistical and geostatistical analyses for geotechnical modelling purposes. The availability of quantitative spatial variability parameters allows the enhanced modelling of the geotechnical systems by providing realistic inputs to, for instance, limit equilibrium and numerical analyses.

Coupling site wide CPT profiles and genetic algorithms for whole-site offshore windfarm layout optimization

J.A. Charles & S.M. Gourvenec

M.E. Vardy
SAND Geophysics, Southampton, UK

ABSTRACT: Offshore windfarm layout is driven by optimizing wind potential at the selected site subject to minimum spacing between turbines. Within these constraints, this paper explores the optimization of turbine layout within a selected site based on geotechnical site conditions. Utilizing an irregular but site-wide grid of CPT profiles, a simple pile design method and a cubic interpolation of pile dimensions, heatmaps of pile length and diameter at every possible coordinate within a site can be generated, providing the opportunity for optimization of layout. This paper demonstrates the ability to optimize the location of a prescribed number of wind turbine foundations, in conjunction with other constraints such as minimum spacing, to minimize total steel usage (a simple proxy for foundation cost and embodied carbon) in the foundation system using a genetic algorithm (GA)-based approach. Existing work on windfarm layout optimization uses such techniques to maximize wind energy generation but negligible work exists on extending the methodologies to minimize foundation costs. This paper demonstrates the viability of using a set of CPT profiles with a GA-based approach for a geotechnically-informed windfarm layout and explores the effects of various meta parameters using publicly available datasets. The work demonstrated in this paper is directly relevant to ongoing advances in geophysics and machine learning that would allow for the generation of a synthetic CPT profile at any point on the site, eliminating the drawbacks of interpolation between actual CPT profiles for design parameters.

1 INTRODUCTION AND LITERATURE REVIEW

The construction of offshore windfarms is a key part of the UK government's renewable energy strategy (BEIS 2019, Supergen ORE, 2021), and internationally, the Global Wind Energy Council (GWEC) forecasts that by 2030, more than 205GW of new offshore wind capacity will be added (Global Wind Energy Council, 2020).

Securing offshore wind turbines to the seabed – whether as fixed or floating devices – requires a step change in site investigation and geotechnical design approaches. Due to the size of offshore windfarms, with Hornsea 1, currently the world's largest, covering an area of 407km^2 and consisting of 174 turbines (Ørsted, 2020a), ground investigation datapoints such as borehole logs and CPT profiles are relatively sparse per structure compared to e.g. a building foundation, or even an offshore hydrocarbon platform. However, using interpolation between CPTs, or synthetic CPT profiles derived from continuous seismic data, continuous ground models of a site can be derived (Vardy et al., 2017).

With continuous site investigation data, a monopile foundation can be designed at any location on a site, from which it is possible to use optimization techniques to minimize the overall foundation cost - in terms of volume of steel used - for the windfarm for a specified number and spacing of turbines. Windfarm layout optimization is typically carried out to maximize the wind energy generated based on aerodynamic considerations (Pérez et al., 2013; Samorani, 2010). This paper seeks to demonstrate that foundation efficiency can also be optimized for, and hence include geotechnical parameters as additional variables in typical wind turbine layout optimization. Combining or comparing the significance or trade-offs of these different considerations is beyond the scope of this paper, which seeks to explore and demonstrate the opportunity to include geotechnical assessment in wind farm layout optimization.

Designing a monopile at a location with a CPT profile is straightforward. Many techniques with varying complexity exist in literature and in commercial software packages (Bhattacharya, 2019, Kay et al. 2021). Designing a monopile at locations in between available CPT profiles may apply similar methods but is

associated with greater uncertainty. Since this paper aims to demonstrate a proof of concept for a geotechnically-informed windfarm layout optimization procedure, a simple cubic interpolation approach has been adopted to derive pile dimensions between locations of actual CPT profiles based on the calculated dimensions at each CPT location.

The site examined as a case study, Burbo Bank Extension (Ørsted, 2020b), located off the coast of Liverpool, UK, in the Irish Sea and has an area of the order of 40km² and around 42 CPT profiles in an irregular grid as shown in Figure 1. Coordinates are given in northings and eastings which are measured in kilometers. For Burbo Bank Extension, the maximum north-south distance is approximately 4.2km and the maximum east-west distance is approximately 11.8km. The final constructed windfarm extension consisted of 32 8MW turbines that together can power around 230,000 homes (Ørsted, 2020b). Although not utilized in this paper, the Burbo Bank Extension site investigation (and many others) feature large amounts of geophysical data. A geophysical survey involves sending seismic waves into the seafloor and determining soil properties based on reflected waves. Whereas CPT and borehole data is discrete, geophysical data is continuous, but does not directly measure physical parameters that have to date been robustly linked to engineering properties needed for geotechnical design. However, recent advances allow for synthetic CPT data to be generated from seismic data via machine learning at any point on a site with geophysical data of sufficient quality (Sauvin et al., 2019). This process, in future work, would allow for a drop-in replacement to the simple interpolation process used in this proof of concept.

This paper first details a simple CPT based pile design method and provides a brief summary of alternative/more detailed approaches. The process by which pile length and diameter are interpolated across the site is provided, along with discussions on the emerging techniques that would allow for improvements. Finally, a demonstration of how a genetic algorithm (GA) can be used to automatically select the locations for a specified number of monopiles to minimize a given condition, in this case steel volume, is presented. The general method presented here can be applied to any potential site or foundation type, and involve other constraints such as bathymetry or areas of ecological significance or anthropogenic activity.
Figure 1. Locations of CPT tests at the Burbo Bank Extension.

2 GEOTECHNICAL DESIGN OF MONOPILES

There are many methods by which a monopile can be designed for a given CPT profile with varying levels of complexity. Although more complex methods such as PISA (Byrne et al., 2015) or the methodologies implemented in the web app based LAP software (Doherty, 2017, 2020) are available which consider factors such as serviceability, for this proof of concept only capacity will be considered.

The primary loading on a wind turbine foundation is horizontal loading, both hydrodynamic (wave, current) and aerodynamic (wind), taken together as 16MN for this study which is a typical value cited in literature (Lesny & Wiemann, 2005). A typical safety factor of 3 has been applied to this load for a total 48MN. Note that factoring has been applied only to the applied load and not to soil or material properties. The failure mechanism examined is rotational failure. To ensure the foundation is sufficient to resist this load, lateral resistance can be calculated at each point along the length of the pile based on the values obtained in the CPT profile. Taking moments about a representative lever arm for both wind and wave loading, 35 m in this case, the depth to the rotation point can be found. The local lateral resistance values can then be multiplied by the length they apply to and summed, with those below the point of rotation being negative.

Several equations exist to calculate discretized resistance along the pile. Equation 1 shows the piecewise resistance in clay (Truong & Lehane, 2014) and Equation 2 is the equivalent for sand (Suryasentana & Lehane, 2014). Note that there are various other possibilities for sands and clays as well as equations for other types of soil and rock (Randolph & Gourvenec, 2017).

$$p_u = Dq_{net}\left(\left(\frac{3}{4.7 + 1.6\ln I_r}\right) + (1.5 - 0.14\ln I_r)\tanh\left(\frac{0.65d}{D}\right)\right) \quad (1)$$

$$p_u = 2.4\sigma'_v D\left(\frac{q_c}{\sigma'_v}\right)^{0.67}\left(\frac{d}{D}\right)^{0.75} \quad (2)$$

In Equations 1 and 2, p_u refers to local lateral resistance per unit length, D is the diameter of the monopile, I_r is rigidity index (assumed to be 125 for this study), d is depth below the seafloor to the local point being calculated, σ'_v is effective vertical stress calculated at the local point, q_c is cone resistance where $q_c = Q_c/A_c$, i.e. the force required to push the cone into the ground over cone area, and q_{net} is the net cone resistance where $q_{net} = q_t - \sigma_v$, i.e. corrected cone resistance minus total vertical stress. Corrected cone resistance $q_t = q_c + u_2(1 - a)$ where u_2 is pore water pressure and a is a constant (Robertson, 1990).

As these equations are defined in terms of pile diameter (along with the pile length determining how many discretization points are to be summed together) the easiest way to size a pile is a brute force approach. Table 1 shows the range of lengths and diameters used in this study which are based on the selection used in Sauvin et al. (2019), with the addition of lower 5m and 6m diameters. It should be noted that due to the simplicity of the design criteria chosen that the possible pile dimensions in Table 1 are illustrative and not intended to represent a robust detailed design methodology for the loading conditions, and do not take into account other considerations such as installability or other failure mechanisms such as bending.

Table 1. Typical pile dimensions as used in this study.

Property					
Diameter (m)	5	6	7	7.7	8.5
Length (m)	3D	3.5D	4D	4.5D	5D

Python code was written to automatically identify soil type based on the standard Robertson charts (Robertson, 1990, 2009). For simplicity, datapoints along the CPT profiles were classified as either sand or clay allowing for automated selection of the relevant lateral resistance equation. Of the nine possible Robertson chart classifications, sensitive fine grained, organic, clay, silt-mixtures, and very stiff fine-grained were labelled as clay, and sand-mixtures, sand, gravelly sand to sand, and very stiff sand to clayey sand were labelled as sand. Figure 2 shows a plot of a Burbo Bank Extension CPT profile colored based on soil classification. The axis in the figure are normalized cone resistance $Q_t = (q_t - \sigma_v)/\sigma_v'$ and friction ratio $R_f = (f_s/q_t) \times 100\%$ where sleeve friction $f_s = F_s/A_s$ with F_s and A_s being the recorded frictional force and friction sleeve area respectively (Robertson, 1990).
Figure 2. Example CPT profile from Burbo Bank Extension categorized into sand and clay.

3 WHOLE SITE INTERPOLATION

Although it is ideal to design a monopile that is co-located with a CPT profile, often it is necessary to design a pile that is located between actual CPT profile locations. To achieve this, a monopile was designed at each CPT location across the site, with pile length and diameter then interpolated for locations in between the discrete irregular grid.

It should be noted that this methodology has several limitations, including overlooking the actual variation in soil conditions in between CPT locations. Nonetheless, for the purpose of this proof of concept, using interpolation allows the construction of heatmaps of monopile length, diameter, and volume to be constructed over the whole site, which is a necessary step in freely selecting the location of a set of monopiles.

There are emerging techniques that would potentially eliminate the issues of this interpolation step. On a site with continuous geophysical survey data and discrete CPT data, it is possible to combine seismic inversion methods with machine learning algorithms predict a synthetic CPT profile at any location on the site (Vardy et al., 2018; Sauvin et al., 2019). This technique would potentially represent a significant improvement to site wide characterization and work is actively ongoing in this area, but has not seen widespread application, and therefore the suitability of the method for different site conditions is unclear.

It is the hope of the authors that such techniques would represent a drop-in replacement for the interpolation step presented in this paper. However, for now, cubic interpolation serves as an acceptable placeholder to allow for the demonstration of foundation-based site layout optimization.

Figure 3 shows the heatmaps generated for pile diameter, length, and volume across the site. It should be noted that due to the interpolation process it is possible that some regions on the heatmap drop below the discrete pile dimensions provided in Table 1.

Calculation of pile volume requires an additional wall thickness term. The American Petroleum Institute (API, 2005) recommend a minimum thickness t based on Equation 3. A thickness of 0.1m was found to satisfy this requirement for all pile diameters considered in this study.

$$t[mm] = 6.35 + D[mm]/100 \qquad (3)$$

4 LAYOUT OPTIMISATION USING A GENETIC ALGORITHM

With heatmaps produced for required pile diameter and length across the whole site, it is possible to check the pile dimensions and hence steel volume necessary
Figure 3. Heatmaps of pile diameter, length, and volume for the Burbo Bank Extension site.

at any arbitrary coordinate. It is therefore possible to sum the steel usage for a set of n arbitrarily located piles, and to compare the sums of steel usage for two different sets of piles. Using some means of optimization, in this paper, a genetic algorithm (GA), it is possible to select a set of n coordinates that minimize the required steel usage in foundations across the site.

A GA is an evolutionary algorithm (Poli et al., 2008) that mimics natural selection (Darwin, 1859). Populations of solutions (turbine layouts in this case) are ranked by fitness (steel usage in this case) with the best continuing to future generations and the less good not doing so. After many generations, the solutions tend to improve.

Although there are numerous existing libraries implementing GA functionality (e.g. Fortin et al., 2012; Gad, 2021), due to the relative simplicity of the problem, and simply being able to look up the steel usage for a given coordinate, the GA functionality for this study was implemented from scratch in Python. The steps are outlined below:

1. Generation of a specimen. Code was created to randomly select a coordinate within the site, check that specified constraints are not violated (i.e. being too close to an existing coordinate) and either add it to the list, or discard it, moving on to the next randomly selected coordinate until the desired number of coordinate positions is reached.
2. Implementation of cost function. Code was created to take a specimen as an input and calculate or look up the required steel volume for each coordinate, and then sum all values, enabling ranking of a population of specimens.
3. Creation of the next generation. Code was created to advance the population of specimens to the next generation. User specified meta-parameters

allow for a subset of specimens to advance as they are; a second subset are mutated by randomly adjusting a random selection of the associated coordinates; and a third subset is adjusted by randomly mutating the coordinates of the highest volume piles.

It is noted that advancing the best specimens without changes guarantees that the fittest solution at a given time will never become worse with additional generations. Further, for this use case the GA technique of "crossover" in which two specimens are merged has been omitted as merging half of the list of coordinates from two separate specimens without violating the distance constraint proved to not be possible without additional logic that effectively nullified any benefits of the crossover process.

There are many choices for the aforementioned meta-parameters, for example, the number of generations, the number of specimens generated, the number of specimens in each category, the rankings assigned to each category, whether or not specimens can be included in more than one category etc. Commentary and plots are provided on some meta-parameters in the following section, but an exhaustive search is beyond the scope of this paper.

5 RESULTS AND DISCUSSION

To demonstrate the methodology, the GA was run for multiple combinations of parameters. Initially, the method was used to find the optimal layout of 32 piles, the number constructed in the actual Burbo Bank Extension site development, with 100 specimens (i.e. lists of coordinates) used per generation, with 100 generations.

It should be noted that the real site layout features 32 piles packed as closely as possible along linear transects to minimize wind turbulence and maximize wind yield. An industry typical spacing would be 8 blade diameters (DNV GL Energy, 2019). Enforcing this restriction would allow no leeway to demonstrate the ability of a GA to select locations to minimize total foundation costs and as such a lower minimum spacing of 800m was enforced, representative of wind turbines of diameter 100m or spacing of the actual ~160m diameter wind turbines at 5 blade diameters.

Using smaller turbines than is currently standard or adopting smaller spacing would negatively affect energy generated, and therefore be an unattractive prospect for windfarm operators, but implementations of the presented methodology allow for fine adjustments to more traditional layouts that minimize foundation and potentially installation cost that may be beneficially offset against reduced wind power generation.

Figure 4 shows the layouts generated by the GA after 3, 20, and 60 generations. As the genetic algorithm process involves randomness it is not

deterministic and rerunning the process will likely return similar but slightly different layouts. After just 3 generations nearly every turbine is placed in a lower volume area but there are still improvements that can be seen by eye between the 3 and 20 generation layouts. The differences between 20 and 60 generations are difficult to spot in the layout maps, but small improvements can be found when examining the total site pile volume. Table 2 shows total pile volume for each of the layouts in Figure 4.
Figure 4. Layouts of 32 turbines after 3, 20, and 60 generations.

Table 2. Total pile volume per generation for the 32-pile layouts shown in Figure 4.

Generation	Total volume (m^3)	Mean volume per pile (m^3)	Difference from mean volume at CPT locations (36.96 m^3)
3	1100.8	34.4	-6.9%
20	1045.1	32.7	-11.5%
60	1039.7	32.5	-12.1%

Figure 5 shows the effects of various meta-parameters on the layout and total volume of 32 mono-piles. Considering the relationship between number of generations and volume of steel used, 10 trials were carried out with the average volume plotted per generation number, and for the plot of specimens, 5 trials were carried out for each value. As stated previously, there is an infinite possibility of potential setups for parameters for a GA and the two plots presented here do not represent an exhaustive analysis but were selected due to their relative simplicity and their effects on computational time. It is evident that increasing the number of generations that the GA operates for,

provides a more optimal result, i.e. less steel used for the same number of monopiles. The implementation in fact ensures that a generation is at least as good as the one before. Most improvement happens relatively soon, within the first 10 or 20 generations, and although further improvement can be seen there are significant diminishing returns after generation 50 or so.

The relationship between number of specimens and total volume has a clear correlation but the effect is relatively modest in comparison with the number of generations. It is possible that due to the impracticality of including the GA crossover technique in the current problem formulation that the benefits of a larger population are less pronounced than they would be for a different problem. In this case, 20 specimens appear to be enough.
Figure 5. Effect of selected meta parameters on total pile volume.

It is important to note that there is no guarantee that a GA can find the global optimum solution, even if the improvements between generations appear to plateau. The global best solution would be the ideal solution in which there can be no improvements. GAs however can potentially tend towards a local optimum solution. A local optimum solution can be thought of as an evolutionary "dead end" in which a solution has been found that is good but is sufficiently different from the global optimum that no random mutations exist that will move from one to the other. Finding a local rather than global minima for site wide foundation cost would be more expensive but would not have safety implications.

6 CONCLUSIONS AND FUTURE WORK

Using a GA to help identify offshore windfarm site layouts that minimize foundation steel volume (and implied cost, both direct, and embodied carbon) has been illustrated. The illustrated example includes several idealizations and placeholder techniques have been used that need to be revisited to refine the approach. These include (1) Incorporating the emerging technique of generating synthetic CPT data from geophysical surveys via machine learning; (2) Additional constraints based on probabilistic analysis of the CPTs, i.e. areas in which there is high uncertainty in synthetic CPT data may be

better avoided; and (3) More complex higher order pile design approaches.

Finally, it is noted that an approach such as put forward in this paper is intended to complement, not replace other constraints and conditions for wind-farm layout optimization, such as aerodynamic effects for optimal energy generation.

CPT-based model calibration for effective stress analysis of layered soil deposits

A. Chiaradonna
University of L'Aquila, L'Aquila, Italy

N. Ntritsos & M. Cubrinovski
University of Canterbury, Christchurch, New Zealand

ABSTRACT: Recent research recognized the advantages of effective stress dynamic analysis in estimating the seismic response of layered soil profiles. One of the key challenges in performing effective stress analysis is the calibration of constitutive models able to simulate complex soil behavior under seismic loading. To overcome this problem, calibration procedures have been developed to guide the definition of model parameters on the results of in-situ tests. In this study, a reference layered soil profile from Christchurch in New Zealand, which experienced liquefaction during the 2010-2011 Canterbury earthquake sequence, was used to verify the goodness of the CPT-based calibration procedure of a simplified pore water pressure model. Comparisons with the seismic response predicted using an advanced state concept-based constitutive model were also reported. Despite the simplifications adopted in the calibration process, the analysis results replicate the occurrence of liquefaction and encourage CPT-based model parameter definition for routine effective stress dynamic analyses.

1 INTRODUCTION

Recent research recognized the importance of effective stress dynamic analysis in estimating the seismic response of layered soil profiles with interbedded liquefiable and non-liquefiable soils (Cubrinovski et al. 2019). Two distinct approaches can be adopted to perform an effective stress analysis: (1) a 'loosely coupled' approach that predicts seismic-induced pore pressure build-up by adopting simplified relationships used in combination with constitutive models that address total stress (e.g., pore pressure prediction based on accumulated strains or stresses) and (2) a 'fully coupled' approach that uses a plasticity-based effective stress constitutive model to predict both the stress-strain and the pore pressure response of the soil (Tropeano et al. 2019).

One of the key challenges in performing effective stress analysis is the calibration of constitutive models able to simulate the dynamic soil behavior under seismic loading. To overcome this problem, calibration procedures have been developed to guide the definition of the parameters of advanced constitutive models based on data from in-situ tests, such as Cone Penetration Test - CPT (Ntritsos & Cubrinovski 2020). Following this philosophy, the calibration of a simplified stress-based pore water pressure model, originally based only on cyclic laboratory test data, was

generalized to include the results of field tests commonly used in engineering practice (Chiaradonna et al. 2020).

In this study, the above-mentioned simplified stress-based pore water pressure model is adopted with the two-fold goal to (1) verify the goodness of the CPT-based calibration procedure in predicting the liquefaction of a layered profile, (2) compare the model performances with those provided by an advanced state concept-based constitutive model assumed as a reference, which was calibrated on the same CPT.

To pursue these aims, a representative layered soil profile from Christchurch in New Zealand, which experienced liquefaction multiple times during the 2010-2011 Canterbury earthquake sequence, was considered in the numerical simulations. The adopted studied area was largely investigated in Cubrinovski et al. (2019), where the geotechnical model and effective-stress analyses by using the advanced state concept-based constitutive model are detailed.

One-dimensional (1D) dynamic analyses were preliminarily carried out by assuming visco-elastic linear behavior of the soils, to check that the same boundary conditions were applied in both approaches (advanced and simplified). Comparisons with equivalent linear and nonlinear codes were also provided.

Then, a 1D effective stress analysis was performed with the simplified pore water pressure model,

according to a loosely coupled approach (Chiaradonna et al. 2019). The parameters of the stress-based pore water pressure model were mainly defined on the cone tip resistance of each soil layer following the CPT-based procedure proposed by Chiaradonna et al. (2020). The same geotechnical model was also simulated through the advanced state concept-based constitutive model, whose parameters were calibrated on the same CPT data by Cubrinovski et al. (2019). Results of the 1D effective stress analyses provided insights on the capability of the loosely coupled approach to correctly predict the attainment of liquefaction in sites with complex stratigraphic conditions, also compared to the performance of a fully coupled approach assumed as reference.

2 SIMPLIFIED PORE PRESSURE MODEL AND CPT-BASED CALIBRATION

A simplified stress-based pore water pressure model, hereafter called 'PWP model' (Chiaradonna et al. 2018; 2019) permits the comparison of the irregular seismic loading with the soil liquefaction resistance, through an accumulation stress-based variable κ, called 'damage parameter'. It is an incremental function of the applied load that considers the cyclic strength of the soil. This latter is expressed in terms of cyclic resistance curve, analytically described by the equation:

$$\frac{(CRR - CSR_t)}{(CSR_r - CSR_t)} = \left(\frac{N_r}{N_L}\right)^{\frac{1}{\alpha}} \qquad (1)$$

where CSR is the shear stress amplitude normalized by the initial effective confining pressure; N is the number of cycles, CSR_r is the ordinate of the curve for $N_L = 15$ (usually adopted as a reference number of cycles). For a regular shear stress history, κ is proportional to the number of cycles, N; it is, therefore, possible to express the pore pressure ratio, r_u (ratio between the excess pore pressure and the initial effective confining pressure), as a function of the damage parameter, through the relationship proposed by the authors (Chiaradonna et al. 2018):

$$r_u = a\left(\frac{\kappa}{\kappa_L}\right)^b + (0.9 - a)\left(\frac{\kappa}{\kappa_L}\right)^d \qquad (2)$$

where a, b and d are parameters that control the shape of the curve.

According to the CPT-based calibration proposed by Chiaradonna et al. (2020), The parameters of the curve CRR-N_L (Eq. 1) can be computed as a function of the effective stress state and the normalized and corrected cone tip resistance, q_{c1Ncs}, of the CPT; while the parameters of the curve $r_u - N/N_L$ (Eq. 2) can be defined as a function of the fine content and relative density; this latter being usually estimated from CPT data (Robertson & Cabal 2015). In so doing, the pore water pressure model parameters can be easily calibrated directly on the results of CPTs, through the charts in Figure 1.

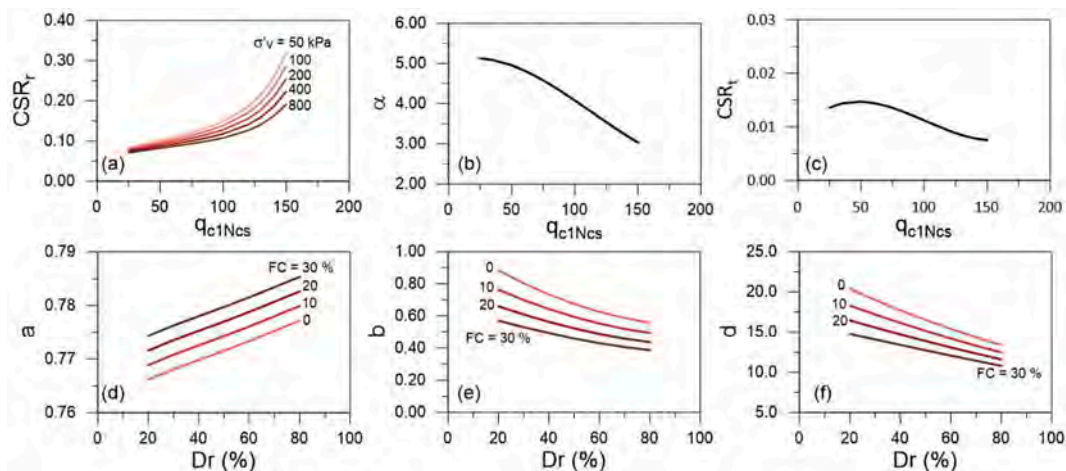
The PWP model was implemented in the non-linear code SCOSSA which models the soil profile as a system of consistent lumped masses, connected by viscous dampers and springs with hysteretic behavior. The non-linear shear stress-strain relationship is described by the MKZ model and the modified Masing rules. More details about the numerical implementation can be found in Tropeano et al. (2019).


Figure 1. Parameters of the PWP model: (a) CSR_r, (b) α and (c) CSR_t of Eq. (1) as a function of q_{c1Ncs}; (d) a, (e) b and (f) d of the Eq. (2) as a function of the fines content, FC, and the relative density, Dr.

3 ADVANCED STATE CONCEPT-BASED SOIL CONSTITUTIVE MODEL

An advanced soil constitutive model, called "Stress-Density" model (S-D Model) is formulated by Cubrinovski & Ishihara (1998a,b).

The S-D Model is a state-concept based model that accounts for the combined effects of density and confining stress on sand behavior through the state-concept framework. The benefit of this, in addition to the consistent modeling of stress-density effects on sand behavior, is that the model is a true material model with a single set of parameters representing a given soil across all relevant density-stress states.

Soil properties required for the S-D Model fall into four categories: critical state line (used to define the state of the soil relative to the reference state, the critical state); plastic stress-strain parameters (defining the shear stress-plastic shear strain relationship); stress-dilatancy parameters (providing the link between plastic shear strain and plastic volumetric strain increments); and elastic parameters (determining an incremental stress-strain relationship for elastic behavior).

The S-D Model is implemented in the finite element code DIANA-J (Corporation Taisei 1997), allowing to perform effective stress dynamic analysis according to a fully coupled approach.

4 CASE STUDY

The considered case study is the "YY-site" excited by the 22 February 2011 Canterbury earthquake. Figure 2 reports the outcrop motion of the deconvolved fault-normal component of the 22 February 2011 earthquake record at the Canterbury Aero Club (CACS) strong motion station, considered in the simulations.
Figure 2. Reference input motion.

The soil column consists of a 20 m deposit, where eight different soil layers, named from "mat1" to "mat8", are identified (Figure 3). The soil properties (specific gravity, Gs, porosity, n, shear wave velocity, V_S, small-strain damping, D_0, permeability coefficient, k), of each material are the results of the soil investigations carried out by Cubrinovski et al.

(2019), and are reported in Table 1. The small-strain shear modulus of each layer was inferred from the shear wave velocity profile shown in Figure 3.

The groundwater table depth identifies the thickness of the liquefiable layer between 1.8 and 10 m depth.

This liquefiable deposit was divided into four different materials (from "mat2" to "mat5") as a function of the normalized and corrected cone tip resistance, q_{c1Ncs}, as reported by Cubrinovski et al. (2019).
Figure 3. Layering and V_S profile.

Table 1. Soil properties.

Soil	Gs	n	V_S (m/s)	D_0 (%)	k (m/s)
mat1	2.65	0.412	93	1.406	$4*10^{-6}$
mat2	2.65	0.462	91	1.073	$4*10^{-6}$
mat3	2.65	0.460	101	0.969	$1*10^{-4}$
mat4	2.65	0.444	116	0.882	$2*10^{-4}$
mat5	2.65	0.412	130	0.834	$3*10^{-4}$
mat6	2.65	0.500	202	0.797	$1*10^{-4}$
mat7	2.65	0.500	242	0.750	$1*10^{-4}$
mat8	2.65	0.500	266	0.712	$1*10^{-4}$

5 PRELIMINARY VISCO-ELASTIC LINEAR ANALYSES

Preliminarily visco-elastic linear analyses of the considered case study were performed by both loosely and fully coupled approaches, implemented in the SCOSSA and DIANA-J codes respectively. These preliminarily dynamic analyses aimed to check that the boundary conditions and small-strain soil behavior were reasonably reproduced in the same way in both approaches. To furtherly identify possible sources of discrepancies, the same analysis was carried out with two additional computer codes widely adopted in the professional practice: the equivalent linear code in the frequency domain STRATA (Kottke et al. 2003), and the nonlinear code in the time domain Deepsoil (Hashash et al. 2016). For this latter, two conditions of the bedrock were considered, a perfectly rigid half-space, and a deformable one with a shear wave velocity of 800 m/s, a unit weight equal to 22 kN/m^3 and a viscous damping ratio equal to 0.5%. The same options are available in the computer code SCOSSA. A deformable bedrock was also adopted in the analysis performed with STRATA.

In the DIANA-J code, the soil column is excited at the base by a horizontal force-time history which is proportional to the known velocity time history of the input ground motion (Ntritos & Cubrinovski 2020).

The small-strain shear modulus inferred from the V_S and damping ratio, D_0, adopted as a target for the analyses are reported in Table 1. While the small-strain modulus is introduced in the different codes as an elastic modulus, the small-strain damping D_0 is modeled in different ways in the adopted codes.

STRATA adopted a frequency-independent formulation, where the damping ratio is assumed to be constant with the shear strain level. The nonlinear codes SCOSSA and Deepsoil used a full Rayleigh damping formulation with two frequencies control. Finally, a full Rayleigh damping formulation with a single frequency control is used in DIANA-J. To match as close as possible the damping curves used in the different analyses, the parameters of the single-frequency control damping ratio curve in DIANA-J were defined as equivalent parameters, i.e., yielding the same damping-frequency function as the double frequency method used by SCOSSA.

The results of the visco-elastic analyses in terms of profiles of maximum acceleration, shear strain and shear stress are reported in Figure 4.

It can be observed that all the analyses showed similar responses, with amplification of the acceleration at the surface and higher shear strains attained in the liquefiable layers. Closer results can be noted in the analyses where the deformability of the seismic bedrock is considered, while higher maximum acceleration and shear strains are ascribed to the analyses where a rigid bedrock is modeled. This effect is due to the lack of radiation damping through the bedrock, which usually causes the free surface motion amplitudes of the case of deformable bedrock to be smaller than those in the case of rigid bedrock.
Figure 4. Vertical profiles of maximum (a) acceleration, (b) shear strain and (c) shear stress attained during the visco-elastic linear analyses.

6 NON-LINEAR EFFECTIVE STRESS ANALYSES

6.1 Loosely coupled approach

In the loosely coupled approach adopted in SCOSSA, the nonlinear and dissipative soil behavior were simulated through the definition of the normalized shear modulus, G/G_0, and damping ratio, D, with the shear strain, γ. The curves proposed by Darendeli (2001) as a function of the effective confining pressure of each layer were adopted and analytically fitted by the MKZ model (Figure 5).
Figure 5. Normalized shear modulus and damping ratio vs shear strain.

The parameters of the PWP model to be assigned to the four liquefiable soils were defined through the charts in Figure 1, as a function of the geostatic effective vertical stress at the mean depth of each layer, the q_{c1Ncs} and fines content equal to 0. The defined curves are plotted in Figure 6 and the related model parameters are reported in Table 2.
Figure 6. (a) Cyclic resistance and (b) excess pore water pressure ratio curves.

Table 2. Parameters of the PWP model.

| Soil | q_{c1Ncs} | CRR - N_L | | | r_u – N/N_L | | |
		CSR_r	α	CSR_t	a	b	d
mat2	80	4.486	0.013	0.127	0.771	0.723	17.02
mat3	90	4.289	0.012	0.134	0.772	0.692	16.46
mat4	115	3.755	0.010	0.164	0.774	0.630	15.29
mat5	140	3.224	0.008	0.232	0.775	0.582	14.37

6.2 Fully coupled approach

For the considered soil column, the S-D Model parameters were determined by combining the use of empirical relationships and generic data for sandy soils. For non-liquefiable soils, the target cyclic stress-strain relationship is defined using strain-dependent stiffness degradation and damping ratio curves, commonly employed in site response analyses. For the liquefiable soils, the model parameters were constrained to simulate the target liquefaction resistance curves for the four soil layers determined based on the simplified liquefaction triggering procedure of Boulanger and Idriss (2014), as described in Cubrinovski et al. (2019). The model parameters and calibrated values of the considered case are reported in Cubrinovski et al. (2019), and not reported here for sake of brevity.

6.3 Results of the effective stress analyses

The results of the effective stress analyses in terms of profiles of maximum acceleration, shear strain and shear stress are reported in Figure 7. The profiles of maximum acceleration show a certain variability, with higher values of SCOSSA compared to DIANA-J in the liquefiable deposit between approximately 5 and 10 m (Figure 7a). In the remaining layers, the prediction of DIANA-J overcomes that of SCOSSA, especially at the ground level, with a predicted value of 0.38 g. The integral of the acceleration profiles in both analyses leads to a similar shear stress profile, with a slightly higher prediction provided by the analysis performed with the DIANA-J code (Figure 7b).

In the loosely coupled approach, the liquefaction condition is attained in the two shallow critical layers, mat2 and mat3, between 2 and 5 m (Figure 7c), where the lowest value of the cone tip resistance induces the lowest cyclic resistance curves (Figure 6a). It should be pointed out that at liquefaction r_u= 0.9 to guarantee numerical stability (Tropeano et al. 2019). In the fully coupled approach, the liquefaction is triggered in the mat2, while $r_u<0.7$ is observed in the other liquefiable soils. The main differences
Figure 7. Vertical profiles of maximum (a) acceleration, (b) shear stress and (c) excess porewater pressure ratio attained during the nonlinear effective stress analyses.

between the two approaches are also due to the way the dissipation and redistribution of excess pore water pressure along the soil column are implemented. DIANA-J can simulate the water flow in the shallowest and unsaturated layer (mat 1), while this latter remains perfectly dry in the SCOSSA analysis.

Additionally, the simplified PWP model generated higher pore water pressure than the S-D model between 5 and 10 m, which is anyway in accordance with a quite conservative approach expected in the simplified soil modeling.

7 CONCLUSIONS

This paper investigated the performance of the CPT-based calibration procedure of a simplified PWP model in predicting the liquefaction of a layered liquefiable soil column. A case study from the liquefaction observed in Christchurch after the 2011 earthquake is considered, and also a comparison with an advanced constitutive model is provided. Some limitations of the simplified approach are mainly associated with the overestimation of the generated pore pressure induced by the seismic event. However, despite the simplifications adopted in the CPT-based calibration process, the effective stress analyses performed replicated the occurrence of liquefaction observed at the site and furtherly encourage CPT-based model parameter definition for routine effective stress dynamic analyses.

ABSTRACT: The paper describes the experimental activities carried out in a test site, set up to evaluate the increase of soil stiffness and horizontal effective stress, mainly in saturated low-medium density sandy layers and in silty sand, after the driving of tapered precast piles.

The experimentation consisted in driving some prefabricated tapered piles with different energies and spacing between them in an area where some soil layers had a high liquefaction potential. To evaluate the pile driving effects on the stress state around them, preliminary CPTu and DMT tests were carried out and repeated after the driving activity.

In particular, the change of the CPTu sleeve resistances was compared with that of the DMT K_D data, to evaluate the increase in horizontal stress using different methods, a phenomenon influencing the soil susceptibility to liquefaction and the pile bearing capacity.

1 INTRODUCTION

To reduce the potential liquefaction-induced settlement in cohesionless soils, many ground improvement techniques are adopted, among them vibrocompaction, rammed aggregate piers (RAP), stone columns, drilled displacement piles, driven displacement piles, deep dynamic compaction, and blast densification (Han 2015). In particular numerous studies have been performed to evaluate the ability of deep vibratory compaction (Van Impe et al., 1994, Massarch & Fellenius 2002, Massarch et al. 2020), of drilled displacement piles (Siegel et al. 2007, Siegel et al. 2008) and RAP (Rollins et al. 2021) to mitigate the risk of liquefaction in sandy soils, while few refer to the use of driven precast tapered piles.

With deep vibratory compaction cyclic stresses are generated in the ground, resulting in a denser particle arrangement and changes in effective stresses. The installation process of drilled displacement piles

consists in displacement of soil and subsequent placement of fluid cement grout within the dislocated volume. For RAPs, the improvement mechanisms include increased lateral pressure and increased shear stiffness.

These processes can result in a measurable densification and in an increase in lateral stress. Therefore, these methods are used to mitigate cyclic liquefaction in sandy soils.

To recognize the deriving soil improvement, the most widely in situ tests used are the cone penetration test (CPT), CPT with pore water pressure measurement (CPTu), the seismic cone penetration test, the Marchetti flat dilatometer test (DMT) or the seismic dilatometer test (Mayne et al. 2009).

Indeed, the CPT and the DMT measured data enable to detect changes in strength, stiffness, and horizontal stress in the soil.

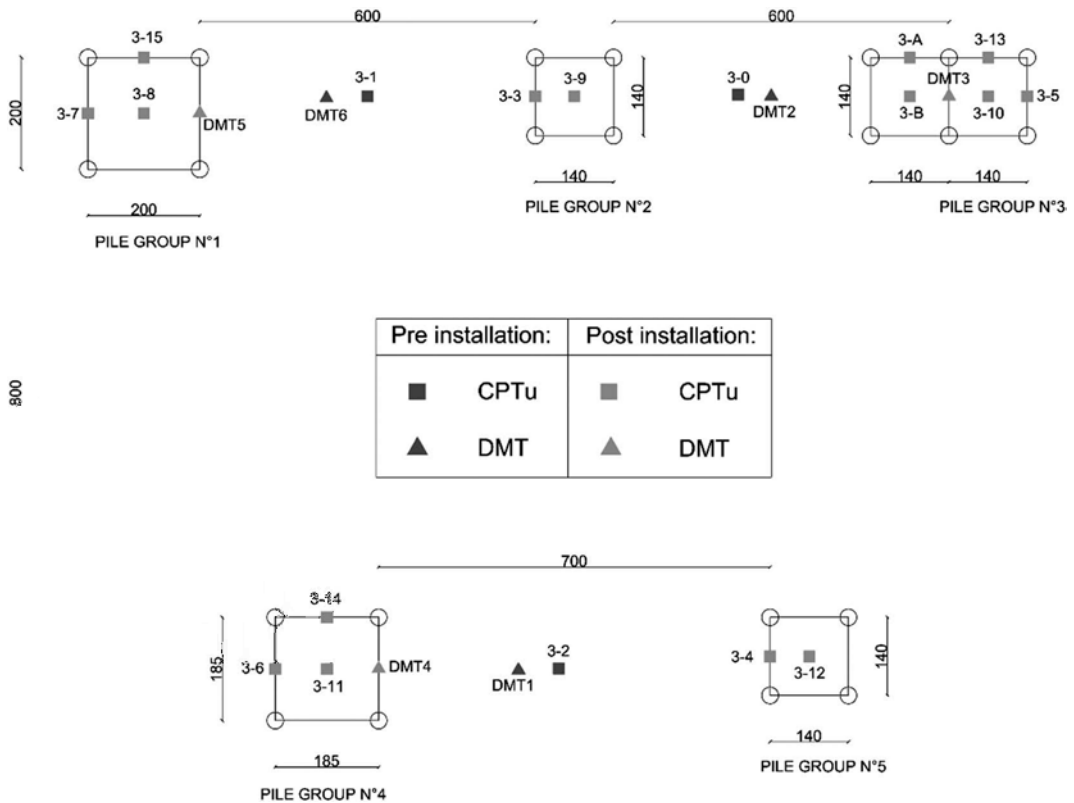
The installation process of driven precast piles determines, seemingly, similar phenomena, but there is a lack of knowledge about their quantification.


Figure 1. Configurations of pile groups and relative CPTu/DMT locations.

Therefore, the paper describes the experimental activities carried out in a test site, set up to evaluate the possible existence of these phenomena after the driving of precast piles.

The experimentation consisted in driving some prefabricated tapered piles with different energies and spacing between them in an area where some soil layers had a high liquefaction potential. To evaluate the pile driving effects on the stress state around them, preliminary CPTu and DMT tests were carried out and repeated at various distances from the pile center, after the driving activity.

One of the most interesting objectives of the research is to evaluate the change of the tip (q_t) and sleeve resistances (f_s) of the CPTu tests, comparing them with the data acquired using the DMT tests, principally the horizontal stress index K_D. Among the various phenomena influencing the soil susceptibility to liquefaction and the pile bearing capacity, the increase of horizontal stresses, resulting in a preloading effect, and its accurate determination could allow economic benefits in the design of deep foundations.

2 TEST SITE CHARACTERIZATION

2.1 Soil characteristics

The experimental site was chosen in the area where the most significant and widespread liquefaction phenomena had occurred during the 2012 Emilia seismic sequence. In particular the choice fell on an area near the Mirabello village (Ferrara, Italy), previously investigated in detail since a blast test was carried out in a neighboring area, in 2016 (Amoroso et al. 2017). During these previous studies, geological, geotechnical and geophysical characterization was carried out in proximity to the observed liquefaction evidence. The geotechnical in situ investigation included several standard penetration tests, piezocone tests, seismic dilatometer tests and deep boreholes, while geophysical tests included down-hole tests (DH1), MASWs (Multichannel Analysis of Surface Waves), P-wave and S-wave topographies, electrical resistivity topographies (Amoroso et al. 2017). During the new research further CPTu and DMT tests were carried out in the specific test area (CPTu 3-0, 3-1 and 3-2 and DMT 1, 2 and 3 – Figure 1) to confirm the main soil characteristic recognized previously.

On the basis of the abovementioned investigations, a geotechnical model was determined and the layers with the higher probability of liquefaction were identified. In the following, the main units are listed with their Unified Soil Classification System (USCS) descriptors according to ASTM D2487-11 (2011):

- Topsoil from 0 to 1 m bgl (CH) – Layer 1;
- Silty clay from 1 to 4 m bgl (CH) – Layer 2;
- Clayey silt with sand from 4 to 6 m bgl (CL-CH) – Layer 3;
- Silty sand and sandy silt (fluvial Apenninic deposits) from 6 to 8 m bgl (ML-SM) – Layer 4;
- Silty sand (paleochannel of the Po River) from 8 to 17 m bgl (SM) – Layer 5;
- Silty sand (Syn-Glacial braided Po River deposits) from 17 to 20 m bgl (SM) – Layer 6.

2.2 *Pile test characteristics*

In the area four pile groups, with four piles each, and one with six piles were set up (Figure 1).

The piles were tapered precast piles 16.0 m long, with a tip/head diameter of 260/500 mm and a taper of 15 mm/m.

In pile groups N.2, N.3 and N.4 piles have the same center distance, but were driven with different energies, measured using a Pile Driving Analyser (PDA).

Chosen the installation energy of the piles ensuring the best performance as regards the improvement of the soil characteristics, two other pile groups were set up with a larger center distance than the previous ones. In Table 1 are shown the data regarding center distance and installation energy.

Table 1. Installation energy and center distance of piles in the pile groups.

Pile group	Energy (E) kNm	Center distance (i) m
1	43.0	2.00
2	25.0	1.40
3	43.0	1.40
4	43.0	1.85
5	20.0	1.40

3 RESULTS

3.1 *Analysis of q_t data*

Figures 2, 3 and 4 show the profiles of the corrected cone tip resistance (q_t) acquired before and after the pile driving activity for the different pile groups. The CPTu tests after the pile driving were performed
Figure 2. Corrected cone tip resistance q_t before and after pile driving and R(q_t) value - Pile group N.3 [E=43 kNm, i=1.4 m].

both in the center position of the group and along one or two sides of the group of piles.

The influence of tapered precast pile installation may be represented by the ratio post-installation q_t to the pre-installation q_t, the Improvement Ratio [R(q_t)], defined by the following expression:

$$R(q_t) = \frac{q_{t\,post\,installation}}{q_{t\,pre\,installation}} \qquad (1)$$

It was computed at each measurement depth and shown in the same figures.

The $q_{t\,post\,installation}$ data differ considerably depending on both the pile driving energy used and the distance between the piles.

Considering the group of piles N.3, there is a high increase in q_t along the entire profile of the pile, after the installation, in the layers 4 and 5 (Figure 2) with an average increase of about 2 in soils with initial q_t greater than 6 MPa and even greater with values lower than 6 MPa. In the latter case, some of the very high values could depend on the comparison of different type soils (clay in the pre-installation CPTu and sand in the post-installation CPTu).

In the case of pile group N.2, the piles have the same center distance as group N.3, but they have been driven with lower energy (Table 1). R(q_t) is
Figure 3. Corrected cone tip resistance q_t before and after pile driving and $R(q_t)$ value - Pile group N.2 [E=25 kNm, i=1.4 m].
Figure 4. Corrected cone tip resistance q_t before and after pile driving and $R(q_t)$ value -Pile group N.4 [E=43 kNm, i=1.85 m].

significantly greater than 1 (Figure 3) only in the first meters of the silty sand layer 5, probably due to the effect of the lateral spreading of the soil, and is equal to 1 at deeper levels.

Finally, in the case of pile group N.4 (Figure 4), in which the piles have been driven with the same energy used for those of stand 3, but with a center

distance of approximately 1.85 m, R has a value substantially equal to one, showing a lack of improvement, albeit a probable stratigraphic variability is present at various depths. A similar situation is also observed in the case of pile group N.1.

3.2 *Analysis of K_D and f_s data*

A similar comparison was carried out taking into account the horizontal stress index K_D of DMT tests carried out before and after the installation of the piles. The DMTs after installation were performed along one side of the pile groups.

K_D of the dilatometric test is strictly correlated with the horizontal earth stress coefficient and therefore with the horizontal stresses.

As in the previous cases, the influence of tapered precast pile installation may be represented by the ratio post-installation K_D to the pre-installation K_D, the Improvement Ratio [$R(K_D)$], defined by the following expression:

$$R(K_D) = \frac{K_{D\ post\ installation}}{K_{D\ pre\ installation}} \qquad (2)$$

Also in this case for pile group N.3 (Figure 5) there is a marked increase in post-installation K_D with $R(K_D)$ values between 3 and 5, while for pile group N.4 the improvement is absent, except in the loose silty sand and sandy silt layer between 6.0 and 8.0 m, having a low cone resistance (Figure 6).
Figure 5. K_D before and after pile driving and $R(K_D)$ value - Pile group N.3 [E=43 kNm, i=1.4 m].
Figure 6. K_D before and after pile driving and $R(K_D)$ value - Pile group N.4 [E=43 kNm, i=1.85 m].
Figure 7. $R(K_D)$ and $R(F)$ - Pile group N.3 [E=43 kNm, i=1.40 m].

Robertson (2016) highlighted that the normalized CPT sleeve resistance ($F = f_s/\sigma'_{vo}$) can be used to estimate the DMT K_D; therefore, the trend along the depth between R (K_D) and R (F) of various pile groups was compared, where R (F) is the following expression

$$R(F) = \frac{F_{post\ installation}}{F_{pre\ installation}} \qquad (3)$$

Both ratios show the same phenomena, improvement of soil characteristics in correspondence of pile group N.3 (Figure 7) and modest if not zero improvement in pile group N.4 (Figure 8). Therefore, both, again, highlight the decrease of the improvement as the distance between the piles increases. The $R(K_D)$ ratio also is more sensitive than R(F) to the effects of the pile driving.

3.3 Cumulative settlement prediction

Adopting the Zhang et al. (2002) method to estimate liquefaction-induced ground settlements using CPT data, the effectiveness of the driving of piles on the decrease of the potential liquefaction effects was determined.

The Zhang approach combining the CPT estimate liquefaction resistance with laboratory test results on clean sand evaluates the liquefaction-induced volumetric strains for sandy and silty soils.

Zhang et al. (2002) assume that little or no lateral displacement occurs after the earthquake, such that the volumetric strain will be equal or close to the vertical strain. Integrating with depth the vertical strain in each soil layer, the potential liquefaction-induced ground settlement due to an earthquake is estimated by Equation 4,
Figure 8. $R(K_D)$ and $R(F)$ - Pile group N.4 [E=43 kNm, i=1.85 m].
Figure 9. Post liquefaction settlement using Zhang et al. method (2002) - Pile group N.3 [E=43 kNm, i=1.4 m].

$$w = \sum_{i=1}^{j} \varepsilon_{vi} \, \Delta z_i \qquad (4)$$

where w is the calculated liquefaction-induced ground settlement at the CPT location; ε_{vi} is the postliquefaction volumetric strain for the soil sublayer i; Δz_i is the thickness of the sublayer i; and j is the number of soil sublayers.

The analysis of data related to the pile group N.3 (Figure 9) shows a great decrease of potential post liquefaction settlement and consequently that the improvement is large. Therefore, with groups of more piles than in this case, significant improvements can be achieved from the point of view of a potential soil liquefaction settlement lower than the virgin soil.

4 CONCLUSIONS

The CPTu and DMT in situ tests were used to evaluate the improvement of the soil characteristics due to the driving of precast tapered piles.

The data acquired using the CPT and DMT tests show that the installation of prefabricated tapered piles determines an increase of the soil resistance, pointed out by the increase in q_t, as well as a change in effective lateral stress highlighted by both the increase of F and K_D.

The phenomenon is clearly remarkable up to a distance of about 4-5 pile diameters; beyond this distance the phenomenon tends to run out.

In the present case, the driving energy played a non-negligible role in the amount of the improvement.

Referring to the potential post-liquefaction settlement due to an earthquake and determined with the

Zhang et al. (2002) calculation method, the improvement of the soil behavior achievable through the installation of driving piles was clearly highlighted.

ABSTRACT: The paper describes a study on the liquefaction potential of flood defences along the rivers running through the delta area of the Netherlands. The study concentrates on an area south of Rotterdam. The dykes used as primary flood defences protect an urban, rural, and industrial area of 102,400 ha. In this paper the data from more than 4200 Cone Penetration Tests, CPT traces are used to assess more than 200 km of dykes. The pore pressure, u2 data is analysed, then used to separate the material response into contractive and dilative zones. Using the separation of liquefaction susceptible soils, and geometry of the riverbed a regional hazard map is generated. The choices for the data visualisation and their effect on the generated map are discussed and presented. The final liquefaction susceptibility map is used by the water governing authority Waterschap Hollandse Delta as a decision-making tool to improve the efficacy of liquefaction hazard assessment such as the location and return period of bathymetry measurements, and the scale of site- and laboratory investigation.

1   INTRODUCTION

In the Dutch delta, the majority of rural, industrial, and residential land are founded below mean sea level. These areas are reliant on flood defences for everyday protection. In 1953 a major flood following a heavy storm led to some of these dykes failing, which in turn led to large scale flood inundation and loss of life. Since 1953 extensive flood defences along the delta have reduced the risk of coastline flooding significantly. Dykes in the Netherlands are separated into two general types i) primary dykes which protect along the coast and rivers that have large fluctuations in water level during normal operation; and ii) regional dykes, which surround polder-systems where water levels are artificially maintained with little to no fluctuation. The responsibility to protect against inundation in the Netherlands has been given to separate water governing authorities. The water governing authority Waterschap Hollandse Delta (WSHD) are responsible for the safety of the primary and regional dykes around the Islands in the province of South Holland. There are approximately 200 km of primary dykes preventing the local area from flooding. These dykes need to be assessed frequently, considering several different failure mechanisms and their safety needs to be evaluated

and in turn reported to the national government. As part of their most recent assessment, WSHD conducted a large site-investigation campaign consisting of more than 5,000 (or exactly 5,137) Cone Penetration Tests (CPT), 800 boreholes and substantial laboratory tests on the soft deltaic soils. This study utilises this dataset to check for the potential of sand liquefaction beneath the Dykes.

Static liquefaction can occur when loose saturated cohesion less soils are loaded rapidly, for example due to slope over-steepening. Erosion of rivers in the governance area of WSHD affects the slopes of the river channel. This erosion can lead to underwater slope instability potentially leading to a static liquefaction type failure. The current assessment criteria (Rijkswaterstaat 2019) proposes a stepwise approach, where high hazard locations are identified based on their geometry, informed by both the bathymetry of the river basin and the physical geometry of the dyke. High hazard locations are then subjected to more detailed analysis. This study proposes to add to the geometrical data used to pre-screen high hazard locations by using the material behaviour chart (Robertson 2016) to identify underlying soil susceptible to liquefaction in the WSHD area.

2 GEOLOGY OF AREA

The area of investigation lies in the Rhine-Meuse delta which discharges to the North Sea. The river basin consists of silty clay and organic (clay) deposited on top of a Pleistocene sand layer typically located at depths from Dutch Ordnance Datum Level (NAP), NAP -15 m to NAP -20 m depth (≈15 to 20m below ground level in this low-lying coastal region). The clay and organic soil layers are intersected by several meandering streams forming channel belts, these are mapped by (Cohen, et al. 2012). Currently the rivers are 'locked' in place, meaning that old river channels locations have been fixed in location by engineering works. Dykes have been built to prevent flooding which can change the natural flow path of a river whilst additionally the riverbed is frequently dredged to allow for the safe operation of inland ships serving the Port of Rotterdam and maintain the discharge capacity of the river.

3 METHODOLOGY

Loose silts and fine sands will tend to contract when loaded. During regular static loading where loads are applied slowly (e.g. during construction of a building or dyke) pore pressures dissipate, and settlement occurs. However, if the rate of loading (or unloading) is high, e.g. during erosion, excess pore pressures develop and may lead to liquefaction and sudden large failure e.g. as shown in Figure 1. In dense sands this is not an issue as the particles want to dilate under loading, increasing the voids between particles and consequently the volume for water to occupy. One of the indicators of contractive/dilative behaviour is a sands relative density.

In an extensive site-investigation campaign WSHD has performed, 2 CPTs per 100 m length on both the top of the dyke and the inner slope (the slope facing the water being the outer slope). This dataset is used to assess the liquefaction potential

Figure 1. Example liquefaction occurrence, 1968-10-04, Oud-Kempenshofstedepolder (Tholen), by Kotvis, (1986).

along the primary dykes in the governing area of WSHD. The potential for liquefaction is determined by the layer thickness of the contractive sand or the relative density of the material when it is less than 66%. If the relative density decreases or the thickness of the contractive sand layer increases the relative risk of liquefaction in the area increases.

4 CURRENT NATIONAL GUIDELINES

The current Dutch Water Act (DWA, BWBR0025458) which came into effect on January 29th 2009, gives rules and design recommendations for the use and maintenance of Dutch water systems. The water governing authorities in the Netherlands are the primary executive organisations tasked with ensuring the water system and its defences comply with the DWA. Part of the DWA includes design rules for assessing direct and indirect failure mechanisms of dykes. With liquefaction recognised as one of the main indirect failure mechanisms, meaning that should an event happen, it will most likely not be the direct cause of a dyke failure but may contribute to one.

The recommended approach contains three assessments, each more detailed than the one before. The test are: a simple test, a detailed test, and a custom test. The methods of the simple and detailed test are prescribed in the technical guidelines whilst the custom test allows one to utilise the latest scientific insights to make the assessment.

The simple test is a geometric test with conservative assumptions. The detailed test considers soil properties, geometry, water levels and load types. The test itself determines whether there is enough dike forefront left after a liquefaction event to prevent failure (inundation). The DWA is revaluated regularly to incorporate the latest insights in water safety. The latest official code came into effect in 2017 (WBI 2017). While the next instalment is expected in 2023.

Currently there is a large difference in the complexity and as a result the level of detail required in parameter determination between the simple test and the detailed test. Incorporating information from the material behaviour chart into the simple test would allow the WSHD to identify areas more susceptible to liquefaction. This would facilitate them to focus their subsequent detailed assessments on areas with a high liquefaction hazard.

5 DETERMINING CONTRACTIVE ZONES

To identify whether a soil is contractive and subsequently susceptible to liquefaction, the following CPT based procedure developed by (Robertson 1990, Robertson 2016) has been followed. First measured q_c values are normalised into Q_t using the following relations see equations 1 to 3:

$$Q_t = \frac{q_t - \sigma_{v0}}{\sigma'_{v0}} \qquad (1)$$

$$F_r = \frac{f_s}{q_t - \sigma_{v0}} * 100\% \qquad (2)$$

$$q_t = q_c + u_2(1-a) \qquad (3)$$

Where Q_t is the normalized cone resistance, q_t is the cone resistance corrected for water effects, σ_{v0} is the current in-situ total vertical stress, σ'_{v0} is the current in-situ effective vertical stress, F_r is the normalized friction ratio, f_s is the measured sleeve resistance, q_c is the measured cone resistance, u_2 is the shoulder penetration pore pressure (behind cone tip) and a is the cone area ratio. When normalised CPT parameters have been obtained the soil behaviour indices I_c and I_B as well as the contractive dilative boundary (CD) can be obtained using the following relations, see Equations 4 to 8.

$$I_c = \left[(3.47 - logQ_t)^2 + (logF_r + 1.22)^2\right]^{0.5} \qquad (4)$$

$$Q_{tn} = \left[\frac{q_t - \sigma_{v0}}{p_a}\right]\left(\frac{p_a}{\sigma'_{v0}}\right)^n \qquad (5)$$

$$n = 0.381(I_c) + 0.05\left(\frac{\sigma'_{v0}}{p_a}\right) - 0.15 \qquad (6)$$

$$I_B = 100(Q_{tn} + 10)(Q_{tn}F_r + 70) \qquad (7)$$

$$CD = 70 = (Q_{tn} - 11)(1 + 0.06F_r)^{17} \qquad (8)$$

where p_a being the atmospheric reference pressure and n is the stress exponent defined by equation 6. After obtaining Q_{tn} and F_r and using the boundaries based on I_b and CD suggested by (Robertson 2016) the soil can be classified by the soil type behaviour. The relative density, D_r of young, uncemented silica sands (Kulhawy and Mayne 1990) can be obtained using:

$$D_r = \sqrt{\frac{Q_{tn}}{350}} \qquad (9)$$

Figure 2 gives two examples of analysed CPTs using the soil behaviour chart as suggested by Robertson (2016). The following zones are named, CCS (clay-like, contractive, sensitive) CC (clay-like, contractive), CD (clay-like, dilative), TC (transitional, contractive), TD (transitional, dilative), SC (sand-like, contractive) and SD (sand-like, dilative). Figure 2a shows a CPT having a large number (606) of contractive points, and in Figure 2b fewer (296) contractive points are found.

6 IDENTIFICATION AND VISUALISATION OF LIQUEFACTION HAZARD

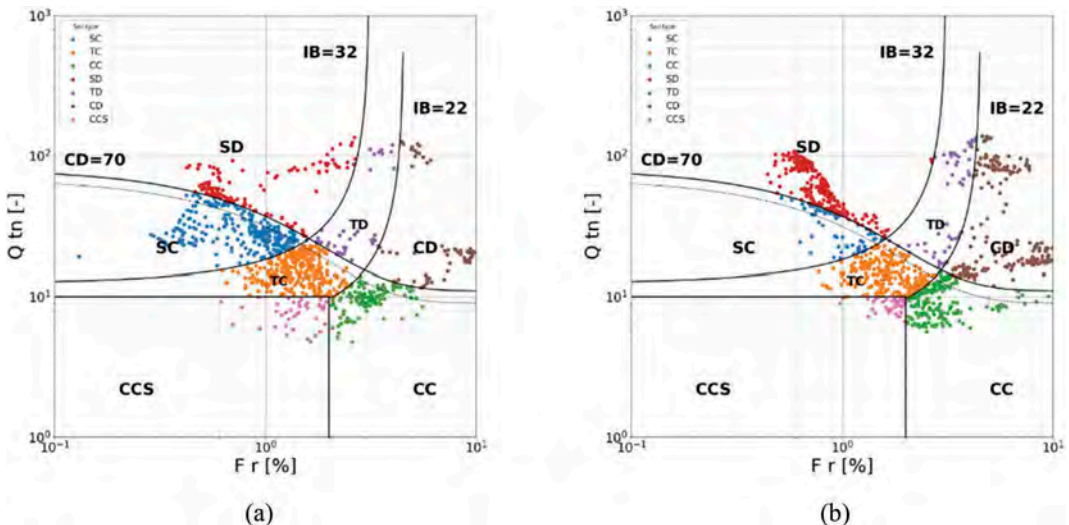
To identify the liquefaction potential the CPTs are automatically processed. For the calculation of


Figure 2. Example soil behaviour chart after Robertson (2016) for two CPTs a) containing a large number (606) of contractive soil points and b) containing fewer (296) contractive points.
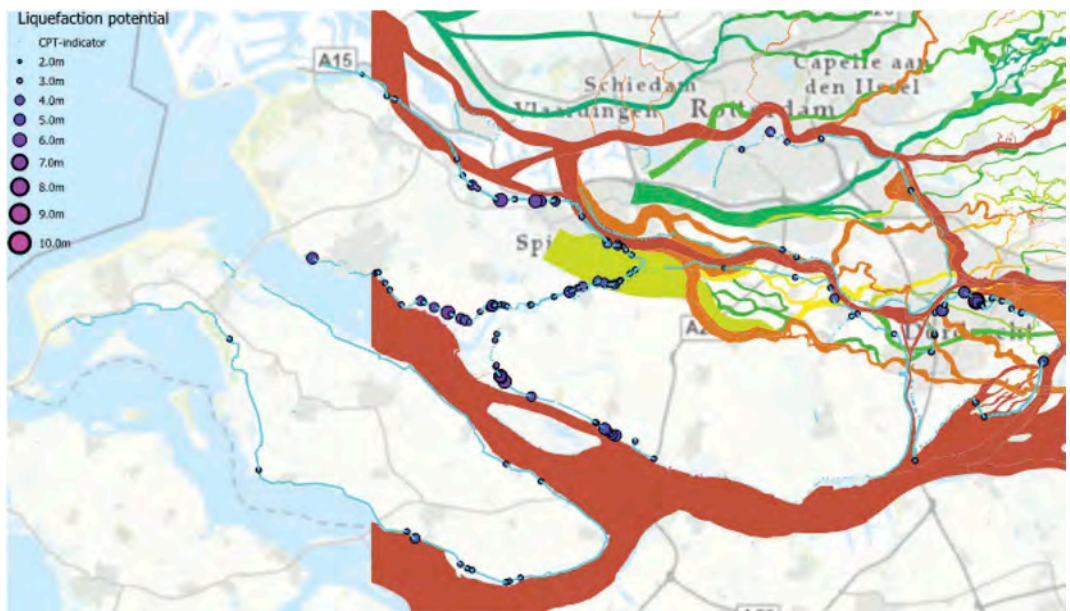
Figure 3. Governing area of WSHD overlaid with the old and current channel belts map, SC-SD-TC-TD 66% window is 200cm, CPT point size scaled to number of liquefaction susceptible points.


Figure 4. Governing area of WSHD overlaid with the old and current channel belts map, SC-TC 100% window is 200cm, CPT point size scaled to number of liquefaction susceptible points.

effective stress, the phreatic level is assumed to be fixed at the reference level of NAP +0.0 m with hydrostatic conditions assumed with depth. The liquefaction potential is analysed over a fixed depth of NAP +0.0 m to NAP -12.0 m. Each CPT is analysed using a moving window approach, once points in the window are identified as being susceptible to liquefaction, they are aggregated and the total number of susceptible points at a CPT location is used as an indicator of liquefaction hazard.

For all the CPTs analysed, two different criteria of liquefaction susceptibility have been used i) contractive sands and contractive transitional soils and ii) sands and transitional soils with a relative density below 66%. A moving window is used to tally the number of liquefaction susceptible points, the liquefaction susceptible points are counted if all points meet the requirement criteria. After processing, the highest liquefaction potential is associated to the highest number of concurrent liquefiable points.

Figure 3 shows the results of a batch analysis looking within all CPTs for zones that contain a relative density below 66% for transitional soils and contractive sands, it shows that most of the locations tested in the WSHD area contain significant volumes of loosely packed sand that may be susceptible to static liquefaction. Figure 4 presents the results for 2.0 m or larger continuous contractive sands and transitional soil layers. Figure 4 still highlights a number of liquefaction prone areas in the governing area of WSHD, however much fewer are identified than when the relative density approach is used.

7 DISCUSSION AND CONCLUSIONS

This paper presents two analyses performed using a large dataset of CPTs in the governing area of Waterschap Hollandse Delta (WSHD). Each CPT profile was analysed for the liquefaction susceptibility based on relative density and contractive behaviour. Based on the relative density analysis, many dykes were shown to be built on soil profiles containing significant depths of loose sand. This loose material has the potential to liquefy but does show consistent contractive behaviour over 2.0 m depths both according to the CPT analysis. The analysis based on the soil behaviour type highlights several locations where continuous depths of soil that would exhibit contractive behaviour are observed. As this has the potential to trigger liquefaction and cause large dyke failures to occur these areas will be more closly monitored by WSHD.

The analyses included some simplifications that can be examined in future studies. Rather than assuming hydrostatic pore pressures, an accurate assessment of in-situ pore water pressures should be conducted. The impact of dyke geometry and the resulting effective stress conditions should be included. Combining the liquefaction analysis with the geometry and bathymetry of the riverbed is an area of interest for the liquefaction susceptibility analysis. It is important to confirm the applicability of the relative density correlation and the trigger level of D_r below 66% to the Pleistocene sand layers considered. And finally, a major question remains, on what is the optimum moving window size for highlighting when contractive soil layers can cause large liquefaction induced failure.

Application of the CPT for liquefaction assessment of gravelly reclamations at the port of Wellington

R. Dhakal & M. Cubrinovski
University of Canterbury, Christchurch, New Zealand

J.D. Bray
University of California, Berkeley, USA

ABSTRACT: Widespread liquefaction occurred in the reclamations at CentrePort, Wellington (New Zealand) during the 2016 Kaikōura earthquake (M_w7.8) which produced a relatively moderate seismic demand (peak horizontal ground acceleration of 0.2-0.3g at the site). Most of the damage occurred in the end-dumped fills (i.e., the Thorndon reclamation) which are comprised of 60-80% gravels and 20-40% sand-silt mixtures. This study presents results from CPT-based liquefaction assessment on a representative profile from the Thorndon reclamation using both a semi-empirical simplified method and advanced dynamic effective stress analysis. The simplified assessment results are generally consistent with observations since the CPT is able to capture the response of the finer sand-silt fraction in the matrix, which likely controlled the liquefaction behavior during the Kaikōura earthquake. The preliminary effective stress analysis provides insights on the timing and onset of liquefaction, and processes involving dynamic interactions within the deposit, thus illustrating important response characteristics which are beyond the capability of simplified methods. This paper illustrates the use of the CPT in performing conventional simplified and dynamic liquefaction analysis when applied to non-conventional or problematic soils for the assessment with reference to a well-documented case study.

1 INTRODUCTION

The cone penetration test (CPT) is commonly used for geotechnical characterization and liquefaction assessment (e.g., Boulanger and Idriss, 2014; Robertson and Wride, 1998). However, several issues exist in the use of the CPT for assessment of soil liquefaction. For example, there are challenges in the application of simplified semi-empirical CPT-based methods, developed primarily using case histories of naturally deposited sands and sands with fines, to nonstandard soils such as reclaimed gravels (Cubrinovski et al., 2019). In addition, there is a growing need for advanced numerical techniques such as seismic effective stress analysis, which can provide insights on liquefaction behavior beyond the scope of the simplified procedures. When applying an effective stress analysis, the constitutive model can be calibrated using either laboratory data on high-quality samples or empirical relationships (e.g., Ntritsos and Cubrinovski, 2020). This paper illustrates the use of the CPT for simplified and advanced liquefaction analysis for a well-documented case study of gravelly reclamation from the port of Wellington, New Zealand. In the advanced analyses, CPT-based relationships are used to calibrate the constitutive model for liquefaction evaluation of the gravelly reclamations.

2 CENTREPORT RECLAMATIONS

2.1 *Reclamation history*

Wellington is located at the southern tip of the North Island of New Zealand. The city was developed over the past 170 years, where the original coastline sat approximately 200 m to 500 m inland from the present coastline delineating a belt of reclaimed land. An aerial view of the port of Wellington (CentrePort) is shown in Figure 1, which was developed over several periods of major reclamation. In the most recent reclamation works (from 1965 to 1976), the area south of the buried seawall depicted in Figure 1 (i.e., the Thorndon reclamation) was constructed by end-tipping of gravelly soils sourced from nearby quarries (Cubrinovski et al., 2017). Gravelly soils were dumped into the sea to construct fills of 10 m to 22 m thickness. The fill below 2-3 m depth, aligning with the approximate depth to the water table, is uncompacted. Underlying these reclamations are Pleistocene deposits consisting of weathered alluvium, colluvium, and marine deposits. The greywacke basement rock under these deposits is at 100-150 m depth.
Figure 1. Aerial view of CentrePort (shaded in red), an old buried seawall, locations of two strong motion stations, and the location of one CPT (CPTu042). The inset shows the location of Wellington and the source and rupture propagation of the 2016 Kaikōura earthquake (modified from Cubrinovski et al., 2018).

2.2 *Liquefaction performance during the 2016 Kaikōura earthquake*

On 14 November 2016, the M_w7.8 Kaikōura earthquake occurred in the South Island of New Zealand (location depicted in the inset of Figure 1). The closest distance from the causative faults to CentrePort was approximately 60 km, resulting in relatively long duration but moderate amplitudes of ground shaking (i.e., estimated horizontal peak ground accelerations, *PGA*, of 0.2-0.3g at the port).

The Kaikōura earthquake triggered widespread liquefaction that severely damaged port buildings and wharves (Cubrinovski et al., 2017). The most severe damage occurred in the Thorndon reclamation where up to 1 m horizontal movement and over half a meter of vertical settlements were observed. Large volumes of gravelly ejecta with thickness up to 150-200 mm were also observed on the ground surface (e.g., Figure 2a). Reconnaissance efforts included collection and index testing of ejected gravelly

samples, results of which are summarized in Figure 2b, which indicates the fill consists of 60% to 80% gravels (i.e., > 2 mm particle size) with the remaining 20% to 40% of the mixture consisting of silt and sand fractions. The fines content (*FC*) is typically between 5% and 15%.
Figure 2. (a) Gravelly ejecta observed after the Kaikōura earthquake at the Thorndon reclamation (Cubrinovski et al., 2017), and (b) grain-size distribution of the Thorndon reclamation gravelly fill (Dhakal et al., 2020a).

2.3 *In-situ site investigations*

Comprehensive site investigation following the Kaikōura earthquake characterizes the subsurface soils at CentrePort by using over 100 CPTs, soil samples collected from over 30 boreholes, and shear-wave velocity profiles measured using direct-push and surface wave methods (Cubrinovski et al., 2018; Dhakal et al., 2020a; Dhakal et al., 2020b). The trace of measured cone tip resistance (q_c) and calculated soil behavior type index (I_c) of a representative CPT profile from the Thorndon reclamation (CPTu042) are shown in Figures 3a and 3b, respectively.

The gravel-sand-silt fill from 3 m to 14.7 m depth show characteristic values of q_c (6–8 MPa) and I_c (1.9–2.3) throughout depth despite its complex soil

composition. The relatively low penetration resistance and intermediate values of I_c for soils containing large amounts of gravel imply that these fills comprising gravel-sand-silt mixtures display soil behavior type typical for silty sand and reflects a dominant influence of the finer fractions (sand and silt) in the soil matrix. This in turn implies that the finer sand-silt fractions will have a governing role in the seismic response of the fill, despite the fact that the gravel-size particles are dominant by volume (Cubrinovski et al., 2019). The coarser gravel particles only have a minor influence, as manifested in the observed occasional spikes in q_c (associated with low I_c values).

3 SIMPLIFIED LIQUEFACTION ANALYSIS

The CPT data is used to evaluate liquefaction triggering using the Boulanger and Idriss (2014) procedure, which compares the earthquake-induced cyclic stress ratio (CSR) to the cyclic resistance ratio (CRR) of the soil to estimate a factor of safety against liquefaction triggering. The conventionally adopted criterion of $I_c < 2.6$ is used to identify soils susceptible to liquefaction. The liquefaction assessment is conducted assuming a level ground condition for a $M_w7.8$ event with $PGA = 0.25$ g which represents the geometric mean of the shaking induced by the 2016 Kaikōura earthquake (Cubrinovski et al., 2018). The groundwater level is carefully considered in the analyses including effects of tidal fluctuations using data from nearby piezometers to estimate the water level at the location of the CPTs, at the time of the earthquake (Dhakal et al., 2020b). The probability of liquefaction triggering of $P_L = 50\%$ is used for the back-analysis of this case history instead of the deterministic value of $P_L = 16\%$, which is conventionally used in forward analysis and design. The FC is approximated as 15% in the analysis.

Figure 3 shows the computed profiles of CRR and CSR alongside the q_c and I_c data for the representative Thorndon reclamation CPT. The results in Figure 3c indicate CRR of the reclamation is well below the seismic demand imposed by the 2016 Kaikōura earthquake (i.e., the CSR). Hence, the CPT-based simplified procedure indicates that liquefaction should have been triggered throughout the depth of the Thorndon gravelly reclamation in CentrePort. As widespread liquefaction effects (e.g., soil ejecta, vertical settlements, and horizontal ground movements) were observed at the port after this event, the simplified CPT-based liquefaction triggering procedure provides results that are consistent with the field observations. This agreement reflects the fact that the sand and silt fractions in the soil matrix have a governing influence during the earthquake, which the CPT captures. On this basis, general applicability of CPT-based simplified liquefaction assessment procedures to the complex gravelly reclamations at CentrePort could be justified.

However, several challenges and limitations in the simplified liquefaction evaluation have been identified for the gravelly reclamations (Cubrinovski et al., 2019). For example, there are several areas in other gravel reclamations north of the old buried seawall (depicted in Figure 1) with poor estimates of liquefaction damage (Dhakal et al., 2020a). Furthermore, the simplified procedures provided much smaller degree of variation in the ground performance as compared to actual observations (Dhakal et al., 2020b). Therefore, additional insights are needed from more rigorous dynamic site response analyses to enhance our understanding of soil behavior and evolution of liquefaction in these reclamations.
Figure 3. Profiles of CPTu042 (a) cone tip resistance (q_c), (b) soil behavior type index (I_c), and (c) cyclic stress ratio (CSR) and cyclic resistance ratio (CRR) calculated using the Boulanger and Idriss (2014) procedure under the seismic demand of the 2016 Kaikōura earthquake.

4 EFFECTIVE STRESS ANALYSIS

4.1 Numerical model

A fully coupled nonlinear effective stress analysis of saturated soil is used to perform 1D site response analysis of the Thorndon reclamation soil profile shown in Figure 3. In the analysis, an input earthquake motion is applied at the base of a 1D soil column, a finite element model comprised of 2D quadratic elements constrained to deform in simple shear mode of deformation. A key requirement in such analyses is the use of a realistic ground motion, for the site and earthquake of interest, to input at a reference subsurface layer (Ntritsos et al., 2021). Rigorous scrutiny of deconvolved motions from several nearby strong motion station (SMS) sites have shown that the deconvolved motion from a SMS site on native deposit 590 m from the location of the

analyzed soil profile (i.e., VUWS; location shown in Figure 1) is an appropriate motion for input in 1D analysis (Dhakal et al., 2022). Note that while the entire deconvolved ground motion (i.e., Figure 4b) is used as a base input motion in the dynamic analysis, the simplified analysis only uses the *PGA* of the motion (indicated in Figure 4a) recorded at the surface of the closest SMS site 330 m from the location of the analyzed soil profile (CPLB; location shown in Figure 1) in conjunction with the earthquake magnitude. By considering the entire ground motion time history, the dynamic analysis can provide insights on the timing, onset, and evolution of liquefaction throughout the depth of the fill.
Figure 4. (a) *PGA* of the surface recorded horizontal ground acceleration at CPLB used as input for simplified liquefaction assessment, and (b) the entire horizontal ground acceleration time history of the deconvolved motion at VUWS used as input in the effective stress analysis.

4.2 *Simplified CPT-based soil profiles*

Unlike the simplified methods, in which a nearly continuous record of the CPT trace can be used for liquefaction calculations, discretization of the profile based on its stratification is required for the numerical model of the effective stress analysis. This study illustrates the use of the CPT in identifying the stratification for this purpose. The nearly continuous CPT profile is first discretized into several distinct layers or depth intervals over which the CPT data can be approximated by constant values of the clean-sand equivalent penetration resistance (q_{c1Ncs}) and I_c. In this study, the algorithm developed by Ntritsos and Cubrinovski (2020) is adopted for the determination of the simplified soil profile. The resulting simplified soil profile is illustrated in Figure 5 with the red solid line. The layer discretization is fine enough to allow detection of thin seams of liquefiable soils while keeping the simplified q_{c1Ncs} and I_c profiles as close as possible to the actual, more irregular, CPT traces.

Following the determination of the simplified profile, layers with $q_{c1Ncs} < 170$ and $I_c < 2.6$ are then deemed potentially liquefiable, whereas all other layers are considered as non-liquefiable. The adopted modelling approach for the liquefiable and non-liquefiable layers is summarized in Figure 5d and explained in detail in the subsequent section.

4.3 *Constitutive model calibration*

This study utilizes the Stress-Density model, which is an elastic-plastic constitutive model specifically tailored for analysis of soil liquefaction problems (Cubrinovski and Ishihara, 1998a; 1998b). The model is capable of accurately simulating highly nonlinear stress-strain behavior of liquefiable soils under both monotonic and irregular cyclic loading. A key feature of the model is that it utilizes the state-concept approach for modelling the effects of density and confining stress and therefore can consistently represent the behavior of sand at any density and confining stress by using the same set of material parameters.

A key requirement of the model is to accurately simulate the accumulation of shear strains and consequent development of excess pore-water pressures under cyclic loading. This ability needs to be demonstrated through a series of element-test simulations, which are also used to calibrate the key response characteristic of the constitutive model that will allow to accurately simulate target liquefaction resistance curves (LRCs). Here, LRC represents the combination of *CSR* and number of cycles (N_c) required to cause liquefaction or typically 5% double-amplitude strain, for a specific density and vertical effective stress of a given soil. Target LRCs can be obtained either from laboratory tests on soil samples or based on empirical relationships developed within the simplified triggering methods (e.g., Boulanger and Idriss, 2014). The latter approach is employed in this study, in which the Stress-Density constitutive model is calibrated to simulate LRCs derived from the Boulanger and Idriss (2014) simplified procedure, with calibration details provided in (Ntritsos and Cubrinovski, 2020). Following such calibration of the model, the only input required from the user for the analysis is a CPT profile with discretized layers of q_{c1Ncs} and I_c.

Figure 6 depicts the target LRCs based on Boulanger and Idriss (2014), shown with solid lines, for five different densities (i.e., q_{c1Ncs} values), whereas the Stress-Density model simulations of the LRCs are shown with open symbols. It illustrates that the Stress-Density model can accurately simulate LRCs, or stress-strain behavior and excess pore water pressure development, for soils with a wide range of q_{c1Ncs} (i.e., from very loose to dense soils).

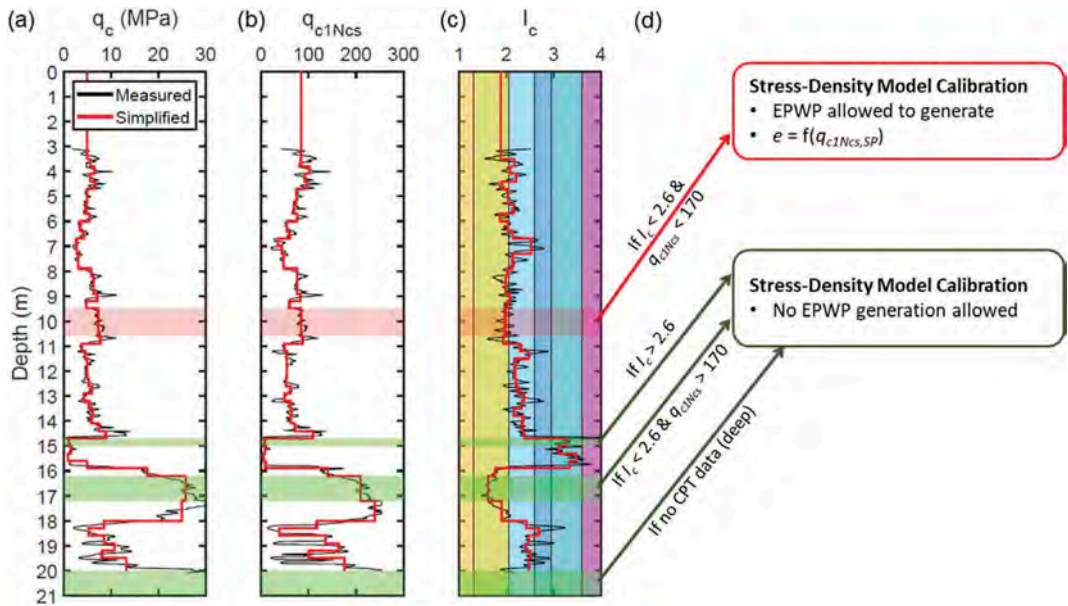
Non-liquefiable layers are modelled with the Stress-Density model's pore-water pressure generation feature turned off using shear modulus and damping relationships with shear strain as target curves in the element test simulations.


Figure 5. Profiles of CPT (a) cone tip resistance (q_c), (b) clean-sand equivalent cone tip resistance (q_{c1Ncs}), and (c) soil behavior type index (I_c) with measured data (shown in black) and simplified (layered) data (shown in red), and (d) associated modelling approaches for a liquefiable layer (shown in red) and non-liquefiable layers (shown in green).
Figure 6. Semi-empirically derived target liquefaction resistance curves (solid lines; Boulanger and Idriss, 2014), and Stress-Density model simulated liquefaction resistance curves (open symbols; Ntritsos and Cubrinovski, 2020) for different clean-sand equivalent resistances (q_{c1Ncs}).

4.4 Analysis results

Figure 7 shows the results of the analysis for the selected CPT profile (CPTu042) including distribution of maximum shear strains and pore-water pressure ratios at different time sections, throughout the depth of the profile. Computed acceleration time histories at four depths are also shown. The results indicate that liquefaction occurs first in a shallower layer (6.5-8 m depth) at approximately 40 seconds after the start of the dynamic analysis (computational time). A second, deeper layer (11.5-13 m) liquefies several seconds later. The onset of liquefaction in these two layers reduces the demand in the deposit as illustrated with the decrease in amplitude and loss of high-frequency content in the acceleration time histories. This in turn reduces pore pressure build-up and development of liquefaction in the remaining part of the profile.

These results are sensitive to key modelling decisions made by the user. For example, the shallow liquefied layer in Figure 7 includes a very thin soil layer at 7 m depth with I_c near the liquefaction susceptibility threshold of 2.6, which may have higher liquefaction resistance than that adopted in the analysis. Also, the intensity of the input ground motion will have a significant effect on how excess pore water pressures and dynamic interactions develop during the deposit. The seismic effective stress analysis provides means to investigate important mechanisms of the liquefaction response which are beyond the capacity of the simplified procedures.

5 CONCLUSIONS

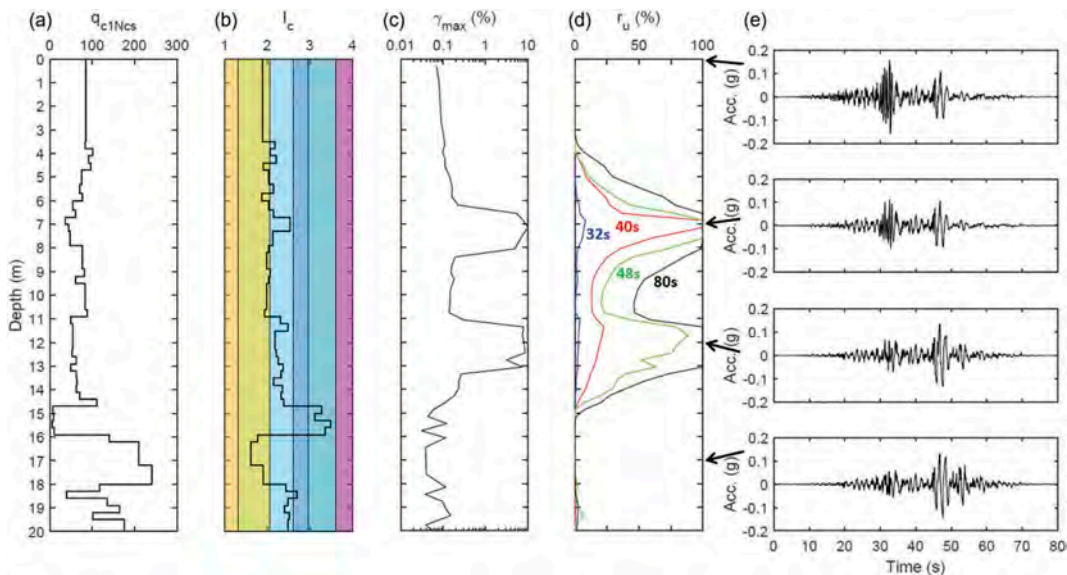
This study illustrates the use of the CPT for liquefaction assessment of reclaimed gravelly soil in the port of Wellington using simplified and advanced methods. CPT data obtained in the fills composed of 60–80% gravels and 20–40% sand-silt fractions indicate the dominant influence of the finer sand-silt matrix in the fill with


Figure 7. Results from the 1D effective stress analysis performed for CPTu042 showing (a) clean-sand equivalent cone tip resistance (q_{c1Ncs}) profile, (b) soil behavior type index (I_c) profile, (c) maximum shear strain (γ_{max}) profile, (d) excess pore-water pressure ratio (r_u) profiles at different computational times, and (e) acceleration time histories at four depths of interest.

relatively low tip resistances (q_c = 6–8 MPa) and soil behavior type values (I_c = 1.9–2.3) characteristic of sand-silt mixtures. The CPT-based simplified assessment result in relatively low cyclic resistances that are below the demand of the 2016 Kaikōura earthquake, which is generally consistent with observations. Advanced seismic effective stress analysis is also conducted through careful modeling of 1D soil layers using a sophisticated constitutive model calibrated to CPT-based semi-empirical liquefaction resistance curves. Unlike the simplified analysis which only provides a pseudo-static factor of safety, the effective stress analysis provides further details beyond the capability of simplified methods, such as the timing and onset of liquefaction, and dynamic interaction between different layers.

ABSTRACT: Due to the rapid expansion of the offshore energy market, driven by the installation of wind turbines founded on single- or multi-piled foundations, the design and optimisation of laterally loaded piles has attracted enormous interest in the last decade. Current industrial design practice, for offshore and onshore piles, typically employs lateral load-displacement springs (*p-y*) to model the soil response under serviceability, ultimate or fatigue limit state scenarios of this foundation type, supplemented by moment and axial springs. Correlations based on CPT data are commonly used to determine soil properties and, in turn, the stiffness and resistance of the *p-y* reaction curves, in advance of detailed laboratory testing that follows later in the project schedule. To extend the potential for in situ testing to support lateral pile design, this paper presents the novel idea of complementing a CPT device with a new module capable of probing the soil in such manner that the monotonic and cyclic *p-y* soil response (including its evolution during the foundation design life) can be directly measured in the field. The stress and strain fields induced by such a module resemble those of a miniature laterally loaded pile element and differ from circular or flat cavity expansions induced by pressuremeters or dilatometers. The new device will be developed in a collaborative research project 'ROBOCONE' financed by the UK and Irish research councils. The background thinking and initial conceptual design of the device, including the review and selection of appropriate motion mechanisms and instrumentation, is presented in this manuscript.

1 INTRODUCTION

Modern society demands more efficient infrastructure under stricter and more challenging operational and climatic conditions, such as offshore energy structures in harsh environments and urban developments in overly congested areas. The loading conditions are complex and time variant, and the mechanical properties of the ground can vary spatially and temporally. In this setting, a 'whole-life' design approach (Gourvenec, 2020; White et al. 2022), acknowledging the evolution of these actions and responses is important. Developing new technologies and methods to characterise the whole-life engineering properties of the ground is essential to meet the required safety, resilience and efficiency of geotechnical design and civil infrastructure.

The CPT has been the primary platform and manipulator for 50 years for in situ geotechnical characterisation of ground properties. CPT data have also underpinned the design of many geotechnical structures, including onshore and offshore pile foundations.

It is customary geotechnical practice to relate the parameters of lateral resistance-displacement soil springs (*p-y* curves), used in the design of laterally loaded piles, directly to CPT data or to soil strength and stiffness parameters inferred from CPT data (Truong and Lehane, 2014). These procedures are almost invariably based on empirically derived correlations.

The extension of the kinematic range of in situ geotechnical tests, via modern robotics, could permit the application of kinematic mechanisms and strain histories to the ground that mimic more closely the stress paths expected from the geotechnical infrastructure, such as a pile. This could allow the direct measurement of the soil '*p-y*' response and its whole design life evolution, if appropriate stress and/or strain histories are imposed.

This paper presents the initial feasibility study and background thinking for the future development of a new additional '*p-y*' modular section which can complement the standard CPT equipment. The work is part of a new collaborative research project

involving the University of Bristol, University of Southampton and Trinity College Dublin, financially supported by the UK-Ireland research councils.

2 CONTEXT AND NOVELTY OF THE PROPOSED DEVELOPMENT

Since its early development in the 1950s at the Dutch Laboratory for Soil Mechanics in Delft, the CPT has been considerably upgraded in the testing and control procedure as well through the inclusion of new sensors. The latter, for example, include seismic, electric resistivity and acoustic transducers (i.e. Campanella et al. 1986; Shinn et al. 1998; Houlsby and Ruck, 1998).

Alongside sensor development, the kinematic range of the CPT has also been expanded. The cone-pressuremeter combines a standard cone penetrometer with the capability of a standard pressuremeter, enabling the application of cavity expansion kinematics on surrounding soil (Houlsby & Withers, 1988).

A series of friction sleeves with torsional load and axial load sensing capabilities and with varying surface texture have also been included behind a standard cone penetrometer through recent development at the Georgia Institute of Technology (Martinez & Frost, 2018). The system is coupled with a series of pore pressure sensors, enabling the measurement of excess pore water pressure ahead and after each axial and/or torsional friction sleeve. The device can monitor both quasi-static and cyclic behaviour enabling an insight into cyclic strength degradation as well as liquefaction potential.

Other attempts have been made to impose cyclic vertical motions to simulate the cyclic response of axially loaded piles or to evaluate the cyclic liquefaction potential of soils (Diambra et al. 2014; Hosseini-Sadrabadi et al. 2019). Vibrational movements have also been imposed by Stähler et al. (2018) to assess the liquefaction resistance of soil deposits.

None of the proposed kinematic mechanisms has considered the possibility to explore the horizontal ('p-y') soil resistance, mimicking the soil loading imposed by a laterally loaded pile. This could be achieved through an additional module behind the cone, similar to the torsional frictional sleeves. Through modern robotics, the p-y module could impose complex stress histories involving cycles of loading and unloading, similar to laboratory element testing. Relative to laboratory testing, this would eliminate the challenges of sample disturbance and recapturing stress states as well as the time-consuming and expensive operations of drilling and sampling as well as the laboratory testing itself.

The developments within the RIGSS (Remote Intelligent Geotechnical Seabed Surveys Joint Industry Project (White et al, 2017, 2022) demonstrate the benefits of introducing robotic and smart testing in the geotechnical characterisation of shallow seabed sediments. The present project aims at transferring some of the RIGSS capabilities to deeper soil layers.

3 OVERVIEW OF THE PROPOSED P-Y MODULE

3.1 *Main principles*

A diagram of the working mechanism for the proposed p-y module is shown in Figure 1. A module capable of horizontal translation is included behind the standard cone penetrometer. This device mimics the load and displacement history imposed by a laterally loaded pile element, so that the module response can be upscaled for pile design or used to determine constitutive soil parameters. The development of appropriate theoretical frameworks for the interpretation of the module response will be also a fundamental contribution of the forthcoming research project. The aim is to be able to derive full monotonic and static reaction curves and their evolution after application of particular stress histories.
Figure 1. Diagram of the 'p-y' CPT module and whole life stress histories that could be imposed.

The difference between the displacement field and soil reactions induced by the proposed p-y module and those produced by pressuremeters or flat dilatometers is shown in Figure 2. The proposed p-y module induces an asymmetric bulb of pressure creating a flow of soil around its cylinder, similarly to a laterally loaded pile.
Figure 2. Cross-section of displacement field and soil reactions induced by 'p-y' module (left), pressuremeter (middle) and flat dilatometer (right).

901

3.2 *Application of whole-life stress histories*

Robotic control and a precise actuation system is necessary in order to enable the application of complex load histories, mimicking whole-life stress histories as shown in Figure 1. Geotechnical design recognises that the strength and stiffness of ground, and therefore the performance, safety and resilience of our infrastructure, evolves through time under the exposure to in-service loadings. For example, offshore facilities on soft marine sediments can experience transient falls in strength, potentially by a factor of 2, but long-term gains by a factor of 4 due to loading episodes and consolidation (Zhou et al. 2019). Driven piles, for example in sand and chalk, can also exhibit similar levels of short-term degradation and long-term recovery depending on the loading history (Jardine and Standing, 2012; Ciavaglia et al. 2017). These advanced aspects of ground behaviour are progressively entering into engineering practice and so it is timely for in situ testing protocols to also advance in parallel, to provide the necessary site characterisation.

4 MAIN DESIGN REQUIREMENTS AND CONSTRAINTS

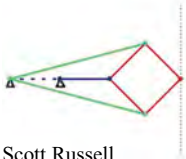
The initial background thinking and design of the module has revealed a number of design requirements and challenges to be addressed in order to achieve the successful development of the '*p-y*' module. Among others, the following challenges have been recognized in this early stage of development. The module mechanical arrangement requires the following characteristics:

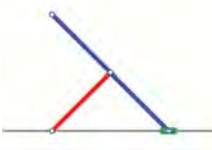
- Application of straight-line horizontal motion to the module. This may include a mechanism that transforms vertical movement or rotary motion (from a motor or other drive unit) into straight line horizontal movement.
- Ability to provide appropriate force capacity to overcome the soil resistance.
- Ability to offer adequate precision and resolution to be able to measure the stiffness of the soil over the required strain range.
- Sufficient robustness.
- Capable of hosting sensors to measure soil response, including pore water pressures.
- Resilient against soil becoming trapped between the moving parts.

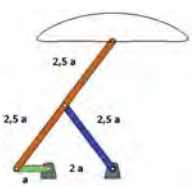
Include sensors to measure soil pressure, module movements (over the very small to large displacement domain) and generated pore water pressure. Some of the above points are further elaborated in the following.

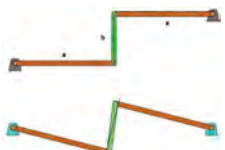
5 DEFORMATION AND CAPACITY REQUIREMENTS

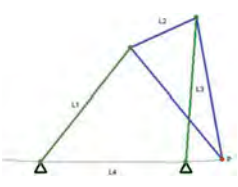
5.1 *Required capacity*

The pushing force required to displace and bring the soil to failure can be determined by inversely applying the *p-y* theory to the translating module. The horizontal force exerted from the soil and, therefore, the required force to move a typical 44mm diameter (i.e. 15cm^2 cone) is shown in Figures 3 and 4 for both sands and clays for varying depth and undrained shear strength, respectively. Both sets of graphs show these forces for differing heights of the module. The required force for the sand is estimated using the *p-y* curve proposed by Reese et al. (1974), assuming a soil friction angle of 40°. The required force for the clay is estimated using both the Matlock et al. (1970) *p-y* curves for soft clay and the Reese et al. (1975) *p-y* curves for stiff clay. The relevant movements are on the order of 0.1 diameters
Figure 3. Required Horizontal Force vs Depth for sand to invoke lateral displacement of CPT module.










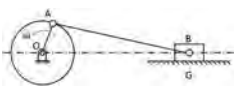


Figure 4. Required Horizontal Force vs Undrained Shear Strength for clay to invoke lateral displacement of CPT module.

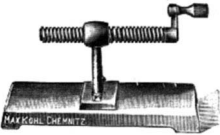
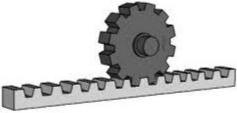
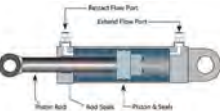
5.2 *Displacement resolution and control*






Stiffness information over the shear strain range 0.01-1% are typically important for design and can be

Table 1. Potential mechanical systems to use on the ROBOCONE 'p-y' module (based on Hricko, 2014 and ENIM, 2020).

Mechanism	Description	Strengths (+)/Weaknesses (-)
Peaucellier Lipkin	Planar linkage transforming rotary to straight-line motion.	+ Compact + Exact straight-line ———————— - Complex revolute joints - Fragile mechanism with high stress
Scott Russell	Linkage transforming vertical to horizontal motion. Consists of three links all equal with a rolling or sliding connection.	+ Compact + Exact straight-line ———————— - Weakness at revolute joints - Rapid wear
Hoekens	A four bar linkage converting rotational to straight line motion.	+ Compact ———————— - Approximate straight line - Weakness due to revolute joints
Watt	Three bars bolted together in a chain. The three bars pivot around two bolts on the central bar to move a central point in a near straight line.	+ Compact ———————— - Approximate straight line - Weakness due to revolute joints
Chebyshev	Linkage consisting of three bars that converts rotational to straight line motion for a central point.	+ Compact ———————— - Approximate straight line - Weakness due to revolute joints
Roberts	Linkage consisting of five bars that converts rotational to approximate straight line motion.	+ Compact ———————— - Approximate straight line - Weakness due to revolute joints
Slider crank	A four link mechanism with three revolute joints and one sliding joint. Rotation of the crank drives linear motion.	+ Exact straight line + Resilient ———————— - High friction - Bulky due to the sliding pair

(*Continued*)

Table 1.   (Cont.)

Mechanism	Description	Strengths (+)/Weaknesses (-)
Screw nut	Very simple mechanism that converts rotational to linear motion and torque to a linear force.	+ Exact straight line + Resilient + High forces ─────────── - High wear rate - Needs accurate adjustments.
Rack-pinion	A circular gear (pinion) connected to a linear gear (pinion) to convert rotational to straight line motion.	+ Exact straight line + Produces high forces + Accurate movement ─────────── - High friction - Fragile
Hydraulic pistons	A hydraulic cylinder or motor that acts as a mechanical actuator used to give a unidirectional force through a unidirectional stroke.	+ Can provide high energy and force + Easily controlled using valves/levers. ─────────── - Requires maintenance to avoid leaks and fluid contamination.

obtained from tests featuring unload-reload loops. This cyclic loading can be applied with the proposed *p-y* module in addition to monotonic loading to investigate a wide range of soil properties. The resolution threshold of 0.01% is slightly too high to detect the small strain elastic stiffness, $G0$, and if possible a lower resolution should aim to be achieved. Precision of 1 μm is typical of pressuremeter expansion and will be targeted in these developments.

6   REVIEW AND SELECTION OF STRAIGHT LINE MECHANISMS

Table 1 provides a review of available mechanical systems to transform a vertical or rotary motion into straight-line horizontal motion. Table 1 also considers the potential use of a hydraulic horizontal pushing system. A schematic, description and account of strengths/weaknesses are listed for each option.

The main outcome from this preliminary assessment is that many mechanical systems do not provide a perfect straight-line mechanism. As such these mechanisms have been discarded.

It appears that the Scott Russell mechanism is one of the few mechanisms that converts perfect vertical to horizontal motion. Its simplicity makes it a viable option for the proposed module, although there are concerns about its robustness. A second option could be the use of a hydraulic system with micro-pistons. These two options are analyzed in greater detail in the following section.

7   FIRST TRIALS AND ANALYSES OF STRAIGHT-LINE MECHANISM

7.1   *Scott Russell mechanism*

The Scott Russell linkage consists of three links, all equal length that are used to form a right-angle change of motion from vertical to horizontal linear motion as shown in Figure 5. As Point A moves vertically upwards, Point C moves horizontally assuming a rolling or sliding connection.
Figure 5. Scott Russell mechanism that can be used in 'p-y' module.

An initial 3-D printed prototype shown in Figure 6 has been fabricated for this mechanism type. Pulling up the vertical bar in tension triggers an outward movement of the cone while avoiding buckling of the main vertical bar. Several Scott-Russell mechanisms in series linked to a single pulling bar can be included to increase the system robustness and stability, although it appears that this mechanism may be suitable for low strength soils or

at shallow depths. It should be noted that the force conversion efficiency depends on the inclination of the bar AC in Figure 5, and it decreases as the orientation of the bar moves away from 45°.
Figure 6. Initial 3-D printed prototype of the 'p-y' module with the Scott-Russell mechanism.

For the first development of a real cone, a functioning range in sands up to 10 m depth and in clays with an undrained shear strength up to 75 kPa can be assumed. According to the preliminary capacity requirements from Figures 3 and 4 with a module height of 200 mm, maximum overall horizontal forces up to 5 kN are expected for these conditions.

Considering the loss of efficiency as the inclination of the bar AB departs from the 45° (Figure 5), a vertical pull-out force equal to 10 kN could be assumed for preliminary sizing of the vertical pulling rod. This would result in a 6 mm diameter steel rod assuming a yield tensile strength for steel of 350 MPa.

A hydraulic actuation system can be used to pull the rod up and down in order to trigger the lateral movement of the p-y module. This may be placed within the fixed parts of the cone, either above or below the module. A cylindrical system with a diameter of 35 mm and an allowable fluid pressure of 12 MPa would be sufficient to provide the required 10 kN.

If four Scott Russell mechanisms are considered, the necessary horizontal force F_c (Figure 5) at each linkage would be 1.25 kN. The connection of the Scott Russell mechanism should be designed for a such force range.

The dimensions derived above may pose challenges considering the standard cone dimensions. Slight geometrical modification to the cone diameter and module height may prove beneficial if the Scott Russell mechanical system is adopted.

7.2 Hydraulic piston system

A miniature horizontal hydraulic drive system has also been considered where oil flow can be used to control pistons that trigger the horizontal motion of

the p-y module. The hydraulic system can provide high forces using simple and miniature design. The direction of oil flow, the pressure and flow rate within the circuit can be controlled using valves and hydraulic systems. This allows for more accurate control of the moving module than a mechanical system, although accuracy and precision will finally depend on the actual piston design.

A preliminary diagram of the p-y module with the horizontal hydraulic piston actuation is shown in Figure 7. A series of miniature pistons is placed within the fixed part of the cone, above and below the module. When oil flows inside hole 1 within the top section, pistons force the bar to move the middle section horizontally, representing the test position. Then, when oil flows in hole 2, pistons move the bar and the middle section back to its standard position.

Similar to the initial design of the Scott Russell mechanism, a required horizontal force of 5 kN is assumed for an initial sizing of the hydraulic pistons. A maximum fluid pressure of 12 MPa in the pistons is also assumed. Using fundamental pressure formula and force equilibrium, the minimum diameter of the pistons can be calculated for varying number of pistons to provide the required horizontal force. Results are provided in Table 2.
Figure 7. Diagram of 'p-y' module using hydraulic pistons system.

It appears that a configuration with four pistons of 12 mm diameter may be appropriate and sufficient. Two pistons can be placed in the top section and two in the bottom section of the cone. This configuration ensures that the soil pressure acting on the outer surface is evenly distributed over an appropriate number of pistons. It should be noted that using four pistons of 17 mm diameter will provide a twofold increase in horizontal force, suggesting that this system may be a good candidate for future upscaling to larger forces.

Table 2. Calculated minimum piston diameter, D, for varying number of pistons, n, to provide required horizontal force.

Max pressure (MPa)	No. pistons	D (mm)	F (kN)
12	2	17	5.44
12	4	12	5.43
12	6	10	5.65
12	8	8.5	5.44

8 CONCLUSIONS

This paper has presented an initial feasibility study and background thinking for the future development of a novel '*p-y*' modular section to be attached behind a standard cone penetrometer. The module will enable in situ probing of the soil similar to a laterally loaded pile element while also imposing complex whole-life stress histories and explore how soil response changes during the design life.

A number of challenges and design requirements have been identified in this paper. Available mechanical systems to produce the desired horizontal translation of the module have been reviewed and the use of hydraulic actuation with multiple systems appear a good candidate for future developments.

The full development of the proposed module and the interpretative framework is the main objective of a collaborative research proposal 'ROBOCONE' involving the University of Bristol, University of Southampton and Trinity College Dublin.

ABSTRACT: Injection of expanding polyurethane resins is a popular method to improve both the stiffness and the shear strength of the ground below existing foundations. The effect of the polyurethane resin expansion is to increase the soil confining stress and density around the injection holes. An estimation of the horizontal stress and volumetric strain changes that are induced within the ground is derived from the theory of cavity expansion in elasto-plastic materials. A series of case-histories is presented to document the feasibility of different *in*-situ tests to evaluate the achieved ground improvement. The tests have been performed before and after the injection of polyurethane resins and the obtained results have been compared with theoretical predictions. The considered investigation methods include the dynamic probing tests and the cone penetration tests. The preliminary results that have been achieved using an experimental miniature cone penetration test are also illustrated. The advantages and limitations of different test methods are discussed and practical indications for conducting such verifications of polyurethane resin injection effectiveness are provided.

1 INTRODUCTION

The use of polyurethane expanding resins is a widespread technique adopted to solve ground-related engineering problems. Due to their significant swelling capacity, polyurethane resins are currently deployed successfully in the following cases (Dominijanni and Manassero, 2014):

- filling and stabilization of underground cavity;
- reduction of soils hydraulic conductivity;
- heaving of pavement and foundations in settlements problems;
- ground improvement and compaction.

Ground improvement and compaction with expanding polyurethane resins aim to increase soil density and soil mechanical parameters such as stiffness and strength. This type of treatment, often performed below existing foundations, can be considered part of the treatment methods related to compaction grouting techniques. However, this type of treatment is different from conventional compaction grouting techniques due to the physical and mechanical processes governing the expansion of the expanding polyurethane resin in the subsoil. The cavity expansion theory represents a relatively simple and reliable approach for modelling the changes in the stress state and the density of the soil induced by the expansion of the resin (Yu, 2000; ASCE, 2010; Dominijanni and Manassero, 2014).

Despite the possibility of using well-established design methodologies, the assessment of the success of the ground treatment with expanding polyurethane resins still represents a major challenge. When the ground treatment is performed before the construction of structures and buildings, it is possible to carry standard in-situ tests, such as cone penetration tests (CPT), to evaluate the achieved ground improvement. However, when the treatment is performed below existing structures, the use of standard in-situ testing equipment might not be feasible due to the space required for this type of equipment.

A solution to this issue is provided by the performance of reduced scale in situ testing, such as mini-CPT and small dynamic probing tests. This paper illustrates some examples of using these types of testing equipment, besides the adoption of CPT testing, to evaluate the effectiveness of the ground improvement with expanding polyurethane resin.

2 GROUND TREATMENT WITH POLYURETHANE RESINS

Polyurethane resins are obtained from the exothermic reaction occurring by the mixing of a polyol and an isocyanate. The swelling capacity is the key feature of this material, and it is responsible for a volume increase under unconfined conditions (null mechanical stress) of about thirty times (Dei Svaldi et al., 2005; Buzzi et al., 2008). When the resins are injected underground, the expansion process occurs in confined conditions leading to a compaction of the soil surrounding the injection point until a mechanical equilibrium between the resin and the soil is achieved. The injection can be performed at different depths using either several injection tubes with single-point injection at the bottom end of the tube or a single tube with several lateral injection points (multi-point). In both cases, the injections are performed with small tubes (external diameter of about 10-15 mm) and equipment, reducing the treatment's impact on the existing structure as much as possible.

From a design point of view, the cavity expansion theory represents an efficient tool that can be used by engineers (Yu and Houlsby, 1991; Shrivastava et al., 2018). In this framework, spherical cavities expansion can be considered when single point injection tubes are adopted for the treatment. On the other hand, when multi-point injection tubes are used, it is possible to consider a cylindrical cavity expansion (Figure 1). This design approach allows engineers to estimate the amount of a specific type of resin to be injected to obtain a given increase of the soil density and mechanical parameters.

The efficiency of the treatment depends on several factors, such as the type of soil, the presence of groundwater, the soil stiffness and strength, the injection layout, the amount and type of injected resin. When compaction is the aim of the treatment, the efficiency of the treatment is higher under drained conditions (Kovacevic et al., 2000).

In fact, under drained conditions, the mean effective stress increases monotonically, and the soil compresses along a compression curve for first loading, with a consequent increase in density, stiffness and shear strength.
Figure 1. Schematic layout of the two types of tubes usually adopted for the injection of polyurethane resins, along with the expansion process of the injected resin.

Instead, under undrained conditions, the soil is not allowed to compress, and the mean effective stress decreases due to the formation of excess pore pressures. During the subsequent consolidation phase, the soil follows an unload/reload compression curve until the original mean effective stress is reached. However, because of the higher rigidity of the unload/reload compression curve with respect to the curve for first loading, the amount of compression is lower than that achieved under drained conditions.

Therefore, the use of polyurethane has to be firstly considered either in coarse-grained soil or in partially saturated fine-grained soil.

The evaluation of the soil geotechnical parameters is often performed with in-situ tests, such as dynamic and static penetration tests, using empirical correlations available in the scientific literature. Moreover, penetration tests may also be adopted to evaluate the efficiency of the treatment by comparing the results of the tests performed before and after the treatment in the soil surrounding the injection points. The role of in-situ testing is, therefore, fundamental not only for the design of the ground treatment but also for the assessment of the treatment efficiency.

3 IN-SITU PENETRATION TESTS

Beside the standard CPT test, the use of smaller equipment is often required to evaluate the effectiveness of the ground treatment with polyurethane resins. In the following two subsections, a brief overview of the miniature cone penetrometer (mini-CPT) and the medium-light dynamic probing penetrometer

(DPM 30-20) are introduced. These types of penetrometers have the advantage of being easy to transport, install, and use.

3.1 Mini CPT

The miniature cone penetrometer is a reduced scale cone with a diameter of 18 mm and an apex angle equal to 60°. Examples of the use of the mini cone penetrometer can be found in Squeglia and Lo Presti (2010), where this equipment has been adopted to develop an innovative methodology for the evaluation of the compaction degree of earth works, and in de Vries et al. (2018) where a comparison with standard CPT tests is illustrated. The cone is pushed downward in the soil at a constant rate equal to 2 cm/s by an electric motor. The tip resistance (q_c) is evaluated by a load cell placed above the penetrometer with maximum load of 5 kN and accuracy of 5 N.

The performance of mini-CPT tests is not common for soil geotechnical characterization. Therefore, this test method suffers of a lack of empirical correlations to estimate geotechnical parameters, as well as a direct comparison with the standard CPT test. To face this issue, mini-CPT tests are often carried out along with standard CPT or, in case this is not possible, with dynamic probing tests.

3.2 Dynamic penetrometer DMP 30-20

Dynamic probing tests (DP) consist of driving into the soil a steel cone located at the end of a set of driving rods by blowing the upper end of the rods with a specific hummer (Cestari, 2012). DP tests can be classified in different category (light, medium, heavy, super-heavy), depending on the hammer weight, falling height, cone size and geometry, rods size, etc.

In the framework of ground treatment with polyurethane resins, the use of a medium-light penetrometer, the DPM 30-20, is particularly considered in Italy. This equipment is based on the measurement of the blow number required for a penetration of the cone equal to 10 cm (N_{10}). Although this equipment is not included in any standard, its main features are similar to the standard light and medium dynamic penetrometer. The mass of hammer is 30 kg and falling height is 20 cm. The cone has a base diameter equal to 35.7 mm and an apex angle equal to 60° (Cestari, 2012).

Although the possibility to correlated the DPM 30-20 test results (N_{10}) to the standard penetration test (N_{SPT}), the main disadvantage of this type of test is represented by the absence of the measurement of the skin friction during the penetration of the cone. Therefore, the measured penetration resistance might be overestimated due to the missing contribution of the skin friction.

4 CASE STUDIES

In this section a series of case studies are presented, where the assessment of the effectiveness of the ground treatment with polyurethane resins is evaluated by performing standard CPT, mini-CPT and DPM 30-20 in situ tests. The examples refer to ground treatment works related to resin injections below shallow foundations of residential buildings.

4.1 Case a)

The first case study refers to the ground treatment performed below the plate foundation of a residential building that experienced differential settlements during construction. During the design phase, an insitu testing investigation composed of four CPT tests was carried out. The map of the building is presented in Figure 2, along with the location of the four CPT tests. Figure 3 illustrates the tip resistance (q_c) profile obtained from the tests CPT-1 and CPT-2. From this outcome, the foundation soil can be roughly divided in a shallow layer of granular soil (mainly sand) with thickness equal to 3 m overlaying a deeper layer of fine-grained soil with a thickness equal to 7 m.
Figure 2. Map of the building along with the position of the four CPT tests (n.1 to n.4) performed before construction, the treated are with resin injections, and the four CPT tests (n.5 to n.8) performed after ground treatment.

As illustrated in Figure 2, the ground treatment was performed on the north side of the building, which was subjected to major settlements. The injection points were placed on a regular squared grid with spacing equal to 1 m, and they were performed first in correspondence of the building perimeter and then below the building. Moreover, the resin was injected first at a depth between -5 and -7 m with
Figure 3. Comparison of tip resistance (q_c) profile between the CPT tests performed before (CPT-1) and after (CPT-5 and CPT-6) the ground treatment with polyurethane resins.

multipoint injection tubes. A second set of injection was then carried out at a shallower depth between -2 and -5 m with single-point injection tubes every 1 m.

A second series of in-situ tests, composed of four standard CPT, was performed after the ground treatment to evaluate the achieved improvement. The position of these tests is illustrated in the Figure 2 where the tests are numbered from 5 to 8. In particular, the CPT-5 and CPT-6 are carried out close the treated area, while the CPT-7 and CPT-8 are further and, therefore, less influenced by the injections.

Figure 3 shows a comparison between the tip resistance profiles obtained from the test performed before the treatment (CPT-1 is taken as a reference) and the tests performed after treatment (CPT-5 and CPT-6). In the shallow soil layer below the foundation (down to -3 m depth), a pronounced increase of the tip resistance is highlighted by both CPT tests (CPT-5 and CPT-6). The average value of q_c referred to this layer is higher than 10 MPa. On the other hand, in the in the depth range between -3 m and -7 m, the increase of the tip resistance exhibited by the two CPT tests is less pronounced. On average, the q_c value obtained from the two tests carried out after treatment is more than twice the average value measured before treatment.

4.2 Case b)

The second case study refers to the work carried out for the ground consolidation below an office building with dimensions equal to 15x7 m. The injections are performed along the building perimeter underneath the foundation starting from of a depth equal to 1.2 m. A

combination of multi-point tubes and single point tube is adopted to treat a thickness of the ground equal to 3 m (from -1.3 m to -4.3 m). The injection points along the perimeter are spaced of 1 m.

Figure 4 shows the map of the building along with the location of the in-situ tests carried out to assess the efficiency of the treatment. Due to the presence of the existing structures, mini-CPT tests were adopted and performed in three different points. In each point, two tests were carried out one before and one after ground treatment. The two tests of each point were located close to each other to minimize the possible influence of different ground conditions.
Figure 4. Map of the building illustrating the location of the mini-CPT tests performed evaluate the efficiency of the ground treatment.

Figure 5 illustrates the tip resistance profiles of the three mini-CPT tests performed before ground treatment. From these findings, the soil can be

mainly classified as sand-silt mixture. In particular, the test S5 exhibited the lower tip resistance, highlighting the presence of silt/clayey silt below a depth equal to -3 m.
Figure 5. Tip resistance (q_c) profile of the three mini-CPT tests (S1, S3, S5) performed before the ground treatment.
Figure 6. Comparison of the tip-resistance profiles obtained from the mini-CPT tests S5 and S6 performed before and after ground treatment.

The evaluation of the ground treatment is carried comparing the tip resistance profiles from two mini-CPT tests performed before and after treatment. In Figure 6 is illustrated an example obtained from the mini-CPT S5 and S6. The graph clearly highlights the increase of tip resistance measured at depths corresponding to the resin injection.

In the range between -1.3 m and -2.8 m the tip resistance increased from 1.6 MPa to 4.0 MPa, while in the range between -2.8 m and -4.3 m the tip resistance increased from 0.6 MPa to 2.4 MPa.

4.3 *Case c)*

The last case study illustrates the treatment with polyurethane resins of the ground foundation below an existing residential building. The treatment involved just part of the building as illustrate in the Figure 7. The injections were performed below the building foundation located at -1.2 m depth and along the perimeter of the building, with a spacing equal to 1 m, using multi-point tubes. The thickness of the soil layer treated is 2 m, from -1.2 m (depth of the foundation) to -3.2 m. The ground below the foundation is mainly composed of a mixture of loose fine soil and gravel.

In this example, the efficiency of the ground treatment was evaluated with dynamic probing tests, adopting the medium-light penetrometer DPM 30-20. As illustrated in the Figure 7, two DPM 30-20 tests were carried out: P1 before the treatment and P2 after the treatment.
Figure 7. Map of the building along with the location of the treatment zone and the location of the DPM 30-20 tests performed before (P1) and after (P2) the ground treatment.

Figure 8 shows the results of both the two DPM 30-20 tests. From the results of the test P1, two soil layers were identified: (i) from -1.2 m to -2.3 m with an average N_{10} value equal to 7 and (ii) from -2.3 m to -3.3 m with an average N_{10} value equal to 2.4. After the treatment, the performed DPM 30-20 test highlighted an increase of the average N_{10} value for both layers. In particular, the layer 1 exhibited an average value equal to 27, while the layer 2 exhibited an average N_{10} value equal to 21.

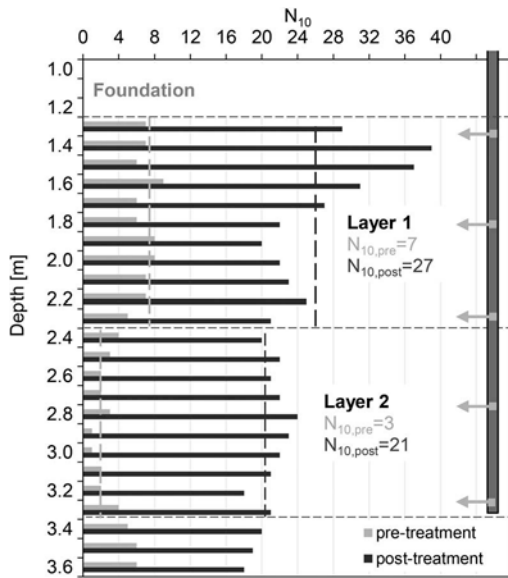
A design tool based on the cavity expansion theory in a finite medium (Uretek, 2021) was used to assess the achieved ground improvement in terms of increase in relative density and to verify the amount of resin injected. A perfect elasto-plastic Mohr-Coulomb model with a non-associated flow rule was adopted for the soil, considering two sets of parameters for the two different layers (Table 1). As the spacing of the injection


Figure 8. Comparison of the test results in terms of N_{10} obtained from the tests performed before (P1) and after (P2) the ground treatment.

holes was equal to 1 m, the radial distance of the fixed (no-displacement) boundary of the medium was set equal to 0.5 m, i.e. half of the injection hole spacing. The average increase in relative density obtained from the theoretical analyses was 12% for layer 1 (from 31% to 43%) and 21% for layer 2 (from 17% to 38%). The total amount of resin required to obtain such improvement resulted in being equal to 18.3 kg, which is in good agreement with the amount of resin injected in-situ (16.9 kg). This example highlights the potential of the cavity expansion theory to simulate ground behavior when treated with expanding polyurethane resins.

Table 1. Parameters of the soil adopted for the calculations.

Layer	1	2
Unit weight [kN/m^3]	18	18
Young modulus [MPa]	10	6
Poisson ratio [-]	0.25	0.25
Shear strength angle [°]	34	34
Cohesion [kPa]	0	0
Dilatancy angle [°]	-5	-8
Max void ratio [-]	0.65	0.65
Min void ratio [-]	0.30	0.30
Initial void ratio [-]	0.541	0.589

5 CONCLUSIONS

Expanding polyurethane resins represent a valid alternative to conventional grout for ground improvement and compaction. The effectiveness of the ground treatment can be assessed by performing in-situ tests with static and dynamic penetrometers. This paper presents a series of case studies where standard CPT, mini-CPT, and DPM 30-20 tests were adopted.

The main advantage of the standard CPT test is the possibility of using the test results not only for treatment performance evaluation but also for the geotechnical characterization of the subsoil. However, it is often difficult to adopt such equipment when the treatment is carried out inside an existing structure.

The reduced size of the mini-CPT and DPM 30-20 equipment represents their main advantage. On the other hand, the lack of well-established empirical correlations to estimate soil geotechnical parameters from these tests is their main drawback.

Based on the examples presented in this work, all three in-situ tests can be regarded as suitable tools to assess the efficiency of the ground treatment with expanding polyurethane resins.

ABSTRACT: Flow liquefaction is a behavior observed in saturated or nearly saturated geomaterials that show a strain softening response during undrained shear, most common in very loose sands and silts as well as very sensitive clays. In the mining industry, flow liquefaction is a subject of high relevance due to the geotechnical characteristics of the tailings. Many methodologies have been developed to evaluate the susceptibility to flow liquefaction using in-situ tests, especially the CPTu test, since it provides high accuracy and good repeatability. This paper compares four methodologies based on the CPTu test to evaluate the susceptibility to flow liquefaction: i) Plewes et al. (1992), ii) Olson (2001), iii) Shuttle & Cunning (2008) and iv) Robertson (2016). The results obtained highlight the need to correct the original contour suggested by Olson (2001) for medium and high compressibility geomaterials. Furthermore, all other methods evaluated presented similar results in the overall classification.

1 INTRODUCTION

Casagrande (1975) showed that loose sands tend to contract during drained shear while dense sands tend to dilate under the same condition until it reaches the critical void ratio. If sheared under an undrained condition loose sands will generate positive excess porewater pressure, reducing the effective stress and, therefore, its shear strength, while the opposite would occur for dense sands.

Flow liquefaction is a behavior observed in saturated on nearly saturated soils that show a strain softening response in undrained shear due to its contractive behavior under drained conditions, most common in very loose sands and silts as well as sensitive clays.

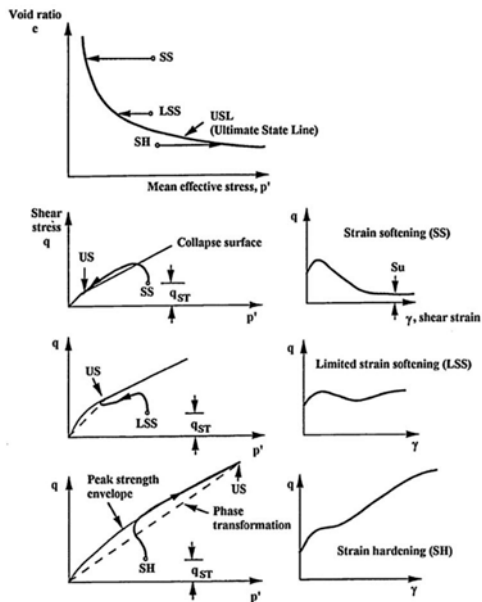
As shown in Figure 1 presented by Robertson & Wride (1998), sand-like soils that are looser than the critical state will generate positive excess porewater pressure and show a strain softening behavior in undrained shear, illustrated by the Strain Softening Condition (SS). If the state prior to shear is close to the critical state, these soils can experience a limited contraction, exhibited as a Limited Strain Softening (LSS) condition in Figure 1, also referred in the literature as quasi-steady state condition. If the soil is denser than the critical state, however, it will tend to exhibit


Figure 1. Typical undrained monotonic behavior of sand-like soils in triaxial compression tests - Robertson & Wride (1998).

a Strain Hardening (SH) behavior and the undrained strength will be greater than the drained strength.

2 SUSCEPTBILITY TO FLOW LIQUEFACTION

This paper is going to evaluate the susceptibility of a sandy-silt tailings to flow liquefaction using the results of a Cone Penetration Testing (CPTu) performed in the interior of a Tailings Storage Facility (TSF). Four methodologies will be used herein to evaluate the state of the tailings: i) Plewes et al. (1992), Olson (2001), Shuttle & Cunning (2008) and Robertson (2016).

2.1 Plewes et al. (1992)

Plewes et al. (1992) suggested a relationship between the slope of the critical state line (λ_{10}) and the normalized friction ratio (F or F_r) as shown by Equation 1.

$$\lambda_{10} = \frac{F}{10} \qquad (1)$$

$$F \text{ or } F_r = \frac{f_s}{(q_t - \sigma_{v0})} \times 100\% \qquad (2)$$

where:

f_s = sleeve friction resistance
q_t = corrected cone resistance
σ_{v0} = total vertical stress

Once the slope of the critical state line (λ_{10}) is determined the state parameter (ψ) can be calculated using the equation suggested by Shuttle & Cunning (2007).

$$Q_p(1 - B_q) + 1 = \bar{k}e^{-\bar{m}\psi} \qquad (3)$$

Where Q_p is the tip resistance normalized by the mean affective stress (p'_0) and B_q is the pore pressure ratio, defined as shown below.

$$Q_p = \frac{(q_t - p_0)}{p'_0} \qquad (4)$$

$$B_q = \frac{(u_2 - u_0)}{(q_t - \sigma_{v0})} \qquad (5)$$

where:
u_2 = pore pressure measured behind the cone
u_0 = in situ pore pressure
As a screening-level assessment, Jefferies & Been (2016) suggested that the effective inversion coefficients, $\bar{k}$ and $\bar{m}$, could be determined using Equation 6

and Equation 7, as a function of the slope of the critical state line.

$$\frac{\bar{k}}{M} = 3 + \frac{0.85}{\lambda_{10}} \qquad (6)$$

$$\bar{m} = 11.9 - 13.3\lambda_{10} \qquad (7)$$

where M is the critical friction ratio (M=q_c/p'_c) and λ_{10} is the slope of the critical state line (CSL) measured in $\log_{10} p'$ - e space. It was assumed M_{tc}=1,45 herein, using the average value of the range suggested by Jefferies & Been (2016).

2.2 Olson (2001)

Olson (2001) performed an extensive evaluation of 33 case histories of liquefaction flow failures and developed a comprehensive procedure to evaluate i) liquefaction susceptibility, ii) triggering of liquefaction and iii) post-triggering/flow failure stability.

In order to evaluate the susceptibility to flow liquefaction, Olson (2001) suggested the use of the contour proposed by Fear & Robertson (1995) based on the Standard Penetration Test (SPT). To convert the boundary from SPT to CPT, Olson (2001) used a relationship q_c/N_{60}=0.60, typical of clean sands, as shown in Figure 2. The contour proposed by the author to distinguish between contractive and
Figure 2. Boundary separating contractive from dilative behavior suggested by Olson (2001) to evaluate the susceptibility to flow liquefaction.

dilative behavior is represented by Equation 8, based on the corrected tip resistance (q_{c1}) and the vertical effective stress (σ'_{v0}).

$$\left(\sigma'_{v0}\right)_{boundary} = 1.1047 \times 10^{-2} (q_{c1})^{4.7863} \quad (8)$$

The corrected CPT tip resistance, q_{c1}, is obtained as follows:

$$q_{c1} = q_c \times C_q \quad (9)$$

where q_c is the measured cone resistance and C_q is the CPT-based overburden correction factor suggested by Kayen et al. (1992), defined by Equation 10.

$$C_q = \frac{1.8}{0.8 + \left(\frac{\sigma'_{v0}}{P_a}\right)} \quad (10)$$

where P_a is one atmosphere of pressure in the same units as σ'_{v0}.

Olson (2009) discussed the effect of compressibility on the evaluation of liquefaction susceptibility and suggested the use of the slope of the critical state line (λ_{10}) to update the original boundary suggested by Olson (2001) as shown by Figure 3. According to the author, the original boundary should only be used for low compressibility soils ($\lambda_{10} \sim 0.03$) which is
Figure 3. Contours suggested by Olson (2009) to separate contractive from dilative conditions for soils of low, medium and high compressibility.

associated with the ratio of $q_c/N_{60}=0.6$. Many investigators (Burland & Burbidge 1985; Jefferies & Davies 1993; Robertson & Campanella 1983; Schnaid & Odebrecht 2012; Stark & Olson 1995) demonstrated that the ratio q_c/N_{60} is a function of soil type (usually expressed as a function of the mean grain size – D_{50}).

This paper suggests the use of the ratio q_c/N_{60} to account for the effect of compressibility and Equation 11 is suggested for this purpose.

$$q_{c1,contour} = \frac{\left[7.69\delta\sigma'^{(0.209+n)}_{v0} P_a^{(1-n)}\right]}{0.8P_a + \sigma'_{v0}} \quad (11)$$

where δ = Ratio q_c/N_{60}.

To evaluate the susceptibility to flow liquefaction it is suggested the use of Equation 12.

$$\beta = (q_{c1})_{contour} - (q_{c1})_{measured} \quad (12)$$

Therefore, $\beta > 0$ will indicate that $(q_{c1})_{contour} > (q_{c1})_{measured}$ for the same vertical effective stress, which indicates that the point in the profile is in a contractive state.

2.3 Shuttle & Cunning (2008)

Shuttle & Cunning (2007) presented a very detailed study using finite element analysis with cavity expansion theory and the NorSand Model to evaluate the liquefaction potential of a very loose silt tailings (*Rose Creek silt tailings*). Following discussions with Peter K. Robertson, Shuttle & Cunning (2008) presented a contour to distinguish between contractive and dilative behavior using the soil behavior chart suggested by Jefferies & Davies (1991), as presented in Figure 4.

Since the authors did not present the equation corresponding to the suggested contour, it is suggested herein the use of Equation 13 to be used to represent this boundary.

$$[Q(1 - B_q) + 1] = 2,35 + \frac{93,15}{\left[1 + \left(\frac{F}{25,40}\right)^{0,634}\right]^{9,93}} \quad (13)$$

where,

$$Q \text{ or } Q_t = \frac{(q_t - \sigma_{v0})}{\sigma'_{v0}} \quad (14)$$

To characterize the behavior of the soil with depth the parameter α will be used, defined by Equation 15. Following this definition, positive values of α will indicate that $[Q(1-B_q)+1]_{Contour} > [Q(1-B_q)+1]_{Measured}$, meaning that the measured value is located below the
Figure 4. Boundary separating contractive from dilative behavior suggested by Shuttle & Cunning (2008) - Jefferies & Been (2016).

envelope shown in Figure 4 and, therefore, is susceptible to flow liquefaction.

$$\alpha = \left[Q\left(1 - B_q\right) + 1\right]_{Contour} - \left[Q\left(1 - B_q\right) + 1\right]_{Measured} \quad (15)$$

2.4 Robertson (2016)

Robertson (2016) updated the CPT-based normalized soil behavior type (SBTn) classification system proposed by Robertson (2009) to use behavior-based instead of textural-based descriptions, as presented in Figure 5.
Figure 5. Updated CPT-based normalized soil behavior type chart proposed by Robertson (2016).

The author updated the soil behavior type index to use a hyperbolic shape, as indicated by Equation 16.

$$I_B = \frac{100(Q_{tn} + 10)}{(Q_{tn}F_r + 70)} \quad (16)$$

where,

$$Q_{tn} = \left[\frac{(q_t - \sigma_{v0})}{p_a}\right]\left(\frac{p_a}{\sigma'_{v0}}\right)^n \quad (17)$$

$$n = 0.381(I_c) + 0.05\left(\frac{\sigma'_{v0}}{p_a}\right) - 0.15 \quad (18)$$

where n≤1.0.

The soil behavior type index, I_c, was first proposed by Jefferies & Davies (1993) who recognized that the boundaries between the soil behavior type zones could be approximated by concentric circles whose radius indicates the soil behavior type index. Robertson & Wride (1998) modified the definition of I_c to apply to the Robertson (1990) chart, as defined by Equation 19.

$$I_c = \left[(3.47 - \log Q_t)^2 + (\log F_r + 1.22)^2\right]^{0.5} \quad (19)$$

Robertson (2016) suggested the use of the contour CD=70 (also shown in Figure 5) to differentiate soils that are contractive and dilative at large strains. The CD=70 boundary combines two different criteria: i) $Q_{tn,cs}$=70 for sand-like soils and OCR=4 for transitional and clay-like soils. Equation 20 is suggested by the author to represent the contour CD=70.

$$CD = 70 = (Q_{tn} - 11)(1 + 0.06F_r)^{17} \quad (20)$$

3 RESULTS

The tailings evaluated herein is a by-product of the mining of iron ore in the state of Minas Gerais/ Brazil. The assessment of the tailings included the collection of disturbed samples to evaluate: i) the grain size distribution curve, ii) the water content (w), iii) the specific gravity of soil solids (G_s), iv) the unit weight (γ and γ_d), v) the liquid limit (LL) and vi) the plastic limit (PL).

The grain size distribution curves of the samples collected are shown in Figure 6. In terms of mean values, roughly 79% of the tailings corresponds to silt-sized particles, 4% to clay-sized particles and the remaining (17%) is fine sand. The fines were nonplastic and the mean values of the unit weight was γ=23.4 kN/m³ and γ_d=19.4 kN/m³.

The collected samples were also used to determine the water content (w) and these values were converted to void ratio (e) using Equation 21. The
Figure 6. Grain size distribution curves of the sandy-silt tailings according to the ASTM D422-63 (2007).

mean value of water content was 21.4% and the void ratio was 0.93.

$$e = \frac{G_s \gamma_w}{\gamma_d} - 1 \qquad (21)$$

The specific gravity (G_s) was determined following the procedures of the ASTM D854-14, to give a mean value of 3.8.

The normalized parameters (Q_t, F_r and B_q) from the CPTu performed on the sandy-silt tailings is shown in Figure 7. As can be seen, the initial portion of the sounding did not show excess porewater pressure up until 20m. Furthermore, below 27m the tailings exhibit a very low tip resistance and high B_q values. It is also important to notice the high heterogeneity on the tailings profile due to the interbedded layers of clay-like and sand-like behavior.

In order to evaluate the susceptibility of the tailings to flow liquefaction the contours suggested by Robertson (2016), Shuttle & Cunning (2008) and Plewes et al. (1992) are presented in Figure 8. Based on the behavior observed in the sounding, the profile

was divided into three main regions: i) Region I: Predominantly dilative behavior (0-16m), ii) Region II: Interbedded layers of contractive and dilative behavior (16-27m) and iii) Region III: Predominantly contractive behavior (below 27m).

The results of the Fear & Robertson (1995) boundary suggested by Olson (2001) is shown in Figure 9. As can be observed, using this method most of the tailings profile is classified as contractive. In fact, only
Figure 8. Evaluation of the susceptibility to flow liquefaction using a) Robertson (2016), b) Shuttle & Cunning (2008) and c) Plewes et al. (1992).
Figure 9. Results of the susceptibility to flow liquefaction using the Fear & Robertson (1995) contour suggested by Olson (2001).

Figure 7. Normalized CPTu parameters of the sounding performed in the sandy-silt tailings.
Figure 10. Evaluation of the susceptibility to flow liquefaction using a) Olson (2001) corrected for q_c/N_{60}=0.07, b) Shuttle & Cunning (2008) and c) Plewes et al. (1992).

the first 2m of the profile (σ'_{v0}<50kPa) was deemed to be in a dilative state.

The limitations of the original contour suggested by Olson (2001) for medium and high compressibility soils was discussed herein in the section 2.2. Equation 12 was applied in this paper to account for the effect of compressibility and it was determined the ratio q_c/N_{60} that would be necessary for the boundary suggested by Olson (2001) to yield results similar to the other methodologies evaluated. As can be seen in Figure 10, it was necessary to use a ratio of q_c/N_{60} =0.07 (a reduction by a factor of 8.6 in relation to the original contour) to calibrate the Fear & Robertson (1995) boundary for use with the sandy-silt tailings.

4 CONCLUSION

This paper presented an evaluation of the susceptibility to flow liquefaction of a sandy-silt tailings using four different methodologies: i) Plewes et al. (1992), ii) Olson (2001), iii) Shuttle & Cunning (2008) and iv) Robertson (2016).

The results of the study showed that for the tailings evaluated herein the contours suggested by Plewes et al. (1992), Shuttle & Cunning (2008) and Robertson (2016) yielded similar results (Figure 8).

The original boundary suggested by Olson (2001) resulted in a very conservative assessment (Figure 9). Equation 12 was used herein to account for the effect of compressibility and the ratio q_c/N_{60}=0.07 was used to correct the contour to yield results similar to the other methodologies evaluated.

The results of the study are useful to highlight the importance of the correction of the boundary suggested by Olson (2001) for soils of medium and high compressibility (specially tailings). Due to its inherent limitations, the authors do not recommend the use of the contour suggested by Olson (2001) to evaluate the susceptibility to flow liquefaction in soils of medium to high compressibility.

It is also important to emphasize that all these methods should be used as a screening-level assessment. Moreover, there are instances where the methodologies discussed herein can yield to different conclusions regarding the state of the soils and further investigations (including laboratory tests) would certainly be an effective tool to guide towards a better understanding of the behavior of the geomaterials.

Prospects on data mining approach for pile geotechnical design utilizing CPT and CPTu records: Case study: AUT database

A. Eslami & S. Heidarie Golafzani
Amirkabir University of Technology, Tehran, Iran

S. Moshfeghi
University of British Columbia (UBC), Vancouver, Canada

ABSTRACT: A comprehensive database has been compiled including CPT soundings performed adjacent to pile load test and related geotechnical information, namely AUT (Amirkabir University of Technology): Geo-CPT&Pile Database. In this paper, after a brief review of existing CPT and pile databases, the specifications of the updated AUT: Geo-CPT&Pile Database as well as different categories of data are presented. Subsequently, several procedures developed using this database from different geotechnical aspects are reviewed and introduced. These implementations are extended for appraisal of currently used CPT-based methods for pile geotechnical design by focusing on methods screening, uncertainty- reliability measures, and Performance-Based Design (PBD) approach regarding resistance factors. After all, an algorithm is presented including a formulated procedure of pile geotechnical design by means of smart database collections, reproduction of CPT profile, assortment of competitive methods, integration of geotechnical aspects i.e., capacity, load-displacement performance and resistance distribution. Correspondingly, via realizing prospects on implementation of major aspects leads towards optimum pile performance-based design upon a data mining approach.

1 BACKGROUNDS

The application of databases in geotechnical engineering returns to long decades ago since researchers tried to develop correlations among in-situ or lab measured parameters and design geotechnical parameters. Cone penetration testing (CPT) is one of reliable in-situ testing with less measurement error in comparison to others (Phoon and Kulhawy 1999). It provides continuous records with depth and due to its similarity to piles, a broad range of correlations have been made for prediction of ultimate pile bearing capacity (Eslami and Fellenius 1997). Piles are important foundation systems in geotechnical engineering facilitating construction in offshore and onshore areas or even in abnormal subsoil conditions or extreme loads imposed by superstructure in high-rise buildings and skyscrapers.

CPT-based methods differ in many areas such as the compiled CPT and pile database regarding the pile characteristics and the subsoil conditions where these piles were installed, model assumptions and simplifications, input parameters for predicting unite side and toe resistances, data processing for excess pore water pressure in back shoulder of CPT cone, failure pattern around the pile toe and so on. For instance, some methods consider loading directions or friction fatigue

in their correlations while others do not, or some methods have been develop based on total stress analysis (TSA) while some were developed based on effective stress analysis (ESA) or empirical correlations. Accordingly, various assessment criteria have been introduced to measure accuracy, precision and efficiency of these predictive methods (Eslami et al. 2019a).

The application of CPT and pile databases cannot be limited to performance assessment of predictive methods and these databases can provide us with more information.

Present study introduces a comprehensive geotechnical engineering database in the field of CPT and pile. This database named as AUT:Geo-CPT&Pile database has had different applications in the pile engineering such as reliability-based assessment of drilled displacement piles (Moshfeghi & Eslami 2019), assessing the performance of CPT-based methods in predicting axial bearing capacity of helical piles, reproduction and realization of CPT records (Jamshidi Chenari et al. 2018), predicting the load displacement behavior of driven piles regarding CPT records, and uncertainty appraisal of CPT-based methods regarding statistical, probabilistic and reliability-based criteria (Eslami et al. 2020, Heidarie Golafzani & Eslami 2021) and the

importance of relevant data-based approach in geotechnical pile design (Eslami & Heidarie Golafzani 2020). Eventual1y, a CPT and pile data-based approach is introduced for pile design regarding the researches have been done.

2 AUT: GEO-CPT&PILE DATABASE; AN EFFICIENT TOOL IN DATA MINING FOR GEOTECHNICAL PILE DESIGN

The AUT:Geo-CPT&Pile database has been compiled from well-published and documented geotechnical engineering sources and includes 600 records of pile loading tests along with the results of adjacent cone or piezocone penetration tests (Moshfeghi et al. 2015; Eslami et al. 2019b).

This database was primarily aimed to assess the performance of different CPT-based methods. Moshfeghi & Eslami (2018, 2019) compiled a database of fourty-three and seventy-six records of driven piles installed in sandy soils and their adjacent CPT records from AUT:Geo-CPT&Pile database and studied the effect of different criteria for interpretating static pile load test records to select the most consistent approach with the CPT-based methods. Among the four selected criteria, the Brinch Hansen 80% criterion and the load at the displacement of 10% of the pile diameter were the two most consistent criteria with the CPT-based approaches. They also assessed the performance of different CPT-based methods considering wasted capacity index (WCI) and cost optimization regarding safety factor. Assessments indicate that the German (Kempfert & Becker 2010), LCPC (Bustamante & Gianeselli 1982), Meyerhof (1983), UniCone (Eslami & Fellenius 1997) and UWA-05 (Lehane et al. 2005) methods have shown the most efficient predictions at their optimum factor of safety.

Askari Fateh et al. assessed the performance of ten direct CPT-based methods for helical piles via considering thirty-seven cases of helical piles installed in different soil types. Also, the accuracy of two different assumptions of failure mechanism around helical piles was examined through comparing the predicted axial bearing capacity and measured ones in static pile load tests. Finally, they suggested a new CPT-based method to estimate the bearing capacity of helical piles (Eslami et al. 2019a).

Jamshidi et al. (2018) developed an algorithm for realization of CPT data based on non-stationary random field theory. The proposed algorithm imposes soil layering alongside inherent soil variability based on Eslami and Fellenius (1997) soil classification chart. After detection of soil layering based on the simplified proposed approach, the statistical characteristics of each soil layer are defined as multi-criteria functions, assembled into the non-stationary autocovariance matrix and the routines continue in Monte Carlo scheme for production of CPT records.

Valikhah et al. proposed a new analytical-numerical method to estimate axial load-displacement behaviour of driven piles in granular soils using CPT records. Implementing the method of stress characteristics, they analysed the stress field below and around the pile and in effect, the failure mechanism. This failure mechanism has then been used by implementation of the kinematical approach of the limit analysis to compute the displacement field (Eslami et al. 2019a).

The application of artificial intelligence has been developed in geotechnical engineering in recent years. Implementing group method of data handling type neural networks optimized using genetic algorithms, Ardalan et al. (2009) estimated the pile unit shaft resistance.

Eslami et al. (2020b) by employing a database of instrumented pile load tests as well as CPT records correlated the pile unit shaft resistance with CPT sleeve friction. They proposed an analytical-empirical procedure for estimating pile shaft capacity considering scale effects. Factors such as mechanism and rate of penetration, size effect (i.e., length and diameter), friction fatigue are taken into account in this approach.

Heidarie Golafzani et al. (2020a, b) compiled a database of sixty driven piles installed in different soil types and studied the performance of different approaches, i.e., static analyses, SPT-based methods and CPT-based methods including twelve methods. In their studies, they considered different statistical, probabilistic and reliability-based criteria, including mean and coefficient of variation, best fitted line, 20% accuracy level, cumulative distribution function (i.e., P_{50} and P_{90}-P_{50}), confidence interval, root mean square error (RMSE) and efficiency ratio (i.e., the ratio of load and resistance factor (LRFD) resistance factor to the model parameter). The model parameter was defined as the ratio of measured to predicted bearing capacity. They concluded that modified first order second moment (FOSM) is less time-consuming and complicated, and leads to statistically identical resistance factors to first order reliability (FORM) method and Monte Carlo simulations (MCS). They also compared the performance of the considered approaches and methods via radar charts and deduced that CPT-based methods perform better than two other approaches.

Eslami & Heidarie Golafzani (2020) stated that selection of predictive methods for pile geotechnical design has a pivotal role in an optimum and site-specific design. Results indicated that methods prioritized by statistical, probabilistic and reliability-based criteria attain higher resistance factor in load and resistance factor design (LRFD) or lower safety factor in allowable stress design (ASD) approaches. They emphasized that the global safety factor cannot stands alone against all uncertainty sources and methods attaining similar safety factors, do not result in the same probability of failure and reliability index (i.e., β).

3 GEOTECHNICAL DATA-BASED PILE DESIGN

As reviewed, CPT and pile databases support the geotechnical designer with invaluable information about the performance of predictive methods for special pile types installed in a particular project site/with definite characterizations or even for a wide range of pile types installed in various site locations and conditions. Furthermore, databases can be mined for extra information aiding in geotechnical pile design. Figure 1 illustrates the steps for this new suggested/proposed approach.

In this approach, it is necessary to compile a database of geotechnical information about various sites including pile load test results along with adjacent CPT records to the investigated piles.

In the first step, the engineer should evaluate the site conditions in terms of its available geotechnical information and categorizes it as no testing, minimum number of testing and comprehensive geotechnical site investigation.

If the number of tests is minimum or tests are unavailable, it is referred to the database for either gaining extra information via smart selection according to the available akin sites or data production generally such as CPT data or specifically such as P-Δ and resistance distribution if necessary. These procedures constitute the first stage of data collection.

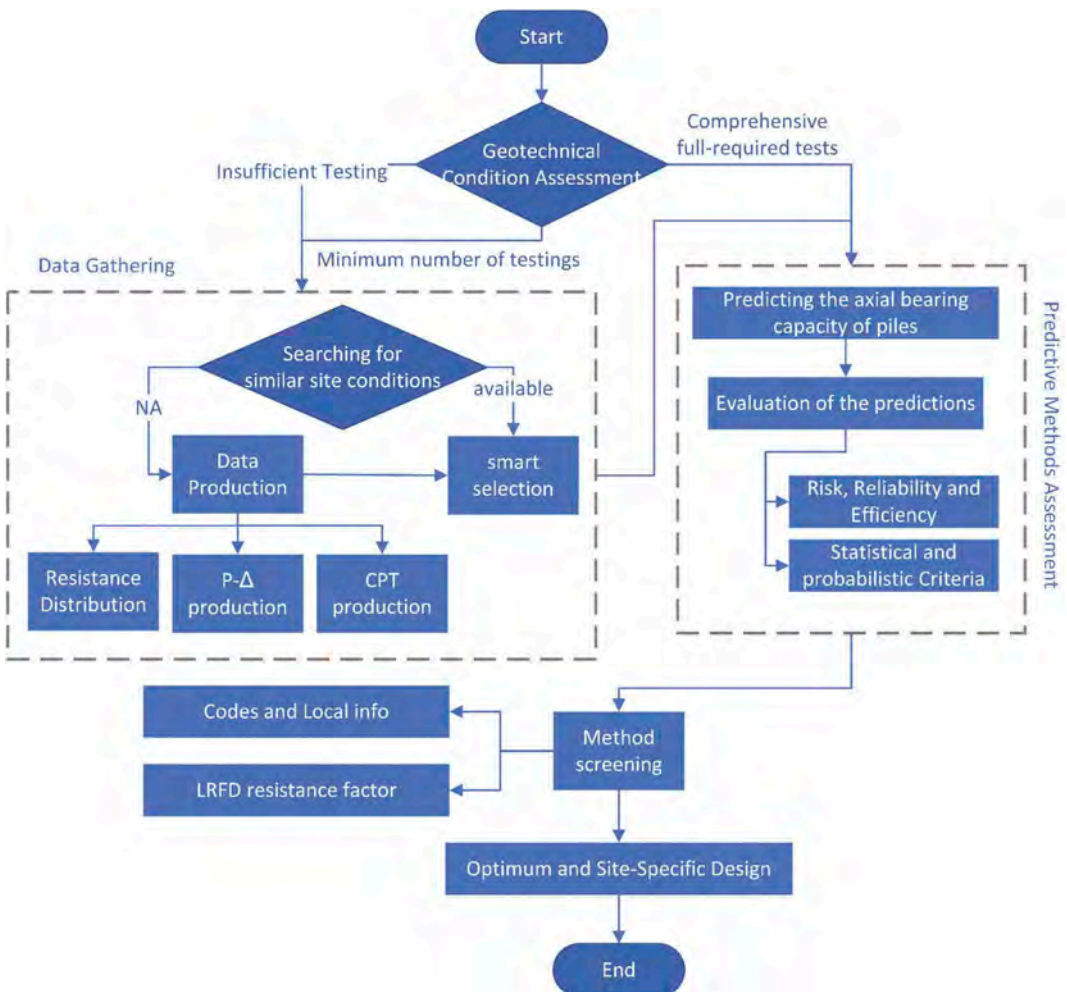
The second stage is about processing the axial pile bearing capacity predictions. Various methods and approaches result in a wide range of predictions. Regardingly, applying miscellaneous evaluation criteria including statistical and probabilistic criteria and risk, reliability and efficiency-based criteria, leads to selection of appropriate methods according to the available site conditions, codes and local information. Indeed, this stage is dedicated to method screening leading to optimum geotechnical design. Eventually,


Figure 1. Geotechnical data-based pile design algorithm.

the understanding of the geotechnical engineer is improved and an optimum site-specific design approach is attained.

4 ENGINEERING IMPLEMENTATION

A database of sixty driven piles was gathered from the AUT:Geo-CPT&Pile database with their adjacent CPT records worldwide to illustrate the application of the proposed data-based geotechnical pile design approach. Most of the piles are installed in clayey soils (i.e., about 45% of the piles in the compiled database), followed by sandy soils (i.e., about 32%) and mixed soils (I.e., about 23%). According to what explained in the earlier section, for an optimum geotechnical pile design, it is appropriate to perform a comprehensive in-situ and lab tests to characterize the subsoil conditions and further consider it. In the case, the number of tests was limited or was not available for the current project, the geotechnical practitioner can gather extra information about the project site by searching through the available geotechnical site investigation reports for the nearby projects or a by smart selection from CPT and pile databases.

From the investigated database a driven pile was selected. This circular concrete pile was installed in sandy soils of Norway with embedment length of 15.5 m and diameter of 280 mm. By searching for similar site and pile conditions, a concrete square pile installed in Sweden was selected with embedment length of 12.8 m and width of 235 mm. Figure 2 provides the soil behavior classification (SBC) for these two close sites. As it is presented, the most majority of soil types are silt-sand and sand-gravel regarding the Eslami and Fellenius (1997) soil behavior classification.

Figure 3 illustrates the static pile load test (PLT) results for these two piles. Both piles behaved similarly under compression loading. As stated earlier, in case insufficient geotechnical data, Jamshidi Chenari et al. (2018) proposed a non-stationary algorithm for reproduction and realization of CPT records regarding soil stratigraphy.

Figure 4 compares the reproduced CPT records, i.e., q_c and f_s and their analogous real ones for the two investigated sites in Norway and Sweden. The geotechnical engineer can reproduce these CPT records with different inherent soil variability changing from low to high in soil characteristics reflecting the subsoil condition.

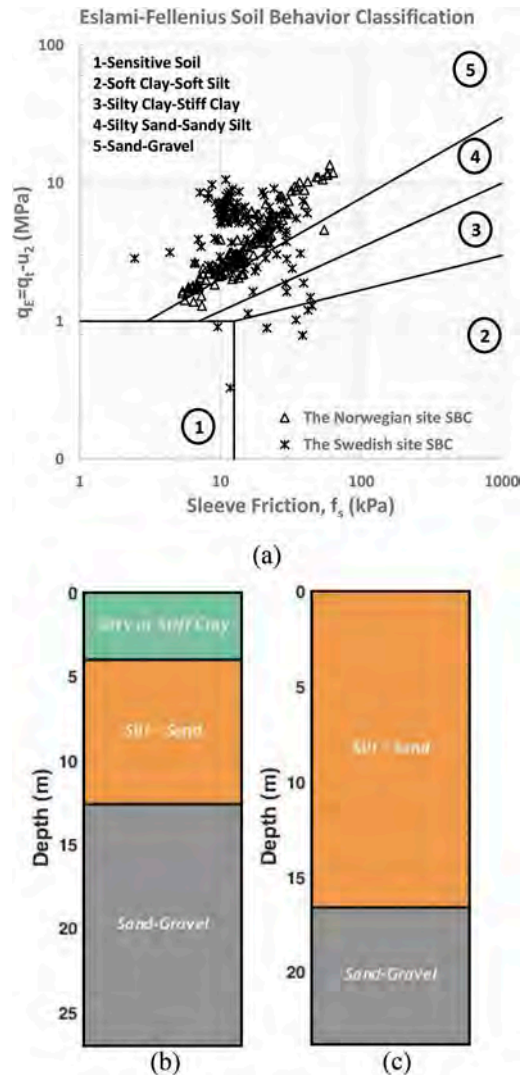
Figure 5 compares the performance of different CPT-based methods for these two piles via model parameter and it is the ratio of measured to predicted bearing capacity, i.e., Q_m/Q_p. The site conditions for these two considered piles, influence the performance of predictive methods appropriately in a similar way. For instance, if the acceptable limit for Q_m/Q_p changes from 0.8 to 1.2 as is shown in Figure 5, methods such as LCPC (Bustamante and Gianesselli


Figure 2. Soil stratigraphy; (a) soil behavior classification for the two sites (Eslami and Fellenius 1997), (b) the subsoil layering in Sweden, (c) the subsoil layering in Norway.

1983), Meyerhof (1983), UniCone (Eslami and Fellenius 1997), German (Kempfert and Becker 2010), and Modified UniCone (Niazi and Mayne 2016) have led to close predictions. However, other investigated methods, including Schmertmann (1978), Dutch (de Ruiter and Beringen 1979) andFugro-05 (Kolk et al. 2005) resulted in less accurate predictions due to the differences mentioned earlier. Regardingly, finding matching piles with similar dimensions and embedment length installed in close or near close site conditions, enhances the geotechnical engineer to have an optimum site-specific design by selecting appropriate criteria and implementing multi-criteria decision-making models.
Figure 3. Pile load test results for the two considered piles.
Figure 5. The performance of different CPT-based methods for these two considered piles.
5 CONCLUSIONS

Uncertainties are an inseparable part of geotechnical engineering, and many attempts have been made to consider their influence on geotechnical designs in the last decades. Characterizing the subsoil conditions is one of the essential steps in geotechnical designs, and CPT by producing continuous and reliable records has a crucial role in determining inherent soil variability. One of the primary applications of CPT soundings is predicting axial pile bearing capacity due to its similarity to the pile. In this regard, several methods have been developed based on CPT records. However, these methods result in a wide range of predictions according to the embedded uncertainties. To overcome the difficulties of selecting an appropriate predictive method, CPT and pile databases assist the geotechnical engineer. Accordingly, AUT:Geo-CPT&Pile database was introduced, and its implementation in various pile engineering issues was reviewed. However, the data mining of such a database is not limited to performance assessment of predictive methods, and an algorithm for data-based pile design approach is its other prospect. In this approach, with the aid of available data in the compiled database, the designer can search for the matching site and pile conditions in the absence of necessary and sufficient site geotechnical information or even reproduce and realize CPT records. After gathering adequate CPT and pile data, various predictive methods can be assessed via statistical, probabilistic, and reliability-based criteria. Eventually, the methods' screening procedure is finalized via considering codes and local info, and the superior methods are selected. Correspondingly, the final pile

Figure 4. Reproduced CPT records for the two site conditions, (a) the Swedish site, (b) the Norwegian site.

geotechnical design will be an optimum pile performance-based design upon a data mining approach. The Application of this algorithm was presented through an example.

ABSTRACT: Precast piles are driven to 23 m depth to improve the capacity of foundations located on saturated liquefiable sands on top underlain by a thick soft to medium stiff clay. Analyses show excessive kinematic moment at borderline of the two layers during liquefaction. It was decided to drive additional shorter piles (12 m) to mitigate liquefaction hoping that kinematic moments shall be reduced within allowable limits. CPTu tests were carried out before and after pile driving. The results show that q_c did not change considerably in the top saturated silty sand layer as well as the clayey soil underneath. The friction sleeve, however, increased more significantly due to radial displacement and compaction/consolidation attributed to cavity expansion during pile driving. Analyses showed that pile arrangement was not sufficient to overcome liquefaction during earthquake. However, safety factor increased sufficiently to reduce kinematic moment within the allowable limits. The details of the site operations, CPTu data before and after pile driving, analyses and interpretations are presented and discussed.

Keywords: Pizeocone Penetration Test (CPTu), Liquefaction, Precast pile, Kinematic moment

1 INTRODUCTION

Soil deposits at a site subjected to an earthquake may experience increases in pore water pressure and time-dependent vertical and lateral ground movements. As a consequence of the earthquake-induced ground movements, piles and other deep foundations will be subjected to two sources of additional lateral loading:

a. Inertial Forces/Moments: forces and moments that are induced in the piles because of the accelerations generated within the structure by the earthquake.
b. Kinematic Forces/Moments: forces and bending moments that are induced in the piles because of the ground movements resulting from the earthquake. Such movements will interact with the piles and because of the difference in stiffness of the piles and the moving soil, there will be lateral stresses developed between the pile and the soil, resulting in the development of shear forces and bending moments in the piles.

Tajimi (1969) and Penzien (1970) were among the first researchers to study the problem through using analytical and numerical approaches, respectively. Following these early efforts, the problem of kinematic effects was analyzed by Blaney et al. (1976), Kagawa & Kraft (1980), Dobry & O'Rourke (1983), Nikolaou et al. (1995), Luo & Murono (2001) and others. Determination of the kinematic forces acting on the pile depends on the liquefaction potential and soil parameters before and during liquefaction.

Conventional experiences have held that driving displacement piles into loose and medium dense sand will densify the soil volume close to the pile. Some researchers including Meyerhof (1959), Nataraja & Cook (1983), Bement & Selby (1997), Gianella et al. (2015), Stuedlein et al. (2016) and Stuedlein & Gianella (2017) and Rhyner (2018) have studied the densification effects caused by driving piles into granular soil. By changing the soil properties due to pile driving and subsequent alterations in the soil liquefaction potential, the amount of kinematic forces on the pile will change. Similarly, some have evaluated the effects of pile driving on variations of stress state and consolidation surrounding the pile shaft (e.g., Khanmohammadi & Fakharian, 2018; Fakharian & Khanmohmmnadi, 2022). Fakharian et al. (2014) evaluated the effect of surcharge pressure of the reaction system on the load-movement response of piles.

This paper presents a case study conducted to evaluate the effects of pile driving on loose, clean and silty

sand properties. The subsoil condition before pile driving was characterized using CPTu test as well as boreholes and soil sampling. Square precast concrete piles were designed and driven down to 23 m of embedment depth as the main piles or bearing piles. Analytical calculations showed excessive kinematic moments at the borderline of the two layers when liquefaction occurs. It was decided to drive additional shorter 12 m piles (compaction or improvement piles) to mitigate the liquefaction hoping that the kinematic moments shall be reduced within the allowable limits of the pile section. After driving the main piles and consolidation piles, hereinafter referred to as bearing and compaction piles, another 4 CPTu were conducted to see how the pile driving had contributed to the soil improvement between the piles. The site geological condition, CPTu data before and after pile driving, kinematic moment analyses before and after pile driving are carried out and interpretations are presented and discussed.

2 FIELD DESCRIPTION

2.1 Subsoil conditions

The trial field is located in Jask approximately 250 km south-east of Bandar-e-Abbas city in Hormozgan province, on coastal area of Gulf of Oman, Iran. Project area extends North-South, with an apparent length of 1600 m and width of 400 m. The soil stratification of the trial zone consists of three different layers (Figure 1):

Layer (I): The layer mostly consists of sand and cohesionless silt and classified as medium dense to dense silty sand. This layer has been observed from ground surface down to 8 m depth. GWT is 1.5 m deep any lies in Layer I.

Layer (II): Second layer consists of firm to stiff clay and silty clay. This layer underlying layer (I) starts from the depth of 8 m and in some areas has extended to a depth of 28 m.

Layer (III): This Layer is situated below the second layer (deeper than 28 m) and consists of medium dense to very dense sand and silty sand.

Figure 2 shows the distribution zones of clay, silt and sand with depth. In fact the red line with square points shows the border of clay-silt and the yellow line with triangle points shows the border of silt-sand. Down to 8 m, soil dominantly constitutes sand and silt, and the percentage of clay is less than 40%. From depth of 8 to about 26 m, the clay fraction is between 60 to 80%.

2.2 Main and compaction piles layout

Square 400 × 400 mm precast concrete piles were designed and driven down to 23 m of depth as the "main piles". Ultimate bending moment of piles is 143 kNm. During liquefaction, however, analytical calculations show that kinematic moment at the borderline of the two layers (Layer I and Layer II) is greater than the

ultimate bending moment. It was decided to drive additional shorter piles (12 m) as "compaction piles" to mitigate the liquefaction hoping that the kinematic moments shall be reduced within the allowable limit of the pile section. Figure 3 shows the bearing and compaction piles layout in the trial field.

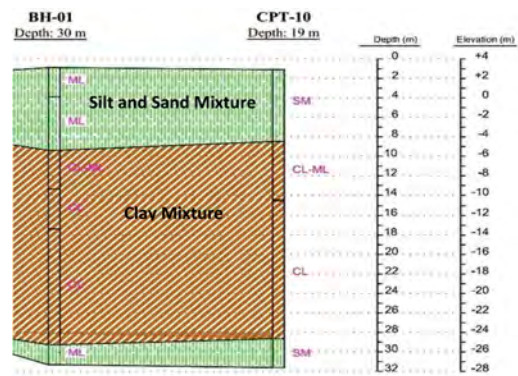
After driving the bearing and compaction piles, four CPTu tests were performed to evaluate the changes in soil condition at locations surrounded by piles and beyond. All tests were performed about 45 days after pile driving. The location of the post-pile driving tests is shown in Figure 3. CPT-10 and CPT-Ref are outside of the piling area and in a way indicates the initial state (*in situ*) of the soil. CPT-ZA3 and CPT-ZA4 are located between the bearing and compaction piles, and CPT-ZA5 is located between compaction piles.


Figure 1. Geotechnical cross-section of the trial field in Jask, on Coastlines of Sea of Oman.
Figure 2. Grain fraction proportions with depth.

927

2.3 Pre- and post-driving trial tests

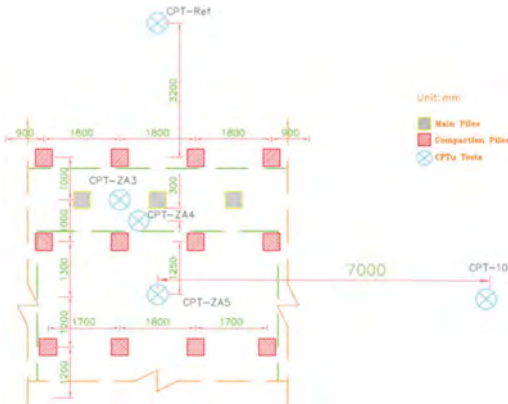
Results of pre- and post-driving CPTu tests are shown in Figure 4. The results after pile driving indicates that no considerable changes are observed in q_c in both layers (I) and (II) till depth 12 m, equivalent to the length of compaction piles. The friction sleeve f_s, however, has increased significantly. The pore pressure variations show that original *in situ* condition has induced higher pore pressure from starting the clayey soil of Layer II (CPT-10 and CPT-Ref). However, after pile driving, both ZA3 and ZA4 points situated in between the piles have generated negative to hydrostatic values of u down to 12 m of depth equivalent to the depth of compaction piles. This is understood to be attributed to compaction of sand as a result of increase in radial stress around the pile shaft, contributing to dilative response during shearing and hence generation of negative PWP as CPT loading is rapid hence considered as undrained. Friction ratio R_f has significantly increased within the 12 m of the compaction piles and even down to 15 m.


Figure 3. "Main" and "compaction" piles layout at trial field.

As shown in Figure 2, the soil has a significant percentage of fine-grained at most depths. Especially from depth of 8 m, the percentage of sand in the soil is zero indicating that the soil has very low compactibility, and as a result, q_c has not increased significantly.

Pile penetration induces soil compaction and consolidation which is manifested by an increase in horizontal effective stress, i.e., it causes the *in-situ* earth pressure coefficient, K_0, to increase. Sleeve friction is defined as the product of horizontal effective stress and the friction coefficient at the soil–CPT sleeve interface. Assuming the coefficient of friction between the soil and CPT sleeve is constant, sleeve friction increases due to the increase in horizontal effective stress (normal to sleeve).

The analysis of CPTu results using Robertson (1990) soil classification chart (Figure 5) shows that the pile driving process has dragged the CPTu

classification results into the zone of the soils presenting the overconslidated or cemented type.

3 INTERPRETATIONS

3.1 Assessment of soil liquefaction potential

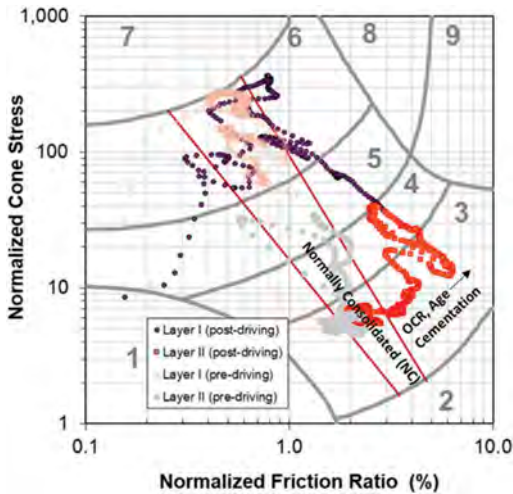
A procedure suggested by Robertson & Wride (1998) is used to evaluate the potential for cyclic softening and cyclic liquefaction. The procedure used the basic methodology, developed by Seed & Idriss (1971), calculating cyclic stress ratio (CSR) induced by the


Figure 5. Robertson (1990) soil classification of pre- and post-driving CPTu results.

earthquake, and cyclic resistance ratio (CRR) of the soil. If CSR is greater than CRR, then liquefaction can occur. The proposed procedure estimates CRR based on the "sand-like" or "clay-like" classification identified by factor $I_c=2.6$. The updated procedure is well established in 2009 by Robertson (2009). Sand-like behavior is allocated to soils having $I_c<2.5$. Such soils have the potential for cyclic liquefaction. Clay-like soils have $I_c>2.7$ in which cyclic softening potential is recognized. The transition from sand-like to clay-like behavior generally occurs when $2.5<I_c<2.7$. Fine- grained soils transition depends on Atterberg Limits and Plasticity Index.

Figure 6 shows the evaluation of "cyclic liquefaction" and "cyclic softening" potential for CPT-Ref, CPT-ZA3 and CPT-ZA4. Down to 6 m depth, I_c value is lower than 2.5 where the probability of cyclic liquefaction is significant. CPT-Ref, CPT-ZA3 and CPT-ZA4 show cyclic liquefaction factor of safety (FS) lower than 1 between 4 to 6 m. Considering the effects of the main and compaction pile driving, CPT-ZA3 and CPT-ZA4 demonstrate the cyclic liquefaction safety factor is higher than the CPT-Ref in this layer (average FS of 0.74 at ZA3 point versus average FS of 0.45 at the Ref. point) Despite the higher FS, the calculations still show that cyclic liquefaction potential in this zone still exist. However, about 60% increase in FS has contributed to significant reduction of the kinematic forces induced in the piles.

The soils between 6 to 9 m are classified as transition soils. As the main and compaction piles penetrate through the soil, the CPT-ZA3 and CPT-ZA4 have shown higher sleeve friction, f_s. Thus, the soil behavior categorized in the transition zone has turned into clay-like behavior dominated by the potential for cyclic softening. As illustrated in the subjected zone

for CPT-ZA3 and CPT-ZA4, the cyclic softening FS is above 1 compared to the cyclic liquefaction FS of CPT-Ref which is lower than unity.

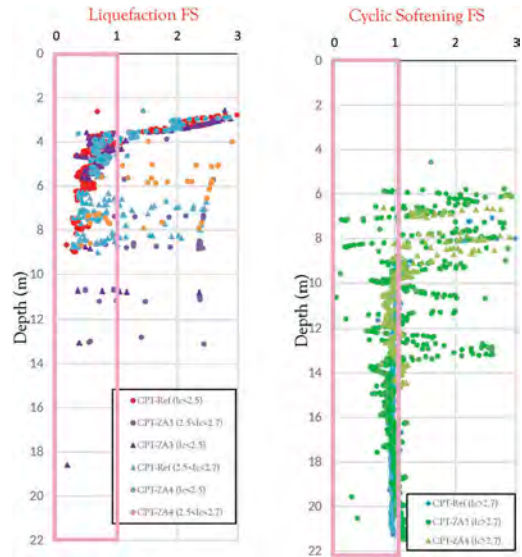
In depths below 9 m, calculation of potential for cyclic softening is performed, considering the domination of clay-like behavior of the soil. The uniform form of the calculated safety factor profile for the CPT-Ref (generally lower than 1) has changed due to the installation of the compaction piles down to about 12 m. This shows the effectiveness of driving compaction piles and raising FS to greater values.


Figure 6. Changes of FS for "liquefaction" and "cyclic softening" for pre- and post-driving CPTu results.

3.2 Assessment of kinematic loading effects

The kinematic moment is evaluated using a method proposed by Nikolaou et al. (2001). In this method, pile is modeled as a beam on a dynamic Winkler foundation (BDWF), with homogenous, isotropic, and linearly elastic soil in each layer and a constant soil-damping ratio. They found that induced moments were maximum at interfaces between layers of different stiffness, and then performed a series of calculations to determine the bending moment at the interface between the two layers. The method does not consider any particular condition about the thickness of the two layers and is therefore, applicable for any depth of the layer interface.

The method proposes a reduction factor η to be applied to the maximum steady-state pile bending moment within the frequency domain to arrive at the corresponding peak value in the time domain. In the current study, the parameter η is equivalent to 0.37.

$$M_{pk} = \eta M_{res} \qquad (1)$$

where M_{res} is the bending moment developed under resonant conditions and it is calculated using the following relation:

$$M_{res} = 0.042 \tau_c d^3 (L/d)^{0.3} (E_P/E_1)^{0.65} (V_{s2}/V_{s1})^{0.5} \qquad (2)$$

in which d is pile diameter, L pile length, E_p Young's modulus of pile, E_1 Young's modulus of upper layer, V_{s1} average shear wave velocity in upper layer, V_{s2} average shear wave velocity in lower layer, ρ_1 the mass density of upper layer and h_1 is the thickness of upper layer.

Shear stress τ_c which is proportional to the actual shear stress is likely to develop at the interface, as a function of the free-field acceleration at the soil surface, a_s:

$$\tau_c = a_s \rho_1 h_1 \qquad (3)$$

Predictions obtained using the above formula are shown in Figure 7 for the Ref point and ZA3. The magnitude of kinematic moment is significantly lower in the test results of post-driven point, CPT-ZA3. This is understood to be attributed to the effect of the main and compaction piles driven down to 23 m and 12 m, respectively.

After driving the compaction piles, the thickness of the liquefied layer has reduced from 8.5 m (left graph of Figure 7) to 5.5 m (right graph).
Figure 7. Schematic of kinematic loading value at interfaces between layers for a) CPT-Ref, b) CPT-ZA3.

The reduction of the maximum kinematic bending moment is resulted from: (1) increase in fs (due to increase in lateral stress in soil) and hence reduction in liquefaction potential of the soil, (2) reduction of the liquefied layer thickness.

The presented results and the differences in CPTu parameters between the initial *in situ* condition and after the pile driving sequences are indications of effective improvement role of the driven main and compaction piles.

4 CONCLUSIONS

A case study is presented on the effect of driving "main bearing" and "compaction or improvement" piles in the silty sand to silty clay strata at a study field having high seismic and liquefaction/cyclic softening potential. CPTu tests were performed both prior and after driving the piles. Analyses were performed to evaluate the maximum kinematic moments at the interface of the two sand-like (top) and clay-like (bottom) layers. On the basis of the presented results, the main conclusions are summarized below:

- The q_c increased slightly in the top saturated layer as well as the clayey soil underneath till depth of 12 m, equivalent to the length of compaction piles.
- The friction sleeve (and hence friction ratio), however, increased more significantly due to radial displacement and compaction/consolidation attributed to cavity expansion surrounding the pile during driving.
- Liquefaction analyses show that the pile arrangement was not sufficient to overcome the liquefaction for the earthquake of the site with 0.4g acceleration and M=7.
- However, the factor of safety increased sufficiently to reduce kinematic moments within the allowable limits.

Verification of 3D FEM analysis of ground improvement works using CPT test results

G.A. Faour & K.N. Khouri

NSCC International Ltd, Abu Dhabi, United Arab Emirates

ABSTRACT: The cone penetration test (CPT) has been widely used as one of the most well-known and reliable performance tests for ground improvement works. A comprehensive CPT testing campaign was conducted for the proposed ground improvement works of a highly technical project in Oman. The ground improvement works were evaluated based on the results of pre and post improvement CPT testing. CPT was the basis for choosing rigid inclusions (RI) and Vibro-compaction (VC) as the most suitable and economical ground improvement techniques for this project. The acceptance criteria based on the Post improvement CPT results incorporated the liquefaction potential and both allowable immediate and long-term settlements. The degree of ground improvement was evaluated by verifying that the final test results in the field met the project design criteria. It was concluded that CPT testing can be accurately correlated with multiple ground improvement acceptance criteria including liquefaction and settlement.

1 INTRODUCTION

1.1 Project description

A Development Company are constructing a 1.50 million square meters, world class multi cluster entertainment and leisure park in Barka, Oman. NSCC International was contracted for the design, construction and verification of the ground improvement works. The design was conducted to provide a cost-effective solution to mitigate liquefaction and achieve both immediate and long-term settlement criteria. The project was divided into two main areas: Retail, Dining, Entertainment (RDE) area and Theme Park area (TP). This paper elaborates on the design of the ground improvement schemes and their verification using CPT testing for these two areas.

1.2 Site investigation program

A series of one hundred additional cone penetration tests (CPT) (to compliment the borehole test results provided by the tender stage soil investigation report) were undertaken to provide a detailed evaluation of the subsurface conditions prior to construction for both RDE and TP areas. Figures 1 and 2 illustrate the approximate locations of the conducted boreholes and CPTs for both the RDE and TP areas respectively.

1.3 Subsurface conditions

The soil conditions generally consisted of sandy layers overlying silt layers which are underlain by
Figure 1. Pre-CPT campaign - RDE area.

Figure 2. Pre-CPT campaign - Theme Park area.

interchangeable layers of siltstone and sandstone. The sand layer was typically about 6.0m in thickness with occasional interlayering of a cohesive silt zone up to 1.0m thick encountered at 1.50m below the existing ground level. Another silt layer was found at a depth of 6.50m below the existing ground level with

a thickness of 2.0m. The underlying siltstone and sandstone layers were typically located at about 8.0m in depth. Figure 3 shows the variation of the cone penetration resistance values (qc) with depth for the different soil strata encountered in both RDE & TP areas.

The groundwater table was encountered at about 4 to 4.50m depth below the existing ground level (-2.00m MSL); however, a conservative design groundwater table level of 0.00m MSL was considered in the design and the analysis to allow for seasonal variations.
Figure 3. Variation of qc with depth.

2 GEOTECHNICAL EVALUATION

2.1 *Retail, Dining, Entertainment (RDE) area*

Pre-CPT analyses were carried out to assess the liquefaction susceptibility and to estimate the resultant immediate and long-term settlement of the encountered soils under the RDE structures. The methodology to estimate the liquefaction potential requires an estimate of the cyclic stress ratio (CSR) profile caused by the design earthquake and the cyclic resistance ratio (CRR) of the ground. If the CSR is greater than the cyclic resistance ratio (CRR), liquefaction can occur. The CSR is usually estimated based on potential triggering shear stresses resulting from a 1 in 475-year design earthquake exerting a firm ground (i.e., Bedrock) peak horizontal acceleration of 0.15g. In our case this gave a potential ground surface peak horizontal acceleration of 0.23g, due to soil amplification. A simplified method to estimate CSR was developed by Seed and Idriss (1971) based on the maximum ground acceleration at the site. The results of the analyses revealed

that a soil layer of approximately 1m in thickness and susceptible to liquefaction was found at about 2.0m depth below the existing ground level; which may be underlain by thin discontinuity lenses of liquifiable soil within a zone from about 4.0m to 6.5m in depth.

In addition to the above, settlement analyses were performed for all RDE foundations by checking both immediate and long-term settlements. Based on the calculated settlement values and the Factor of Safety against liquefaction, it was deemed necessary to implement ground improvement techniques for foundations underlain by these potentially liquifiable zones to meet the project performance criteria. Several ground improvement methods were evaluated to eliminate the susceptibility of liquifiable soil and to eliminate excessive settlements. Based on the evaluation of the different ground improvement methods, the vibro-compaction method was selected to address both settlement and soil liquefaction concerns under all the RDE structures.

2.2 *Theme Park (TP) area*

The same analyses were repeated for the Theme Park area by analysing the pre-CPTs illustrated in Figure 2. The results of the analyses indicated that there is no risk of liquefaction for this area except for a few structures (Entry, Citadel, and Pond 11 & 12). However, our calculations show excessive long-term settlements for all structures founded in this area due to the presence of a consistent thick silt layer. Based on the above analyses, vibro-compaction was chosen to mitigate liquefaction, followed by rigid inclusions to minimise the foundations settlements. For structures which are not prone to liquefaction, only rigid inclusions were adopted. The following section depicts the full liquefaction and settlement analyses established for one of the structures in the Theme Park area, namely, the Citadel & Entry structure.

3 AN APPLICATION CASE TO CITADEL AND ENTRY STRUCTURE

3.1 *Structure properties*

Figure 4 portrays the overall geometry of Citadel & Entry structure along with the CPTs conducted in this area. The total area of this structure is 3,976m^2 with a design total service loading of 125kPa.

3.2 *Liquefaction and settlement assessment*

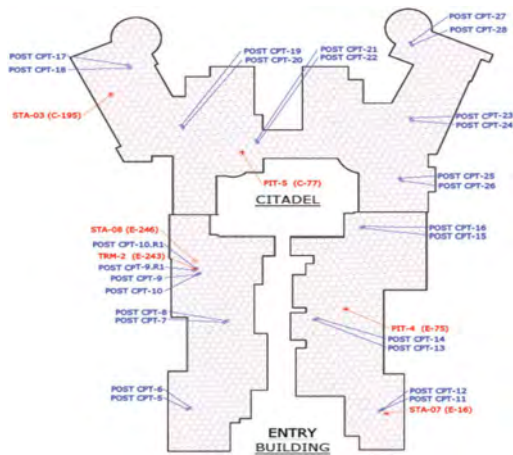
Both liquefaction and settlement analyses were implemented using the results of the conducted pre-CPTs. The results of the analyses show the presence of soil layers susceptible to liquefaction. To mitigate liquefaction risk under this structure, Vibro-compaction was performed by adopting a 3.0m triangular grid to an improvement depth of 8.50m. The grid spacing was


Figure 4. Citadel and entry layout.

chosen based on the results of the trial campaign conducted in that area. The effectiveness of the grid spacing was verified using the results of the zone load tests (ZLT) with four CPTs executed at the four corners of the ZLT. PLAXIS 3D analysis was carried out to compare the theoretical ZLT settlement results with the measured ones.

3.3 *Liquefaction analysis using CLiq*

The effectiveness of liquefaction mitigation under the Citadel & Entry structure was corroborated by carrying out a post testing campaign as shown in Figure 4. A pair of post treatment CPTUs were performed at 1/3 the distance between two Vibro-compaction points and at the centre of the triangle formed by three vibro-compaction points. Evaluation of liquefaction potential was assessed using CLiq software developed by Geologismiki using Robertson (NCEER R&W 1998, 2009). Each post-CPT pair was checked for liquefaction susceptibility by considering an earthquake magnitude of 6.0, a PGA of 0.15g at bedrock and a Factor of Safety against liquefaction of 1.25. The results of the liquefaction analysis for all post-CPTs conducted in the area are shown in Figure 5. The results confirm that liquefaction is mitigated by the vibro-compaction technique with a minimum factor of safety of 1.25 except for thin confined localized layers with thickness of approximately 0.30m. These thin layers are classified by Robertson (2011) as transition zones and are not susceptible to liquefaction. The liquefaction analyses resulted in minimum seismic vertical and horizontal settlements.

3.4 *Liquefaction analysis using PLAXIS 3D*

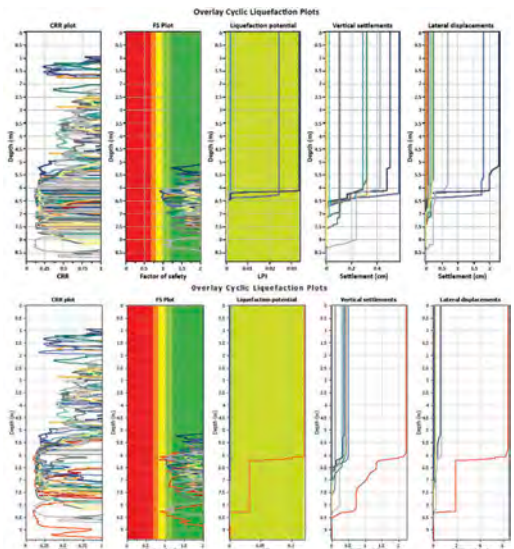
The above results were checked by carrying out liquefaction analysis using PLAXIS by adopting the UBC3D – PLM Sand Model and by defining the


Figure 5. Liquefaction results using CLiq software.

following response spectrum curve and time history. UBC3D-PLM Sand model is an effective stress elasto-plastic model which can simulate the liquefaction behavior of sands and silty sands under seismic loading. (Tsegaye (2010), Petalas & Galavi (2012)).
Figure 6. Earthquake parameters for PLAXIS liquefaction analysis.

934

The Factor of Safety against liquefaction using PLAXIS was calculated as the ratio of the excessive pore pressure changes and the initial effective pressure. Plaxis liquefaction analysis resulted in a FoS of 1.51 which is greater than the empirical factor of safety calculated using CLiq software thus confirming that the liquefaction mitigation criteria were achieved. The advantages of the dynamic analysis using UBC Sand is the ability to simulate the excess pore water pressure generation in the soil, as well as the ability of checking the amplification, liquefaction/plastic points.

3.5 Settlement analysis using Taspie

The settlement analyses of the post-CPTs indicate that the settlement criteria were not achieved by Vibro-compaction only due to the resultant settlement exceeding 25mm. Therefore, it was decided to install 450mm diameter rigid inclusions, 10.0m in length in the vibro-compacted ground, to ensure the calculated settlement be less than the allowable (25mm) under 125kPa loading. The rigid inclusions were overlain with a 40cm thick load transfer platform (LTP). The LTP plays an indispensable role in transferring the loads to the toe of the rigid inclusions and to uniformly transfer the settlement under the structure. The post-CPTs were used to derive the geotechnical parameters of the in-situ soil. As for the LTP, a compacted gravel layer was considered. Layering and material parameters of the LTP and foundation soils are listed in Table 1. The Ground level elevation is at 3.0m MSL and the ground water level is at 0.00m MSL.

Figure 7. Load transfer mechanism (Taspie Software).

The above figure reveals that the settlement criteria was achieved with an associated settlement of approximately 25mm. The rigid inclusion settlement was approximately 14mm with a maximum stress of 4.55Mpa located at the neutral axis (-2.80m MSL).

3.6 Settlement analysis using PLAXIS 3D

To validate the estimated settlements by Taspie software, a full PLAXIS 3D finite element analysis was conducted for Citadel & Entry structure as shown in Figure 8 below. The rigid inclusions were defined as embedded beams and the slab on grade as plate elements. Soil properties illustrated in Table 1 were defined using the Mohr-Coulomb material model.

Table 1. Material parameters and foundation soils.

Layer #	Thickness (m)	γ (kN/m^3)	E (Mpa)	φ (Deg)	ν
LTP (Gravel)	0.5	19.50	50.00	38	0.25
MD Sand 1	0.58	18.00	37.50	33	0.35
MD Sand 2	0.62	18.00	53.40	33	0.35
MD Sand 3	1.00	18.00	27.00	33	0.35
Silt	0.44	16.50	6.50	26	0.35
MD Sand 4	0.94	17.50	36.70	33	0.35
VD Sand	0.42	19.00	76.00	34	0.35

* γ: unit weight, ν: Poisson's ratio, E: elastic modulus, φ': drained friction angle, MD: Medium dense, VD: Very dense

Figure 8. PLAXIS 3D View (Citadel & Entry).

The above PLAXIS 3D analysis has shown a maximum settlement of 19mm as depicted in Figure 9. Moreover, the same load transfer mechanism shown in Figure 7 using the Taspie software was also created by the PLAXIS 3D run as demonstrated in Figure 10.

3.7 Measured vs theoretical results

According to Chapter 8 of ASIRI guidelines, static load tests on an isolated inclusion in compression

The RI design is performed using Taspie by adopting a unit cell model. This software follows the general recommendations for the design and construction of rigid inclusions in ASIRI (2012).

Figure 7 displays the resultant settlement along with the stresses exerted on both soil and rigid inclusions for one of the post-CPTs pair conducted in the Citadel & Entry area.

Figure 9. Settlement distribution.

Axial forces N (scaled up 5.10*10⁻³ times)

Maximum value = -377.3 kN (Element 1761 at Node 881798)

Minimum value = -710.5 kN (Element 1756 at Node 881788)
Figure 10. Load Transfer Mechanism (PLAXIS 3D).

should be conducted. Three static load tests were conducted in the Citadel & Entry area as shown in Figure 4 by applying a testing load equivalent to the sum of the head load acting on the rigid inclusion and the negative skin friction acting on the RI from its head to its neutral plane.

The effectiveness of rigid inclusions in the field response of Citadel/Entry foundation was assessed by comparing the measured settlements with the theoretical calculations using both Taspie and PLAXIS 3D software.

The following table enumerates the resultant settlement of the static tests compared with the theoretical calculations.

Table 2. Measured versus theoretical comparison.

Static Load Test	Testing Load (kN)	RI (Settlement-Taspie) (mm)	RI (Settlement-PLAXIS 3D) (mm)	RI (Settlement-Measured) (mm)
STA-07	1273	15.50	13.77	3.960
STA-08	1116	19.50	14.11	3.880
STA-03	1222	16.00	14.80	8.060

Table 2 shows that the theoretical settlements derived from both Taspie and PLAXIS 3D analyses are conservative compared to the measured settlements.

3.8 *Conclusion*

The CPT testing technique has proven to be an invaluable tool for calibrating and verifying the effectiveness of both Vibro-compaction and rigid inclusions techniques, particularly in its ability to identify the strength of the silt layers. The CPT testing used in both the PLAXIS 3D and Taspie software runs have resulted in conservative settlement calculations which favourably compare with the measured static load test settlements. Moreover, CPT testing has proven to be well correlated with the liquefaction acceptability criteria as calculated by carrying both static and dynamic liquefaction analyses using both CLiq and PLAXIS software respectively.

A comprehensive design procedure for pile groups in liquefiable soils

M. Franceschini, F. Fiorelli & E. Bandiera

Teleios Srl – Società di Ingegneria, Castel Maggiore, Bologna, Italy

ABSTRACT: Among the various strategies to mitigate the effects of soil liquefaction one of the most effective is the design of deep foundations. The designs of piles in liquefiable soils are too often concerned with the only axial bearing capacity, addressed by simply neglecting pile resistance in the liquefiable layer. This approach is inadequate to properly face the complexity of the problem. In the present paper we intend to examine this theme throughout its multiple aspects. We have synthesized a design procedure of analysis that has been already applied in some projects in different areas of Emilia-Romagna region characterized by high risk of liquefaction. The proposed design procedure is based on the most updated theories and design references concerning piles in liquefiable soil, such as those of Cubrinovsky, Olson & Stark, Rollins, Bhattacharya, Madabhushi and others, primarily referring to CPTu.

1 INTRODUCTION

When designing a structure interacting with the soil in a site subjected to a high risk of liquefaction during earthquake, there are many solutions that can be evaluated to reduce and mitigate this risk.

For foundations resting on liquefiable soil one of the most effective solutions is the use of piles. But, in this case, their design has to properly account for the effects induced on piles by liquefaction.

The phenomena involving a pile under seismic cyclic loading in presence of liquefiable soils are complicated. There are different important aspect to be accounted for: the change in shaft resistance, the reduction of base capacity also in deeper layer not directly liquefacting, the equilibrium instability due to the loss of lateral support from liquefied soil and the modification of the geotechnical model under liquefaction, directly conditioning the analyses of pile groups with geotechnical numerical models.

In order to properly face the design of deep foundations on liquefiable soils we have resumed the principal bibliographic studies with the aim to build a comprehensive design procedure. In the paper we will describe in detail the various step of this procedure and we will also propose a real design example in which we have already applied this process.

2 GEOTECHNICAL MODEL

In a geotechnical design the first, and maybe most important, step is the construction of an accurate and reliable geotechnical model, i.e the parameters and the constitutive laws that mathematically represent the mechanical response of the soil.

In the case of high risk of liquefaction, the geotechnical model valid under seismic conditions significantly differs from the static one because of liquefaction effects on soil properties. The liquefiable soil layer is described below in terms of both modified stiffness and strength parameters.

2.1 *Stiffness parameters*

As regards stiffness parameters we referred to the theory proposed by Cubrinovski et al. (2009). In a simplified 3-layers model, in which the central one is potentially liquefiable, the pile is modelled as a beam connected to a series of springs representing the lateral stiffness of the soil.

As expected, the stiffness offered by the liquefied soil (k_2) is significantly lower than the one of the same non-liquefied soil (k_1). The results observed in full-scale tests on piles show that the stiffness degradation factor $\beta_2 = k_1/k_2$ typically varies in a range of $1/50 \div 1/10$ for cyclic liquefaction (Figure 1). In our design procedure we chose to refer to the lower bound, i.e. to $\beta_2 = 1/50$.

The degradation factor β_2 is applied to the stiffness parameters of the liquefiable soil layer, in particular to the initial tangent value of soil elastic modulus within the numerical Boundary Element Method analyses perfomed adopting a non-linear hyperbolic constitutive model. The above theory (Cubrinovski et al. 2009) was originally developed for "p-δ" curves methods: we extended the same approach to numerical BEM analyses.
Figure 1. Degradation of stiffness in the liquefied layer observed in full-size test on piles. From Cubrinovski et al. (2009).

2.2 Strength parameters

The liquefiable soil is described in terms of strength parameters, in seismic conditions, via its residual undrained strength $s_{u(LIQ)}$, as proposed by Olson & Stark (2002).

$$\frac{s_{u(LIQ)}}{\sigma'_{v0}} = 0.03 + 0.0143 \cdot q_{c1} \pm 0.03 \quad (1)$$
$$\text{for } q_{c1} \leq 6.5 \text{ MPa}$$

The formulation proposed in Equation 1 is valid for CPT tests. As in can be seen, it is structured to define an interval of values with an amplitude of 0.03 MPa. Many researchers have studied post-seismic conditions: residual undrained strength was evaluated on the basis of the deformed configuration of the foundation after the earthquake.

From Bowen & Cubrinovski (2008) it can be seen how, in case of cyclic liquefaction, it is safe to refer to the mean value of the interval. That is what we chose to apply in the design procedure.

3 PILE AXIAL CAPACITY

Once defined the geotechnical model, next step consists in evaluating the pile axial capacity. Many different approaches can be used: correlations with strength parameters of the soil, direct correlations with in-situ soundings (CPT & CPTu, DMT, SPT, etc.), pile load tests. As concern the design procedure, we have focused on direct methods based on CPTu: in particular, the method proposed by Eslami & Fellenius (1997) improved by Niazi (2013).

3.1 Base capacity

The axial capacity of piles in liquefiable soils is well illustrated by Madabhushi et al. (2009).

When liquefaction occurs, the degree of growth of the pore pressure can be described by the interstitial pressure ratio ru:

$$r_u = \frac{\Delta_u}{\sigma'_{v0}} \quad (2)$$

According to Equation 2, soil shows liquefaction when $r_u = 1$. Liquefaction can easily occur in superficial sandy layers. Usually, indeed, deeper coarse grained soil layers show a higher resistance to liquefaction because their higher density and also because the greater effective pressure. So, when deep foundations are designed to resist to liquefaction, it can occurs that pile toes are placed in non-liquefiable deeper sandy layer. But also in these deeper layers pore water pressure can increase, so $r_u > 0$ and so soil resistance decrease. This fact, not immediately perceivable, has to be properly taken into account in designing piles.

Starting from the model for the base resistance of a pile (Vesic 1972) and considering the effects due to the increase of pore water pressure, Knappet & Madabhushi (2008b) showed how the tip resistance of piles in liquefiable soil is related to its corresponding value in static conditions by the relation reported in Equation (3):

$$\frac{Q_{base,E}}{Q_{base,S}} = (1 - r_u)^{\frac{3-sin\phi}{3\cdot(1+sin\phi)}} \quad (3)$$

Where r_u has been defined in Equation 2, ϕ is the angle of shearing resistance of the coarse grained soil in which the pile toe is placed while $Q_{base,E}$ and $Q_{base,S}$ are the tip bearing capacity of the pile, respectively, in seismic and static conditions.

From Equation 3 it can be seen how the resistance is related to r_u but this factor is not simple to evaluate. It would be necessary to perform advanced site effect analyses, accounting also for the liquefaction of the soil. This cannot be done in ordinary practice, so a simplified approach has been developed.

Given a liquefiable soil layer, in which liquefaction occurs ($r_u = 1$) it is assumed that excess pore pressure remain constant for depth greater than its
Figure 2. Effective stress conditions around piles for full liquefaction until z_L depth. From Madabhushi et al. (2009).

thickness z_L. Considering the growth of effective stresses with depth as almost linear, this lead to a bilinear shape of the factor r_u. Once the trend of r_u and the geometry of the pile are known it is easy to evaluate the interstitial pressure ratio at pile tip level L_p. It can be derived (see Figure 2).

$$r_{u,\,base} = \frac{z_L}{L_p} \qquad (4)$$

3.2 Shaft capacity

Madabhushi et al. (2009) have extended their studies also to the shaft bearing resistance of a pile, obtaining the formulation reported in Equation 5, that follows a philosophy similar to Equation 3.

$$Q_{shaft,E} = Q_{shaft,S} \cdot (1 - r_u) = Q_{shaft,S} \cdot \frac{L_p - z_L}{L_p} \qquad (5)$$

Where $Q_{shaft,E}$ and $Q_{shaft,S}$ are the shaft bearing capacity of the pile evaluated, respectively, in seismic and in static conditions.

So, in a more general way, it is possible to define the total bearing capacity of a pile in a liquefiable soil P_{bc} from Equation 6.

$$P_{bc} = Q_{base,S} \cdot (1 - r_u)^{\frac{3 - sin\phi}{3 \cdot (1 + sin\phi)}} + Q_{shaft,S} \cdot \frac{L_p - z_L}{L_p} \qquad (6)$$

According to Equations 5 and 6, the shaft resistance of a pile in a liquefiable soil can be significantly reduced when the factor r_u increase, but it is not strictly equal to zero. Also other researches (Rollins 2015), basing on experimental data, have demonstrated that the contribution of the liquefiable layer to shaft resistance is not null, but can decrease to about 50% of its corresponding static value. Anyway, in the present design procedure we propose to completely neglect the contribution of the liquefiable soil layers to the shaft resistance of the piles.

4 PILE INSTABILITY

Liquefaction causes the loss of lateral support of the soil to the piles and the subsequently significant variation of lateral stiffness of the foundation. In these conditions piles can face a crisis for buckling.

Pile instability due to liquefaction has been studied by Bhattacharya (2003) and Bhattacharya et al. (2004) considering a simplified model in which liquefied soil has no strength and stiffness. The pile crossing this layer will behave like an axially loaded column. Under these hypotheses the critical load P_{cr} corresponding to the loss of the elastic equilibrium is given by the well-known Eulero's expression.

Anyway, experimental tests (Knappet 2006) have shown how critical loads are not so small as those predicted by theoretical formulations. This evidence has been explained with the fact that liquefied soil has a small, but not null, stiffness neglected in the theoretical model. So Eulero's expression has been updated by Madabhushi et al. (2009), accounting for finite, small, stiffness of the liquefied layer by the factor $r_{u,base}$, as reported in Equation 7:

$$P_{cr} = \frac{\pi^2 \cdot E \cdot I}{(\beta \cdot r_{u,base} \cdot h)^2} \qquad (7)$$

Where E and I are elastic modulus and moment of inertia of the section of the pile, h is the length of the pile crossing the liquefiable layer and β is a factor accounting for the fixity at both ends of the pile. ($\beta \cdot h$) represent the equivalent length of the unsupported pile tract. Introducing the radius of gyration of the section r_g, the slenderness ratio λ is defined:

$$\lambda = \frac{\beta \cdot h}{r_g} \qquad (8)$$

Bhattacharya & Lombardi (2012), basing on data collected from real cases, have defined an admissible domain, bounded by a slenderness ratio $\lambda = 50$ (dashed black line in Figure 3), separating deep foundations that have shown good performances from those who have not. From Figure 3 it can be seen how the choice of the limit value of slenderness $\lambda = 50$ can be excessively precautionary. For that reason we propose to refer to a limit value equal to $\lambda = 75$ (continuous red line in Figure 3).

In reality piles can suffer buckling for axial load lower than the one predicted by Equations 7 also because imperfections not accounted in theoretical models, inducing geometrical second order problem (P-δ effect). Named δ_0 the displacement induced by the horizontal action (earthquake), the total lateral
Figure 3. Admissible domain: measured performances of deep foundations after real earthquakes. From Bhattacharya & Lombardi (2012).

displacement δ in presence of a vertical action P will be greater. Equation 9 describes the normalized trend of the amplification factor δ/ δ₀.

$$\frac{\delta}{\delta_0} = \frac{1}{1 - \frac{P}{P_{cr}}} \qquad (9)$$

The normalized movement δ/ δ₀ is almost linear for values of vertical load ψ = P/P_{cr} ≈ 0.30 so it can be assumed:

$$P_{ult} = \psi \cdot P_{cr} \qquad (10)$$

As suggested by Bhattacharya & Lombardi (2012), and also as considered in the proposed design procedure, it is adopted ψ = 0.35 as limit.

According to Equations 6 and 7 both the total axial bearing capacity of the pile P_{bc} and its critical load P_{cr} depend from factor r_u. So critical values of r_u can be derived, corresponding to reaching these two limiting conditions.

Following this approach Madabhushi et al. (2009) describe a series of graphs in which, depending on pile geometry (diameter D_0 and elastic properties E, I) and required factor of safety FOS, the domain of use of the pile is defined (see Figure 4). These graphs can be derived for the specific design case considering the liquefaction conditions of the site, and can be enriched by also plotting the hyperbolic trend of $r_{u,base}$, in that way also accounting for the thickness and depth of the liquefiable layer.

The piles have to be anyway verified against their structural strength because of the stresses (bending moment and shear) due by the inertial and kinematic interaction with the superstructure.
Figure 4. Design chart for a solid circular RC pile in loose sand (D_r= 35%): D_0= 0.5m, FOS= 2. From Madabhushi et al. (2009). In the blank areas the pile is verified, in those identified by "S" the pile encounter a crisis by bearing capacity while in those identified by "I" the crisis is because of instability.

5 CALCULATION METHODS

Designing a deep foundation on liquefiable soil is complex and, as seen in the previous sections, many aspects have to be properly considered to correctly face the problem. So it is clear how also the adoption of a correct method to analyze the pile group is fundamental in order to not nullify the benefits of the adopted advanced theories, as previously reported.

We used numerical BEM analyses with the software Repute, developed by Geocentric (Bond & Basile 2010, Basile 1999), adopting for the soil a nonlinear hyperbolic constitutive model. In that way pile group effects and other phenomena, as pile plasticization and shadowing, can be properly accounted.

The procedures described in the previous section mainly refers to single piles. Instead we propose to extend these analyses to pile groups by adopting correct calculation methods, such as the one mentioned above, in addition to the definition of a correct geotechnical model, accounting for liquefaction (see section 2).

6 DESIGN EXAMPLE

The design procedure that we propose to design a piled foundation on liquefiable soil has been described in detail by theoretical point of view in the previous sections of the paper. Now we want to describe how this procedure has already been applied is some real case in which the authors designed deep foundations to mitigate the liquefaction risk.

The two major works in which we adopted our design procedure are the enlargement and seismic retrofit of the Cento (Ferrara, Italy) sports hall and the construction of the new Pavillion 37 as part of the revamping project of the fair quarter of Bologna (Italy). Due to the space available in the paper, we will only describe the first of these two projects.

6.1 *Investigation campaign and geotechnical characterization*

A first investigation campaign, consisting in four cone penetration tests with piezocone CPTu and seismic piezocone SCPTu, two flat dilatometer DMT tests, geophysical tests and laboratory ones, has been firstly carried out. From these data an high risk of liquefaction was found out so it was decided to perform an integrative campaign to better go insight the liquefaction problem. Four CPTu and dynamic laboratory tests (resonant column RC and cyclic triaxial TX CYC), on samples taken from two boreholes, have been performed.

Liquefaction risk has been assessed with different approaches: from CPTu (Robertson 2009), from DMT (Monaco et al. 2005), from dynamic lab tests.

The liquefaction potential index LPI, evaluated adopting the Sonmez (2003) approach, results ranging from the various investigations from about 8 to 18, identifying an high risk of liquefaction.

Liquefaction is induced by a layer of loose sands that extends from about 1 to 6 meters of depth from ground level. The geotechnical model in seismic condition accounting for liquefaction, reported in Table 1, has been defined according to what has been described in section 2.

Table 1. Geotechnical model in seismic conditions, accounting for liquefaction.

Layer	From -	To [m]	Undrained strength S_u [kPa]	Frinction angle ϕ [°]	Tangent modulus E_0 [MPa]
Liquefi-able sand	1.0	6.0	1	-	2
Clay	6.0	11.0	30	-	90
Clay	11.0	18.0	75	-	105
Sand	18.0	26.0	-	32	135
Clay	26.0	-	75	-	150

6.2 Description of the intervention

The project primarily consists in the construction of a new grandstand: this element, as enlargement of the existing sport hall, contains two reinforced concrete cores that are the principal part of the bracing system adopted to increase seismic resistance of the whole structure. These cores absorb the great amount of the seismic forces because they are designed to support and to brace the roof of the hall. Since there where no limits on this side for operating machines, we chose to adopt FDP (Full Displacement Piles) piles: due to the particular shape of the drilling tip the pile is realized without removing soil, so also a positive densifying effect is induced.

In the opposite side of the hall there is the existing tribune, supported by an RC frame. Also this zone has been involved in the seismic retrofitting, and the existing shallow foundation have been reinforced with micropiles designed according to the proposed procedure. Here they will not be discussed.

6.3 Foundation analysis

Given the loads acting on foundation from super-structures and defined the geotechnical properties of the soil, each foundation has been analyzed adopting a numerical approach: BEM analyses have been carried out with the software Repute (see section 5).

For each seismic core a deep foundation consisting in 24 FDP piles, diameter 600mm, with a length of 22.0 meters (depth of pile tip from g.l.) has been adopted. The pile cap have dimensions 12.10 × 9.20 meters and is 1.2m thick. The overall foundation plan is reported in Figure 5.

Following the design procedure described in the previous sections of the paper, after have been
Figure 5. Foundation plan of the sport hall. In red the two seismic cores are highlighted.

defined the geotechnical model valid in seismic conditions under liquefaction, the pile ultimate axial capacity have been defined.

Pile base capacity in static conditions has been evaluated adopting the formulation proposed by Berezantsev (1965), because pile tip in placed in the lower sandy layer, finding out a value of $Q_{base,S}$ = 1190 kN. Considering the development of excess pore pressures also in the lower sandy layer, it does not reach liquefaction but the tip resistance decrease. According to Equation 3 a ratio of 0.86 between the seismic and static value of base resistance has been evaluated, corresponding to a value of 0.238 for the factor $r_{u,base}$ (Eq. 4). This means that in seismic conditions the pile base resistance decrease to:

$$Q_{base,E} = 0.86 \cdot 1190 \approx 1000 \text{ kN} \quad (11)$$

Pile shaft capacity has been calculated via a direct correlation with data from CPTu adopting the method of Eslami & Fellenius (1997) improved by Niazi (2013). We referred to the 6 CPTu performed on site, finding out values of $Q_{shaft,S}$ ranging from 1390 kN to 1778 kN, with a mean value of 1600 kN.

As described in § 3.2, in our proposed design procedure the shaft capacity is completely neglected in the liquefiable layer. Adopting the same calculation procedure of the static case, in seismic conditions we found out values of $Q_{shaft,E}$ ranging from 1070 kN to 1448 kN, with a mean value of 1263 kN.

The BEM analyses of the piled foundation of the core (Figure 6) give axial forces on piles as reported in Table 2. According to the design criteria defined by the Italian code NTC pile axial capacity check is satisfied in static condition with a maximum exploitation of 81% and in seismic condition at 92%.

The last step of the design involve the check of piles against instability. It can be considered that FDP piles are rigidly connected at the top to the pile cap. The same fixity can be considered at the base, because the liquefiable sandy layer is near the ground and the piles

Table 2. Maximum axial forces on piles from BEM analyses.

Action	u.m.	Static	Seismic
Maximum compressive force	[kN]	1047	964
Maximum tensile force	[kN]	-	15
Maximum horizontal shear force	[kN]	81	79
Maximum vertical settlement	[mm]	6.9	5.9
Maximum horizontal displacement	[mm]	0.5	11.2
Figure 6. Repute calculation model of the piled foundation of the core.

continue below in the non-liquefiable clayey layers. Nevertheless, as a precaution, we assumed the equivalent length ($\beta \cdot h$) as twice the thickness of the liquefiable layer (equal to 5.0m, see Table 1). Considering the elastic properties of the cross-section of the piles (E·I = 159.04 MNm^2), the interstitial pressure ratio ($r_{u,base}$ = 0.238) and limiting the critical load by the factor ψ = 0.35 (see Eq. 10) the ultimate axial load can be evaluated as $P_{ult} \approx 96900$ kN, more than 100 times the maximum axial force acting on piles under seismic loading (see Table 2). The slenderness ratio λ = 67 is lower than the assumed upper admissible limit of 75.

The piled foundations, designed according to the proposed procedure, satisfy all the safety criteria.

7 CONCLUSIONS

In the paper a design procedure to correctly deal with the design of pile groups on liquefiable soil has been presented. The procedure provides guidance as concern the geotechnical model (modified strength and stiffness parameters under liquefaction), the pile axial capacity (shaft and base components) and the pile instability. Each step of the procedure is based on specific theories from various authors, in order to base the design on solid scientific bases.

Cone penetration tests are fundamental in many steps of the procedure: just think to the geotechnical characterization and the pile capacity evaluation.

The procedure is intended as a guide for designers who have to face the design of a deep foundation on liquefiable soil. This is a very sensitive problem, so we hope the guide can help geotechnical engineers in this challenging work.

ABSTRACT: The present paper concerns the design of driven precast tapered piles, that have been used within the project of the new Pavillion 37 of the fair quarter of Bologna. A particular focus will be reserved to the evaluation of the axial bearing capacity of these elements and to the prevision of their load-settlement curve. The geotechnical characterization, as well as the prediction of the axial resistance of the piles, has been mainly based on Cone Penetration Test with piezocone CPTu. The previsions will be compared with the results of a series of static load tests performed during the construction.

1 INTRODUCTION

The present paper concerns the design of deep foundation for a new exhibition hall, especially as regard the prediction of the axial bearing capacity of the piles and of their load-settlement curve.

The framework of the project and the geometry will be described first, following with the description of the geotechnical campaign and the soil characterization. Then we will assess the project prediction by comparison with the results of the static load tests performed on-site during construction.

All these evaluations are based on CPTu test, as described in the following.

2 PROJECT DESCRIPTION

Within the revamping project of the fair quarter of Bologna, the new Pavilion 37 rises as flagship of the exhibition centre with its remarkable opening roof and its planimetric dimensions of 80 x 184 meters (Figure 1). The steel structure of the roof stands on 8 reinforced concrete towers, whose foundations represent the most important and complex geotechnical elements of the whole project.

The choice was to adopt deep foundation for all the RC towers, consisting in driven precast tapered piles arranged in groups (Figure 2). The adoption of

deep foundation was basically justified by the high loads transmitted by the roof, together with the geotechnical conditions of the site.

The whole project concern also two other adjacent buildings (the so-called "Mall" and "East entrance"), not object of the present paper, whose foundations have been designed similarly.
Figure 1. Typical deep foundation of the RC towers supporting the roof of the pavilion.

3 PILE DESCRIPTION

Driven precast tapered piles were used in the project. The choice was due to different aspects, both geotechnical and construction-related:

– Driven piles have good geotechnical performances. In addition, because of the installation process, an increase in density is induced in the soil.
– They are rapid to install and it is possible to control the performance of piles during driving.
– In soft soils or in presence of water neither predrilling nor hole support are required.
– There is no excavation material, so the organization of the construction site is clean and easier.

The adopted piles have a diameter of 53/26 cm (head/toe), a taper of 1.5 cm/m and a length of 18 meters. The piles were precasted in factory with a specific centrifugation process.
Figure 2. Typical tapered precast pile with length L= 18m. Vertical sections and reinforcements.

For driving were used hydraulic hammers with weight of 6 and 7 tons. The driving energy was 36 kNm and the settlement during driving was measured in the range from 5 to 7 mm/blow.

4 GEOTECHNICAL CHARACTERIZATION

The site was characterized by performing an investigation campaign consisting mainly in on-site soundings. Four cone penetration tests with piezocone CPTu, a borehole (with soil sampling and SPTs) and geophysical MASW and HVSR tests have been carried out.

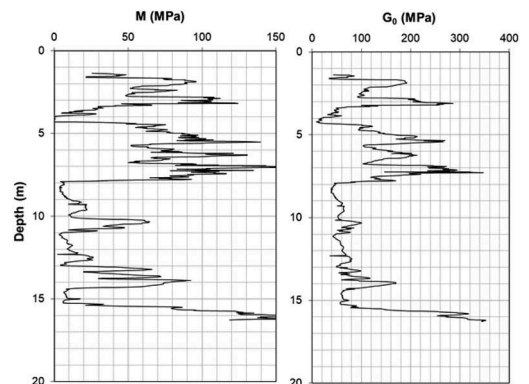
The geotechnical characterization is mainly based on the interpretation of the performed CPTu. They are very effective in recognizing soil behavior and strength and stiffness parameters. In Figures 3, 4 and 5 some of the principal results from the interpretations are showed.
Figure 3. Point resistance and soil index vertical profiles from the interpretation of one of the performed CPTu.
Figure 4. Friction angle and undrained strength vertical profiles from the interpretation of one of the performed CPTu.


Figure 5. Confined and initial shear moduli vertical profiles from the interpretation of one of the performed CPTu.

An alternation of coarse-grained and fine-grained material was found out, described by the following geotechnical model (Table 1).

Table 1. Geotechnical model.

Layer	From - To [m]		Undr. strenght c_u [kPa]	Effective cohesion c' [kPa]	Friction angle φ [°]	Tangent modulus E_0 [MPa]
Sandy silt	0.0	8.0	-	0	32-34	200-250
Clay	8.0	15.0	60-70	5	27-30	120-170
Sandy gravel	15.0	20.0	-	0	38-40	≥ 500
Sandy to clayey silt	20.0	35.0	70-80	5	27-30	300-350

Soil stiffness was described in terms of the initial tangent modulus because the deep foundations have been analysed adopting a numerical BEM (Boundary Element Method) approach with the software Repute, developed by Geocentrix (Bond & Basile 2010, Basile 1999).

5 BEARING CAPACITY OF PILES

In the design phase, pile axial capacity has been predicted adopting calculation methods directly correlated to CPTu.

Then, during construction, pile capacity has also been evaluated by interpreting the measured load-settlement curves derived from the pile load tests, in order to validate the design predictions.

5.1 Analytical evaluation of pile capacity

We referred to different methods based, directly or indirectly, on CPTu tests. The first is the method proposed by Eslami & Fellenius (1997). In this case the beneficial effect of tapering has been taken into account by increasing the shaft capacity by a factor that, as from Nordlund (1963) and Horvath (2002), varies between about 1.5 for clayey-like soil layer to 2.0 for sandy ones. An example is reported in Figure 6.

The second method is the one proposed by Togliani (2010). This method, in particular, is specific for tapered piles and is able to directly evaluate both the shaft capacity of the pile, related to its side area, and the component related to the tapering benefit.

The axial ultimate capacity of the tapered piles, predicted applying the previous methods, is reported in Table 2, the values are referred to a limit settlement of about 10 mm.

5.2 Load tests interpretation

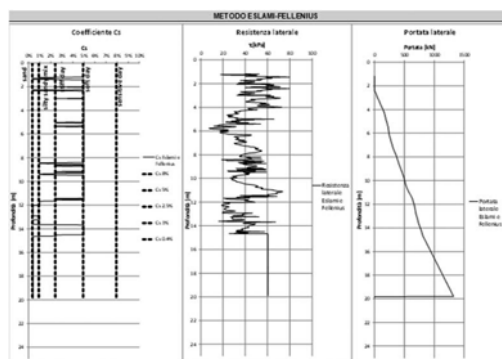
Four static load tests have been performed on the L= 18 m tapered piles during construction, as part of the


Figure 6. Tapered pile axial capacity evaluation from CPTu adopting the Eslami & Fellenius method.

Table 2. Pile axial ultimate capacity from CPTu.

CPTu sounding	Shaft capacity [kN]				Base capacity [kN]	
	Eslami&Fellenius		Togliani			
	Shaft	Taper benefit	Shaft	Taper benefit	E & F	Togliani
CPTu 1	1322	794	1306	843	340	385
CPTu 2	1593	956	1536	1180	367	416
CPTu 3	1502	1201	1527	1354	394	441
CPTu 4	1364	1228	1556	1480	344	378

acceptance testing, under a maximum vertical load approximately equal to 1.5 time the exercise load (Figure 7). The results obtained from acceptance testing are well aligned to the design prediction from direct correlations with CPTu, considering also that these load tests have not kept to failure but were intended to verify the correct installation and performance of the piles.

Moreover during the construction of a nearby building two static load tests were performed, on the same type of pile, reaching loads of 2000 kN and 2400 kN. These last two load tests have been interpreted according to the approach proposed by Chin (1970) to evaluate the ultimate capacity of the tested pile, in Figure 8 an example of the interpretation is proposed.

6 LOAD-SETTLEMENT CURVES PREVISION

The load-settlement curves, representing the response of the single pile, have been predicted adopting an analytical model (Randolph & Wroth 1978), two numerical approaches by BEM analysis with the software Repute and by FEM analysis with the software Plaxis and adopting a mixed approach based on the cavity expansion theory (Dei Svaldi et al., 2012).
Figure 7. Acceptance testing curves.
Figure 8. Interpretation of the static load test n.1 with the Chin method.

All these predictions were based on the parameters of the geotechnical model obtained from CPTu tests (Table 1).

After carrying out the load tests, the measured curves have been compared to the predicted ones, finding out what is graphically represented in Figure 9.

The design prediction does not deviate much from to the experimental measures, and generally show
Figure 9. Load-settlement curves: comparison between design predictions and load tests.

a lower stiffness with respect to them, giving to the foundation design a certain margin of safety.

On the basis of the load-settlement curve for the single pile, a calibration analysis of the model of the deep foundation of the RC tower was carried out, by evaluating with different methods the settlements under the action of the vertical load (15785 kN). The foundation consists of a reinforced concrete raft 1.6 m thick resting on 28 tapered piles (Figure 2).

For the calibration has been adopted the following methods: the formulation proposed by Mandolini (1994), the BEM method and the traditional multi-layer one-dimensional method, where the pile-soil system was considered as a layer with stiffness modulus (Table 3) evaluated through an interaction analysis between pile, plate and soil based on the concept of efficiency (Fleming et al., 1992). Table 4 reports the results of the calibration analysis.

Table 3. Equivalent stiffness modulus of soil-pile system.

η_w	0.280	efficiency	
K_p	525	MN/m	single pile stiffness
K_{pg}	148	MN/m	pile group stiffness
E_{eq}	1108	MPa	

Table 4. Settlement of RC tower under vertical load.

	Settlement (mm)
Mandolini	
BEM	3.94
Equivalent stiffness	3.8

Once calibrated the BEM method was used to study the behaviour of the RC tower under the different load combinations in compliance with the Italian Technical Standards for Buildings (DM 17.01.2028).

An example of settlements and pile reactions under the action of ultimate state loads, obtained from BEM analysis, are shown in Figure 10.
Figure 10. RC tower - settlements and reactions of the piles obtained from BEM analysis under USL loads.

7 CONCLUSIONS

The interpretative criteria of the CPTu tests allow to reliably define the stratigraphy and the mechanical characteristics of the soils at the basis of the foundation design.

For a complete design of the piled rafts it is not only important to calculate the bearing capacity of piles but also to define their behaviour through the construction of the load-settlement curve. In this context, it is possible to use complex numerical models but also simpler methods which, in any case, allow to obtain usable results for the design.

A final aspect to highlight is that in order to obtain reliable results in complex analyses with numerical methods, the calibration by comparing the results of simple analyses with other calculation methods is relevant.

Geological, seismic and soil survey of the Emilia-Romagna Region, Bologna, Italy

ABSTRACT: This paper describes an attempt to develop and calibrate a simple tool to forecast the natural subsidence of coastal Holocene deposits. An empirical correlation has been calibrated between the penetration resistance measured by a static cone penetrometric tests and i) the normal compression line NCL of fine grained, coastal deposits ii) the current void ratio and iii) the void ratio on the NCL at the site effective stress. The comparison between the site void ratio and the normally consolidated void ratio can be used to roughly estimate if the soil is overconsolidated, normally consolidated or under-consolidated/structured and, in the latter case, if the fine layer is in the condition of further developing consolidation settlement to reach the self-weight equilibrium.

1 INTRODUCTION

The vulnerability of coastal areas to climate change and, in particular, to sea level rise, is a cause for alarm at an international level. The geological survey group of the Emilia-Romagna Region (SGSS), in Italy, has carried out a study to highlight the effect of on-shore subsidence on the potential sea transgression, and the action of subsidence has resulted decisive in some areas of the coast, where the altimetric altitude is close to zero. The origins and possible evolution of subsidence need to be evaluated to limit its impact on the risk of inland sea transgression. In this context, a study has been carried out to estimate the natural component of subsidence linked to the compaction of recent coastal deposits of fine grained soils. The research has been based on three main components: i) two near shore pilot sites, well characterized from a geotechnical point of view, where subsidence rate is monitored by means of assestimetric measures; ii) several site where both CPTUs and oedometric tests on fine grained samples were available, iii) a large database of CPTUs carried out in sites spread all along the Emilia-Romagna coast.

The results of CPTUs and oedometric tests on Holocene fine grained soils have been used to link the cone penetration resistance q_c to i) the compression index C_c; ii) the altitude e_1 of the 1-D compression line in the e-logσ'_v plane defined at $\sigma'_v = 1$ kPa; iii) the current void ratio e_c.

A tool has been calibrated which allows to derive from a q_c profile and for fine grained layers two relevant void ratio values: the current site void ratio e_c and the void ratio the soil would have at the site effective stress if normally consolidated e_{NC}. The comparison between these values roughly indicates if the soil is overconsolidated, normally consolidated or under-consolidated/structured and, in the latter case, allows to estimate the possible consolidation settlement the layer could still develop to reach the self-weight equilibrium.

The tool has been validated for the pilot sites and used to estimate the expectable natural subsidence of fine grained deposits at selected sites of the coastal areas where CPTUs were available.

2 GEOLOGICAL SETTING AND REFERENCE SITES

The study area belongs to the outer sector of the Pliocene-Quaternary Apennine foredeep (Ricci et al. 1986), progressively affected by recent phases of compressive deformation of the Apennine chain. The Quaternary succession is over 2000 m thick and records the gradual filling of the highly subsiding basin. The land lowering due to tectonics is still active and maximum rates have been estimated about 1 mm/y (Cuffaro et al. 2010). The most recent succession (Middle Pleistocene-Holocene) is

characterized by the sedimentary cyclicity consisting of the metric alternation of sandy and highly compactable fine levels, induced by the glacial-eustatic fluctuations of the late Quaternary. The upper 30-40 metres of this succession, testify the transgressive-regressive Holocene cycle (Amorosi et al. 2003; Stefani and Vincenzi 2005,) characterized by paralic and marine deposits overlying the Pleistocenic alluvial plain in the lower portion and, in the central and upper portion, by a thick sedimentary wedge deposited by the deltaic and beach prograding systems.

From a lithological point of view, in the littoral sector, the shallowest succession is constituted by coastal and delta sands in the upper part and by thick prodelta and beach fine deposits in the lower part. The natural compaction of these recent fine deposits may be responsible for the observed subsidence (Teatini et al. 2011), that reaches maximum rates of 12 mm/year.

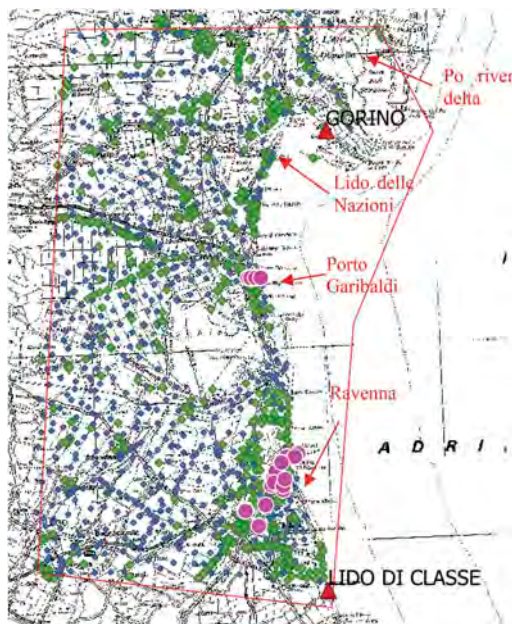
In the study area, sediment deposition during progradation took place through complex phases of feeding, switching and abandonment of the ancient Po delta branches; this has generated variable depositional history even for sediments that are very similar in appearance.


Figure 1. Location of pilot sites and available data: corings (green dots), CPTUs (blue dots) and selected tests (pink dots).

As part of the studies aimed at evaluating the natural subsidence of the superficial plio-quaternary deposits of the coastal areas, SGSS has selected two pilot sites evidenced in Figure 1 at the localities of Gorino (Ferrara Province) and Lido di Classe (Ravenna Province), where it is possible to exclude the occurrence of subsidence of anthropogenic origin. Both sites are characterized in the first 30 m of depth

by Holocene deposits of clays, silts and sands. Gorino stratigraphy is representative of the coastal deposits originated by the Po river typical of the northern sector of the regional coasts; Lido di Classe soil profile is typical of the southern sector coastal deposits, originated by the activity of Apennine rivers.

Both sites were characterized by means of continuous core drilling and undisturbed sampling, CPTU and SCPTU tests, oedometric tests on undisturbed sample of fine soil. The boreholes were equipped with settlement gauges, anchored to the Pleistocene deposits deeper than 30 m and cemented to the hole, for monitoring the subsidence of the deposit over time. The analyzes carried out so far have shown in both sites a progressive lowering of about 1 mm/year.

Gorino site (q_c profiles in Figure 2) is characterized within the first 5-6 m of depth from the ground surface by a predominantly sandy layer with frequent alternations of finer soils, followed by a clayey silty stratum up to 27-29 m of depth. This layer, made of inorganic and medium to high plasticity fines, resulted mainly normally consolidated from oedometric tests and is followed by Pleistocene sandy deposits. The ground water table is in average 0.5 m deep.

At Lido di Classe, a superficial 8 - 9 m thick layer of clean sands is followed by a dense alternation of silty sands, sandy and clayey silts up to about 24 m of depth, then by silty clays. The fine grained layers, characterized by low plasticity, are slightly over consolidate from the ground surface to 9 m of depth, overconsolidated from 9 to 15 m of depth, normally consolidated at higher depths. The ground water table is 1.7 m deep.
Figure 2. CPTSs at pilot sites, a) Gorino, b) Lido di Clsse.

In both sites, oedometric tests have been repeated also on reconstituted specimens. In some cases, the undisturbed oedometric curve lied above the intrinsic

compression line (Burland 1990), indicating presence of structure, possibly due to flocculated deposition occurred in conditions of high sedimentation rates in the delta front and proximal prodelta environment. These results are consistent with the geological and depositional history of the sites.

In both sites, the void ratio at the depths of undisturbed sampling, computed as a function of the water content and specific gravity and assuming complete saturation, resulted in some cases higher than the void ratio derived from the oedometric curve at the specific vertical stress, indicating still in progress consolidation phenomena, accordingly with the estensimetric measures, or presence of structure.

In addition to the 2 pilot sites, 5 extra sites were considered in this study, 2 located in the norther sector of the regional coast at the locality of Porto Garibaldi, 3 in the southern sector, in the area of the city of Ravenna (Figure 1), all characterized by similar geological origin and stratigraphy as the two pilot sites. For all the sites considered, CPTUs and oedometric tests on undisturbed samples were available. Figure 3 reports the grain size fractions and plastic index as a function of depth measured on the undisturbed samples overall analyzed.

3 EMPIRICAL CORRELATION

From each oedometric curve available, the compression index C_c (slope of the normal compression line in the e - $\log\sigma'_v$ plane) and the void ratio e_1 (altitude of the normal compression line at $\sigma'_v = 1$ kPa) have been derived. Figure 4 shows the C_c measures vs. depth; in Figure 5 e_1 is plotted versus C_c. A linear relation exists between C_c and e_1, which can be expressed as:

$$e_1 = 4 \cdot C_c + 0.3 \tag{1}$$

The site void ratio at the sampling depth has been derived as a function of the measured water content w and specific gravity G_s as:

$$e_c = w \cdot G_S/S \tag{2}$$

where the degree of saturation S has been assumed equal to 1.

From the CPTU carried out nearest to the borehole from which the undisturbed samples tested in oedometer came, an average q_c value was derived at the depth of sampling. Figures 6 and 7 show the compression index C_c and the site void ratio e_c plotted versus the average q_c normalized over the atmospheric pressure p_a. C_c is in the range 0.25 – 0.5 when q_c/p_a is between 5 and 15 and decreases as the normalized cone resistance increases, indicating a decrease of compressibility as the soil resistance increases.

Despite the significant dispersion in Figures 6 and 7, and acknowledging the rather low correlation coefficients, a power function and an exponential function have been drawn to try to link C_c and e_c to the normalized cone resistance:

$$C_c = 0.48 \cdot (q_c/p_a)^{-0.167} \tag{3}$$

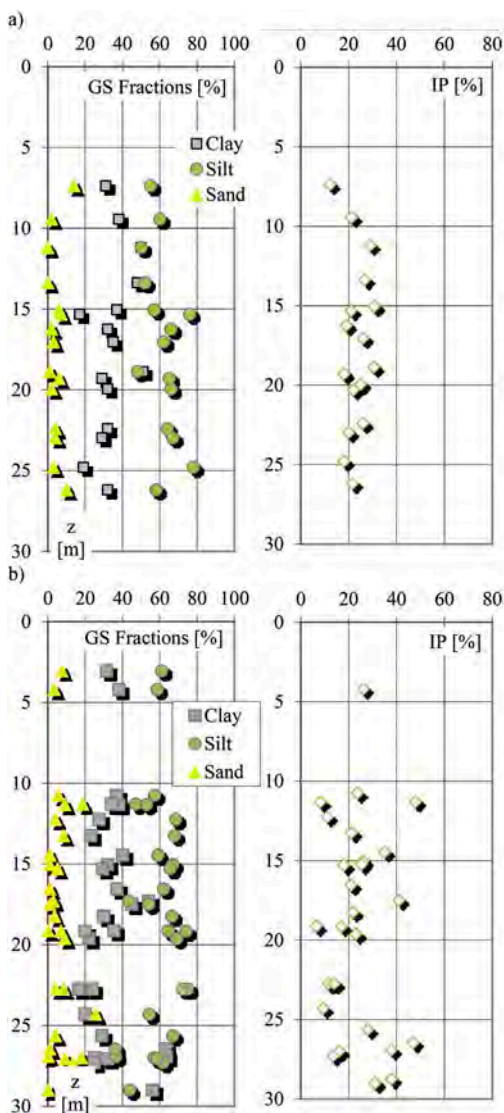
$$e_c = 1.127 \cdot e^{-0.015 \cdot q_c/p_a} \tag{4}$$


Figure 3. Grain size fraction and plastic index, a) Norther sector, b) Southern sector.

These tentative relations allow, given a generic q_c profile, to derive, for fine grain layers, C_c, e_c and e_1 according to eqs. 1, 3 and 4. The computed site void ratio e_c,

compared with the normally consolidate void ratio e_{NC}, allows to establish if the layer is normally consolidated, overconsolidated or underconsolidated; e_{NC} can be computed at a certain depth, known e_1 and C_c, as:

$$e_{NC} = e_1 - C_c \cdot \log(\sigma'_v) \qquad (5)$$

For the pilot sites, C_c and e_1 are measured quantities; e_c was computed via eq. 2 from w and Gs measured on undisturbed samples.

Figure 8 compares, for the site of Gorino:

– the profile of e_{NC_lab} computed via eq. 5 and using e_1 and C_c from laboratory measures;
– the site void ratio e_{c_lab} at sampling depth from eq. 2;
– the profile of e_{NC_CPT} computed via eq. 5 and using e_1 and C_c estimated from q_c via eqs. 3 and 1;
– the site void ratio e_{c_CPT} at sampling depth from eq.4.
Figure 4. Compression index as a function of depth.

The discontinuities which characterise the e_{NC_lab} profile (black line) are due to change in C_c and e_1 derived from direct measures on undisturbed samples. On the other hand, the profile e_{NC_CPT} (green line) is more regular, as it mirrors the q_c profile. The comparison between e_{c_lab} value and the e_{NC_lab} profile shows that from 6 to 10 m the soil is slightly over-consolidated; between 10 and 14 m the ground is normally consolidated; at greater depths the current void ratio is greater than the normally consolidated value, indicating either that the ground on site is still subject to consolidation compression or that it is slightly structured. In the first case, subsidence settlement due to the one-dimensional compression of the layer present between 14 and 27 is of the
Figure 5. Altitude of the normal compression line e_1 vs. C_c.

order of 50 cm. This value is obtained as integral of the difference $\Delta e = e_{c\_lab} - e_{NC\_lab}$, at the depths where $e_{NC\_lab} > e_{c\_lab}$.

Regarding to the profile e_{NC_CPT} (obtained via Eq. 4) it can be noted that although it differs from e_{NC_lab} profile, it is in relation to e_{c_CPT} similarly to the lab profiles. In this case, the possible consolidation settlement is of the order of 74 cm.
Figure 6. Compression index C_c as a function of q_c/p_a.
Figure 7. Site void ratio e_c as a function of q_c/p_a.

4 LARGE SCALE APPLICATION

The procedure described above was applied to CPTUs selected from the SGSS database and located in the two sectors of the regional coast evidenced in Figure 1 (blue dots). Figure 9 shows for one of the test sites (where a silty clay layer, with frequent sandy

intercalations, is present from 14 m to 30 m of depth from the ground surface, topped by a sandy deposit), the measured tip resistance q_c, lateral friction f_s, interstitial overpressure u_2, the estimated hydrostatic profile u, the profiles of the normal consolidated void ratio e_{NC_CPT} and the current void ratio e_{c_CPT}. From the large scale application resulted that the settlements estimated for the norther sector are lower than those expected in the southern area (average value of 0.38 m in the Ferrara area and 0.58 m in the Ravenna area).
Figure 8. Gorino site: computed and measured void ratio.

Higher thickness of the layers of fine-grained soil returns higher estimated settlements. The local values of estimated consolidation settlement have been interpolated over the areas of interest to derive a map of expectable subsidence.

The function was tested to the CPTs in the northern coastal sector, between Casalborsetti and Lido di Volano. The potential settlement values for each point were interpolated with the inverse distance weighting method, obtaining the map shown in Figure 10. The spatial distribution and the range of settlements are consistent with the subsoil nature, characterized by a marked lithological heterogeneity. The lowest settlements are expected near the Reno river mouth and between Porto Garibaldi and Lido delle Nazioni where the delta and the coastal sandy deposits are thick. On the other hand, in the areas affected by the highest settlements, prodelta clays, lagoonal silts and marsh peat are prevailing.

The map provides important information to interpret the subsidence monitoring data and it also supports spatial planning, highlighting the areas most vulnerable to coastal risks, such as marine submersion due to land lowering.
Figure 9. Application of the correlation to a CPTU.

5 CONCLUSION

The results of a significant number of CPTU and laboratory tests (particle size analyzes, Atterberg limits, oedometric tests) carried out in coastal sites characterized by the presence of recently deposited, fine-grained soil deposits, have been analyzed and interpreted to calibrate a semi-empirical correlation between the compressibility of fine grained soils and the results of static penetrometric tests.

The interpretation of all the available data allowed the elaboration of correlations between:

– the tip resistance q_c measured by a CPTU and the compression index C_c measured during the oedometric tests;
– the resistance q_c and the site void ratio e_c;
– the compression index C_c and the altitude e_1 of the normal compression line in the e-logσ'_v plane.

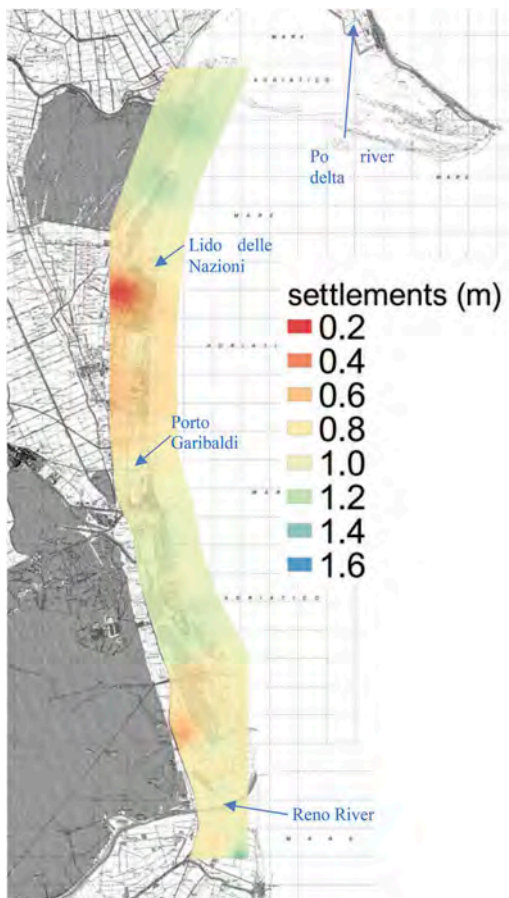
These correlations, even if characterized by significant dispersion, have been used to elaborate


Figure 10. Map of expectable settlements in the coastal sector between Casalborsetti (RA) and Lido di Volano (FE).

a procedure that allows to evaluate, starting from the results of a CPTU, the site void ratio profile e_c of the fine-grained layers and the voids ratio profile that the fine soil would have if normally consolidated, e_{NC}. The comparison between the two profiles allows to establish if the fine soil layer is:

– overconsolidated ($e_c < e_{NC}$);
– normally consolidated ($e_c \approx e_{NC}$) or
– it has yet to reach the condition of equilibrium due to its own weight, or the soil has a structure or microcementation ($e_c > e_{NC}$); at present it is not possible to distinguish the two different conditions.

In the first two cases the layer is stable and no subsidence is expected in the absence of lithostatic load variations. In the third case, the difference between the current void index and the normal consolidated theoretical one allows to estimate any settlements that the deposit has yet to/could show due to consolidation or destructuring.

The procedure elaborated has been used to compute the possible subsidence settlement at selected sites along the Emilia-Romagna coast and to derive

expected subsidence map, which provides important information to interpret the subsidence monitoring data and supports spatial planning, highlighting the areas most vulnerable to coastal risks, such as marine submersion due to land lowering.

It should be pointed out that

– the estimated settlements is probably an upper limit, as it's not possible to distinguish underconsolidation from structuring, and its course over time is not known;
– if the difference between the current site void ratio and the normal consolidated void ratio were due to cementation or the presence of a structure, in the absence of variation in the lithostatic conditions, the soil would be stable and would not show spontaneous subsidence;
– the calibrated correlations are based on a limited sample, albeit significant, of geotechnical data that must be integrated to allow for a refinement of the proposed equations;
– nevertheless, the database employed is the first attempt of systematical collection, analysis and interpretation of compressibility data in area strongly affected by subsidence of natural and anthropic origin;
– in the definition of the empirical correlations, only coastal sites located along the regional coast were taken into consideration, therefore the calibrated equations could only have local validity and should be used only in contexts similar to those studied;
– the calibrated equations should be used only for large-scale areal considerations; for local assessments at the scale of the artefact, alternatives to the necessary geotechnical investigations on site and in the laboratory cannot be considered;
– refinement of calibrated correlations through the execution of test fields and site and laboratory geotechnical investigations is desirable.

ABSTRACT: Liquefaction potential assessment is of particular significance to geotechnical engineers in order to evaluate the risks for construction of high rise buildings, railway embankments, canal, road embankments, earth dams etc. in areas susceptible to liquefaction. Investigations were made at Rajarhat area of Kolkata, India by means of CPT, DMT, SPT and SDMT measurements. The main purpose of carrying out these tests is to grab a relatively rare opportunity to compare the results of all these methods for arriving at a conclusive evidence in predicting liquefaction. It was found that the results of all the in-situ techniques were relatively consistent in predicting liquefaction within a depth range of 0 to 17.0 m below the ground surface. CPT, DMT, SPT and SDMT are basically field-based in-situ tests for measurements of important geotechnical parameters and also provide reliable data for assessment of liquefaction potential of a site. In recent times Finite Element Method based (FEM), a powerful viable alternative tool is available to the geotechnical engineers for application in various fields. In the present investigation, an attempt has been made to study the assessment of liquefaction based on the numerical simulation using Finite element software in addition to all the field techniques mentioned before. The main objective of the present study is to evaluate the correlation between factor of safety against liquefaction using different in-situ test approaches as well as the FEM tool. Finally, the paper presents the correlation between the depth and factor of safety for this particular Rajarhat area of Kolkata for understanding the vulnerability of this area to liquefaction.

Keywords: Dilatometer and seismic dilatometer test, cone penetration test, standard penetration test, Finite Element Method, liquefaction potential

1 INTRODUCTION

1.1 *Background*

Soil plays a vital role for the proper installation of footing. Footings are placed for transferring the super-structure load to soil. Hence, proper findings out of geotechnical parameters including liquefaction susceptibility of sub-soil maintains an important role for the stability of the soil. If it is not accounted properly, the entire stability of structure can be adversely affected due to failures of the sub-soil.

Soil liquefaction is a phenomenon occurred due to vibration (generally during earthquake) to the sub-soil and results to the failure of sub-soil. During earthquake cyclic loading is triggered and passes through the sub-soil. Therefore rise of pore water pressures takes place through sub-soil in addition to the vertical stress and it results in the loss of shear strength of saturated soil mass. This particular phenomenon is known as liquefaction. Therefore, estimation of liquefaction susceptibility of soil is important prior to any construction of structures for avoiding the future vulnerability to any calamity.

1.2 *Objectives*

The aim of this study is to assess the liquefaction susceptibility and evaluate the factor of safety against liquefaction by using different in-situ test approaches (i.e., SPT, CPT, DMT and SDMT) as well as the FEM (finite element method) tool (i.e., NovoLIQ and Plaxis 2D software). Finally, present the variation of factor of safety (FOS) along depth for Rajarhat area of Kolkata.

2 MATERIALS AND METHODS

2.1 *Liquefaction susceptibility criteria of Rajarhat*

Excessive pore water pressure generation is the cause of liquefaction. It is directly connected to the compositional characteristics of the soil i.e., fine content, gradation, plasticity index etc.

Generally, cohesion less soils (sand, silty sand or sandy silt) undergo liquefaction but this phenomenon may be also occurred on plastic & cohesive silty clay and sensitive clay (Updike et al., 1988; Kramer, 1996). Wang (1979) suggested Chinese Criteria to evaluate liquefaction susceptibility based on the earthquake observations in China.

There are four criteria which might be considered to evaluate liquefaction susceptibility for the fine grained sediments (Wang, 1979; Kramer, 1996). These criteria are given below

1) Fraction finer than 0.005 mm ≤ 15%
2) Liquid limit, LL ≤ 35%
3) Natural Water Content ≥ 0.9LL
4) Liquidity Index ≤ 0.75

However, many researchers have followed some varying criteria on estimating the liquefaction susceptibility which unless if properly addressed, may cause the extensive damage when silty or clayey soils containing more than 15% clay size particles are found (Bray et al., 2004; Bray and Sancio, 2006).

On the other hand, based on water content (wc), liquid limit (LL) and plasticity index (PI), Bray and Sancio (2006) had proposed a new compositional criteria obtained from the results of cyclic triaxial test to determine liquefaction susceptibility:

1) Highly Susceptible towards liquefaction: $PI < 12$ and $(w_c/LL) \geq 0.85$.
2) Moderately Susceptible towards liquefaction: $12 < PI < 18$ and $0.85 > (w_c/LL) \geq 0.8$.
3) Non-Susceptible towards liquefaction: $PI > 18$ and $(w_c/LL) < 0.8$.

The subsurface condition of Kolkata, Rajarhat site specify that the sedimentary deposits underlying the city involve predominantly of grain size favorable for liquefaction and this area is formed on coarse grained artificial non engineered fill. So the site may be susceptible to soil liquefaction. [Nath et al., 2018]

2.2 *Methods*

Different Methods used for liquefaction susceptibility analysis in this study were given below:

1. Estimation of Soil property.
2. Determination of earthquake magnitude from peer ground motion database.
3. Determination of CSR.
4. Determination of CRR from SPT, CPT and DMT tests data.

5. Computation of Factor of safety (FOS) from SPT, CPT and DMT tests data.
6. Plaxis 2D and NovoLIQ software were used as a finite element tools.

3 RESULTS AND DISCUSSIONS

3.1 *Estimation of soil property*

The in situ investigation was done by two numbers of boreholes of up to 30 m depth in which the standard penetration test (SPT) were performed. The cone penetration tests (CPT), Flat Dilatometer tests (DMT) and seismic Dilatometer test (SDMT) were performed up an average depth of 20m. Undisturbed soil samples were collected and unconsolidated undrained (UU) tri-axial tests were performed. In addition, the grain size distribution tests were performed on collected soil samples to obtain the fine fraction of the sub- soil.

Two numbers of CPT (CPT1 and CPT2) tests were conducted out up to a depth of 19.0m below the ground level, at Rajarhat, Kolkata. The CPT tests were carried out by using the attached CPT assembly provided with Pagani TG 63-150 penetrometer. The CPT tests were performed at 2cm/s penetration rate vertically downward. On every 200mm depth interval readings were taken.

Two numbers of DMT tests i.e., DMT1 and DMT2 (aligned to the straight line with the CPT points), were carried out by giving 500mm spacing between the respective CPT tests points. At one of the DMT points (i.e., DMT2), seismic tests (SDMT) were performed to evaluate shear wave velocity (Vs) by striking a hammer (≈10kg) to a steel plate placed at the ground level under the base of the penetrom-eter (Pagani TG-63/150) stand aligned perpendicular to the plane of DMT blade. This seismic test was performed on every 500mm depth interval starting from 1m below the existing ground level. This seismic test was executed during the Dilatometer Test. The shear wave velocity (Vs) measurement was done with the aid of seismic module attached to the control unit. One number of DMT test and one number of seismic dilatometer test (SDMT) were also performed up to a depth of 18.0m below ground level at this site.

CPT1 and DMT1 points were located near the Borehole1 (BH1) and the rest test points (i.e., CPT2 and DMT2) were located near the Borehole 2 (BH2), as shown in Figure 1.

3.2 *Determination of earthquake magnitude from PEER GROUND MOTION DATABASE*

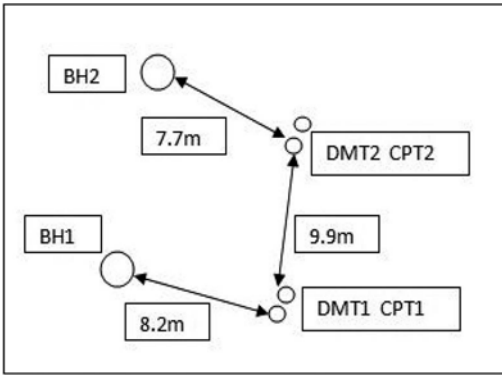
Authentic ground motion database is needed as an important parameter of earthquakes that is likely to occur in Rajarhat area of kolkata. To get the data history of earthquake, it was collected from the website of the PEER GROUND MOTION DATABASE. From the previous earthquake database results, it


Figure 1. Location plan of the testing points.

Figure 2. Photographs of the test progress.

was observed that the earthquake magnitude in the study area is 6.5 MW (Moment Magnitude) which was used as boundary earthquake magnitude for liquefaction susceptibility analysis of the study area.

As per Indian standard (i.e., IS 1893 (Part-1): 2016), the zone wise Peak Ground Acceleration (PGA) is mentioned. On that basis Kolkata is classified into the zone III having PGA of 0.3g.

3.3 Determination of CSR

The CSR value had been determined using Equation-1, given below. The components of the equation are horizontal earthquake peak acceleration on the soil surface (a_{max}), gravity, stress reduction coefficient, and overburden stress value. All variables are formulated in the following equation:

$$CSR = \frac{\tau_{av}}{\sigma'_{vo}} = 0.65 \times \left(\frac{a_{max}}{g}\right) \times \left(\frac{\sigma_{vo}}{\sigma'_{vo}}\right) \times r_d \quad (1)$$

Where,
  a_{max} = peak horizontal acceleration on the surface of soil caused by earthquake
  g = gravitational acceleration
  σ_v = vertical overburden stress
  σ'_{vo} = effective vertical overburden stress
  r_d = coefficient of stress reduction

3.4 Determination of CRR

3.4.1 Determination of CRR from SPT
Seed & Idriss (1983 -1985) proposed $CRR_{M=7.5}$ equation as:

$$CRR_{M=7.5} = \frac{1}{34 - (N1)_{60CS}} + \frac{(N1)_{60CS}}{135} + \frac{50}{[10 \times (N1)_{60CS} + 45]^2} - \frac{1}{200} \quad (2)$$

Where:
$(N_1)_{60cs}$: Corrected Value of N SPT

3.4.2 Determination of CRR from CPT
CRR from CPT had been calculated using this following graph:
Figure 3. Graph of CRR Vs (qc1N)cs recommended by Robertson and Wride (1998).

Where:
$(q_{c1N})_{cs}$: Value of corrected cone resistance

3.4.3 Determination of CRR from DMT
Cyclic Resistance Ratio (CRR) was calculated from horizontal stress index (K_d) values using the equation proposed by Monaco et al (2005).

$$CRR = 0.0107K_d^3 - 0.0741K_d^2 + 0.2169K_d - 0.1306 \quad (3)$$

3.5 *Computation of factor of safety (FOS) from SPT, CPT, DMT tests data*

Furthermore, CRR value was compared to the value of CSR of each layer of soil for evaluating the value of FOS. FOS was plotted against depth, showing the value of FOS for each test depth (i.e., 200 mm). Below is a graph of the variation of factor of safety along depth for SPT tests.
Figure 4. Variation of CRR with depth for DMT1, CPT1, SPT1 tests points.
Figure 5. Variation of CRR with depth for DMT2, CPT2, SPT2 tests points.

3.6 *NovoLIQ and PLAXIS 2D software were used as finite element tools*

3.6.1 *NovoLIQ software*
NovoLIQ finite element based software had been used for liquefaction analysis based on SPT and SDMT tests data.The following graphs show the variation of FOS with depth

3.6.2 *Plaxis software*
Plaxis 2D finite element based software had been used for liquefaction analysis based on DMT tests data.
Figure 6. Variation of FOS with depth for DMT1, CPT1, SPT1 tests points.
Figure 7. Variation of FOS with depth for DMT2, CPT2, SPT2 tests points.
Figure 8. Variation of FOS with depth at the test location of BH-01 based of SPT.

A Plate had been assumed to be placed on the soil. The properties of the plate is given below.
d_{eff} (effective depth) =150mm,
EA = 4107919.18 kN/m for isolated footing
EI = 7702.3 kN m^2/m for isolated footing

958
Figure 9. Variation of FOS with depth at the test location of BH-02 based on SPT.
Figure 10. Variation of FOS with depth at the test location of SDMT.

On these plates a static load of 85 kPa with a eartquake of magnitude of 6.5, corresponding settlement of the foundation soil profile has been estimated. The value of the settlement had been compared with the findings of Tokimatsu, K., & Seed, H. B. (1987)., Evaluation of settlements in sands due to earthquake shaking paper.

3.7 *Discussion*

In this paper, the value of factor of safety against liquefaction were estimated from in-situ test's results (i.e, CPT, DMT and SPT) and had been plotted for respective tests depths. Also the computed factor of safety against liquefaction from SDMT and SPT tests had been compared and plotted by using finite element based software (i.e., Novoliq).

Apart from, the settlement of a shallow foundation had been calculated by using Plaxis2D software against earthquake magnitude of 6.5 and compared with the allowable limit proposed by Tokimatsu, K., & Seed, H. B. (1987).
Figure 11. Settlement of 2m × 2m isolated footing when an earthquake of magnitude 6.50 is applied.

4 CONCLUSION

From the above result and discussion it can be concluded that

- For SPT, CPT and DMT, the graph of factor of safety with depth showing a similar pattern upto an average depth of 11.0m but in case DMT the graph is showing an irregularity upto an average depth of 4.0m. Soil description estimated from DMT test shows that there is a fill layer of 4.0m at the test location. Hence it can be concluded that the liquefaction analysis done by DMT is more realistic in nature with respect to CPT and SPT.
- The liquefaction Analysis done by the finite element software 'NovoLIQ' based on SPT data shows a similar pattern with coventional approach. But when liquefaction analysis is done based on SDMT data, it shows that the soil is liquefiable upto a depth of 14.0m f. Hence it can be concluded that the liquefaction analysis based on SDMT data is conservative in nature.
- The liquefaction Analysis had been done by the finite element software 'Plaxis 2D' for 2m × 2m isolated footing based on DMT data. It shows a settlement of 169mm when an earthquake of magnitude 6.50 is applied on the foundation. This value of settlement suggested that the foundation will fail due to the liquefaction effect according to the table (Tokimatsu et al., 1987) given below.

Table-1

Layer	Thickness (ft)	Settlement (in)
1	5	0.13
2	5	0.22
3	10	0.67
4	10	0.77
5	10	0.86
6	10	0.72

Hence, more research is required for liquefaction analysis of soil based on insitu tests in Kolkata.

ABSTRACT: In recent years, offshore wind power has been widely developed. Because of the complexity of marine geology and the large spatial variability of soils, it is necessary to obtain CPTU data before the foundation design. However, how to reasonably interpret the CPTU data will greatly affect the reliability and safety of the offshore windfarm foundation. In addition, there is a need to predict soil conditions at the locations without CPTU data. In this study, based on the available CPTU data of offshore wind farm in east China sea, kriging method is used to interpret the CPTU data, and the soil conditions in a large area can be predicted. This method can be used to develop ground model for a large offshore wind farm, and estimate the relevant soil parameters based on CPTU data. The analysis methods can provide reference for other projects of offshore wind farm.

Keywords: offshore wind farm, CPTU, kriging method, marine geology

1 INTRODUCTION

Offshore wind power has been widely used as the clean energy in many countries. Dinh and Nguyen (2019) proposed that offshore wind power has the advantages of higher full load hours per year, longer service life and higher rotor speed comparing with onshore wind power. In practical engineering, foundation design should be carried out before the installation of offshore wind turbine.

Marine soil has the characteristics of large spatial variability (Dasaka and Zhang 2012; Ching and Phoon 2013; Li et al. 2014; Lloret-Cabot et al. 2014). Before the foundation design of the offshore wind turbine, it is necessary to obtain the CPTU data of relevant soil layers. Then the obtained CPTU data can be interpreted to get soil parameters. For example, Robertson method (Robertson and Wride, 1998) can be used to determine the classification of marine soil layer based on the CPTU data. However, due to the high cost of offshore work, the CPTU tests in a large area are usually limited. Therefore, how to predict soil conditions at

the locations without CPTU data has become an important engineering problem which needs to be solved.

Based on the above background, taking the CPTU data of offshore wind farm in east China sea as an example, this study used the Kriging method to predict the CPTU data in the unknown area, and then used the Robertson method (Robertson and Wride, 1998) to obtain the soil classification of the whole seabed profile. The predicted results can reach the 95% confidence interval in statistics. The algorithm can provide reference and guidance for the foundation design of offshore wind turbine.

2 INVESTIGATION SITE OF OFFSHORE WIND FARM

The site of the offshore wind farm is in the east China sea. The positions of the boreholes are shown in Figure 1. This site contains 27 boreholes. The drilling depth of each borehole is more than 35 m, and CPTU data is measured every 0.02 m along the

depth. In Figure 1, the interval of boreholes in different columns is 11000 m which is too large, so 15 boreholes in the same column are selected for analysis as shown in the frame. The measured CPTU data contain cone penetration resistance (q), sleeve friction (f) and pore pressure (u).

According to the soil samples at the site, the actual soil layers of boreholes no. 50, no. 72 and no. 77 have been already known which are shown in Figure 2. It can be seen from Figure 2 that the actual seabed geological conditions are generally divided into four layers: Ooze clay, clay, silty clay, and silty sands. The soil layers in the first 25 m are relatively homogeneous, and they are Ooze clay. The soil layers beyond 25 m vary from location to location. Figure 3 shows the typical CPTU data along depth of borehole no. 50. It can be seen that the trend of the curve at the first 25 m is increasing linearly, and the trend of the curve is much more complicated beyond 25 m.

Figure 3(a). Measured cone resistance along depth below seafloor
Figure 3(b). Measured sleeve friction along depth below seafloor

Figure 1. The position of the boreholes.
Figure 3(c). Measured pore pressure along depth below seafloor.

Figure 3. The variation of CPTU data with depth in borehole no. 50.

Figure 2. Soil conditions of known boreholes (Borehole no. 50, no. 72 and no. 77).

Based on CPTU data, the classification of soil layer can be obtained. There are many traditional

soil classification methods, such as Jefferies method (Jefferies and Davies, 1991), Olsen method (Olsen and Mitchell, 1995), Robertson method (Robertson and Wride, 1998) and so on. Liu et al. (2013) proposed that the Robertson method is suitable for the Chinese soil classification. Therefore, the Robertson method is used for soil classification in this study. The calculation formulas are shown from Equation 1 to Equation 6,

$$Q_{tn} = \frac{q_t - \sigma_{v0}}{\sigma'_{v0}} \qquad (1)$$

$$F_r = \frac{f_s}{q_t - \sigma_{v0}} \times 100\% \qquad (2)$$

$$B_q = \frac{u - u_0}{q_t - \sigma'_{v0}} \qquad (3)$$

$$I_c = \sqrt{[3.47 - \lg(Q_{tn})]^2 + [\lg(F_r) + 1.22]^2} \qquad (4)$$

$$q_t = q + (1 - a)u \qquad (5)$$

$$a = d^2/D^2 \qquad (6)$$

where Q_{tn} is normalized cone penetration resistance; F_r is normalized sleeve friction; B_q is normalized pore pressure; σ_{v0} is the total overburden stress; σ'_{v0} is effective overburden stress; u_0 is equilibrium pore pressure; q_t is corrected cone penetration resistance; a is the net area ratio between load cell support diameter, d, and cone diameter, D; I_c is soil classification index. The soil types are attributed from I_c which is shown in Table 1.

Table 1. The soil classification based on Robertson method.

I_c	Soil type
$I_c > 3.6$	Ooze clay
$2.95 < I_c < 3.6$	Clay
$2.60 < I_c < 2.95$	Silty clay
$2.05 < I_c < 2.60$	Sandy silt
$1.31 < I_c < 2.05$	Silty sands
$I_c < 1.31$	Dense sand

3 KRIGING METHOD

Kriging interpolation (Liu et al., 2016) is an optimal linear unbiased interpolation method. For ordinary Kriging, there is a group of observation

points in region D, whose position coordinates are x_1, x_2, x_3 to x_n, respectively, and the corresponding observation values are $Z(x_1)$, $Z(x_2)$, $Z(x_3)$ to $Z(x_n)$, respectively. Then the formula of the estimated value at unknown position x_0 in region D is shown in Equation 7,

$$Z^*(x_0) = \sum_{i=1}^{n} \lambda_i Z(x_i) \qquad (7)$$

where λ_i is the weight coefficient of Kriging interpolation. The values of λ_i should be known. The semivariogram is used to calculate the λ_i. The semivariogram of the observation data can be calculated by Equation 8,

$$\gamma(h) = \frac{1}{2N_h} \sum_{i=1}^{N_h} [Z(x_i + h) - Z(x_i)]^2 \qquad (8)$$

where N_h is the number of the observation points and h is the separation distance between different points. Based on the semivariogram values of the observation points, the Gaussian model and exponential model are usually used to fit the trend of the semivariogram which are shown in Equation 9 and Equation 10,

$$\gamma(h) = C_0 + C(1 - e^{-\frac{3h^2}{a^2}}) \qquad (9)$$

$$\gamma(h) = C_0 + C(1 - e^{-\frac{3h}{a}}) \qquad (10)$$

where C_0 is nugget; C is partial sill and a is range. Before fitting the semivariogram, it is essential that the data is stationary; that is, the mean and covariance of the data depend only upon separation, not on absolute location. If the data are non-stationary, treatment must be given to transform the data to a stationary set by removing the deterministic component called the trend, and the stationary residual random component is then analyzed.

After fitting the semivariogram, the weight coefficient λ_i can be calculated based on Equation 11,

$$\begin{bmatrix} \gamma_{11} & \gamma_{12} & \cdots & \gamma_{1n} & 1 \\ \gamma_{21} & \gamma_{22} & \cdots & \gamma_{2n} & 1 \\ \vdots & \vdots & & \vdots & 1 \\ \gamma_{n1} & \gamma_{n2} & \cdots & \gamma_{nn} & 1 \\ 1 & 1 & \cdots & 1 & 0 \end{bmatrix} * \begin{bmatrix} \lambda_1 \\ \lambda_2 \\ \vdots \\ \lambda_n \\ \mu \end{bmatrix} = \begin{bmatrix} \gamma_{01} \\ \gamma_{02} \\ \vdots \\ \gamma_{0n} \\ 1 \end{bmatrix} \qquad (11)$$

where γ_{ij} is the modelled semivariogram values based on the distance between the two samples pertaining to

the ith and jth locations, and μ is the Lagrange parameter. The formula for calculating the variance is shown in Equation 12,

$$\sigma_{OK}^2 = \sum_{i=1}^{n} \lambda_i \gamma_{0i} + \mu \tag{12}$$

where σ_{OK} is the OK standard variance of the Kriging method. Assuming that the parameter is normally distributed with a mean value z_0 (estimated value) and a standard variance σ_{OK}, the 95% confidence interval of the estimation is [z_0-1.96σ_{OK}, z_0+1.96σ_{OK}] (Ang and Tang, 2007).

Taking the CPTU data in depth 10 m for analysis as an example, the fitting equations of the deterministic component are shown in Equation 13, Equation14 and Equation 15, respectively,

$$q_{\text{trend}} = 0.2871x - 34.2453 \tag{13}$$

$$f_{\text{trend}} = 0.0061x - 0.7291 \tag{14}$$

$$u_{\text{trend}} = 0.5127x - 61.5089 \tag{15}$$

where q_{trend}, f_{trend} and u_{trend} are trend values of cone penetration resistance, sleeve friction and pore pressure, and x is the longitude coordinate of the observation points.

After removing the deterministic component, the stationary residual random components are used to fit the semivariogram. In this case study, comparing with Gaussian model, exponential model has higher fitting goodness. As a result, the exponential function is used to fit the semivariogram. The number of lag distances is 105 in total. Taking about 200 m as a group, the lag distances are divided into 14 groups. The lag distances of 14 groups are averaged to obtain the best fitting results and they are shown in Figure 4.

Cheon and Gilbert (2014) indicated that it is reasonable to have a horizontal range of more than 1000 m in offshore engineering. Based on the results, the range of the three residuals are all 120 m which are reasonable. Then, the CPTU data in unknown positions can be predicted based on the modelled semivariogram.

4 PREDICTION OF SOIL TYPES

From Figure 2, there are mainly four soil layers in the seabed. According to the calculation, different soil layers have different modelled semivariograms. As a result, four modelled semivariograms were used to analyze the depths below seafloor at depth of 1m to 25 m, 26 m to 29 m, 29 m to 31 m, and 31 m to 35 m, respectively.
Figure 4(a). The semivariogram of cone resistance
Figure 4(b). The semivariogram of sleeve friction
Figure 4(c). The semivariogram of pore pressure

Figure 4. The semivariogram of CPTU data in depth 10 m.

In order to verify the accuracy of the Kriging method, the soil types at boreholes no. 50 and no. 77 were predicted. The predicted results are shown in

Figure 5 and Figure 6. The results were compared with the actual soil types at the two boreholes. It can be seen that the predicted soil types are basically consistent with the actual soil types. The results prove that the Kriging method is reasonable.

B1 is the first unknown position without CPTU data which needs to be predicted. The longitude and latitude of B1 are 120.556 degree and 27.14 degree, respectively. For the depth of 15 m, 27 m, 30 m and 35 m, the estimators of cone penetration resistance of B1 are 0.521 MPa, 1.213 MPa, 2.105 MPa and 3.290 MPa; the estimators of sleeve friction of B1 are 6.7 kPa, 18 kPa, 21.3 kPa and 61.3 kPa, and the estimators of pore pressure of B1 are 0.414 MPa, 0.601 MPa, 0.808 MPa and 0.822 MPa. The 95% interval of confidence is shown in Table 2 and the predicted soil types are shown in Figure 7. For Table 2, it just means that the value will be within this interval.

Table 2. The predicted CPTU data in B1 (95% confidence interval).

Depth (m)	q (MPa)	f (kPa)	u (MPa)
15	[0.521, 0.521]	[6.690, 6.705]	[0.411, 0.418]
27	[1.106, 1.321]	[17.3, 18.7]	[0.572, 0.630]
30	[0, 8.794]	[20.80, 21.8]	[0.443, 1.173]
35	[0, 31.725]	[0.056, 0.067]	[0.176, 1.469]

B2 is the second unknown position without CPTU data which also needs to be predicted. The longitude and latitude of B2 are 120.592 degree and 27.14 degree, respectively. For the depth of 15 m, 27 m, 30 m and 35 m, the estimators of cone penetration resistance of B2 are 0.520 MPa, 1.186 MPa, 2.038 MPa and 3.066 MPa; the estimators of sleeve friction of B2 are 6.8 kPa, 17.3 kPa, 21.5 kPa and 57.3 kPa, and the estimators of pore pressure of B2 are 0.414 MPa, 0.643 MPa, 0.760 MPa and 0.827 MPa. The 95% interval of confidence is shown in Table 3. For Table 3, it just means that the value will be within this interval.

According to the soil classification criteria, the predicted soil types are the same with that at location B1, which can be seen in Figure 7.

Table 3. The prediction CPTU data in B2 (95% confidence interval).

Depth (m)	q (MPa)	f (kPa)	u (MPa)
15	[0.52, 0.52]	[6.79, 6.805]	[0.410, 0.417]
27	[1.081, 1.291]	[16.6, 18.02]	[0.622, 0.665]
30	[0, 8.636]	[0.021, 0.022]	[0.415, 1.104]
35	[0, 30.797]	[0.052, 0.062]	[0.189, 1.465]

Based on the CPTU data of boreholes, the seabed profile can be predicted and the results are shown in
Figure 5. The comparison between prediction value and actual data in borehole no. 50.
Figure 6. The comparison between prediction value and actual data in borehole no. 77.
Figure 7. The prediction of soil classification in B1 and B2 (95% CI).
Figure 8. The prediction soil layer of seabed profile.

Figure 8. It can be seen that the seabed profile mainly has four soil layers containing ooze clay, clay, silty clay and sandy silt. In the first 25 m, the soil is homogeneous which is ooze clay. Beyond 25 m, the soil conditions become much more complex. The general conditions of soil layer are consistent with the actual soil conditions. It means that Kriging method can predict the soil conditions at unknown positions effectively, which can be used to guide the foundation design of offshore wind turbine.

5 CONCLUSIONS

In this study, the offshore wind farm in east China sea is analyzed as a case study. The results indicate that Robertson method is suitable for the soil classification in the east China sea and Kriging method can predict the soil conditions in unknown positions with 95% interval of confidence. The algorithm can be used to provide guidance and reference for the foundation design of offshore wind turbine.

ABSTRACT: In offshore engineering, it's difficult to obtain undisturbed samples. CPT-based design method of pile has become recommending method. In this paper focusing on offshore pile foundation engineering, the typical CPT-based design methods are introduced. Various design methods are evaluated in respect of friction fatigue, pile loading direction, and the plug ratio of open-ended pile in capacity contribution, and the determination of design parameters. CPT-based design methods in the clay are compared with API method. For the typical stratum in the China East Sea, the monopiles of an offshore wind farm are analysed. The calculated capacities of monopiles with different methods are compared with the measured value, and the reliability of methods are evaluated. At last according to the vertical loading condition of the offshore monopile, reasonable suggestions for the current design methods and parameters determination are given.

1 INTRODUCTION

At present, the popular methods for the vertical bearing capacity of pile foundations in offshore engineering are either based on the empirical formula of CPT tip resistance or are directly related to soil parameters, such as undrained strength, yield stress, sensitivity, internal friction angle, etc. The CPT-based design method of pile has gradually replaced design methods based on lab tests or previous experience, and it has become the preferred method for offshore pile foundation. It is generally believed that the cone tip resistance obtained by CPTu is more reliable than the sleeve friction, which is the main design method parameter. Table 1 summarizes the current design methods for offshore piles.

Fellenius (2020) pointed out that all CPT-based pile design methods are established under basically the same geological conditions for specific areas. That is to say, each method is based on limited piles and soil tests. If geological conditions are not similar, these methods are not suitable. Following the completion of a Joint Industry Project, a unified database (Lehane et al., 2017) has been developed which includes ICP, NGI, Fugro, UWA and other databases.

Among the methods applicable to sand, all but API-00 are based on CPT. It is noted that the cone tip resistance has not been corrected by pore pressure. When using these methods, the difference between the calculated results before and after the correction should be fully considered. A unified CPT-based method has been developed by the JIP group of UWA, NGI, Imperial College, Fugro, BP, Delft University of Technology, University of Texas, DNV·GL and Lloyd's Register EMEA (Lehane et al., 2020).

The methods applicable to clay include API-00, Fugro-96, NGI-05, ICP-05, UWA-13 and Fugro-10 methods, of which API-00, Fugro-96, and NGI-05 are based on the undrained strength of clay. The ICP-05 method is based on the tip resistance of CPT and is not corrected by pore pressure. UWA-13 and Fugro-10 are based on the test results of CPTu with the tip resistance of CPT corrected by pore pressure. A new Unified CPT-based method is also being developed by the JIP group.

2 DESIGN METHOD

2.1 *Unified CPT-based method in sand*

The unit shaft friction may be calculated from:

Table 1. Pile design methods referred.

Soil type	Design method	Reference
Sand	Unified CPT-based method	Lehane et al. (2020)
Sand	API-00	API (2000)
Sand	Fugro-05	Kolk et al. (2005)
Sand	ICP-05	Jardine et al. (2005)
Sand	NGI-05	Clausen et al. (2005)
Sand	UWA-05	Lehane et al. (2005)
Clay	API-00	API (2000)
Clay	Fugro-96	Kolk & Van Der Velde (1996)
Clay	Fugro-10	Van Dijk & Kolk (2010)
Clay	ICP-05	Jardine et al. (2005)
Clay	NGI-05	Karlsrud et al. (2005)
Clay	UWA-13	Lehane et al. (2013)

$$\tau_{\mathrm{f}} = \sigma'_{\mathrm{rf}} \tan \delta_{\mathrm{cv}} = \frac{f}{f_{\mathrm{c}}} (\sigma'_{\mathrm{rc}} + \Delta\sigma'_{\mathrm{rd}}) \tan 29° \quad (1)$$

where σ'_{rf} is the radial effective stress at failure, σ'_{rc} is the radial effective stress after installation and equalization, $\Delta\sigma'_{\mathrm{rd}}$ is the change in radial effective stress due to loading stress path (dilation), and f/f_{c} is 1 in compression and 0.75 in tension.

The radial effective stress after installation and equalization may be calculated as:

$$\sigma'_{\mathrm{rc}} = \frac{q_{\mathrm{c}}}{44} \cdot A_{\mathrm{re}}^{0.3} \left[\max\left(\frac{h}{D}, 1\right) \right]^{-0.4} \quad (2)$$

where q_{c} is the cone tip resistance, A_{re} is the effective area ratio, $A_{\mathrm{re}}=1\text{-}PLR\cdot(D_{\mathrm{i}}/D)^2$, PLR is soil plug length ratio, h is the relative distance above the pile tip, D is the outer diameter of pile, D_{i} is the inner diameter of pile.

The change in radial effective stress due to loading stress path (dilation) may be estimated as:

$$\Delta\sigma'_{\mathrm{rd}} = \left(\frac{q_{\mathrm{c}}}{10}\right) \left(\frac{q_{\mathrm{c}}}{\sigma'_{v}}\right)^{-0.33} \left(\frac{d_{\mathrm{CPT}}}{D}\right) \quad (3)$$

where σ'_{v} is the vertical effective stress.

The unit end bearing may be calculated from:

$$q_{\mathrm{b}0.1} = \overline{q_{\mathrm{c}}}(0.12 + 0.38 \cdot A_{\mathrm{re}}) \quad (4)$$

Where $\bar{q}_{\mathrm{c}}$ is the average cone tip resistance within a zone 1.5D above and below the pile tip in relatively homogeneous sands.

2.2 UWA-13 method in clay

The unit shaft friction is calculated from:

$$\tau_{\mathrm{f}} = 0.055 \cdot q_{\mathrm{t}} \cdot \left[\max\left(\frac{h}{R^*}, 1\right) \right]^{-0.2} \quad (5)$$

where q_t is the total cone tip resistance at depth z, h is the relative distance above pile tip, R^* is the equivalent radius $= (R^2 - R_i^2)^{0.5}$, R is the outer radius of pile, and R_i is the inner radius of pile.

The unit end bearing follows the recommendations of Jardine et al. (2005) for undrained loading and assumed that the open-ended piles are always plugged:

$$q_b = 0.8 \cdot \overline{q_t}; \text{undrained, closed} - \text{ended} \quad (6)$$

$$q_b = 0.4 \cdot \overline{q_t}; \text{undrained, open} - \text{ended(plugged)} \quad (7)$$

Where q_{t} is the average total cone tip resistance over $\pm 1.5D$ at pile tip.

The method ignores the effects of reversed end bearing or base suction for piles in tension.

2.3 Fugro-10 method in clay

The unit shaft friction is calculated from:

$$\tau_{\mathrm{f}} = k_{\mathrm{s}} \cdot q_{\mathrm{n}} \quad (8)$$

$$k_{\mathrm{s}} = \min\left[0.16 \cdot \left(\frac{h}{uL}\right)^{-0.3} \cdot \left(\frac{q_{\mathrm{n}}}{\sigma'_{\mathrm{v}0}}\right)^{-0.4}, 0.08 \right] \quad (9)$$

where q_{n} is the net cone tip resistance at depth z, $\sigma_{\mathrm{v}0}$ is the total vertical stress at depth z, $\sigma'_{\mathrm{v}0}$ is effective vertical stress at depth z, h is the relative distance above pile tip, and uL is unit length to render the expression dimensionless (= 1.0 m).

The unit end bearing (q_{b}) and reversed end bearing (q_{rb}) may be calculated from:

$$q_{\mathrm{b}} = 0.7 \cdot q_{\mathrm{n,avg}} \quad (10)$$

$$q_{\mathrm{rb}} = \min[0.7 \cdot q_{\mathrm{n,avg}} - u_{\mathrm{b}}, \ 100 \ (\mathrm{kPa})] \quad (11)$$

where $q_{\mathrm{n,avg}}$ is the average net cone tip resistance over $\pm 1.5D$ at pile tip, and u_b is the hydrostatic pressure at pile tip (in kPa).

3 EVALUATION OF SOIL PLUG

Lehane et al. (2017) suggested in the absence of any better method, Equation (12) was therefore

employed for the calculation of plug lenth ratio in sand and clay. This is consistent with field test.

$$PLR = \min\left[(D_i/1.5)^{0.2}, 1\right] \qquad (12)$$

where *PLR* is soil plug length ratio, and D_i is the pile internal diameter expressed in metres.

Lehane et al. (2020) proposed a new empirical formula for soil length plug ratio:

$$PLR = \tan h\left[0.3(D_i/d_{CPT})^{0.5}\right] \qquad (13)$$

where d_{CPT} is the diameter of standard static cone penetration, 35.7mm.

Based on the unified database (Lehane et al., 2017), the relationship between the soil plug length ratio and the pile inner diameter is plotted together, as shown in Figure 1. It can be seen that there is no obvious difference in the law of soil plugging in clay and sand, that is to say, the relationship between soil plugging and soil properties is not significant, only related to the inner diameter of pile. Equations (12) and (13) reflect that soil plugging varies with pile diameter with the same trend, especially in the range of 0.4~1.2m pile diameter. However, in terms of small diameter piles, equation (13) is closer to the actual cases.
Figure 1. Relationship between plug length ratio and pile inner diameter.

The typical pile diameter to wall thickness ratio of steel pipe piles is 30-60. For offshore piles with a pile diameter greater than 1.5m, the soil plug ratios calculated by equations (12) and (13) are both greater than 0.96. So for steel pipe piles with a diameter of larger than 1.5m, there is no soil plug formed or the soil plug length ratio is equal to one which is in coring mode.

4 REVIEW OF DESIGN METHODS FOR AXIAL CAPACITY OF PILES

The Unified CPT-based method of driven pile in sand proposed by the JIP group has replaced the API-00 method as the preferred recommended method in the new version of the API specification. According to statistical analysis of 71 piles' database, the Unified CPT-based method in sand has the lowest coefficient of variation among all the design methods of pile in sand (Lehane et al., 2020).

Unified CPT-based method, UWA-13 and Fugro-10 methods all take into account the friction fatigue effects caused by pile construction.

Through a large number of database examinations for different design methods, the reliability statistics analysis results are shown in Table 2. There are 49 piles, with diameters ranging from 0.2 to 0.8m. Compared with the pile design method in sand, the calculation results of pile capacity in clay have a larger variation coefficient. This is because there are more design parameters for piles in clay compared to sand, and they are also more complicated and diverse. Among the CPT-based design methods, the variation coefficient of the UWA-13 method is smaller than that of the Fugro-10 method. The API-00 method is a bit conservative and Fugro-10 method is sometimes unsafe compared to UWA-13 method.

Table 2. Method uncertainties for piles in clay (Lehane et al., 2017).

Method	No of sample	Q_c/Q_m		
		μ_w	σ_w	CoV_w
API-00	23	0.73	0.29	0.40
UWA-13	43	0.99	0.48	0.49
Fugro-10	43	1.17	0.69	0.59

In Table 2, Q_c is the calculated capacity, Q_m is the measured capacity, μ_w is weighted mean, σ_w is weighted standard deviation, and CoV_w is coefficient of variation.

The comparison of open-ended pile design methods in clay is shown in Table 3. It is believed that the soil inside large-diameter steel pipe pile is in soil coring mode, and there is no soil plug occurring. The API-00 method considers that the total bearing capacity is equal to the sum of the outer shaft resistance, the inner shaft resistance and the base resistance of the annulus area, and use the same unit shaft friction to calculate the inner and outer shaft resistance. Neither the UWA-13 method nor the Fugro-10 method directly mentions the inner shaft resistance in the calculation. Instead, they use the equivalent base resistance to calculate total bearing capacity of the pile, where the base area is equal to the area of the outer diameter circle. The base resistance used by the soil core is a reduction of the unit end bearing of the annulus area or closed-ended pile. The reduction factor in the Unified CPT-based method is 24% for sand, and in the UWA-13 method, it's about 40% for clay.

Table 3. Comparison of design methods for open-ended pile.

Method	Soil type	Capacity calculation
API-00	Clay sand	If $Q_{b,plug}<Q_{s,inner}$, plugged, $Q_{total}=Q_{s,outer}+Q_{b,plug}+Q_{b,ann}$; If $Q_{b,plug}\geq Q_{s,inner}$, unplugged, $Q_{total}=Q_{s,outer}+Q_{s,inner}+Q_{b,ann}$.
Unified CPT-based method	Sand	Unplugged is the same as plugged, $Q_{total}=Q_{s,outer}+Q_{b,plug}+Q_{b,ann}$.
UWA-13	Clay	Always plugged, $Q_{total}=Q_{s,outer}+Q_{b,plug}+Q_{b,ann}$.
Fugro-10	Clay	Unplugged is the same as plugged, $Q_{total}=Q_{s,outer}+Q_{b,plug}+Q_{b,ann}$.

Figure 2. Profiles of tip resistance, shaft friction and pore pressure in CPTu test.

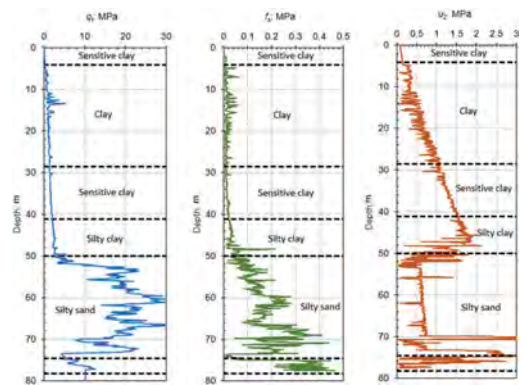
In Table 3, Q_{total} is total bearing capacity, $Q_{s,inner}$ is inner shaft resistance, $Q_{s,outer}$ is outer shaft resistance, $Q_{b,plug}$ is base resistance of the soil plug, and $Q_{b,ann}$ is base resistance of the annulus area.

When the pile is subjected to a tension load in sand, the Unified CPT-based method uses a reduction factor of 0.75 to calculate the shaft resistance, without considering the base resistance. When the pile is subjected to a tension load in clay, none of the methods considers the reduction of the shaft resistance. Fugro-10 propose the unit end bearing when the pile is in tension, while UWA-13 method doesn't consider the base resistance of the pile in tension. API-00 does not explicitly propose a calculation of the base resistance in tension.

5 CASE ANALYSIS OF OFFSHORE PILE

5.1 Soil conditions

A field test of large diameter steel pipe piles was carried out in an offshore wind farm project. The site is about 20 km offshore, with the seabed topography of the total site area not varying much, and water depth at 8~12 m. As for regional geological information, the local Quaternary sediments within the exploration depth, the upper part is the silty clay and clay deposited in the Holocene littoral facies, and the lower part is the silty clay and silty sand deposited in the Upper Pleistocene estuary-littoral facies. According to the soil layer classification method proposed by Robertson et al. (1986), the site stratum distribution is shown in Figure 2.

CPTu cone tip resistance, shaft friction resistance, and pore pressure test results are also shown in Figure 2. It can be seen that the cone tip resistance of the clay increases linearly with depth from 4~50 m, indicating a relatively uniform soil layer. However, the shaft friction resistance changes with depth more discretely. Therefore, pile design methods only use tip resistance as the parameter which is scientific and reasonable. The pile end is buried 69 m deep and is located in the supporting layer of silty sand.


The undrained strength of clay is determined by the empirical expression based on CPT on basis of $N_k=20$ inferred by SHANSEP method (Ladd & Foott, 1974).

5.2 Field test of offshore piles

The pile outer diameter is 1.8 m, the total pile length is 93 m, and the wall thickness is 20~40 mm. The IHC S800 hydraulic hammer is used for pile driving. There is no slipping phenomenon during the pile driving process, and the pile's embedded depth is 69 m. After pile driving, the soil plug/core is 1.45 m slightly above the mudline, and the soil plug ratio of the steel pipe pile which has an inner diameter of about 1.7 m is 1.0, which is a soil coring mode.

The vertical static compression test was carried out 44 days after the pile was driven using the slow maintained loading method, then rested for 25 days, then for the same test pile the vertical static tension test was conducted using the slow maintained loading method. Figure 3 shows the comparison between the axial compression and tension test results of the pile. The axial compression test of a single pile achieves the destruction of the soil around the pile, and the ultimate axial compression capacity is 22 MN; the axial tension test of the single pile also achieves failure, and the ultimate axial tension capacity of the single pile is 18.7 MN. When the pile head displacement is small, the compression load-displacement curve is closer to the tension test curve, and the compression curve is slightly higher than the tension curve; as the pile head displacement gradually increases, the discrepancy between compression and tension becomes larger and larger. After roughly 40 mm, both reach the limit state, and

the difference is also the largest. This is because the contribution of the base resistance of the pile in compression increases as the displacement of the pile increases, while the end resistance can be ignored in tension; in addition, at the depth of 50~74.7 m is all silty sand, and the shaft tension friction in sand is also reduced by 25% compared with compression (Lehane et al, 2020).
Figure 3. Comparison between axial compression and tension load-displacement curves.

5.3 *Comparison between design methods*

Comparisons of measured and calculated results of capacity with different design methods for compression and tension are shown in Table 4 and Table 5. It can be seen in Table 4 that all design methods are safer in calculating compression capacity, resulting in about 79%~95% of the measured value. From the calculated result of tension capacity it can be seen that in tension, the API-00 method based on undrained strength are 17% higher than the measured value, while the CPT-based design methods are 9%~13% lower than the measured value.

The UWA-13 method and Fugro-10 method, which are completely based on CPT, are safe in the calculation of compression and tension capacity.

Table 4. Comparison of measured results and calculated results of compressive capacity of different design methods.

Method	Shaft resistance (MN)	Base resistance (MN)	Total resistance (MN)	Calculated/ Measured (%)
Measured	NA	NA	26.6	NA
API-00	18.1	7.0	25.1	94.5
Fugro-10	13.9	7.0	20.9	78.6
UWA-13	14.5	7.0	21.4	80.8

Note: The compression capacity measured takes into account the weight of pile and soil plug (4.6 MN). The shaft resistance and base resistance in sand use the Unified CPT-based method.

Table 5. Comparison of measured results and calculated results of tension capacity of different design methods.

Method	Shaft resistance (MN)	Base resistance (MN)	Total resistance (MN)	Calculated/ Measured (%)
Measured	NA	0	14.2	NA
API-00	16.6	0	16.6	117.0
Fugro-10	12.3	0	12.3	87.1
UWA-13	12.9	0	12.9	91.2

Note: The tension capacity measured deducts the weight of pile and soil plug (4.6 MN). The shaft resistance and base resistance in sand use the Unified CPT-based method.
Figure 4. Shaft friction distribution with depth during ultimate bearing calculated by different methods: (a) compression; (b) tension.

The compression capacity calculated by the UWA-13 method is 81% of the measured value, and the Fugro-10 method is 79%. The UWA-13 method calculated tension capacity is 91% of the measured value and Fugro-10 method is 87%. Therefore, from this project case, UWA-13 method is slightly better than Fugro-10 method.

Figure 4 is the shaft friction distribution with depth during ultimate bearing calculated by different methods, compared with measured friction. The shaft friction of clay calculated by API-00 method is the greatest. The CPT-based methods calculate a smaller value but are very similar to each other. However, the trends of shaft friction changing with depth are almost the same.

The measured shaft friction is the sum of the inner and outer friction, and the two parts cannot be distinguished, while the shaft friction calculated by each design method is only the outer friction. Therefore, for the UWA-13 and Fugro-10 methods with

more reliable calculation results, it is obvious that the measured total friction is greater than the calculated outer friction, especially in sand below 50 m. It fully indicates that the contribution of the inner friction in the sand is more significant, and relatively the contribution of the inner friction in the clay is smaller. So the internal resistance of the soil core of the pipe pile is mainly exerted in the lower part of pile, which increases the complexity of the calculation of the internal resistance. Therefore, each design method adopts the equivalent base resistance of soil plug or core to calculate the internal resistance which is a method worth promoting.

6 CONCLUSIONS

This paper introduces and evaluates the CPT-based design methods for offshore pile under vertical load which are currently popular in the industry. The main conclusions are as follows:

(a) The Unified CPT-based method is recommended for full-scale offshore pipe in sand. For clay, the UWA-13 method and Fugro-10 method based on CPT are recommended compared to API-00 method.

(b) Through the case analysis of large-diameter steel pipe piles, the UWA-13 method and Fugro-10 method based entirely on CPT are conservative in the calculation of compression and tension capacity in which the calculated bearing capacity is 79%~92% of the measured value. The UWA-13 method is marginally better than Fugro-10 for the case in this paper, and Fugro-10 method is sometimes unsafe.

(c) It is difficult in offshore engineering to determine the undrained strength of the intact clay sample. The strength parameters in different soil layers and different depths can be determined by the relatively mature SHANSEP method, but this method is only suitable for low sensitivity, unnaturally cemented and low structured cohesive soil.

Application of CPT based 3DFE approach for estimating monopile damping in sand

D. Igoe & M.B. Mohammed
Trinity College Dublin, Ireland

ABSTRACT: Monopiles are the most popular foundation type supporting offshore wind turbines. The use of 3DFE modelling to analyse the pile response has grown significantly in recent years, supported by the introduction of the PISA framework and the development of easy to use commercial software such as PLAXIS Monopile Designer. In sands, the small-strain hardening soil (HSS) model is widely adopted for monopile design, partially due to its relatively simple set of soil input parameters. However to date there is no widely used approach for determining the required soil parameters and approaches often differ across the industry. Igoe and Jalilvand (2020) developed an approach to derive the HSS soil model parameters directly from CPT data. This procedure has been validated by the authors for monotonic loading against a database of large-scale field tests including PISA field tests in the Dunkirk marine SAND. This paper examines the use of the 3DFE approach under cyclic loading to determine soil damping for monopiles. The results from the 3DFE analysis are compared to field test data and show a good match with the damping estimated under two-way cyclic loading.

1 BACKGROUND

1.1 Introduction

The global offshore wind market has grown rapidly over the past decade with an average 30% increase per year since 2010 (International Energy Agency, 2019). Monopile foundations, which are large diameter steel tubes driven into the ground, represent around 80% of all offshore wind turbine foundations installed to date and will likely remain the most common foundation solution for offshore wind for at least the next 10 years. The geotechnical design of monopiles is governed by the response to lateral loads and overturning moments. Initially, monopiles were designed using the industry standard API p-y method (API RP2GEO 2014), which was adopted from the oil and gas industry. However, in recent years it became evident that the API p-y method was not suitable for the design of large diameter monopiles (Kallehave et al. 2015). The recently completed PISA project (Burd et al. 2020a,b, Byrne et al. 2020a,b), was formed to develop new design methods for large diameter monopiles. The PISA project proposed a new approach for the geotechnical design of monopiles which was calibrated from a suite of 3DFE analysis, which were validated against large-scale field tests. The new approach, termed the 'PISA design model', is an enhanced form of the p-y method, which is extended to include additional components of soil resistance which are significant for low slenderness piles ($2 < L/D < 6$). Site specific soil reaction curves can be calibrated from

3DFE analyses undertaken for a range of pile geometries and load eccentricities. The commercial software, Plaxis Monopile Designer, has been developed to allow industry practitioners to simply apply the new PISA design model (Brinkgreve et al. 2020). The developments from the PISA project have accelerated the use of 3DFE for monopile design in industry. Despite the widespread use of 3DFE analysis for monopile design, there is no industry standard approach to deriving the required soil input parameters. Igoe and Jalilvand (2020) developed an approach to derive the HSS soil model parameters directly from CPT data, which is used in this paper.

Offshore wind turbines are flexible structures which are dynamically sensitive and offshore loading is primarily cyclic and dynamic in nature. While significant improvement in monopile design was achieved through the PISA project, the project focused on monotonic loading, to define 'backbone curves', which could be extended in the future to account for cyclic and dynamic effects. Accurately calculating the damping of the structure is critical to prevent excessive fatigue damage over the lifetime of the structure. Consequently, the PISA "Soil Damping Project" was a supplementary piece of field testing within the PISA project, focused on obtaining the pile-soil response under two-way cyclic lateral loading at very low load amplitudes. A review of monopile damping is provided in Malekjafarian et al. (2021). This paper presents the development of a 3DFE modelling approach, using CPT data to derive the soil parameters, in order

to estimate monopile damping. The results from the 3DFE are compared to the damping values measured from the PISA field tests.

2 PISA DAMPING FIELD TESTS

The PISA project field tests in sand were undertaken at a test site at Loon Plage, near Dunkirk in northern France. The Dunkirk site consists of a normally consolidated dense to very dense sand, with a top 3 m comprising very dense fill material, below which is a dense natural sand. The ground water level was at about 5.4 m depth. The site was chosen for its extensive pre-existing site investigation history, including in-situ field characterisation alongside substantial suites of laboratory testing (Byrne et al 2020b). The pile test program was designed to provide a high-quality dataset which could be used for validation of 3DFE modelling. The damping tests involved undertaking 2-way cyclic loading on a single pile, designated DM1. The geometry for pile DM1 is provided in Table 1 below. The load test setup for 2-way loading is described in Byrne et al 2020c (see Figure 1). The main loading is applied by a hydraulic actuator located at a height, h, 10 m above the ground. The hydraulic actuator reacts against a much larger (2.0 m) diameter reaction pile. To apply two-way loading and to ensure that the hydraulic loading system is always in tension, a back-stay system with a dead load was used. Although the back-stay imposes a very small additional vertical load to the test pile due to the angle of loading, this has a negligible effect on the lateral response. Results from the PISA Damping Project were presented in Beuckalaers (2017) and are used for comparison with the 3DFE modelling approach developed in this paper.

Table 1. Pile DM1 geometry.

Test	D (m)	L (m)	L/D	t (mm)	h (m)
DM1	0.762	3.97	5.21	14	10.02
Figure 1. Load test setup for DM1 pile (from Byrne et al. 2020b).

3 3D FE MODELING

3.1 *Soil model*

Pile DM1 was modelled in 3DFE using the commercially available finite element software Plaxis 3D v21. The soil elements are modelled as ten-node tetrahedral elements. For sand deposits, Igoe and Jalilvand (2020) developed a procedure to calculate the soil model input parameters for the HSS soil model directly from Cone Penetration Test (CPT) data. The new approach adopted some widely used CPT correlations and was validated against a database of lateral load field tests. This procedure offers a consistent approach to develop all the required soil input parameters and offers improved predictions of the piles monotonic response compared with the current state of the art Plaxis Monopile designer recommendations (Panagoulias, et al 2018).

The CPT data was first used to derive the sand relative density using the expression proposed by Kulhawy and Mayne (1990) as follows:

$$D_R = \sqrt{\frac{Q_{tn}}{305 \times OCR^{0.15}}} \qquad (1)$$

$$Q_{tn} = \left(\frac{q_t - \sigma_{v0}}{p_{ref}}\right)\left(\frac{p_{ref}}{\sigma'_{v0}}\right)^n \qquad (2)$$

$$n = 0.381 \cdot I_c + 0.05\frac{\sigma'_{v0}}{p_{ref}} - 0.15. \qquad (3)$$

$$I_c = \sqrt{\frac{(3.47 - \log_{10}Q_{tn})^2 +}{(1.22 + \log_{10}F_r)^2}} \qquad (4)$$

$$F_r = \frac{f_s}{q_t - \sigma_{v0}} \qquad (5)$$

where q_t is the CPT cone resistance corrected for pore water effects, p_{ref} is a reference stress (atmospheric pressure) taken as $\approx$100 kPa and n is a stress exponent which varies between 0 and 1 depending on soil type and stress level. The Over Consolidation Ratio (OCR) was determined using the following formula from Mayne (2001):

$$OCR = \left[\frac{1.33 * q_t^{0.22}}{K_{0NC} * \sigma'_{vo}^{0.31}}\right]^{\frac{1}{sin\varphi' - 0.27}} \qquad (6)$$

The OCR is used in the determination of relative density, see Eq. (1), but is not input into the plaxis models directly. Instead the coefficient of lateral earth pressure, K_0, is input into Plaxis, which is calculated using the approach proposed by Mayne and Kulhawy (1982)

$$K_0 = K_{0NC} * OCR^{sin\varphi'} \qquad (7)$$

$$K_{0NC} = 1 - sin\varphi' \qquad (8)$$

Igoe and Jalilvand recommend a maximum OCR of 20 was assumed, to avoid unrealistically high K_0 values at shallow depths. The soil peak friction angle was determined using the CPT correlation by Bolton (1986):

$$\varphi' = \varphi'_{cv} + 3(D_R(10 - \ln p') - 1) \qquad (9)$$

where $\varphi'^{\leftarrow}_{cv}$ is the critical state friction angle, was determined from lab test data at each site ($\varphi'^{\leftarrow}_{cv} = 32$ degrees can be assumed in the absence of such data) and $p'^{\leftarrow}$ is the mean effective stress. The stiffness parameters were derived from CPT cone resistance, starting with the small strain shear modulus:

$$G_0 = \alpha \left(q_t \cdot \sigma'_{v0} \cdot p_{ref} \right)^{\frac{1}{3}} \qquad (10)$$

where $\alpha = 185$ was used for Dunkirk Sand (verified against shear wave velocity measurements). The remaining stiffness inputs required for the analysis were derived from the G_0 adjusted for reference stress levels (and therefore indirectly from the CPT cone resistance) as follows (in MPa):

$$G_0^{ref} = G_0 / \left(\frac{K_{0NC} \cdot \sigma'_{vo}}{p_{ref}} \right)^m \qquad (11)$$

where m is the stress exponent taken as 0.5 in cohesionless soils.

$$E_0^{ref} = 2(1 + v)G_0^{ref} \qquad (12)$$

$$E_{ur}{}^{ref} = 10^{\wedge}log\left(0.00464 \cdot \left(E_0{}^{ref} \right)^{1.724} \right) \qquad (13)$$

$$E_{50}{}^{ref} = \frac{E_{ur}{}^{ref}}{3} \qquad (14)$$

$$E_{oed}{}^{ref} = E_{50}{}^{ref} \qquad (15)$$

Full details of the correlations used are provided in Igoe and Jalilvand (2020). An unsaturated soil unit weight of 17.7 kN/m3 and the reference shear strain, $\gamma_{0.7} = 1.5 \times 10^{-4}$ was used in the analysis. The other soil parameters calculated are provided in Table 2.

3.2 Pile model

The pile is modelled at full scale in half-space assuming "wished-in-place" condition. The pile is modelled by shell elements using a linear elastic material model (Young's modulus, *E,* and Poisson's ratio, *v*). Interface elements are added to the pile shaft plate (both internal and external surfaces of the pile). The interfaces have zero thickness and are composed of 12-node elements which consist of pairs of nodes which link the 6-noded plate elements to the soil. The reduction in interface shear strength when slip occurs is accounted for using the strength reduction factor R_{inter} which is selected depending on the soil type and available geotechnical data. An R_{inter} value of 0.7 was used for the sand-steel interface. The vertical model boundaries were set at ±6m in the direction of loading and 4m in the perpendicular direction, while the bottom boundary extended to 13.2m as shown in Figure 2.

Table 2. Soil Parameters used to model Pile DM1.

Depth [m]	$E_{50}{}^{ref}$ [kPa]	$E_{oed}{}^{ref}$ [MPa]	$E_{ur}{}^{ref}$ [MPa]	ϕ [°]	ψ [°]	$G_0{}^{ref}$ [MPa]	K0 [-]
0	90.0	91.5	269.9	43.7	15.9	234.2	2.43

8.2	64.3	64.3	192.8	39.9	10.8	190.8	0.88
Figure 2. Plaxis model for pile DM1.

3.3 Loading

In order to simplify the calculations and reduce the model run time, the loading was applied as a static analysis using the 'plastic' calculation type. The pile was loaded applying a prescribed load to the top of the pile stick-up (as seen in Figure 2). Four separate cyclic load levels of 4, 10, 15 and 20 kN were considered in the analysis. For each load level, 5 cycles were applied, and the 5th cycle loop was used to obtain the damping ratio from displacement and rotation response extracted from the results of Plaxis 3D output. Each cycle was applied in three phases. The first phase applied positive loading, the second phase the pile is loaded in the opposite direction and the third phase the load is brought back to zero. The damping ratio was calculated using a Python code that determines the area of the loop and also elastic potential energy and then uses the equation below to determine the damping ratio:

$$\xi = \frac{1}{4\pi} \frac{E_{diss}}{E_{el}} \qquad (16)$$

where E_{diss} = dissipated energy during a load cycle; E_{el} = elastic stored energy. The global monopile damping is divided into load-displacement damping ratio ξ_v which is calculated from the horizontal load-displacement response and, moment-rotation damping ξ_ψ which is calculated from the moment-rotation response. The area of the loop is calculated using Gauss's area formula. The elastic energy is calculated by finding the area of the shaded triangle shown in Figure 3 in which σ indicates the horizontal force or the moment and ε indicates the displacement or the rotation. It is important to note that in most cases the hysteresis loops do not close in the unload-reload loops. For that case, the initial point at which the loop starts is changed to the final point so as to close the loops for the damping ratio calculation. In order to determine the total damping from both the horizontal displacement and rotational component, the dissipated energy and elastic energy from both components are added together.

$$E_{diss(total)} = E_{diss(v)} + E_{diss(\psi)} \qquad (17)$$

$$E_{el(total)} = E_{el(v)} + E_{el(\psi)} \qquad (18)$$

4 RESULTS AND DISCUSSION

The results from the 3DFE modelling of pile DM1 are presented below. The load-displacement response and moment-rotation response from the 5th cycle for each load level is shown in Figures 4 and 5 respectively. As expected, the higher load levels result in larger areas enclosed in each cycle. The damping for each load level was calculated from these loops and compared to

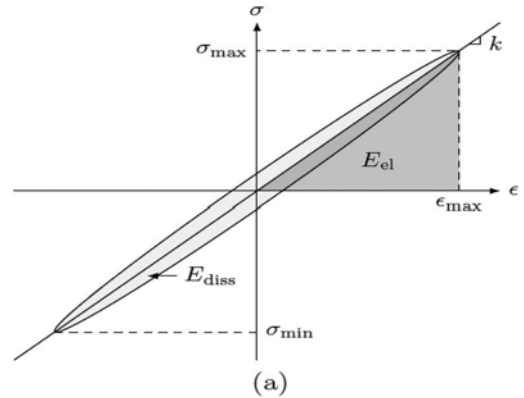
the measure response from the DM1 field test, as report in Beuckalaers (2017). The calculated damping ratios from the load-displacement and moment-rotation responses are compared to the measure response from the DM1 field test (as reported in Beuckalaers 2017) and presented in Figures 6 and 7 respectively. It is evident that the 3DFE underpredicts the damping measured from the load-displacement response at low load levels but matches the field tests well at the higher load levels. For the moment-rotation response, the 3DFE predicts the damping well at low load levels but overpredicts at the higher load levels.


Figure 3. Hysteretic soil stress-strain response (from Beuckelaers, 2017).
Figure 4. Load-Displacement response from 5th cycle of each load level from 3DFE model of pile DM1.

A comparison of the total damping ratios is provided in Figure 8. It is evident that overall the 3DFE is able to provide a reasonably good match for the damping ratio measured in the field tests at low load levels. At higher load levels the 3DFE overestimates the total damping measured.

Figure 8. Comparison between 3DFE and field test total damping ratios (field test data from Beuckelaers 2017).

5 CONCLUSIONS

This paper presents the results from 3DFE modelling of monopile field experiments to determine foundation damping. The small-strain hardening soil (HSS) model was adopted along with a CPT based approach to calibrate the soil parameters developed by Igoe and Jalilvand (2020). The CPT based approach for deriving the soil input parameters had previously been validated against monopile field tests under monotonic loading. This paper examines the use of the 3DFE approach under cyclic loading to determine the monopile soil damping. The results from the analysis are compared to field test data and show a good match with the damping estimated under two-way cyclic loading, particularly at low load levels. At higher load levels the 3DFE tended to over-predict the damping compared with the measured values. The authors are currently undertaking further cyclic monopile field tests which can be used for validation of the 3DFE damping approach.

The use of CPTU for driven piles designed in a backfilled opencast 'marl hole' in an important post-industrial revolution area within the UK

ABSTRACT: The Etruria Formation has historically been an important resource for the pottery and brick-making industry in the Stoke-on-Trent area and was mainly exploited using opencast methods – or 'marl holes' as they were commonly known. These 'marl holes' some of which have been reported to be more than 100m deep, have been subsequently backfilled generally with non-organic pottery, brickmaking and domestic waste. This paper explores the redevelopment of land over a backfilled 'marl hole' at a site in Hanley, Stoke-on-Trent, Staffordshire, UK, for residential properties. The development posed a number of challenges for the design of the foundations due to the historical legacy of the site. Driven steel tubular piles were chosen as a suitable system as there is precedent with this foundation solution, which has been frequently adopted for buildings within the area. However, some of the key challenges for this site included the presence of 'high walls' along the edges of the opencast works where driven piles could be deviated off the sides along with the uncertainty regarding socket lengths of piles driven into the underlying solid strata. To establish a 3D ground model for the 'marl pit', underlying strata, piezocone tests (CPTU) were seen as the most cost-effective and practicable method of site characterisation. Using this data, piles were installed, test/production piles were installed, driven to a set/penetration into the bedrock criteria and then compared to this ground model.

1 INTRODUCTION

This paper discusses the use of piezocone tests, CPTU for characterizing a backfilled opencast site for pile design.

1.1 Site description

The site is situated to the south of Hanley, which forms one of the six towns that make up the City of Stoke-on-Trent, in North Staffordshire, United Kingdom.

The proposed development is made up of a series of low-rise (2–3 storey) self-contained residential units. While the current topography shows a generally flat ground surface, this conceals the historical legacy of this part of Stoke.

1.2 Comments on the geology regarding the proposed development

The geological structure of the North Staffordshire Coalfield, presented in Figure 1, is a syncline, plunging towards the south-south-west, with the productive Coal Measures at the centre of the coalfield and the Etruria Formation forming the outline, particularly along the eastern limb of the syncline (Rees et al., 1998).

It is no coincidence that the six towns forming the city of Stoke (Tunstall, Burslem, Hanley, Stoke, Fenton and Longton) are aligned along the eastern syncline limb above the Etruria Formation.

Unlike the North Staffordshire coal mining, the Etruria was generally exploited by opencast methods – or 'marl holes' as they were called. The outcrop of the Etruria, along the eastern limb of the syncline forms a line of many marl excavations of varying sizes. At Fenton, less than 10 km south-south-east of Hanley, the marl pit is reported to have been more than 100m deep.

The British Geological Survey (BGS) no longer recognises the term 'marl' and so now the Etruria Marl is officially known as the Etruria Formation.

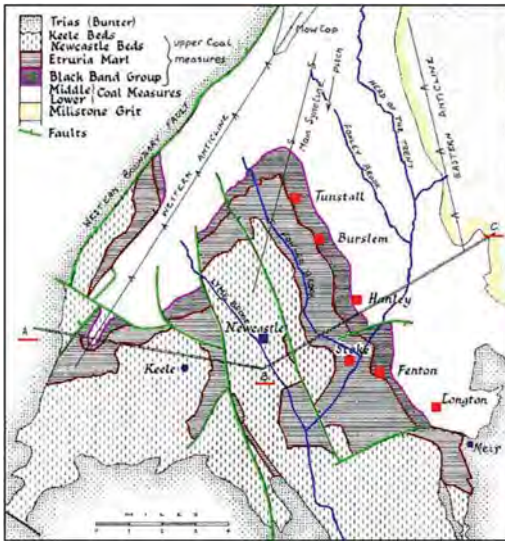
Published information from the BGS suggests this proposed development site is underlain by Glacial Devensian deposits and in turn Carboniferous bedrock. These are mainly formed of a sequence of the


Figure 1. Geological map of North Staffordshire, modified from Millott (1937).

Etruria Formation, which is of Middle Carboniferous age, from 308 to 319 million years ago. It comprises of mudstones, siltstones and sandstones that overlay part of the North Staffordshire productive Coal Measures (Pennine Upper Coal Measures).

Reference to historical data indicates the site sits partly over an old marl pit. Data for an adjacent site indicates that the main extent of this old pit, known as the Mousehole Marl Pit, was to the north-east of the current development. The remainder of the site considered in this paper also appears to straddle the side of this old pit.

The Etruria Formation has a few unique properties that have made it a very important resource for the pottery and brickmaking industry. Firstly, it has a relatively high natural carbonate content common with non-marine semi-lacustrine 'marl' deposits. However, the source material for the Etruria was eroded material from an older Midlands volcanic sequence. Therefore, it has a relatively high iron content that gives rise to the natural colour variations. While the formation is mainly of clay and silt grain size, the Etruria also includes regular sandstone layers termed 'esplays'. These are laterally discontinuous with few recognised as named horizons.

No published records are available for the Mousehole Marl Pit, which is known to extend beneath the proposed development. Following the exploitation of the Etruria Formation, the marl holes were backfilled with non-organic pottery and brickmaking waste. Much of the backfilling was undertaken during the 1960s, 1970s and 1980s (or before), when domestic waste was largely ash, glass and metal goods and it is expected that these products are also present.

Furthermore, there have been many anecdotal reports of industrial waste being dumped within the marl holes during times when the controls on waste disposal were less rigorous than now.

The following photograph presented in Figure 2 shows the nature of the excavations from a nearby well documented marl hole at Daisy Bank. While these pits were active, the high walls were steep probably between 45° and 50° overall, but locally up to 60°.

Figure 2. Air photos depicting the full extent of the Daisy Bank Brickworks, English Heritage (1927).

In respect of future development over the marl holes, probably the worst case is construction over the marl hole sides, often termed the 'high walls'.

2 INTERFACE DELINIATION BETWEEN THE MADE GROUND AND MUDSTONE

2.1 *Ground conditions*

Field work was undertaken in two phases. The first phase took place in September 2019 where 9 boreholes were performed, six to shallow depths to nearly 6m and three deeper boreholes to a maximum of nearly 24m. On the deepest borehole, groundwater was encountered at 16.5m. Ground conditions at the borehole locations comprised a layer of made ground overlaying natural strata considered to be Upper Coal Measures Formation.

Most of this initial investigation terminated in the made ground and no Glacial deposits were found. The made ground was mainly granular loose to medium sandy gravel with occasional cohesive material present in thin layers, typically soft to firm clay. Mudstone was only encountered in a couple of boreholes found below the made ground and was described as very weak rock.
Figure 3. Typical CPTU profile for this site.

During the second phase of site investigation, 52 CPTUs were carried out to a maximum depth of 31.5m.

2.2 *CPTU interpretation*

The delineation of the interface between the made ground and the mudstone was assessed by the cone resistance, q_c, friction sleeve, f_s, porewater pressure, u_2 and inclination. Figure 3 represents a typical CPTU profile from this site.

The typical site level was 145.5mAOD. CPTU results indicate bedrock from between 3-30m depth. Although CPTUs provided a site coverage, it was found that there is no evidence for bedrock between 128 and 124mAOD.

The increase in q_c and f_s with greater depths were immediately noticed when cone was penetrating the mudstone. Results from 42 CPTUs with a penetration of more than 1m into this strata suggest that within mudstone $q_c > 5.5$ MPa, $f_s > 250$ kPa and u_2 has a significant drop to negative measured values. The negative porewater pressure indicates suction. Smoother inclination measurements are another indication that Mudstone is a uniform deposit.

To allow further review of the CPTU results within the mudstone, the data points recorded were plotted in the Robertson 1990 soil behaviour type, SBT chart, as presented in Figure 4.

The majority of results for Etruria Formation fall in zones 8-9, sand to clayey sand and very stiff fine grained, respectively. It is also noticed that some results plot in zones 3-4, which represent clay and silt mixtures.

Figure 5 presents a typical CPTU cross section for this site. The data shows that the rockhead was encountered at shallower depths in the south west of the site. In the eastern boundary of the site, mudstone occurs at greater depths. These results are used to
Figure 4. Mudstone results plotted on Robertson 1990 SBT chart.

develop the ground model for this site, which is also included in the paper.

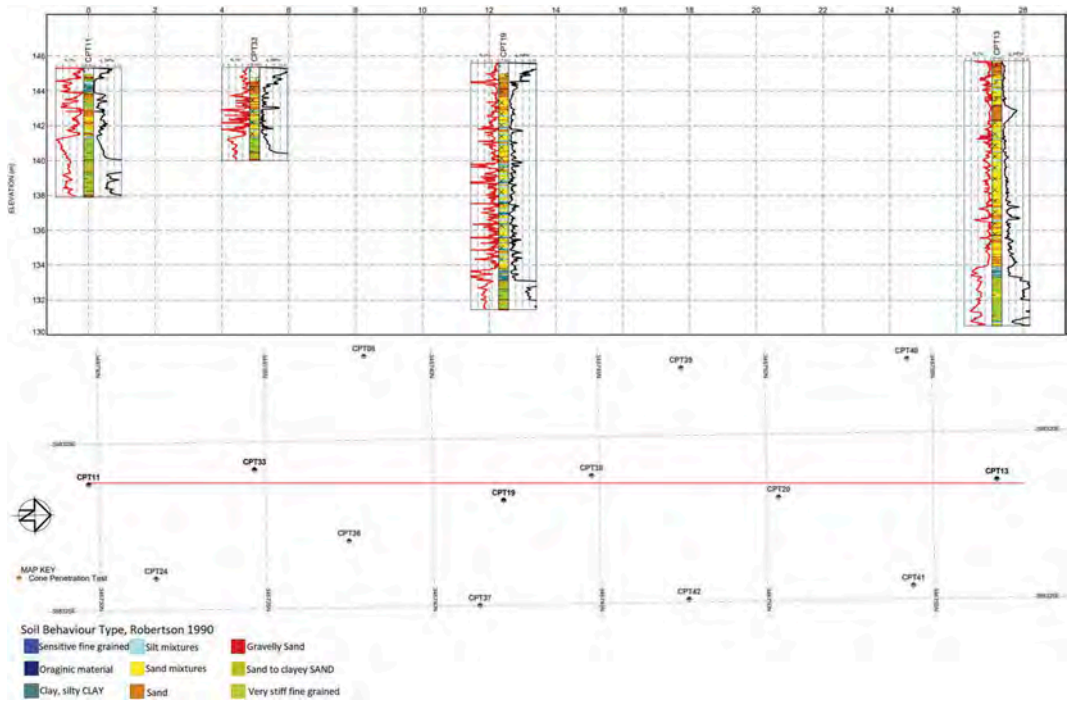
A simplified graph of friction ratio, R_f (%) for mudstone to show the variation of results is presented in Figure 6. Black graphs present the minimum and maximum R_f within the deposit, meanwhile the red graph presents the averaged results. It is seen that this parameter may vary greatly in mudstone and cannot be trusted as the main parameter to interpret it.


Figure 5. Cross section showing the mudstone coming in at a shallower depth to the south and much deeper to the north of the site.

Although CPTU provided a good site coverage, it was found that there were no probes relating to datum levels of between 128 and 124mAOD. Consequently, CPTU data were provided within two zones and between approximate levels of 141 to 128mAOD and 124 to 115mAOD. These are referred to as the upper and lower zones. The stratigraphic plots indicate distinct differences between the upper and lower zones. Although the results show some consistency several distinct layers can also be seen. In particular a more cohesive layer, with typical R_f = 6-8% between 140-138mAOD, and then some more sandy horizons averaging R_f =1% between 133-130mAOD. The lower zone indicates significantly more variation with values of R_f varying from as low as 1% to as high as 9%.

After reviewing the scatter in these results it is suggested that the big variation in R_f results within the deposit can be mainly explained by lithological variations within the marl.

2.3 Discussion of CPTU results

Findings from CPTU tests regarding the delineation of the interface between the made ground and the mudstone for this site are in line with historical facts and previous experiences from investigations of backfilled opencast 'marl holes'.
Figure 6. Friction Ratio (Rf) variation.

982

Among 52 tests carried out in total, only a few tests were refused at shallow depths, due to obstacles encountered in the first meters of backfilled material. 42 CPTU tests penetrated through the mudstone, 18 of which with a penetration of more than 2m into this material, which allowed us to review the results and the findings of this paper were crucial for the ground model and foundation design. Etruria Formation, interpreted as mudstone behaves as very stiff fine grained material, plotting in zone 9 in Robertson 1990 SBT when $q_c > 5.5$ MPa and $f_s > 250$ kPa and as sand to clayey sand when $q_c > 15$ MPa and $f_s > 500$ kPa, plotting in zone 8.

Porewater pressure can be another important measured parameter to interpret Mudstone, due to the sudden drop in the interface with made ground and large suction developed as the penetration continues. Another important indication of the penetration in mudstone is the inclination in both directions, which becomes uniform soon after the start of penetration through this deposit.

Figure 7. Marl Hole Contour Profile 2D.

3 GROUND MODEL

The ground model for this site was developed based on CPTU results that had penetrated into the natural strata beneath the made ground.

For some tests where sensible assessment of this rockhead boundary was unclear, or the CPTU test appeared to have deviated or refused on an obstruction within the made ground, a repeat test was carried out.

Based on the CPTU results a model of the pit was constructed using the contouring package Surfer. Surfer interpolates irregularly spaced XYZ data into a regularly spaced grid. The grid data can then be interpreted using gridding and mapping modelling tools to produce 2D or 3D maps such as contour, shaded relief and surface maps. In addition, calculations such as bilinear interpolation can be carried out where the Z value at the XY location can be calculated from the nearest four grid nodes. In Figures 7 and 8 the marl hole contour profiles is shown, including the pile positions, shown in red.

The initial Surfer plots in Figures 7 and 8 provide a profile of the western high wall of the marl hole. This model was used to check that installed piles have a suitable penetration into the natural strata.

In reviewing the updated ground model, the data shows that rockhead occurs at 144-143mAOD along the western boundary of the site. There is a fairly shallow gradient towards the east until typical rockhead falls to 141-140mAOD. Thereafter the plot shows a steeper incline representing the western edge of the marl hole. Rockhead falls to about 123-122mAOD and then thereafter the gradient is more gradual towards the eastern site boundary.

Nearer the eastern site boundary rockhead levels are typically 120mAOD although with some further reduced levels. Reviewing the steeper part of the
Figure 8. Marl Hole Contour Profile 3D.

western edge of the marl pit the average gradient appears to be about 50 degrees although locally this is indicated as increasing to almost 65 degrees. These back analysed gradients are comparable with those previously indicated for marl pits in the area.

From the results of the CPTU tests a suitable ground model showing the profile of the made ground/bedrock interface across the site has been established in relation to the proposed pile locations. The CPTU testing has provided data which indicates a good profile for the interface, and which looks reasonable when comparing all the available information. Where CPTU results looked anomalous, they have been discounted.

In reviewing and analysing the CPTU data, at least 1-2m bedrock penetration was typically considered sufficient to provide confidence that the probe attained a suitable penetration into the natural material.

This surfer ground model has been used to review the toe depths of the installed piles against the interpolated mudstone levels. It may be noted that the

surfer ground model has been considered as more reliable than particular pile driving records.

4 FOUNDATIONS

The foundation proposal was to adopt top driven tubular steel piles with a 178mm diameter tubular steel section considered. The driving system employed was using a 5.5 tonne hammer. It may also be noted, based on experience, that it was expected that the proposed newly installed piles would achieve a penetration at least comparable to the CPTU tests.

From the piling works a typical penetration of approximately 3 to 4m into natural strata was achieved. This was considered appropriate as it is anticipated that for the proposed piles, using an efficient energy input, a greater penetration compared to the CPTU tests, should be achieved.

As noted in monitoring the installation data all piles used within the foundation system showed reasonable penetration into the mudstone. Only one pile indicated an anomaly, taken as possible deviation, and which was subsequently replaced.

5 CONCLUSIONS

CPTU tests were used to provide a cost effective method to profile and establish a ground model for the backfilled opencast marl hole in Stoke on Trent. There was an initial concern on using CPTU to get to depths due to equipment limitations to penetrate through hard strata and rocks.

At the end of the site investigation program, CPTUs provided effective information for the ground model, which allowed a suitable piling solution to be installed for the site.

From reviewing 42 CPTUs, it may be suggested that Robertson 1990 normalized SBT chart is a good classification method to interpret the mudstone in an accurate way. It provides more consistent results, indicating the behaviour of the deposit as overconsolidated cemented weak rock, plotting data points for this deposit in soil zones 8-9.

Possible inconsistencies in CPTU based classification should be attributed to physical complexity, which may affect the overall behaviour of the deposit especially in the upper zone, where some soils show a more clay-like behaviour and some others a more sand-like behaviour.

Consolidation settlement prediction using cone penetration testing

M. Kermani
Golder Associates Ltd., Montreal, Canada

F. Esford
Golder Associates Ltd., Vancouver, Canada

ABSTRACT: A reduction in the local groundwater table surrounding a mine, in the Abitibi-Témiscamingue region of Quebec, Canada, has led to dissipation of porewater pressure and displacement of the ground surface. The mechanical behavior of the site's fine-grained soil has been studied in the laboratory (consolidation tests) and in-situ tests, particularly cone penetration tests (CPT). Additionally, displacements of the ground surface have been monitored for over 10 years. The consolidation settlements due to the groundwater table drawdown were calculated based on tip resistance values measured during the CPT. By comparing the calculated magnitudes and trends of vertical displacement with measured values, the consolidation calculation method using CPT data was validated. At some locations, there was a good match between the calculated and measured trends. At other survey monuments, the measured displacements were greater than calculated values. It was concluded that additional mechanisms were contributing to the displacements. The possible influence of these mechanisms varies spatially within the studied site.

1 INTRODUCTION

1.1 Problem statement

The studied area is a mine site in the Abitibi-Témiscamingue region of Quebec, Canada. During mine production, conditions both underground and on surface of the mine began to change. The groundwater level declined and inflows to the underground workings increased.

Subsequently, investigations were carried out to understand the conditions and mechanisms associated with the ground surface movements.

As mining progresses, the owner continues to monitor the area, including measuring: surface displacements, bedrock deformations, elevation of the phreatic surface (through monitoring wells, vibrating wire piezometers, and CPT dissipation tests.), water infiltration into the underground workings, blast monitoring, and micro-seismic activity. Data is regularly reviewed and potential interactions between mining activities and site conditions are assessed by a multidisciplinary team.

For the sake of this study, samples, in-situ test data, and displacement monitoring data recorded at fixed survey monuments have been provided by Agnico Eagle Mines Limited (AEM).

1.2 Objectives

This paper makes use of the gathered data during the past 10 years, particularly the in-situ testing and displacement monitoring to assess and estimate the consolidation settlements. Using cone penetration testing data, the validity of the Fellenius (2011) method for estimation of the tangent modulus based on CPT tip resistance values, and the Janbu (1967) method for estimation of consolidation settlements for the studied site are evaluated. To estimate the initial and final vertical effective stresses, the porewater pressure before drawdown and actual porewater pressure were considered. The vertical and lateral coefficients of consolidation were estimated from laboratory oedometer tests and in-situ CPT dissipation tests. Then by using Terzaghi's one-dimensional consolidation theory, settlement versus time plots were generated. For locations where it was estimated that primary consolidation was achieved by 95%, secondary compression settlements were also added to the settlement prediction time plots. Note that in this article all stresses are effective stress, unless otherwise noted.

1.3 Studied site's stratigraphy

The studied site is in the Abitibi-Témiscamingue region of Quebec province in Canada. The stratigraphic profile generally consists of (from top to bottom):

– A desiccated layer of firm to stiff, brown, clay or silty clay, typically 2 m in thickness. The desiccated layer is associated with the annual

fluctuation in the phreatic level and freeze-thaw cycles.

- A soft to firm, sensitive, grey, lacustrine (Lake Barlow-Ojibway clay), varved silty-clay to clay, of low to high plasticity, with a water content close to or above the liquid limit. Varves of silty clay to clay are reported to vary between 2 and 20 mm thick and silt between 1 and 15 mm thick. The undrained shear strength typically varies from 14 to 45 kPa, and sensitivity varies from 5 to 40. The clay is primarily saturated. It can reach thicknesses up to 30 m.
- A cohesionless, grey, silt and/or sand layer or mixture of silty sand or sandy silt, with occasional cobbles. The thickness varies from 2 to 25 m. The silt/sand was initially reported as loose to compact and saturated however, due to the reduction of the groundwater level, the majority of the silt/sand layer in the vicinity of the mine is now unsaturated. As a result, the compactness of this material has increased. It is now reported to be compact to dense at depth.
- A compact to very dense till unit that is variable in composition is discontinuously present. In general, the till is well graded and composed of sand and gravel, some silt and some clay, and occasional cobbles and boulders.
- Bedrock.

2 METHODOLOGY

2.1 Field observations

The field observation data on the displacements include survey monuments and inclinometers. As most of the survey monuments were installed after the onset of displacements, they have not captured the complete deformation history. Therefore, data from the satellite imagery analysis (InSAR) at the location of each survey monument was also used to supplement the measurements. Figure 1 shows an example of how the displacement from satellite (PALSAR and TSX satellite data) measurements has been added to survey monument data to estimate the total displacement since the onset of movements. Conversely, when both sets of data were available, the surface measurements were used to verify the precision of the satellite data. Note the satellite displacement data is measured along the line of sight. The PALSAR data had a grid size pixel spacing of 15 m and TSX had a 6 m spacing.

2.2 Janbu (1967) tangent modulus method

The tangent modulus method was developed by Janbu in the 1960's upon the assumption that the soil modulus of material can be estimated by dividing stress by strain. The modulus decreases as the stress increases. Janbu proposed an empirical equation for the change in modulus with the stress level.

$$M_t = m\sigma_r(\sigma/\sigma_r)^{1-\alpha} \qquad (1)$$

where: M_t = tangent modulus; σ_r = reference stress; σ = effective stress in the direction of strain; m = modulus number; α = dimensionless stress exponent. Both m and α depend on the material type and can be obtained from laboratory tests on high quality samples or in-situ tests (CPT in this study).
Figure 1. Vertical displacement data from surveying combined with satellite data at a specific location.

This approach has been used to calculate the magnitude of future, primary consolidation settlements (after the date each CPT was pushed). These CPTs were generally pushed after partial or full drawdown of the water table had occurred, which in turn altered the initial in-situ conditions. Therefore, this approach was found to be of interest because it considers the soil conditions, as well as porewater pressure at the time the CPT was pushed and allows estimating the settlements going forward with a higher precision.

Two different equations are derived from Janbu (1967) method, one for the fine-grained material, and one for granular materials. The settlement of the clay layer is calculated according to the following equation:

$$\varepsilon = \frac{1}{m_r} ln\frac{\sigma_p}{\sigma_0} + \frac{1}{m} ln\frac{\sigma_1}{\sigma_p} \qquad (2)$$

and the settlement of the silt and sand layer are calculated according to the following equation:

$$\varepsilon = \frac{1}{5m_r}\left(\sqrt{\sigma_p} - \sqrt{\sigma_0}\right) + \frac{1}{5m}\left(\sqrt{\sigma_1} - \sqrt{\sigma_p}\right) \qquad (3)$$

Where: ε = strain induced by an increase in effective stress; m_r = recompression modulus number; m = modulus number; σ_0 = initial effective stress (kPa);

σ_1 = final effective stress (kPa), and σ_p= preconsolidation stress (kPa).

In order to obtain an upper bound for the settlements, a simplifying assumption was made that the soil was in a normally consolidated state (OCR=1). By this assumption, the modulus number m remains the only compressibility material property to estimate the consolidation settlement. As explained in the next section, Fellenius (2011) has proposed an empirical equation that correlates the modulus number to the CPT tip resistance.

2.3 Fellenius (2011) method

Fellenius (2011) suggests the following equation for the estimation of the modulus number based on basic CPT data:

$$m = a \left[\left(\frac{q_t}{(\sigma_r \sigma_v)^{0.5}} \right) \left(\frac{3}{1 + 2K_0} \right)^{0.5} \right]^{0.5} \quad (4)$$

where: a = empirical modulus modifier which depends on soil type; q_t = unadjusted cone resistance (but corrected for pore pressure); σ_v = the vertical effective stress; σ_r = the reference stress, here 100 kPa; and K_0 = the coefficient of lateral earth pressure at rest. The term $3/(1 + 2K_0)$ varies between 1.2 and 1 for a soil with K_0 between 0.5 and 1. This term was assumed to be unity, which provides conservative values for the modulus number.

The modulus modifier, "a" was estimated based on the Soil Behaviour Type (SBT) determined from the CPT data (Table 1).

Table 1. Modulus modifier values based on SBT (from Massarsch et al.,1997).

Figure 2 schematically shows the state of stresses in the clay unit at the location of a given CPT. The total and effective stresses at the moment the CPT was pushed are shown in the figure. The soil unit weight was estimated using Shelby tube samples, as well as interpretation of CPT data. The pore pressure at the moment the CPT was pushed needs to be considered for the calculation of the actual effective stress. CPT dissipation tests provided reliable values for the calculations. If the difference between

saturated and wet unit weights are neglected, the final effective stress after dissipation of pore pressure would equal the current total stress (the red dashed line). For each CPT, the red curve showing the preconsolidation pressure was found using CPT data. The preconsolidation pressure was calculated for each 10 cm increment of the soil using the following correlation:

$$\sigma'_p = (q_t - \sigma_{v0})/N_{\sigma t} \quad (5)$$

where σ_{v0} is the vertical total stress and the parameter $N_{\sigma t}$ is assumed to be 3.4 for Eastern Canada clays (Demers and Leroueil, 2002). Then the values were validated by laboratory oedometer tests and field vane tests (FVT). Equation 6 was used to estimate the preconsolidation pressure from the FVTs (Mesri, 1988).

$$S_{u(mob)} = 0.22\sigma'_p \quad (6)$$

where $S_{u(mob)}$ is the undrained shear strength mobilized on the failure surface in the field. According to Bjerrum (1973), the shear strength from FVT is close to $S_{u(mob)}$ for clays with plasticity indexes close to 20%, which is the case for the studied site.
Figure 2. Schematic of the state of stresses considered for consolidation calculations.

The consolidation settlement is a function of the difference between the actual and final effective stress (the difference between the green line and red dashed line. For the zone between the actual effective stress and the preconsolidation pressure, the calculations were done using the recompression modulus m_r (indicated by the grey arrows), and for the zone

987

between preconsolidation pressure line and final effective stress, the modulus number was used, as presented in equation 1 (indicated by the orange arrows).

2.4 *Distribution of settlement through time*

As explained in the previous sections, the magnitudes of settlements were calculated using the Janbu (1967) and Fellenius (2011) methods. To estimate the distribution of the calculated settlement through time, the rate of consolidation needed to be considered. The rate of consolidation was calculated according to Terzaghi's well-known one-dimensional consolidation theory. The time factor T_v was calculated from the below equation:

$$T_v = \frac{c_v t}{H_{dr}^2} \qquad (7)$$

where t is the time to obtain a certain degree of consolidation, H_{dr} is the length of the longest drainage path, and c_v is the vertical coefficient of consolidation. The consolidation ratio U (%) was calculated using empirical equations (Holtz et al., 2011) as a function of T_v.

Considering the varved nature of the clay, the coefficient of consolidation in the horizontal direction is clearly higher than the vertical direction. In order to adopt a representative coefficient of consolidation for clay, both laboratory oedometer tests and CPT dissipation tests were considered. A slower rate, c_v =13.6 m²/yr, was determined from average vertical coefficients of consolidation from several laboratory oedometer tests. A faster rate, c_v = 63.1 m²/yr, was adopted from average radial coefficients of consolidation based on the interpretation of CPT dissipation tests. Plotting the estimated settlements versus measured displacement during 10 years of monitoring showed that the slower rate provided a better match with the measurements. This is coherent with the mechanism of consolidation in the site, which is ground water table drawdown and the downward drainage of water. If the consolidation calculation method presented in this article is to be used for other sites, the consolidation mechanism and the direction of drainage needs to be considered. For instance, if wicked drains are installed, radial coefficient of consolidation could be more representative of site conditions.

2.5 *Secondary compression*

Where the consolidation was estimated to have been complete by 95%, the secondary compression settlements were also added to the consolidation settlements, using the conventional method:

$$S = \frac{C_\alpha}{1 + e_{0p}} L_0 log \frac{t}{t_p} \qquad (8)$$

where S is the magnitude of secondary compression, C_α is the secondary compression index, L_0 is the initial thickness of the consolidating layer, t_p is the duration of the primary consolidation stage, e_{0p} is the void ratio at the beginning of secondary compression, and t is the time interval of interest that begins from the start of consolidation. C_α was estimated using one-dimensional laboratory consolidation test results on high-quality large diameter samples carefully collected from the same geologic formation at another site in the region.

The determination of the beginning of secondary compression has always been controversial among geotechnical engineers. When calculating secondary compression settlement during a specific period of time (between times t_1 and t_2), when the secondary compression has started before t_1, the following equation can be derived from equation 8:

$$S_2 - S_1 = \frac{C_\alpha}{1 + e_{0p}} L_0 log \frac{t_2}{t_1} \qquad (9)$$

Therefore, the time of the beginning of secondary compression does not influence the results.

3 RESULTS

Figure 3a shows the initial and final effective vertical stresses along with the preconsolidation pressures for each 10 cm soil increment. The preconsolidation pressures from CPT were validated with laboratory oedometer test, as well as field vane tests (FVT). There is generally a good agreement between CPT, FVT and oedometer test results. At depths between 6 m and 9 m, FVT tends to overestimate the σ'_p, possibly because of higher plasticity of clay in these depths. To carry out the consolidation calculations, the preconsolidation pressure from CPT data was used.

As shown in equations 2 and 3 and Figure 2, the compression of clay is a function of the effective stress change from the preconsolidation pressure to the final effective stress, and the modulus number. Figure 3b shows the modulus numbers calculated using equation 4 based on the CPT data for each 10 cm of soil increment. An advantage of the consolidation settlement calculation method presented in this article is that at each elevation a specific soil modulus is considered and the variability throughout the soil column is taken into account. A step change is observed in the calculated modulus numbers at depth 11 m. This is because the SBT changes from 3 to 1 at this depth, meaning that the soil becomes more plastic, and the modulus modifier, a, changes from 5 to 3 (see Table 1).

Considering the equation 2 and relating the modulus number to the conventional consolidation test parameters, the modulus number can be estimated directly form oedometer test results using the following equation:

$$m = ln10\frac{(1+e_0)}{C_c} \qquad (10)$$

where C_c is the compression index and e_0 is the initial void ratio. The modulus numbers estimated based on consolidation test results are shown along with the values from CPT tests (Fellenius 2011 equation) in Figure 3b. The laboratory modulus numbers are slightly greater than CPT values. But there is generally a good match between field and laboratory values. Note that for the consolidation calculations, Fellenius (2011) was used to estimate the compression modulus m in clay. The recompression modulus number m_r in clay, as well as both moduli for silt/sand units were estimated based on laboratory consolidation tests.

Figure 3c shows the cumulative ultimate settlement calculated for each depth. As expected, the majority of settlements occur at the depths where the clay pre-consolidation pressure is close to the current effective stress (6 m to 20 m). Additionally, it can be observed that greater settlements are calculated between depths 11 m and 20 m, where the modulus numbers are smaller compared to depths 6 m to 11 m.

Figure 4 shows the consolidation calculation vs. time for two of the studied CPTs from the date each CPT was pushed, along with the measured vertical displacement at a nearby survey monument. The survey monument readings show some variations due to freeze-thaw cycles but minimum values (fall readings) show the vertical displacement trend and magnitude.

The consolidation calculations estimate the settlements, from the moment the CPT was pushed and considers the geotechnical properties of the encountered soil at the time of the test. For each CPT the settlement vs. time predictions are presented with two different consolidation rates (faster and slower) considering two different coefficients of consolidation, as explained in section 2.4.

The 2011 CPT with the slower rate has captured the general trend of the settlements from the test date. However, the measured total ground displacement has exceeded the calculated total settlement. The higher c_v (from CPT) appears to overestimate the rate of consolidation. The consolidation calculations are carried out for the 2017 CPT with the updated pore water pressure regime, and soil geotechnical characteristics at the time the cone was pushed. It appears that the 2017 CPT data has captured well the ground displacements for the years following the test. The 2017 CPT was located closer to the survey monument (15 m vs. 25 m for the 2011 CPT). The fact that the 2011 CPT provided results which deviated from the measured values could be attributed to the spatial variability of the stratigraphy. Note that for this location, based on the dissipation tests, the 95% primary consolidation has not been attained. Therefore, the secondary compression settlements are not considered.

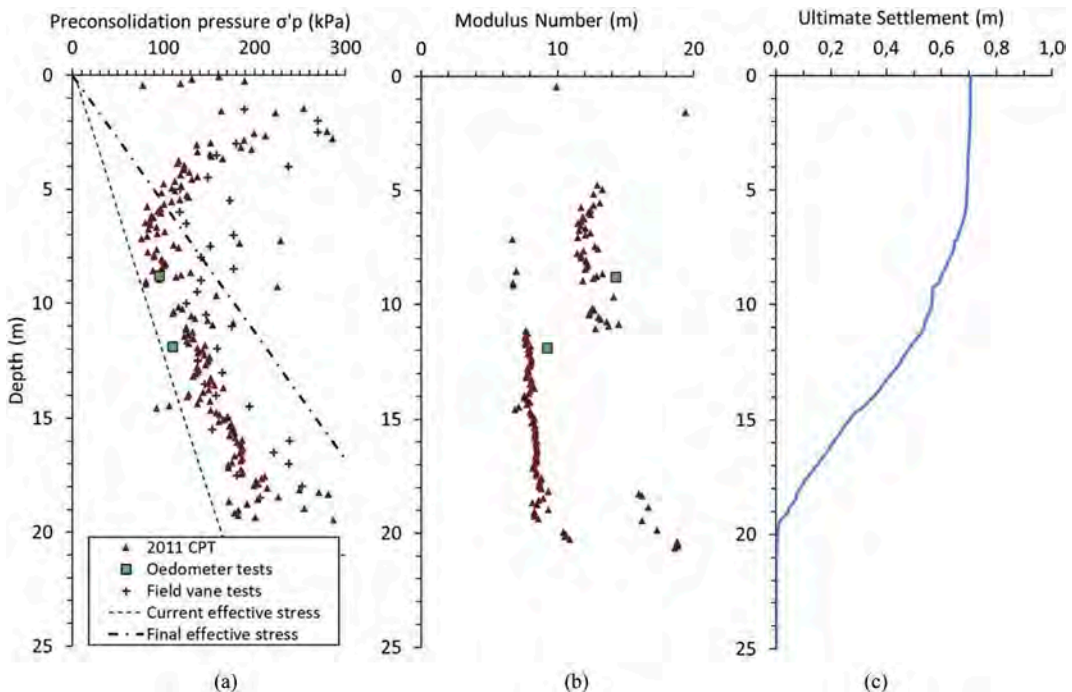
The mismatch between measured and predicted settlements was observed for some monuments. The


Figure 3. Example of calculation of a) initial and final state of stresses, b) modulus number, and c) ultimate settlement.

discrepancy was concluded to be associated with, but not limited to factors such as the following:

Stratigraphic variation: The CPTs were sometimes up to 50 m away from the reference survey monument. Several drilling and site investigation programs on the site have shown that the stratigraphy is highly variable. So, the stratigraphy encountered in the CPT may not necessarily be the same as the subsurface layers below the survey monument.

Further phreatic surface drawdown: The overall ground water table at the site was assumed to remain constant from the moment the study was carried out. Any additional drawdown of the water table (in the partially drained areas) could increase the estimated settlements.

Lateral movements: Lateral movements could contribute to the vertical displacements by reducing the soil confinement.

Development of suction in soil: It was assumed in this study that the final porewater pressure in elevations above the phreatic surface will become zero. Soil-Water Characteristic Curve testing indicated that most of the clay layer will remain in a saturated state in long-term. However, considering that the phreatic surface is below the bottom of the clay layer, it is possible that negative pore pressures (suction) develop in clay, which would increase the final effective stresses beyond the estimated values (higher than the actual total stress). Higher final effective stress would lead to greater deformations in clay, than what is calculated considering a zero final porewater pressure. The installation of vibrating wire piezometers in clay would allow estimating the vertical effective stress with more precision.
Figure 4. Example of measured and predicted settlement vs. time plots.

4 CONCLUSIONS

In this article, a consolidation settlement calculation method using CPT data was presented. A case study of a site where a decline in the phreatic surface has led to consolidation settlements was presented. The results showed that the method can capture the consolidation settlement-time curves. A discussion is presented on the reasons why for some survey monuments, the match between measured and predicted settlements was less accurate.

This method can be used to create a contour map of the predicted consolidation settlements for a site with low stratigraphic variability. It is recommended to space out the CPTs to cover the zone of interest, and to carry out more CPTs close to the sensitive structures to obtain more reliable data. A combination of CPTs and traditional boreholes is recommended to collect high quality samples for laboratory testing to validate the calculations parameters. As CPTs can be carried out faster and at a lower cost, they should be used to capture the variability in site stratigraphy.

It should be noted that the studied case is different from conventional consolidation problems where adding a load forces the porewater out of the soil matrix and leads to an increase in the effective stress. In the studied case, the increase in effective stress is caused by a decline in groundwater table. Therefore, as the groundwater table is below the bottom of the clay layer, negative porewater pressure (suction) could be generated in the clay which may lead to greater effective stress and larger deformations. This aspect is presently being evaluated by measuring potential suction in fine-grained soil layers on the site.

Department of Civil, Structural & Environmental Engineering, Trinity College Dublin, Dublin, Ireland

ABSTRACT: This paper aims to offer novel correlation between all 4 components of PISA soil reaction curves for monopile modelling and Cone Penetration Testing (CPT) data. This approach requires minimum user inputs and offers a consistent approach to develop site-specific soil reaction curves when CPT data are made available. The procedure developed by Igoe and Jalilvand was used to derive small-strain hardening (HS-small) soil model parameters from a range of CPT profile. HS-small parameters are then used to model the monopile response to static lateral loading in sand using Plaxis 3D. This procedure has been validated by the authors against a database of large-scale field tests including PISA tests in the Dunkirk marine sand. Soil reaction curves were directly extracted from the Plaxis models then applied into Timoshenko beam elements to match the 3D FE response and validated the extraction process. It is demonstrated that current CPT based correlations do not match the shape nor the ultimate reaction of 3D FE extracted soil reaction curves. It is also shown that all four components of soil reactions are required to accurately model monopiles which are short and rigid.

1 INTRODUCTION

1.1 Context

Monopiles are the main foundation type supporting about 80% of the installed offshore wind turbines to date in Europe (Wind Europe, 2020). The traditional industry design approach for monopile was adopted from the oil and gas industry. The 'p-y' approach recommended in the main design standards (API 2011, DNV 2013) was validated against a rather small database of long slender piles with diameter smaller than 1 m. On the contrary, monopiles are now designed with a low slenderness ratio (L/D ≈ 3) and a large diameter up to 10 m. Since 2014, it is warned that the API approach has "not been calibrated for monopiles with larger diameters and are in general not valid for such monopiles" (DNV 2014).

The recently completed PISA project was developed with the aim of improving on the traditional API design approach for monopile. In the PISA design model, pile-soil interactions are not limited to the distributed lateral reaction (p-y curves) but also include distributed moment, base shear and base moment (Burd et al. 2020). The PISA framework has now been implemented into the commercial software PLAXIS Monopile Designer (formerly MoDeTo) and is being commonly used in the industry (Minga and Burd 2019). It offers the option to extract site-specific soil reaction curves from 3D finite element models. However, this can be seen as computationally costly and requires careful calibration of the 3DFE soil input parameters.

Soil strength and stiffness parameters are often determined using correlations with Cone Resistance Testing (CPT) results, and therefore researchers have been looking at correlating soil reaction curves with CPT directly. Broms (1964) originally proposed relationship between ultimate lateral reaction, p_u, as a function of the cone resistance, q_c, in silica sands as per equation (1) where D is the pile diameter, p' is the mean effective stress and p_a is a reference stress taken as 100 kPa.

$$\frac{p_u}{D} = 0.1959 \cdot \left(\frac{q_c}{p_a}\right)^{0.4719} \cdot \left(\frac{p'}{p_a}\right)^{-0.6281} \quad (1)$$

Suryasentana and Lehane (2014) developed new p-y formulations for piles in sand based entirely on 3D finite element modelling, as opposed to back analysis of small scale instrumented laterally loaded pile tests as was the traditional approach. Equation (2) below has been calibrated against FE models using the hardening soil model (HS) in Plaxis 3D

foundation and validated against lateral pile field tests with diameters of about 0.6 m and pile penetrations of 17 m (L/D > 28). γ denotes the soil unit weight and Z the depth at which the soil reaction is calculated.

$$\frac{p_u}{D} = 2.4 \cdot \gamma \cdot Z \cdot \left(\frac{q_c}{\gamma \cdot Z}\right)^{0.67} \left(\frac{Z}{D}\right)^{0.75} \quad (2)$$

However, these CPT based correlations are not compatible with the PISA framework and, as only the p-y response is considered, they might not be suitable for modelling monopiles (similarly to API).

1.2 *Proposed approach*

It is proposed here (see Figure 1) to use 3D finite element modelling to derive CPT based correlations of soil reaction curves including distributed lateral reaction, distributed moment, base shear and base moment (as per PISA framework).

Soil parameters required as inputs for the 3D FE are directly derived from CPT profiles as per the approach proposed by Igoe and Jalilvand (2020). This approach requires minimum user inputs and has been validated against a database of lateral pile field tests including PISA tests in the Dunkirk marine sand.

All components of soil reaction are extracted from the 3D FE models for a range of pile geometries and CPT profiles. CPT based correlations are calibrated from this database of soil reaction curves and by matching the 3D FE and 1D FE mudline responses.

The approach is then validated against large scale pile field tests (the same database used by Igoe and Jalilvand 2020).
Figure 1. Flowchart of the proposed approach.

2 PLAXIS 3D FINITE ELEMENT MODELLING

This section presents how the 3D finite element models are set up in PLAXIS 3D and how results are being post-processed.

2.1 *Model set up*

Monopiles are modelled at full scale and half space using the commercially available finite element package PLAXIS 3D (see Figure 2). They are modelled with linear elastic plate elements with Young's modulus of 210 GPa and Poisson's ratio of 0.3. Since the lateral response is the main concern, the self-weight of the monopile is omitted. The piles are assumed wished in-place with no effect of the installation taken into account.

This study is limited to monopile modelling in sand. The hardening soil model with small-strain stiffness (HS-small) is an improvement of the HS model used by Suryasentana and Lehane (2014). It has been successfully used to accurately model monopile lateral response in sand (Igoe and Jalilvand 2020), and thus is considered here. Vertical interfaces are added between the pile shaft and the soil to allow for differential displacements, to introduce an interface strength reduction factor (set to 0.7 here) and to allow extraction of soil distributed reactions (distributed lateral load and distributed moment). At pile toe, an additional horizontal interface is added to allow for extraction of base reactions (base shear and base moment) but with no strength reduction considered.

The lateral loading as a result of wind and wave action is applied as a prescribed displacement at a height, e, above mudline. Burd et al. (2020) showed that there is negligible effect of the loading eccentricity on soil reaction curves. Hence the value of e is taken as 60 m (a mean value to represent both wave and wind dominated scenarios). The lateral loading is applied in the y direction. The size of the domain is taken as 12D in the direction of loading and 4D in the perpendicular direction as recommended in the PLAXIS Monopile Designer manual (Panagoulias et al. 2021), where D is the monopile diameter. The depth of the model is here set to 80 m with 16 soil layers of 5 m thickness each. This is to ensure the soil domain is large enough to avoid boundary effects.
Figure 2. Description of the monopile model in Plaxis 3D.

2.2 Soil parameters

Igoe and Jalilvand (2020) developed an approach to derive all of the required HS-small input parameters using widely used CPT correlations. All correlations used are summarised in Table 1. The approach has been validated against a database of large scale field tests including PISA tests in the Dunkirk marine sand and offers better predictive accuracy metrics than correlations suggested for the Plaxis Monopile Designer (Panagoulias et al. 2021).

By re-arranging the correlations presented in Table 1, synthetic CPT profiles for constant sand relative density are generated. Relative densities of 30% (loose), 50% (medium dense), 70% (dense) and 90% (very dense) are considered. At this stage, only normally consolidated state is considered with OCR set to 1. A constant ratio sleeve friction to cone resistance, f_s/q_c, of 1% is assumed. The constant volume friction angle is taken as 32 degrees for all profiles. The soil unit weight is taken ranging from 17 kN/m^3 to 20 kN/m^3 depending (linearly) on relative density. Finally, the small strain shear modulus profiles are estimated from the cone resistance with α set to 185 as recommended by Igoe & Jalilvand (2021).

Table 1. Correlations used by Igoe & Jalilvand (2021).

$K_0 = (1 - \sin\varphi') \times OCR^{\sin\varphi'}$	Mayne & Kulhawy (1982)

2.3 Monopile geometry

To allow for the calibration of the CPT based correlations, a range of monopile geometries is considered. Literature showed that there is negligible effect of the pile wall thickness and load eccentricity on the soil reaction curves so these are kept constant as t = D/110 and e = 60 m, respectively (representative values based on experience). Outside diameters (D) of 6 m, 8 m, 10 m and 12 m are considered. Slenderness ratios (L/D) of 2, 3, 4, 5 and 6 are considered. This results in pile embedded length (L) ranging from 12 m to 72 m. Hence a total of 20 geometries are considered for each soil profile covering recent, current and future design.

2.4 Soil reaction curves extraction

Unlike Suryasentana and Lehane (2014), soil reaction curves are not calculated from the derivative of shear and bending moment diagrams. The approach briefly presented in the PLAXIS Monopile Designer manual (Panagoulias et al. 2021) has been preferred as it allow for extraction of all components of the soil reaction.

Distributed lateral load and distributed moment are calculated from integration of the normal and tangential stresses acting on monopile shaft (vertical interface). Soil reactions are integrated along 1 m (ΔZ) intervals as shown on Figure 3 and as per equations (3) and (4). Resulting lateral forces, Fy, and vertical forces, Fz, are calculated at each of the 6 Gaussian stress points of each interface elements as per equations (5) and (6), respectively. Where σ_n, τ_1 and τ_2 are the stresses directly extracted from Plaxis, X and Y are the coordinates of the stress point, D is the pile diameter, A is the area of the interface element and w is the weight of the stress point (0.11 for stress points 1 to 3 and 0.22 for stress points 4 to 6).

$$p(Z) = \frac{\int_{Z-\Delta Z/2}^{Z+\Delta Z/2} F_y(z)dz}{\Delta Z} \quad (3)$$

$$dM(Z) = \frac{\int_{Z-\Delta Z/2}^{Z+\Delta Z/2} y \times F_z(z)dz}{\Delta Z} \quad (4)$$

$$F_y = wA\left(\frac{2Y}{D}\sigma_n - \frac{2X}{D}\tau_2\right) \quad (5)$$

$$F_z = wA\tau_1 \quad (6)$$

The base shear and base moments are calculated from the horizontal interface. This is not detailed here as the approach is very similar. All calculations are repeated for each load increment
Figure 3. Integration of distributed lateral reaction and distributed moment.

in order to build the full reaction curves. These are then saved in a formatted .csv file for later use.

3 PRELIMINARY RESULTS

With 4 relative densities considered and 20 monopile geometries for each soil profile, the database consists in 80 3D FE models. On average, it took 1 hour to set up, run and process each model on a relatively high capacity computer (Intel(R) Xeon(R) W-1270P CPU @ 3.80GHz, 32 GB DDR4). The computation times were greatly reduced thanks to the automation of most aspects of the PLAXIS modelling through the PYTHON scripting interface. The database has been recently completed and this section presents and discuss preliminary results obtained.

3.1 *Comparison 1D FE – 3D FE responses*

In order to make sure soil reaction curves are being correctly extracted from PLAXIS, 3D FE and 1D FE monopile response are compared.

For the sake of conciseness, only one model with pile diameter of 10 m, embedment length of 30 m in 70% relative density sand (case RD70%_D10L30) is presented in Figure 4 but all other models show similar results. Both load-displacement (top of the figure) and moment-rotation (bottom of the figure) curves compare relatively well when all reaction components are considered in the 1D FE model. However, when only p-y curves are being considered, the 1D FE response is found to be considerably softer than the 3D FE response. This is in agreement with findings from the PISA project (Byrne et al. 2015) and confirms the need of CPT based correlations including all components of pile-structure interactions and not limited to p-y curves only.

To add to this qualitative assessment, Table 2 compare initial stiffnesses, SLS rotations and ultimate capacities from 1D FE and 3D FE for the same
Figure 4. Comparison of 1D FE and 3D FE monopile lateral responses for case RD70%_D10L30.

model. The initial stiffness and ultimate capacity are defined at a mudline displacement of D/10000 and D/10, respectively. From experience, monopiles are subjected to strict serviceability requirements leading to low utilization in ULS GEO checks ($\approx 1/2$). When the load partial factor of ≈ 1.35 and material partial factor of 1.15 is considered, the SLS load is approximately defined as 1/3 of the ultimate capacity. One may consider that the 1D FE with p-y only may be considered overly conservative with underestimation of the initial stiffness and the ultimate capacity by 16.4% and 21.1%, respectively. The "SLS" rotation is overestimated by 47.7%. When adding other component of soil reactions to the 1D FE model, the match is much better with only a 4% underestimation of initial stiffness and ultimate capacity. The "SLS" rotation is only overestimated by 6.9%.

This quantitative assessment has been repeated for all 80 models. Only results pertaining to the estimation of ultimate capacity are presented in Figure 5 but the other two metrics show the same trend. For a typical slenderness ratio (L/D) of 3, the pile ultimate capacity is underestimated by more than 20% if only 'p-y' curves are used in 1D FE while the error is reduced to about 5% when all components are

Model	Initial Stiffness [MN/m]	SLS Rotation [deg]	Ultimate Capacity [MN]
3D FE	244.4	0.450	43.9
1D FE py only	204.2 (- 16.4 %)	0.664 (+ 47.7 %)	34.6 (- 21.1 %)
1D FE all curves	234.5 (- 4.0 %)	0.481 (+ 6.9 %)	42.1 (- 4.0 %)

considered. For any L/D, the error is always larger when considering p-y curves only which suggests the need for the other component of soil reaction (distrib-uted moment, base shear and base moment). For the p-y only scenario there is a clear trend for the errors to reduce when L/D increases. This is in agreement with the results of Byrne et al. (2015) and it explains why approaches validated for slender piles (API 2011, Broms 1964, Suryasentana and Lehane 2014) had satisfactory results for slender piles. However, for current monopile design with L/D of as low as 3, these approaches are no longer applicable.

It is not yet clear why the errors with all curves included tend to slightly increase with L/D. How-ever, the errors are deemed small enough (typically less than 5%) and the extracted soil reaction curves are deemed satisfactory.
Figure 5. Comparison of ultimate capacity relative errors.

3.2 *Comparison soil reaction curves*

For the same case (RD70%_D10L30), Figure 6 shows the distributed lateral reaction curves (p-y curve) at a depth of 4.5 m as extracted from the 3D FE model and calculated as per API (2011), PISA rule (Burd

et al. 2020) and Broms (1964). Input parameters required for API (friction angle) and PISA rule (rela-tive density) are calculated as per approach set out in Table 1. Broms (1964) approach is directly based on the synthetic CPT profiles presented in section 2.2.

Figure 6 Highlights the need to not only correctly match the ultimate reaction but also accurately describe the shape of the reaction curves. Broms (1964) overly simplify the problem by considering that the full reaction is mobilised at any displacement. In the API (2011), a hyperbolic tangent function is considered with the initial stiffness being a function of sand peak effective friction angle and depth. Although both approaches underestimate the ultimate capacity they will results in stiffer response in most practical cases (until a displacement of about 3% of pile diam-eter). On the contrary, the initial part of the PISA rule curve match relatively well with 3D FE. Although the ultimate capacity is underestimate again, they will results in similar response in most practical case.

In the PISA framework each of the reaction curves (distributed lateral reaction, distributed moment, base shear and base moment) are fitted with 4 parameters: the initial stiffness, the curvature, the ultimate reaction and the displacement at which the ultimate reaction is reached. This results in a total of 16 functions to correlate with CPT.
Figure 6. Comparison of distributed lateral reactions (p-y curves) at 4.5 m depth for case RD70%_D10L30.

4 ALTERNATIVE APPROACH

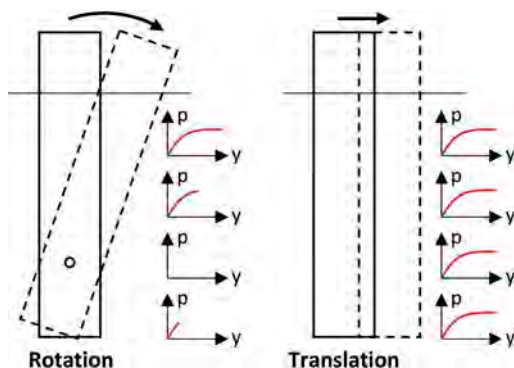
To date, no satisfactory CPT based correlations could be achieved due to a number of limitations with the current approaches. The main one (see sketch on Figure 7) is the lack of reaction close to pile point of rotation due to insufficient displacement. Although the pile is pushed until failure (mudline displacement larger than 10% of the pile diameter), the ultimate reactions are only reached for the top first 30%-40% of the pile length. No reaction at all is recorded close to point of rotation (at about 70% of pile length).


Figure 7. Limitation of the current rotation approach and proposed alternative approach.

An alternative approach is being considered where the pile would be laterally translated rather than rotated. This would allow for full mobilisation of reaction at any depth. Some components of the soil reaction may not be capture (distributed moment, base moment) and will still need to be extracted from the original models or correlated with the other component (distributed lateral reaction, base shear).

On-going works are focusing on comparing p-y curves extracted from both approaches to make sure they are comparable.

5 CONCLUSION

This paper presents a novel approach to derive CPT based correlation of soil reaction curves including distributed lateral reaction (p-y curves) but also distributed moment, base shear and base moment. This approach relies on finite element modelling in Plaxis 3D and the CPT based correlation of hardening soil model with small strain stiffness (HS-small) parameters developed by Igoe and Jalilvand (2020).

A total of 80 FE model are considered based on a range of pile geometry and synthetic CPT profiles for relative densities ranging from 30% (loose sand) to 90% (very dense sand).

All soil reaction curves are directly extracted from Plaxis 3D. Soil reactions are calculated from integration of stress at the pile-soil interface rather than derivation of pile shear force and bending moment profiles with depth. These are incorporated in a 1D FE solver and the obtained responses is compared with 3D FE to ensure the reaction curves are correctly extracted. Both initial stiffness, ultimate capacity and rotation under representative SLS loads are found to match well. By comparing the 1D FE responses when only p-y curves are considered, it is showed that existing approaches relying on p-y curves solely are not satisfactory for monopile modelling with slenderness ratio (L/D) of about 3.

Comparison of 3D FE extracted curves with existing approach shows that the ultimate distributed lateral soil reaction seems to be currently underestimated, but this may not necessarily translate into an under-estimation of the pile response depending on the curve stiffness (and the account of other soil reaction components).

Current work is focusing on the derivation of CPT based correlations for all soil reaction curves including distributed lateral load, distributed moment, base shear and base moment. However, no satisfactory results could be obtained so far.

It is being investigated if the current 3D modelling approach should be revised. The current approach involves rotation of the monopile around of point of rotation. There is no pile displacement close to the point of rotation and hence no soil reactions making most of the data extracted from the 3D FE models un-usable. An alternative approach is being considered where the pile is being laterally translated in order to record soil reaction along the whole length of the monopile rather than only the top 30%-40%.

CPT-based assessment of densification induced by stone column installation

UNIBO, Bologna, Italy

ABSTRACT: The use of CPTs for liquefaction susceptibility assessment has become increasingly common in design practice. In the past, the design of densification soil improvement methods against liquefaction has been commonly based on experience, large scale field tests and, possibly, validation after the intervention. Nevertheless, a design method to assess quantitatively the densification effect induced by stone column installation can be developed following a workflow based on CPTs, in order to estimate the efficiency of the soil improvement and to check the compliance with safety requirements before accessing the site. As by common practice, the assessment of liquefaction susceptibility is performed by means of CPT data and related empirical methods. The design method proposed in this paper is based on the estimation of modifications induced by the soil densification technique, easily detectable by the CPT profile, in order to carry out a liquefaction susceptibility analysis. The approach is applied in particular to a well-documented case study in Northern Italy (Bondeno, Ferrara province), providing a consistent dataset of piezocone tests carried out before and after soil treatment through stone columns, as part of a blast-induced liquefaction experiment. In this way, a clear comparison between pre- and post- intervention conditions along the CPT profiles with depth can be performed, thus allowing a validation of the design methodology.

1 INTRODUCTION

Among the ground improvement solutions available to mitigate the liquefaction hazard, densification is probably the most common and widespread. In particular, vibratory compaction methods are a common and effective form of densification for cohesionless soils (Castro 1969), as proven by extensive research (e.g. D'Apollonia 1954, Mitchell 1981, Baez 1995, Adalier and Elgamal 2004, Wissmann et al. 2015, Vautherin et al. 2017, Amoroso et al. 2018). In spite of its large application in the last decades, design methods to quantify and predict the efficiency of the improvement are not commonly reported in technical manuals.

Soil improvement has been mainly calibrated through real scale field tests; such type of tests presents, however, some issues to face. Real scale tests can be difficult to perform in a design phase, since often the executor of the treatment has not been chosen yet or the permission to operate in the area is not ready. Finally, real scale tests are expensive and need to be designed too.

In the following, a workflow will be described in order to obtain a prediction of the improvement efficiency. The proposed workflow is based on the CPT data. In fact, CPTs are cost effective site investigations and several simplified procedures for liquefaction

susceptibility assessment have been developed and validated in the last decades (e.g. Seed and Idriss 1971, Robertson and Wride 1998, Idriss and Boulanger 2008, Boulanger and Idriss 2014).

The results of the design workflow will be applied to the data coming from the field tests performed in connection with a full-scale controlled blast test in Bondeno (FE), Italy. A detailed geotechnical investigation of the site is presented by Amoroso et al. (in press).

2 THEORETICAL WORKFLOW

In case of real scale field test, common practice suggests following a number of steps:

1. performing investigations on the natural soil (CPT in the present study, PRE index will be used to address these data),
2. assessing liquefaction susceptibility on the data collected,
3. performing the soil improvement treatment,
4. performing new investigations (POST-M index will be used to address these data) in order to compare them with the pre-treatment ones,
5. assessing liquefaction susceptibility on the base of post-treatment data collected.

A soil improvement is recognized to be successful when the liquefaction susceptibility detected in the post-treatment phase in neglectable or tolerable.

The proposed workflow will follow the same steps. Point 4 will be done trying to predict a theoretical post-treatment CPT data (POST-P index will be used to address this data), modifying artificially the cone resistance q_c and sleeve friction f_s measurements, and finally assessing liquefaction susceptibility on the base of this predicted post-treatment test. In the following, the proposed procedure for the determination of the POST-P CPT parameters will be presented in detail.

With reference to the different CPT measurements ($q_{c,PRE}$, $f_{s,PRE}$), the cone resistance is assumed as the main parameter for the procedure. In particular the procedure will be applied to the normalized cone penetration resistance for clean sands, $Q_{tn,cs-PRE}$, defined as per Robertson & Wride (1998). The densification treatment in fact has its proper application on clean sands. Accordingly, it is then possible to back-calculate $q_{t,cs-PRE}$ and $q_{c,cs-PRE}$ from $Q_{tn,cs-PRE}$, according to the following relationships:

$$q_{t,cs,PRE} = \sigma_{v0} + p_a \frac{Q_{tn,cs,PRE}}{(p_a/\sigma'_{v0})^n} \qquad (1)$$

$$q_{c,cs,PRE} = q_{t,cs,PRE} - u \cdot (1 - a) \qquad (2)$$

where p_a = atmospheric pressure; σ_{v0} = vertical total stress; σ'_{v0} = vertical effective stress; u = pore pressure; a = cone area ratio.

Using the Jamiolkowsky et al. (2001) correlation, it is then possible to obtain the relative density ($D_{R,cs,PRE}$) and then the void ratio of the untreated soil ($e_{0,cs,PRE}$):

$$D_{R,cs,PRE} = \frac{1}{C_2} \cdot ln\left[\frac{q_{c,cs,PRE}/p_a}{C_0 \cdot (\sigma'_{v0}/p_a)^{C_1}} \right] \qquad (3)$$

$$e_{0,cs,PRE} = e_{max,cs} - D_{R,cs,PRE} \cdot (e_{max,cs} - e_{min,cs}) \qquad (4)$$

where C_0 = 17.68; C_1= 0.50; C_2 = 3.10 according to Jamiolkowsky et al. (2001) whereas $e_{max,cs}$ and $e_{min,cs}$ are assumed in this study equal to 1 and 0.4 respectively, in agreement with relevant ranges of the maximum and minimum void ratio shown by Cubrinovski & Ishihara (2002).

On the basis of the value assumed by the void ratio, it is possible to quantify the improvement induced by the densification treatment. In particular, the void ratio of the soil after treatment, $e_{0,cs,POST-P}$, can be inferred from a correlation originally proposed by Mitchell (1981) to predict sand compaction due to pile installation. Accordingly, $e_{0,cs,POST-P}$ is given by:

$$e_{0,cs,POST-P} = e_{0,cs,PRE} - A_r \cdot (1 + e_{0,cs,PRE}) \qquad (5)$$

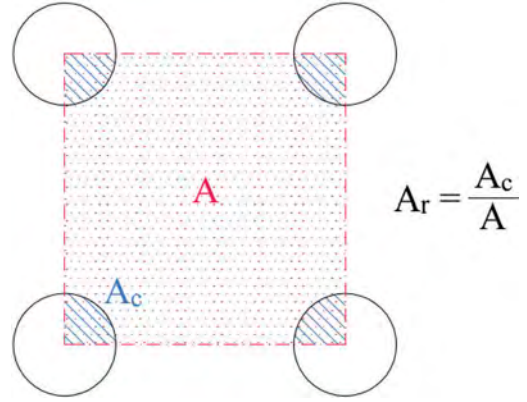
where A_r is the substitution ratio defined as the area of the treating element divided by the area of the treated mesh, as also explained in Figure 1. For the A_r values generally considered in practical applications, equation (5) results in values of $e_{0,cs,POST-P}$ within the range of values typically assumed by the void ratio.


Figure 1. Definition of the A_r parameter.

Based on the improved void ratio, the procedure can be applied backward, giving:

$$D_{R,cs,POST-P} = \frac{e_{max,cs} - e_{0,cs,POST-P}}{e_{max,cs} - e_{min,cs}} \qquad (6)$$

$$q_{c,cs,POST-P} = p_a \cdot C_o \cdot \left(\frac{\sigma'}{p_a}\right)^{C_1} \cdot e^{C_2 \cdot D_{R,cs,POST-P}} \qquad (7)$$

$$q_{t,cs,POST-P} = q_{c,cs,POST-P} + u \cdot (1 - a) \qquad (8)$$

By applying again equations (1) and (2), it is then possible to back-calculate $q_{t,POST-P}$ and $q_{c,POST-P}$. The procedure presented above only involves the parameters defined from cone penetration resistance, whereas the sleeve friction resistance has not been touched yet. A disconnected modification in one of these two parameters would lead to a change in the soil behavior type index (I_c), that is mainly related to the soil class. Assuming that the improvement will not change the soil type, $f_{s,POST-P}$ can be back calculated from the improved cone penetration resistance.

A new profile of the CPT can be then predicted ($q_{c,POST-P}$, $f_{s,POST-P}$). Ordinary procedures to assess liquefaction susceptibility can be performed on the new profile in order to evaluate the efficiency of the soil improvement treatment on a theoretical base.

An additional evaluation has to be performed to assess the suitability of soils for vibratory compaction,

since it is documented in literature that only soils with low fines content react properly to vibratory compaction (Massarsch, 1991).

3 VERIFICATION ON BLAST TEST DATA

Bondeno blast test site offered the occasion to verify if the theoretical framework gives a good prediction of the soil improvement efficiency. The site has been widely investigated in natural conditions, before treatment (Phase I), after the soil improvement (Phase II) and after the blast-induced shaking (Phase III). The soil improvement consisted of a number of 4 x 4 columns in quadrangular grid (2m center-to-center spacing) of Rammed Aggregate Piers (RAP) columns (Saftner et al., 2018), each 9.5m long and with a final diameter of 0.5m ($A_r \approx 5\%$) (Amoroso et al., in press).

Among the available cone penetration tests carried out in the test site, CPT01 performed in Phase I (also referred in the following to as CPT01_PRE) and CPT01bis performed in Phase II (also referred to as CPT01bis_POST-M) have been chosen to test the procedure described above.
Figure 2. Soil classification for assessment of deep compaction based on CPT (Massarsch, 1991).

In particular:

– CPT01 is the test performed before the soil improvement treatment ($q_{c,PRE}$);
– CPT01 will be modified following the workflow exposed in section 2 in order to predict the post-treatment cone resistance profile ($q_{c,POST-P}$);
– CPT01bis is the test carried out after the installation of the RAPs, providing the profile of the measured cone resistance ($q_{c,POST-M}$).

As reported in Amoroso et al. (in press), the Bondeno test site subsoil consists of a silty-clayey hard topsoil in the upper 3.5m, with an average plasticity index (PI) of 20%, followed by a non-plastic silty sand with fine content typically in the range 25-35% and therefore classified as SM.

Suitability for vibratory compaction of CPT01_PRE has been evaluated following Massarsch (1991); Figure 2 shows that the cone penetration data points, in terms of tip resistance q_c and friction ratio F_R (calculated as $100 \cdot q_c/f_s$), fall in the domain of compactable materials.

Figure 3 provides a comparison between CPT01 and CPT01bis, carried out at a distance of 1.5m. Profiles of q_t, soil behaviour type index I_c, relative density D_R, fine content F_C, Factor of Safety against liquefaction SF and Liquefaction Potential Index LPI are provided. The plot clearly shows where and how the soil improvement affected the degree of compaction of the natural soil, taking into account that RAP length was 9.5m.

Liquefaction analyses have been performed following the procedure suggested by Boulanger & Idriss (2014).

4 FINAL RESULTS

Following the theoretical workflow presented in section 2, data from CPT01_PRE test have been elaborated to produce a design prediction of the treated soil. The prediction will be referred to as CPT01_POST-P. A comparison between measured and predicted profiles is presented in Figure 4.

The comparison in terms of q_t shows a very good agreement from 5.5m to 8.0m in depth. In the lower part of the treatment (from 8.0m to 9.5m) the efficiency of the soil improvement seems to decrease; this can be related to the influence of the end depth of the treatment. Getting closer to the tip of the columns, the basic hypothesis of two-dimensional behavior in the horizontal plane, on which eq. (5) relies, can no longer be considered as strictly valid. Three-dimensional effects probably have some influence in the soil volume, causing a decrease in the densification effect.

In the range between 3.4m and 5.3m, the agreement is still quite good, although the predicted q_t profile shows values higher than those measured. The same comments apply to the values of D_R.

The evaluations related to liquefaction susceptibility, expressed in terms of SF and LPI, show similar trend, though the suggested workflow seems to slightly overestimate the efficiency of the soil improvement. Considering the result on LPI, the distribution along depth suggests the same differences discussed above. In particular, from 5.5m down to the end of the test the agreement between prediction and measured data is extremely good. More significant differences are observed in the range 3.4m - 5.3m depth. Results from comparison between CPT01_POST-P and
Figure 3. Comparison between pre-treatment (CPT01_PRE) and post-treatment (CPT01bis_POST-M) investigations.
Figure 4. Comparison between pre-treatment (CPT01_PRE) and post-treatment investigations, as measured in CPT01bis_POST-M and predicted in CPT01_POST-P.

Table 1. Numerical evaluation of predictions.

z m	Soil	q_t MPa	D_R %	SF
3.4-5.3	CPT01_PRE	6.39	56	0.66
	CPT01bis_POST-M	7.09 (+11%)	57 (+3%)	0.80 (+20%)
	CPT01bis_POST-P	9.65 (+51%)	69 (+24%)	1.59 (+139%)
5.8-8.0	CPT01_PRE	8.94	60	0.76
	CPT01bis_POST-M	12.33 (+38%)	69 (+15%)	1.85 (145%)
	CPT01bis_POST-P	13.45 (+50%)	73 (+22%)	2.76 (+264%)
3.4-9.5	CPT01_PRE	7.66	57	0.71
	CPT01bis_POST-M	9.86 (+29%)	63 (+11%)	1.36 (+91%)
	CPT01bis_POST-P	11.55 (+51%)	70 (+23%)	2.20 (+209%)

CPT01bis_POST-M, taking CPT01_PRE as reference, are summarized in Table 1. The percentage increment of q_t, D_R and SF after treatment is given in brackets.

5 CONCLUSIONS

The theoretical workflow proposed in this paper is a guideline for the quantification of soil improvement effectiveness in densification treatment against liquefaction. Following the procedure, it is possible to obtain a design prediction of the soil improvement based only on CPT data. This simple approach is very useful in a design phase where in situ tests are commonly available for liquefaction assessment, but it is hardly possible to carry out full-scale field tests.

The application of the workflow on a case-study in Bondeno (FE) allowed to evaluate the performance of the method by comparing predictions with verification tests. The overall result gives a good agreement in the lower liquefiable layer, though further analyses need to be performed in order to verify local differences with depth. In addition, only one CPT was available for the verification of the workflow, verifying the approach on other test couples performed in different sites with different soil conditions is needed.

The workflow seems to slightly overestimate the soil improvement beneficial effects. This can be related to a variety of factors. A general efficiency factor is a possible solution in order to take into account different aspects related to the installation method. The procedure would also need to be extended through the implementation of efficiency factors accounting for marginally compactable soils (with higher fine and/or plastic contents) and for the reduction of soil treatment efficiency approaching the treatment tip. It is in fact reasonable to consider

that, close to the column tip, the efficiency of the treatment will gradually decrease to zero, while in the method described in this paper the densification effect is solely quantified on the horizontal displacement of the soil.

Geopier Impact technology for liquefaction risk mitigation based on CPTu investigations

G. Martinez & K. Wissmann
Geopier Foundation Company, Davidson, USA

M. Franceschini, E. Bandiera & F. Fiorelli
Teleios Srl-Società di Ingegneria, Castel Maggiore, Bologna, Italy

ABSTRACT: The present paper is focused on the Impact Rammed Aggregate Pier system, a ground improvement technology developed by Geopier Foundation Company. From extensive in-situ tests also including blast tests, Impact elements have proven to be very effective at densifying in-situ granular soils and increasing the factor of safety against liquefaction. The intent of the paper is to verify the methods that are used to evaluate liquefaction mitigation with Impact piers. One method to evaluate the mitigation of liquefaction risk for design of Impact piers is to estimate the increase in CPT tip resistance q_c expected after installation of the Impact elements. In the paper we will consider CPTu tests performed before and after Impact installations in various sites worldwide to attempt to verify the accuracy of formulas from literature and to try to understand which aspects can be refined in future studies. The future aim is to possibly modify the formulas to account for local soil conditions in the Emilia-Romagna region in Italy.

1 INTRODUCTION

Among the various technologies for soil improvement, stone columns are a method extensively used all around the world with different technological variants.

In addition to their demonstrated capacity to increase soil resistance and to reduce foundation settlements against static loads, the increasing interest in soil improvement methods for geotechnical seismic engineering has led to an advance in the study of gravel columns for liquefaction mitigation purposes.

The proposed paper focuses on a specific type of gravel column, the Rammed Aggregate Pier (RAP) Impact technology developed by Geopier Foundation Company. The Impact technology is a displacement system that produces highly compacted gravel columns together with vibro-densification of the in-situ granular soils. Successfully used in several hundred sites worldwide, the Impact system has also proven to be very effective at densification and controlling liquefaction compared to other methods such as timber piles and reinforced gravel rafts (EQC, 2015).

Since predicting densification is a very useful tool for the design engineer when liquefaction mitigation is required, the authors recognize the importance of having reliable predictive correlations and having knowledge of which regions in the world these correlations may need to be modified for. The aim of the article is to present the state of the art of predictive methods for estimating densification based on Piezocone Penetration Tests (CPTu). One method available in literature will be presented and its reliability will be assessed by means of comparison with pre and post-installation CPTu tests performed in various sites around the world.

The future aim of the authors is to develop correlations specific to the local soil conditions in the Emilia-Romagna region in Italy, where the authors have already designed several projects for liquefaction mitigation.

2 RAMMED AGGREGATE PIER ELEMENTS

Rammed Aggregate Pier elements are a ground improvement technology developed over the last 25 years by Geopier Foundation Company. The RAP installation method creates a densified column of aggregate surrounded by a stiffened matrix soil, with the aim of providing settlement control and allowing for higher bearing capacities.

RAP installation methods can be classified as either "drill and fill", such as the GP3 system for non-caving soils, or "displacement" such as the Impact system.

2.1 Impact system

The advantage of the Impact system is that it allows for the construction of a Rammed Aggregate Pier element by displacement of the in-situ soil, aided by the use of a vibratory hammer.

The use of this technology is particularly suitable in the case of loose sand deposits below the groundwater table and for soils where it is not possible to carry out drilling without supporting the walls of the drilled cavities.

The mandrel consists of a steel tube with a specially designed compaction chamber at the tip for achieving high vertical compaction of the aggregate and, consequently, lateral expansion of the cavity. A sacrificial plate is typically used for the initial drive of the mandrel, after which the mandrel is filled with gravel to begin construction of the pier. The mandrel is subsequently raised by about 90 cm, allowing the aggregate to flow into the displaced cavity, and then lowered to compact the gravel, forming layers 30/35 cm thick. The achievable depths are typically up to 15 m, with constructed diameters ranging from 50 to 60 cm. The construction methodology has been described in detail by Majchrzak et al. (2010).
Figure 1. RAP Impact installation sequence.

The installation process is quick and clean (dry installation), and the displacement process produces minimal spoils. The end result of this construction method is a very stiff aggregate column, with the added benefit of densification of the surrounding sandy matrix soil.

3 LIQUEFACTION MITIGATION WITH RAP GROUND IMPROVEMENT ELEMENTS

The Impact technology finds its core applications on structures transmitting medium to medium-high loads, such as industrial sheds or buildings of medium height, tanks, silos, embankments or floorings.

Another specialty use of the RAP Impact technology is its application in reducing liquefaction risk in loose to medium dense sandy soils below the groundwater table. The high vertical compaction and vibratory energy applied during Impact pier installations expands the cavity created by the driven mandrel and densifies the surrounding granular soil, thereby reducing this risk.

Used in a large number of projects worldwide including Italy, the effectiveness of the system in mitigation of liquefaction risk has been demonstrated by both on-site tests and real case histories. In addition, their effectiveness in mitigating liquefaction in clean sandy soils has been well documented by Farrell et al. (2010); Majchrzak et al. (2010); Wissmann et al. (2015) and Saftner et al. (2016).

The effectiveness of RAP Impact elements for liquefaction mitigation in siltier soil has been demonstrated from the full-scale data set collected at Briceño Bridge embankment; a site reinforced with RAP elements that performed well after the Muisne Mw 7.8 earthquake (Smith & Wissmann, 2018; Amoroso et al., 2020; Salocchi et al., 2020). Finally, full-scale blast-induced liquefaction tests were recently carried out in Bondeno, Italy (Amoroso et al., 2020; Rollins et al., 2021) to directly evaluate the effectiveness of RAP Impact elements in mitigating liquefaction hazards in silty sands. Also in this case, improvement with Impact elements was effective in reducing liquefaction-induced settlements to acceptable levels in comparison with the untreated soil.

4 PREDICTION OF LIQUEFACTION MITIGATION WITH CPTU

From a design point of view, there are formulations and methods available in literature to quantify the improvement of the soil matrix after installation of Impact piers for liquefaction risk mitigation. These are based on in-situ CPTu investigations, which are usually the only data provided to the engineer at the design stage.

A popular method to quantify the improvement of the soil matrix after installation of Impact piers is to estimate the densification expected after the installation of the piers. Estimating the increase in CPT tip resistance q_c is a common way of considering densification and this will be the method of focus in this paper. By using the increased q_c, which is dependent on the soil type, depth and other parameters, and by referring to the pre-improvement sleeve friction f_s and soil behavior type index I_c, it is possible to evaluate the updated Factor of Safety against liquefaction.

Additional methods such as evaluation of Shear Stress Attraction (Green et al., 2008; Rayamajhi et al., 2012), the increase in lateral confinement stress and Cyclic Resistance Ratio CRR (Salgado et al., 1997), and use of the stiffness of the Impact piers to reduce post-liquefaction deformations (Rollins et al., 2021) are beyond the scope of this paper.

4.1 *New Zealand-based correlation*

The study undertaken by Vautherin et al. (2017), provides correlations for predicting the degree of densification after Impact pier installations. The study is based on a large database of CPT data spread among 80 sites across Christchurch, New Zealand. The sites were treated with Impact piers after the full-scale trials in 2013 indicated their effectiveness in reduction of liquefaction risk (EQC, 2015).

The authors introduced the ratio Q_c to indicate improvement, and is defined as the ratio between the post treatment q_c and the pre – treatment q_c.

The relationships for Q_c in clean sand are given by equation 1 and 2 as a function of the effective confinement stress σ'_{v0}.

For $\sigma'_{v0} < 30$ kPa:

$$Q_{c\ ratio} = 4.0 - 0.076 \cdot \sigma'_{vo} \tag{1}$$

For $\sigma'_{v0} > 30$ kPa:

$$Q_{c\ ratio} = 1.69 \tag{2}$$

In silty soils, with soil behavior type index I_c comprised between 1.8 and 2.4, the correlations proposed for Q_c are presented below. The authors of the Vautherin (2017) paper highlight that these three equations should not be used for design given the large scatter observed in the data.

For *1.8 < I_c < 2.0*:

$$Q_{c\ ratio} = 2.7 - 0.015 \cdot \sigma'_{vo} \tag{3}$$

With $R^2= 0.16$. For *2.0 < I_c < 2.2*:

$$Q_{c\ ratio} = 2.0 - 0.01 \cdot \sigma'_{vo} \tag{4}$$

With $R^2= 0.06$. For *2.2 < I_c < 2.4*:

$$Q_{c\ ratio} = 1.7 - 0.007 \cdot \sigma'_{vo} \tag{5}$$

With $R^2= 0.03$.

Impact piers in most of the sites were installed at an area replacement ratio (ARR) of 8%. ARR values of 5 to 8% are typically used in liquefaction mitigation projects.

5 PREDICTION ASSESSMENT

The scope of this paper is to both verify the accuracy of the densification formulas from literature, and to attempt to identify areas for improvement for future studies.

In order to assess the reliability of the correlations available, we have considered CPTu tests performed in Christchurch, New Zealand and Bondeno, Italy

both before and after installation of Impact elements; and comparisons are made between the predicted q_c increments and the measured q_c increments.

5.1 *Christchurch, New Zealand sites*

The pre and post-installation CPTs presented below were performed during the full-scale trails carried out in Christchurch, New Zealand in 2013 (EQC, 2015). The tests were performed in three different trial sites (Site 3, Site 4 and Site 6), in which Rammed Aggregate Pier (RAP) columns were installed to 4m depth with a triangular spacing of about 1.50 m, 2.00 m and 1.80 m on-center resulting in Area Replacement Ratios of approximately 14.5%, 8% and 5%, respectively (Amoroso et al., 2015). In all the sites, pre and post-installation CPTu tests were performed in both natural and treated soil to investigate the effects of RAP Impact installations on soil properties, with post-installation CPTs performed at the center of a pier group.

Figures 2-4 plot the measured pre and post installation CPT tip resistance q_c and the predicted q_c using Equations 1-5 as well as the soil behavior type index I_c obtained from the CPTu carried out in untreated and treated soil. The predicted q_c values were plotted separately for $I_c<1.8$ and $I_c>1.8$.
Figure 2. Comparison of measured pre and post-installation q_c profile with depth and predicted ones according to exposed correlations and I_c for site 3.
Figure 3. Comparison of measured pre and post-q_c profile with depth and predicted ones according to exposed correlations and I_c for site 4.
Figure 4. Comparison of measured pre and post-q_c profile with depth and predicted ones according to exposed correlations and I_c for site 6.

5.2 Bondeno test site, Italy

A full-scale trial for blast induced liquefaction was carried out in Bondeno, Italy in 2018. The test was carried

out to assess the effectiveness of RAP elements for liquefaction mitigation (Rollins et al., 2021). In the study, 16 RAP elements were installed to a depth of 9.5 m in a square grid pattern at a spacing of 2m on-center, resulting in an ARR of 5%. The post-installation CPT was performed at the center of a group of four piers. The pre and post-installation CPT results are provided in Figure 5 below obtained from Rollins et al. (2021).
Figure 5. CPTu profile pre and post RAP treatment at the Bondeno test site (Rollins et al., 2021). Pre-RAP q_c data is plotted in black and post-RAP q_c data is plotted in red.

The authors were not able to obtain the CPT data file to plot all the measured and predicted increases in q_c with depth as was done for the New Zealand sites.

5.3 Composite results

We proceeded to analyze several representative layer data points in each of the CPTs from all four sites to compare the predicted and measured increases in CPT tip resistance q_c directly. The points were selected at depths where the pattern of the peaks and valleys of the pre and post-improvement q_c suggest that a similar layer was detected in both CPTs. Points where the post-improvement q_c was lower than the pre-improvement q_c were not selected. It is noted that pre and post-improvement soil behavior type index I_c values may not be closely matched for the selected points since the post-improvement q_c and sleeve friction f_s are different than the pre-improvement values after densification has occurred.

The data points chosen are tabulated in Table 1. Data points for the New Zealand Site 3 were only selected between 0m and 1m depth as the stratigraphy below 1m was more dissimilar between the pre and post-improvement CPTs. The pre and post-improvement q_c values for the Bondeno site were visually approximated using Figure 5 as the CPT data files were not available. The data between 3.5 and 6m depth at this site was discarded due to observed issues

with aggregate flow during pier installations and the corresponding lack of cavity expansion (densification). It is noted that Figure 5 plots the total cone resistance q_t; though, the difference between q_t and q_c may be small for the points selected as most points of the Bondeno data points have I_c values of less than 1.8.

Table 1. Selected data points for comparison. Pre-improvement and post-improvement data tabulated in the same row were considered to pertain to the same soil layer.

	Pre-improvement data points		Post-improvement data points (Measured)	
	Depth	q_c	Depth	q_c
Site	(m)	(MPa)	(m)	(MPa)

The predicted post-improvement q_c values were subsequently estimated with the Vautherin et al (2017) equations using the pre-improvement q_c values in Table 1 and the respective effective confinement stress σ'_{v0} and soil behavior type index I_c for each data point tabulated. The predicted and measured increases in CPT tip resistance q_c (Δ_{qc}) were subsequently estimated and plotted in Figure 6. The results suggest good agreement between the Vautherin et al (2017) correlation and the measured q_c values for the New Zealand sites and suggest that the correlation overpredicts the increase in q_c for the Bondeno site soils. It is possible that aggregate flow negatively impacted densification even below 6m depth at the Bondeno site.
Figure 6. Comparison of predicted increase in q_c with measured increase in q_c profile for all sites.

6 DISCUSSION AND FUTURE DEVELOPMENTS

This study indicated that the correlations used for estimating improvement in q_c show generally good agreement with post-installation q_c measurements, despite the uncertainties and variables that can affect these correlations.

The degree that a soil layer can be densified, which can be expressed in terms of increase in the tip resistance q_c in CPTu tests, is a function of the lithology and confinement stress. Little difference in densification was evident between the Impact pier spacings of 1.5 to 2m used in the Christchurch trials. Additional research could be undertaken to consider the normalized CPT tip resistance q_{c1n} proposed by Boulanger (2003), which automatically eliminates the influence of the soil's effective overburden pressure.

Moreover, New Zealand case histories show that in, certain soils, densification occurred below the bottom depth of the columns. Clearly this is not considered in the bibliographical formulas and is an area that needs an in-depth study.

It is also evident that the greatest accuracy is found in the tests carried out in Christchurch. This is because some areas of the city, following the Canterbury Earthquake Sequence in New Zealand in 2010-2011, were home to a unique large-scale study on the efficacy of the Impact technology along with other type of ground improvement. Thus, a large amount of data and site measurements on the effect of RAP Impact installation has been derived from the Christchurch area.

The final goal is to develop more accurate tools to improve the accuracy of RAP Impact pier designs for liquefaction risk mitigation. The authors, together with the licensed Geopier installer in Italy, have designed and constructed several liquefaction risk mitigation projects with RAP Impact elements in the Emilia-Romagna region, including the cities of Ravenna, Cervia and Forlì. In these sites, "pre and post" CPTu investigations are being carried out to form part of

a future local database. Eventually, a new general correlation could be proposed, or the correlations could be specialized to be specific to the Emilia-Romagna region. This is an ambitious goal and is expected to be developed over a medium-long term time frame. The authors hope to include the pre and post-installation CPTu tests performed at Bondeno test site (Figure 5) into the future Emilia-Romagna local database.

7 CONCLUSION

The Impact pier technology developed by Geopier Foundation Company is a ground improvement method employed worldwide for reduction in site requiring liquefaction risk mitigation. The displacement and vibro-compaction construction technique improve the surrounding sandy soils by means of densification which subsequently reduces the risk of liquefaction.

Numerous tests and bibliographic case histories have demonstrated the effectiveness of this technology for liquefaction risk mitigation. In addition, predictive methods are available for the designer to estimate the densification of the soil based on lithology.

The main purpose of the article was to test the reliability of these methods by means of post-installation CPTu data from sites around the world. The predictive correlations appear to be a useful assessment tool to help in predicting liquefaction mitigation using Impact during the geotechnical design. Nevertheless, further efforts need to be made to extend the existing databases and eventually to specialize them geographically by studying and evaluating site-specific correlations. In this direction the authors are already carrying out more in-depth studies, focused on design phase, that may be the subject of future publications.

Estimating bearing capacity of polar snow using the Cone Penetration Test (CPT)

A.B. McCallum & G. White
School of Science, Technology and Engineering, University of the Sunshine Coast, Sippy Downs, Australia

ABSTRACT: Increased access to the polar regions requires increased infrastructure. Design and construction of this infrastructure can only be achieved by accurately estimating surface bearing capacity. We reviewed contemporary methods for determining bearing capacity in soils and applied these to data obtained from almost 100 cone penetration tests conducted in Antarctica. Numerous direct and indirect methods exist to enable estimation of surface bearing capacity in polar snow, but the preferred method is the rate-controllable, friction-sleeve equipped, cone penetration test (CPT). Application of this and similar techniques is essential to ensure the correct design and construction of infrastructure in ever-more trafficked polar regions.

1 INTRODUCTION

As our climate changes, contestation for polar resources is increasing (Dodds and Hemmings, 2015). This results in increased polar operations and the need for increased supporting infrastructure. White and McCallum (2018) reviewed the design and construction of pavements of snow and ice, including measures of snow bearing capacity.

Abele (1990) says that although the strength of snow can be determined by various methods, there are three primary measurement techniques: surface loading, sample strength testing, or probing, in which a penetrative device is forced into the snow obtaining a proxy for snow strength. Of these, probing is the preferred means of assessing in situ strength because it allows the profile of the snow bearing strength to be measured on undisturbed in situ material (McCallum, 2013).

Numerous instruments have been used historically to probe snow, such as the Swiss Rammsonde (Haefeli, 1936) or the Standard Penetration Test (SPT) or Drop Cone Penetrometer (DCP); more recently lightweight penetrometers have been developed for alpine snow (predominantly avalanche) work (Schneebeli and Johnson, 1998). However, because polar snow is a rate-sensitive material (McCallum, 2017a) a robust, hydraulically-driven, constant-rate penetrometer, such as that used for the Cone Penetration Test (CPT), is preferable for assessing physical characteristics of hard polar snow, to depth (~5 m), from which snow bearing capacity might be estimated. The existence of a friction-sleeve further increases the usefulness of this tool (McCallum, 2017b).

In this paper we validate direct derivation of bearing capacity in polar snow from rate-controllable, friction-sleeve equipped, cone penetration test data.

2 BACKGROUND

Many authors have examined the derivation of bearing capacity and/or settlement of geomaterials, either directly or indirectly. Direct measurement of bearing capacity is derived directly from CPT data after consideration is given to differences in the cone shape, size and penetration rate, by applying modification factors. In contrast, indirect measurement includes measuring material parameters derived from CPT data, and then converting to bearing strength via standard equations. The indirect approach is the common and conventional method for polar snow. These indirect methods use the application of standard bearing capacity theory (Terzaghi, 1943), cavity expansion theory (Yu, 2000) and various numerical models.

The measurement of snow bearing capacity is informed by the practices applied to other geomaterials, such as soil. Many approaches for direct bearing capacity derivation in soils are described in Lunne (1997), including those by Schmertmann (1978), Meyerhof (1976) and Tand (1995). Additionally, Eslami and Gholami (2006) presented an analytical model to directly derive ultimate bearing capacity from cone resistance and Lee and Salgado (2005) proposed a method to directly estimate the bearing capacity of circular footings on sands based on the cone penetration test.

Mayne, who has written extensively on the application of both methods (e.g., Mayne (2020)) noted in

a recent report (Dagger et al., 2018), that many techniques (particularly indirect techniques) are now obsolete and calculation of bearing capacity from cone penetration test data is now the preferable method.

Having briefly examined these techniques in soil, we now briefly inspect similar methods that have been considered for polar snow.

3 HISTORICAL ESTIMATION OF BEARING CAPACITY IN POLAR SNOW

Abele (1963) examined the correlation between snow compressive strength and penetration resistance, as measured by the Rammsonde. Furthermore, Mellor and Smith (1966) examined the impact of temperature on Rammsonde measurements in homogeneous snow. They showed that Rammsonde hardness varied with snow temperature similarly to unconfined compressive strength. Salm (1971) examined the rheological behaviour of snow under high stresses and Mellor (1975) extensively examined snow mechanics, including the rheology, elastic and viscoelastic behaviour, creep behaviour, failure and shear strength. Mellor (1975) noted that the derivation of strength measurements for snow from Rammsonde penetration resistance data is somewhat 'arbitrary' but upon further examination (because of the utility of the Rammsonde) he concluded that correlation between ram resistance and uniaxial compressive strength in snow is important, but variations in snow density and microstructure complicate the relationship, meaning a universal correlation is unlikely to be found.

Barthelemy (1975) summarised snow-road construction techniques and examined the conversion of Rammsonde penetration resistance to hardness values, and additionally related evident relationships between Ramm hardness, confined shear strength and expected bearing potential.

More recently, Petrovic (2003) briefly examined a wide array of snow and ice mechanical properties and Shapiro et al. (1997) in re-reviewing the state of snow mechanics presented an indirect calculation for settlement based on snow density but highlighted that estimating the natural snow's bearing capacity is not easily determined, again because of variations in both density and microstructure/bonding. Models are being developed to assist in such estimation, but necessary empirical data for complex snow load response does not exist (Shapiro et al, 1997).

Land and Harrison (1995) examined the stress-deformation behaviour of snow of various densities and Scapozza and Bartelt (2003) used a specially constructed triaxial testing device to examine the behaviour of snow of different density at different strain rates and confining pressures, also examining the work hardening that occurs after initial failure. So, historically, the estimation of bearing capacity in snow has proven difficult, either directly or indirectly, because of the variability in snow density and microstructure, which also changes with temperature.

The US Army Cold Regions Research and Engineering Laboratory (CRREL) has used an indirect method to estimate bearing capacity for polar infrastructure such as roads, runways and buildings. White and McCallum (2018) recently reviewed this approach; an example nomogram from which necessary snow hardness/strength criteria must be met for various aircraft is shown (Figure 1).
Figure 1. Required hardness (or strength) of a snow pavement for various wheel load conditions (from Abele, 1990).

For surface polar infrastructure, Blaisdell and Weale (2006) examined bulk and differential settlement into the snowpack of a foundation on a deep snowpack at the South Pole (stratigraphy was not described) and Geduhn and Enss (2006) assessed the service life of Neumayer Station, Antarctica, defining failure in terms of settlement and establishing a stress amount to be avoided in order to deny the onset of tertiary creep (McCallum, 2012). Aside from White and McCallum's review of ice and snow runway pavements (White and McCallum, 2018), limited additional consideration of bearing capacity derivation (direct or indirect) for polar snow is apparent.

4 CONTEMPORARY ESTIMATION OF BEARING CAPACITY IN POLAR SNOW

Because snow bearing strength is rate-sensitive, temperature dependant and variable with depth/location, McCallum (2012) postulated that a hydraulically-driven, constant-rate, friction-sleeve equipped penetrometer, could be useful to assess bearing capacity of polar infrastructure, such as snow roads and runways. McCallum conducted almost 100 CPTs in Antarctica and presented initial postulations on the direct and indirect derivation of surface bearing capacity for polar snow, in layered and nonlayered situations (McCallum, 2012). He focussed on direct methods for layered and unlayered snow, in terms of both ultimate (elastic deformation only) and allowable (plastic deformation/settlement occurs) bearing capacity. Typical CPT data considered (Figure 2) and McCallum's postulations
Figure 2. Example CPT data from which McCallum (2012) derived his relationships, for snow of particular initial density.

Table 1. Methods to derive BC from CPT data.

Method	Relationship	BC (kPa) for q_{cavg} of 2 MPa
Ultimate homogeneous (Method 1)	$q_{cavg}/\sim 3$	~ 667
Ultimate homogeneous (Method 2)	$q_{cavg}/\sim 2.2$	~ 909
Allowable homogeneous	$q_{cavg}/\sim 1.5$	~ 1330
Ultimate layered	Depends on strata	N/A
Allowable layered	Depends on strata	N/A
Allowable homogeneous (direct)	$q_{cavg}/\sim 2.4$	~ 840

(Table 1) are presented; q_{cavg} is average tip resistance (MPa).

We now briefly further examine the direct and indirect estimation of bearing capacity in both homogeneous and layered snow.

Homogeneous snow

Homogeneous snow can be considered elastic (Poulos and Davis, 1974) prior to initial failure (McCallum, 2012) and ultimate or allowable bearing capacities can be estimated either indirectly or directly.

Indirect Methods
Kartashov (1965) examined the relationship between settlement and pressure, for snow of varying density and determined a power-law relationship (Equation 1):

$$P = A\left\{\frac{\Delta h}{h}\right\}^{\propto} = A\left\{\frac{\gamma - \gamma_0}{\gamma}\right\}^{\propto} \quad (1)$$

where A and α are parameters; h is the initial sample height; Δh is settlement; γ_o is initial specific weight and γ is final specific weight, with parameters of state A and α depending on microstructure, initial density, temperature and loading rate.

Abele and Gow (1976) examined settlement of compacted snow due to compressive stress and established stress-deformation (pressure-sinkage) relationships that depended on initial density and temperature.

Shoop (1993) examined field terrain characterization for vehicle trafficability on snow using the Rammsonde and other devices, from which bearing capacity could be indirectly calculated; specifics were not given.

Fellin and Lackinger (2007) used cohesion values obtained from rapid unconfined uniaxial compression tests to design strip footings for cable car towers founded upon glacial ice, and Masterson comprehensively examined ice bearing capacity and construction (Masterson, 2009).

Lee (2010) modelled plate indentation in snow using FEA (ABAQUS), calculating an initial yield strength in compression using the Drucker–Prager cohesion (Pa) and snow friction angle. Lee back-calculated these data from indentation tests via an optimization procedure.

McCallum (2012) deliberated extensively on the derivation of strength and bearing capacity (Table 1) from CPT in polar snow, presenting an equation to derive ultimate (elastic) bearing capacity (MPa) for homogeneous snow of initial density ~ 450 kg m^{-3} (Equation 2):

$$BC = 2.8(q_{cavg}/1.7)/(0.5/0.587M) \quad (2)$$

Where M equals 5.3 for snow of initial density ~ 450 kg m^{-3} (McCallum, 2012). McCallum (2012) also built on Johnson's work (Johnson, 2003) to show how his Statistical Micromechanical Theory of Cone Penetration in Granular Materials might be applied to estimate shear strength from CPT for the cohesive granular material, polar snow.

McCallum (2013) presented preliminary relationships to derive snow density from both CPT tip resistance and CPT sleeve friction. Strong qualitative relationships were evident, but quantitative relationships were not significantly examined. Additionally, he presented initial deliberations on deriving snow shear strength from CPT tip resistance data; but this derivation relied on knowing initial snow density values.

Further to this work, McCallum (2014) applied relationships developed by Robertson (2010) for soil, to show that a statistically significant relationship exists between CPT sleeve friction and snow density.

Direct Methods

Irwin (1991), though controlled laboratory experiments in manufactured snow, derived an expression for footing load (bearing capacity) based on pressure-bulb depth, shear stress and compressive stress, derived directly from Rammsonde hardness data, for snow of variable density, temperature, ageing and grain size. This built on previous work in natural snow (Irwin, 1989) and incorporated volumetric compaction of the snow under the footing and shear resistance around the cylindrical perimeter.

McCallum (2012) built on this theory and devised a direct derivation of allowable bearing capacity for polar snow (Table 1) from CPT data by incorporating empirically observed differences in cone shape, size and penetration rate, also incorporating compaction ahead of the penetrating cone.

McCallum (2018b) also applied Einav's work (Einav, 2007a; 2007b) on breakage mechanics theory to postulate on the estimation of pile end bearing capacity from polar snow CPT data.

Non-homogeneous snow

In the more-complicated case of non-homogeneous snow, less indirect and direct methods have been examined.

Indirect Methods

Sturm et al. (2004) used a micromechanical theory to convert high-resolution micro-penetrometer data to snow bond strength and Geduhn and Enss (2006) examined the stress dependent creep behaviour of snow and ice to assess the bearing capacity and settlement of columns used to support Germany's Antarctic Station Neumayer III. They used an idealised depth-density curve to represent actual site stratigraphy.

To estimate the extent of vertical stress transfer within layered snow, estimation of elastic modulus is necessary. Marshall (2005) used ABAQUS to model surface loading within a layered snowpack. He refined a statistical-micromechanical model (Johnson and Schneebeli, 1999) to define a macroscopic elastic modulus based on mini-penetrometer data, concluding that this method could prove valid for (larger diameter) CPT data.

McCallum (2012) subsequently derived macroscopic elastic modulus measurements directly from CPT tip-resistance (for snow of assumed density), obtaining results consistent with values reported by Mellor (1975), concluding that the results were strain rate dependant. McCallum went on to examine ultimate and allowable bearing capacity of layered polar snow, using CPT-derived modulus data, subsequently generating plots of vertical stress diminution with depth using the FEM package Pdisp (Oasys Ltd, 2009).

Subsequent to McCallum's work the Avatech SP1 and SP2 Smartprobes (Avatech, 2014) were developed to measure snowpack stratigraphy and resistance to penetration, but retrieved data are relative, not absolute, and a measure of neither snow strength nor bearing capacity is attained.

Most recently, Haehnel et al. (2019) examined the Phoenix compacted snow airfield near McMurdo Station, Antarctica, to determine strength necessary to support a C-17 aircraft. They defined strength depth profiles in terms of uniaxial compressive strength, determined via numerous variable-rate penetrative methods, including the Rammsonde (RAM), Dynamic Cone Penetrometer (DCP) and the Russian Snow Penetrometer (RSP). They used elastic modulus estimated from snow density (kg m^{-3}) (Shapiro et al., 1997) as input into a back-calculation tool "FAA Backcalculation" (BAKFAA V. 2.0*) from which Major principal stresses versus depth were predicted, for different aircraft at varying snow densities. Subsequently, they generated recommended structural design strengths for the runway, to a depth of 1 m, in terms of unconfined uniaxial compressive strengths, derived from penetrometer strength indices for both the RSP and RAM (e.g., Equation 3 for deriving unconfined uniaxial compressive strength from RAM data (Abele, 1990).

$$\sigma = 0.37R^{0.55} \qquad (3)$$

No additional contemporary indirect methods to derive bearing capacity in non-homogeneous polar snow are known to exist.

Direct Methods

McCallum (2012) examined existing direct methods for soil such as Meyerhof (1976) and Schmertmann (1978) to estimate what the ultimate bearing capacity of snow might be as a percentage of CPT tip resistance. Although he considered the direct manipulation of CPT data due shape, size and penetration rate to derive bearing capacity in homogeneous snow (previously discussed), he did not examine the direct derivation of surface bearing capacity from CPT data in layered non-homogeneous polar snow.

No other research is known to exist that considers the derivation of bearing capacity in layered polar snow directly from CPT data.

5 APPLICATION OF CONTEMPORARY SOIL METHODS TO POLAR SNOW

The limited research on direct snow bearing strength measurements, coupled with the low reliability of indirect measurement, indicates there is significant advantage in applying contemporary soil bearing strength methods, such as those proposed by Dagger (2018) and Lehane (2019).

Lehane (2019) examined how CPT end-resistance (q_t) can be used to directly predict bearing capacity for driven and bored piles in sand, silts and clays, and shallow foundations on sand; he also examined

shaft friction correlations (similar to McCallum's work in snow (McCallum, 2018)). Contemporaneously, the behaviour of shallow foundations on snow is of most interest. Lehane (2019) deduced a direct relationship between CPT tip resistance and shallow foundation settlement (Equation 4).

$$q_{0.1} = 0.16 q_{c,average} \qquad (4)$$

where $q_{0.1}$ equals the applied bearing pressure where foundation settlement divided by foundation width equals 0.1, and $q_{c,\ average}$ equals average cone tip resistance. This relationship is very similar to that derived by Mayne (2012) where ultimate surface footing bearing capacity equals 18% of mean CPT tip resistance. It is interesting how both these formulations are of a similar order to McCallum's initial formulation (Table 1; McCallum (2012).

However, snow is not sand, and although Lehane's derivation (from Terzaghi's initial formulation (Terzaghi, 1956)) considers the effects of horizontal stress, soil compressibility/stiffness, friction angle and consolidation, it does not incorporate cohesion, which snow immediately gains upon formation (Szabo, 2007). Boufrina (2018) also examined design of shallow foundations directly from CPT data but they also did not consider cohesion.

Robertson (2010) briefly considered direct and indirect estimation of shallow foundation bearing capacity from CPT data in cohesive soils (Equations 5 & 6 respectively). Indirect:

$$q_f = N_c s_u + \gamma D \qquad (5)$$

Where q_f is ultimate bearing capacity, N_c is a function of footing width and shape, s_u is undrained shear strength (corrected for Bjerrum's correction (Bjerrum (1973)), γ is soil unit weight and D equals depth of footing. Direct:

$$q_f = K_{su} q_{c(av)} + \gamma D \qquad (6)$$

Where q_f is ultimate bearing capacity, K_{su} varies from 0.3 to 0.6 depending on footing B/D and shape, and soil OCR and sensitivity, γ is soil unit weight and D equals depth of footing.

For a surface footing, application of the indirect equation suggests a bearing capacity of ~5.s_u. This is very close to McCallum's derived relationship between CPT tip resistance and shear strength for polar snow of density 400 kg m^{-3} of ~4.5.s_u (McCallum, 2012). Robertson's indirect relationship is directly applicable to snow, for snow of density 407 kg m^{-3}. Contemporary indirect methods to estimate surface footing bearing capacity for cohesive soils, can probably be used for polar snow.

Examining Robertson's direct equation, for a surface footing, suggests that (depending on footing B/D etc.) bearing capacity equals ~0.5. q_c(av). This is very similar to McCallum's direct derivation of ~0.42. q_c(av). Again, application of a direct soil method for cohesive soils to polar snow appears useful.

Dagger (2018) emphasise that traditional (indirect) techniques are no longer required because direct methods from CPT exist for square, rectangular and circular shallow footings. They propose robust direct methods for all soils and propose a general direct CPT method, but derivation is particular to footing width and accepted settlement, and is not easily comparable here.

6 CONCLUSION

Many techniques, both indirect and direct, exist to estimate surface bearing capacity in soils; far less research has been conducted into snow, a cohesive, rate-sensitive material, whose evolving microstructure depends on initial density and ongoing temperature gradients.

Indirect techniques for snow have been derived (McCallum, 2012 etc.), but in soils, such techniques are no longer preferable, because robust direct-derivation methods now exist (Dagger, 2018).

Direct methods derived for snow, such as those postulated by McCallum (McCallum, 2012), agree well with accepted methods for cohesive soils (Robertson, 2010). Therefore, the preferred method for deducing surface bearing capacity of polar snow, is through application of rate-controllable, friction-sleeve equipped, cone penetration test (CPT) data.

The use of CPT based metamodels to predict the performance of offshore anchor piles

A Mentani & L. Govoni
University of Bologna, Bologna, Italy

F. Bourrier
French National Research Institute for Agriculture, Food and Environment, Grenoble, France

ABSTRACT: The paper presents the development of metamodels for the prediction of the load-displacement response of steel piles driven in sand subjected to pull-out. Two metamodels are created for the evaluation of the tensile capacity and initial stiffness of the pile. They were developed based on the outcomes of a finite element testing campaign, employing models of parameters derived from the tip resistance of cone penetration tests. Two hundreds finite element simulations, which included various soil-pile configurations, were required to calibrate accurate metamodels. Assessment of the procedure was carried out with reference to available data on a model pile and related cone penetration test results. The approach relies on particularly simplified finite element models, but it can be extended to accommodate modelling features of higher complexity. The results find application to the design of offshore piles used as anchors for floating structures.

1 INTRODUCTION

The paper focuses on the drained, static load-displacement response of steel open-ended piles subjected to pull-out. In the offshore environment, tensile loading conditions may become critical for piles employed as anchor foundations, particularly when used with vertical or taut line moorings. In the context of offshore wind exploitation, these solutions offer an attractive alternative to catenaries, as they may allow to contain the area over which a floating wind farm would extend, aiding with a reduction of the investment costs (Castro-Santos & Diaz-Casas 2016).

The tensile response of offshore piles is traditionally estimated using the shaft load-transfer curve approach, combined with ultimate shaft friction prediction methods. The development of load-transfer curves dates back to the Fifties and several formulations are now available as comprehensively reviewed in Bohn et al. (2017). In sand, the tensile capacity is now estimated according to cone penetration test-based procedures (CPT-methods), which predictive performance was assessed in Schneider et al. (2008). The approach is very accurate and its implementation straightforward, however, uncertainties may arise when selecting the most suitable formulation among those available (Foglia et al. 2017, Schmoor et al. 2018).

Finite element or finite difference models can be also employed to describe the pile tensile load-displacement curve (De Nicola & Randolph 1993; van tol & Broere 2006; De Gennaro et al. 2008).

The implementation and calibration of these models can be, however, a complex and computationally onerous task. To overcome this limitation, metamodelling techniques can be employed, as they allow to store the results of finite element analyses in simple mathematical functions, which have the advantage of an easy implementation and low computational cost (Sudret 2008).

In this paper, metamodels are developed to predict some behavioural features of piles driven in a homogeneous sand bed. Building up on the experience matured in the context of the CPT-methods over the last decade, a simple CPT-based Finite Element (FE) modelling strategy is adopted to investigate the pile response when subjected to a tensile load through a parametric study. A Polynomial Chaos Expansion (PCE) metamodel (Xiu & Karniadakis 2002) is built from the results obtained by the FE study. The prediction capacity of the developed metamodel is then assessed with respect to selected data included in the ZJU-ICL experimental database of piles driven in sand (Yang et al. 2015).

2 FE SIMULATION PROGRAMME

A FE parametric study was carried out, in which an upward vertical displacement was applied to

a whished in place model pile. They were total stress, small-strain and static analyses and the software suite Abaqus FEA (ABAQUS 2014) was used to the scope.

2.1 Details of the FE models

The FE models used in the parametric study involved a pile foundation of diameter D, length L and wall thickness t. The pile is subjected to a drained axial pull-out test from a uniform sand deposit, that is characterised by a constant value of the relative density D_r and a constant effective unit weight ($\gamma' = 10$ kN/m^3). The models were axial-symmetric, with zero displacement boundaries set at a distance of 15D from the pile shaft and 10D down the pile tip. A sensitivity study was carried out which showed that, to avoid any convergence issues, a very fine uniform mesh was required in the vicinity of the pile (Figure 1).

Assuming a fully plugged failure, the pile was modelled as a solid, deformable element, obeying to a linear elastic constitutive law. It features a uniform cross section. The equivalent density and elastic properties were calculated to account for the section geometry on the pile weight and axial deformation.

The soil response was modelled as linear-elastic and perfectly plastic, failing according to the Mohr-Coulomb criterion. Model parameters are derived from an artificial cone tip resistance ($q_{c,FE}$). The particular form of the trend is generated according to the relation given by Jamiolkowski et al. (2003) as this was also used in the interpretations made in the ZJU-ICL database (Yang et al. 2015).

$$q_{c,FE} = 20 \cdot \exp\left(\frac{D_r}{0.35}\right) \cdot p_a \cdot \left(\frac{\sigma'_{v0}}{p_a}\right)^{0.5} \quad (1)$$

where p_a = atmospheric pressure and σ'_{v0} = in situ vertical effective stress.

The soil's Young modulus was prescribed to vary with the artificial cone tip resistance according to Robertson (2009)

$$E' = \alpha_E \cdot q_{net,FE} \quad (2)$$

where

$$\alpha_E = 0.015 \cdot \left(10^{0.55 I_c + 1.68}\right) \quad (3)$$

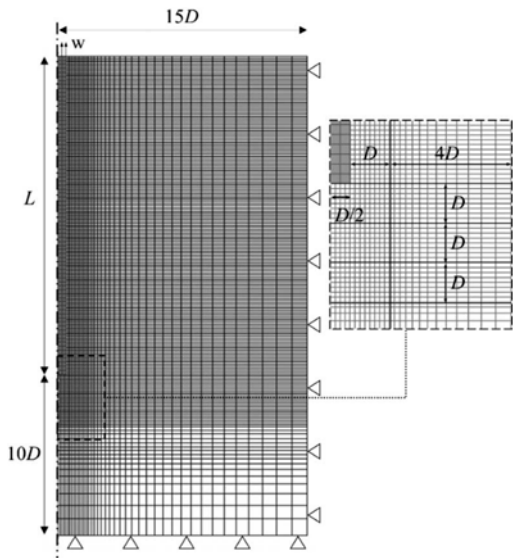
applies to the net tip resistance and I_c = soil behaviour type index. Soil peak strength and dilation angles were implemented in the FE models according to well-established Bolton (1986) correlation. The critical state interface friction angle was taken constant ($\delta_{cv} = 29°$), as it is generally done for steel driven piles in case interface tests are not available


Figure 1. Distribution of the mesh size along the FE models geometry and applied boundary conditions.

(Schneider et al. 2008). Piles were wished in place, therefore the effects of installation on the soil stress state prior to loading was implemented to ensure that the radial stress on the pile was, at any soil depth, that predicted by Jardine et al. (1998)

$$\sigma'_h = 0.029 \cdot q_{c,FE} \cdot \left(\frac{\sigma'_{v0}}{p_a}\right)^{0.13} \cdot \left(\frac{L-z}{R*}\right)^{-0.38} \quad (4)$$

where $R* = 0.25 \cdot [D^2 - (D - 2t)^2]^{0.5}$.

2.2 Sampling and results

Five independent input variables were considered in the design of the FE test programme. The pile was described by three variables, whose range was established to encompass the geometries encountered in the ZJU-ICL experimental database. Two variables were used for the definition of the soil model: the relative density and the modulus factor, α_E, which were

Table 1. Input variables for the FE test programme.

Input variable	Range
Pile diameter D [m]	0.20 – 1.00
Pile slenderness L/D [-]	10 – 70
Pile wall thickness ratio D/t [-]	10 – 100
Soil density D_r [%]	40 – 100
Soil modulus factor α_E [-]	3 – 10

allowed to vary within a realistic range for clean sands (i.e., $I_c = 1.31 - 2.05$). All the input variables are collected in Table 1, along with their domain of variation.

The FE analyses were conducted with certain combination of the input variables by using the Latin Hypercube Sampling technique (LHS, McKay et al. 1979). According to the LHS, each input variable range is divided into intervals of equal probability. The number of intervals is equivalent to the sample dimension and the location of the design point (i.e. the combination of inputs) is taken randomly within the interval. This method allows for an optimum coverage of the input variable domain and the sample size can be easily increased.

In this study, the five input variables were first combined to create a LH sample of size 50 (S_{50}), which was increased to 100 (S_{100}) and then to 200 (S_{200}). In Figure 2, the results of the 200 simulations are shown in terms of normalised vertical force ($V/(\gamma'DL^2)$) and displacement (w/D). Two outputs variables were identified along the curves, the normalised tensile capacity ($V_{ult}/(\gamma'DL^2)$) and the normalised initial stiffness ($K_t/(\gamma'L^2)$), which was evaluated as the initial tangent to the curve.

The input combinations and the resulting outputs were then used for the development and calibration of the PCE metamodels. To validate the metamodels further FE analyses were performed on a new sample of size 50 (S_{val}).

3 DEVELOPING METAMODELS

A metamodel (MM) or surrogate model is the model of a model, and metamodelling is the process of generating such MMs. A metamodel is an explicit mathematical algorithm representing the relation between input
Figure 2. Results of the FE test programme in terms of dimensionless force and displacement.

and output variables and it approximates the complex and implicit function defined by the emulated model (this model is either deterministic or random). They are generally grouped into classification and regression types. When the aim is to predict a continuous target variable, as in the case examined in this paper, the regression type, such as the PCE, is to be used. In this work, the open-source Python package OpenTURNS (Baudin et al. 2016) was used to build the MMs.

3.1 Details of the PCE

A given model is described by a vector $\mathbf{X}$ in which a finite number of input random variables are gathered. The response vector $\mathbf{Y}$, which collects the output quantities, can be represented as the application of a mathematical model to the input vector. The PCE is an algorithm which approximate this function, and the chaos representation of the response vector is defined as the linear combination of selected multivariate orthonormal basis, $\Psi_k(\mathbf{Z})$, and their corresponding coefficient α_k as represented by

$$\mathbf{Y} = f(\mathbf{X}) \approx \hat{f}(\mathbf{X}) = \sum_{k \in K} \alpha_k \Psi_k(\mathbf{Z}) \qquad (5)$$

with $\mathbf{Z}$ obtained by applying an isoprobabilistic transform to the input vector ($\mathbf{Z} = T(\mathbf{X})$).

The choice of the family of orthonormal basis (e.g., Legendre, Hermite, Krawtchouk) depends on the distribution type of the input variables, which are rescaled by the isoprobabilistic transform into common distribution types (e.g., uniform, normal, binomial). The following step consists on the determination of the coefficients, α_k, associated to each polynomial basis. These coefficients are estimated according to a suitable regression strategy (Sudret 2008). The most common are the least squares strategy that minimise the quadratic error between the model response and the polynomial approximation, and the integration strategy, which uses the inner product rules, thanks to the orthogonality and normality property of the polynomial basis.

3.2 Calibration and validation of the PCE

Two MMs were calibrated using the results of the FE test programme as follows. The combinations of the five input variables listed in Table 1 were collected in the input vector $\mathbf{X}$, and the selected outputs (i.e., the normalised pile tensile capacity load and tangent initial stiffness) represented two response surfaces (i.e., $\mathbf{Y}$). A uniform distribution of the input variable was selected as the most suitable to be applied to sample created with the LHS technique. Consequently, the Legendre orthonormal polynomial basis were chosen as associated to this distribution type. As for the evaluation strategy to compute the

polynomials coefficients, the least squares method was selected as it was shown to provide more accurate results, if compared to the integration strategy.

The calibration (i.e. the identification of coefficient α_k) of the two MMs was carried out using the results of the FE test programme originated by the created samples (S_{50}, S_{100}, S_{200}). Accordingly, three MMs (MM_{50}, MM_{100}, MM_{200}) were created for each of the two outputs ($V_{ult}/(\gamma'DL^2)$, $K_t/(\gamma'L^2)$) to explore the influence of the sample size on their accuracy. To the aim, the validation set of input-output combinations (S_{val}) was used, with the predictive coefficient, Q^2, defined by

$$Q^2 = 1 - \frac{\sum_{l=1}^{N}\left(\mathbf{Y}_l - \hat{f}(\mathbf{X}_l)\right)^2}{Var(\mathbf{Y})} \tag{6}$$

where N is the size of the validation sample (N=50) and $Var(\mathbf{Y})$ is the variance of the FE model outputs.

The MMs predictions are compared with the results of the FE testing campaign with reference to the two considered outputs: the tensile capacity (Figure 3a) and the initial stiffness (Figure 3b). Different markers are used to identify the MM's predictions built on different sample sizes. Some scatter is observed in the prediction of MM calibrated with the smaller sample size (MM_{50}), particularly at low and high output values and this is particularly evident for the prediction of the tensile capacity. The increase in the sample size, reduces the error at either end of the output distribution, with MM_{200} ensuring an excellent accuracy, consistent for both the outputs and estimated to be larger than 0.98.

4 ASSESSMENT OF THE PROCEDURE

4.1 Experimental data

The data used to explore the approach potential as a predictive tool were selected among those available in ZJU-ICL experimental database. The database was developed with the scope of validating the CPT-methods for axial pile capacity. Therefore, the results of the pile loading tests are always accompanied by the relevant CPT tip resistance profiles.

Among all, the data of a pile subjected to pull-out was chosen. The selection was made to ensure that the foundation and the soil had characteristics consistent with the FE models used in the calibration procedure and that are describable through the proposed set of input. The adopted pile was steel, open-ended driven, the soil was uniform, dense, fine to medium flandrian marine sand. The q_c profile at the test location is shown in Figure 4a.

The q_c data were processed to estimate the relative density at the pile location according to equation
Figure 3. Accuracy of the MMs in predicting: (a) the tensile capacity; (b) the initial stiffness.

1. For a further and likely estimate of the results, the expression suggested by ISO standards (ISO, 2016) for the implementation of the CPT-methods was also employed

$$D_r = \frac{1}{2.96} \cdot \ln\left(\frac{q_c/p_a}{24.94 \cdot \left(p'_m/p_a\right)}\right)^{0.46} \tag{7}$$

where p'_m = effective mean in situ stress.

The profiles of relative density estimated with equations 1 and 7 are shown in Figure 4b, along with their average values. Application of equation 1

to the two average relative density values returns the artificial tip resistance profiles inserted in Figure 4a, which are implemented in the FE models according to the procedure described in section 1.1.

Table 2 collects the input data used for the FE and MMs. These includes the experimental pile geometry, the average relative densities, and two values of α_E, corresponding to possible upper and lower bound for I_c, estimated using the information on the test site available in Jardine et al. (2006).

Table 2. Input data for FE and MM.

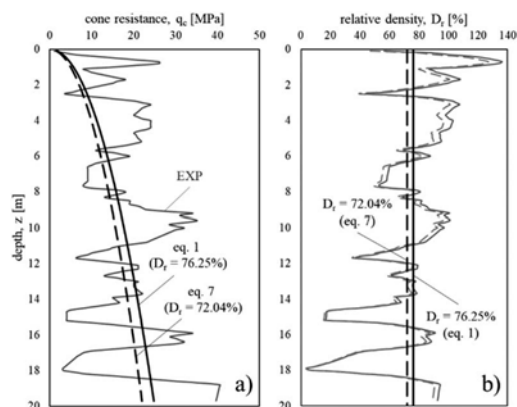
D [m]	L/D [-]	D/t [-]	D_r [%]	α_E [-]
0.457	42.23	33.8	72.04; 76.25	5
			72.04; 76.25	7


Figure 4. a) CPT data at the pile test location(redrawn from Yang et al. 2015 and artificial profile): (a) evolution of the cone resistance q_c and (b) relative density D_r depending on depth.

4.2 FE models and MM prediction

The data in Table 2 were employed first to assess the FE strategy presented in section 1.1. This validation plays a crucial role in the development of MMs, as their performance relies upon the robustness of the mechanical models they stem from.

Four FE analyses were performed (as detailed in Table 2) and the results are shown to compare well with the experimental data in terms of load-displacement curves (Figure 5). A close approximation of the initial stiffness and non-linearity prior to failure are observed, with the experimental capacity falling in the rather narrow band defined by the results obtained with the two sets of FE simulations performed with the two different estimates of relative density. The average FE capacity is 1443 kN, very close to the experimental data (1450 kN). The initial

experimental stiffness (about 380 MN/m) is slightly underestimated by the FE models, which predicted an average value of 310 MN/m and 270 MN/m with α_E equal to 5 and 7, respectively. A better fit could be obtained with a larger value of the modulus factor.

To assess the ability of the MM to reproduce the experimentally observed behaviour, the most accurate MMs were used (MM_{200}). The predictions for the different input combinations of Table 2 are inserted in Table 3.

These results are compared with those predicted with the FE models in Figure 3 (triangular markers), showing consistency of the MM_{200} accuracy. Combining the outputs of the two MMs a bi-linear response can be drawn and a direct comparison with the experimental load-displacement curve can be pursued, as depicted in Figure 6. As the MMs were built to predict selected behavioural features, they were not expected to capture the entire curve, but to provide a good estimation of the initial experimental stiffness and tensile capacity. Capacity values well compared with the results of API and NGI methods: 1450 kN and 1559 kN, respectively. A slightly higher estimate was observed when compared to the prediction of the UWA, ICP and Fugro approaches, respectively 1304 kN, 1310 kN and 1100 kN.

The results were obtained using a very simplified FE strategy and produced encouraging results. A better implementation of the q_c profile as input

Table 3. Predictions of MM_{200}.

Outputs	$D_r = 72\%$; $\alpha_E = 5$	$D_r = 72\%$; $\alpha_E = 7$	$D_r = 76\%$; $\alpha_E = 5$	$D_r = 76\%$; $\alpha_E = 7$
V_{ult} [kN]	1597	1478	1641	1433

variable should be pursued for a more reliable procedure. A possible way could be to follow the approach recently proposed by Cai et al. 2021.

5 CONCLUDING REMARKS

The paper has presented the development of a novel procedure for the prediction of the tensile response of steel displacement piles in sand. The approach has made use of a metamodelling technique, employed to store the results of a FE test programme with the aim of make them available for preliminary design purposes.

The FE models were simple, with soil parameters easily identifiable from CPT results. The modelling choices largely relied on the recent advance in the prediction of the axial capacity of offshore piles in sand with the CPT-based methods, thanks to which, available empirical correlations, had been validated on a large database of model tests.

The results obtained, although preliminary, have shown that:

– a simple CPT-based FE modelling strategy can produce results which compare well with experimental data, encouraging further validation;
– MMs can be built using a relatively small number of FE simulations and provide very accurate results over wide domains of input variables;
– inputs of MMs can be easily identified based on the interpretation of CPT data and produces good estimate of the experimental response.

Overall, the implementation of MMs is rather straightforward, avoiding the laborious FE modelling activities. MMs also run at a negligible

computational cost and are therefore suitable to parametric studies, which can be, in turn, interpreted in a probabilistic framework. The procedure, here presented in its essential steps, can be further extended to accommodate modelling features of higher complexity, increasing the number of input variables and can be employed to predict other behavioural aspects, increasing the numbers of outputs.

Spatial interpolation of sparse PCPT data to optimise infrastructure design

M.P. O'Neill, M.F. Bransby, J. Doherty & P. Watson
ARC Research Hub for Transforming energy Infrastructure through Digital Engineering (TIDE), Oceans Graduate School, The University of Western Australia, Australia

ABSTRACT: In an offshore setting the geotechnical data available to infrastructure designers is usually sparse, and judgement is required in using information from sampled locations to estimate design parameters at unsampled locations. Recent interest in data-centric methods has seen advances in the interpolation of sparse data via statistical and analytical approaches. This paper demonstrates the implementation of one such approach, applying Bayesian Compressive Sensing and Markov Chain Monte Carlo techniques to sparse two-dimensional PCPT data. Through a simplified case study, the paper highlights how the method incorporates estimation uncertainty and its associated impact on the geotechnical design of a representative foundation.

1 INTRODUCTION

1.1 Background

In an offshore project, the number of piezocone penetrometer tests (PCPTs) performed either for a development layout or along a given alignment (e.g. a subsea pipeline or power cable) may be limited by technical constraints and high costs – and hence data is almost always sparse. In addition, infrastructure layouts may change and investigated locations may no longer align. Therefore, geotechnical designers are often required to employ a significant degree of engineering judgement in using the available data (at 'sampled' locations) to estimate PCPT profiles, and by extension soil design parameters, at untested (or 'unsampled') locations. The consequential risks to fabrication and installation costs and satisfactory in-service performance can be significant.

From a geotechnical perspective, the intrinsic balance in such judgement is the trade-off between (i) the risk of *underestimating uncertainty at any point* and therefore giving an 'unconservative' design profile which exposes the designed infrastructure to risk of failure to install or to fail during its service life, versus (ii) the cost of *overestimating uncertainty at any point* and generating a 'conservative' design profile which will lead to increased fabrication and installation costs. Such trade-offs have generally been achieved using engineering judgement, with no formal methodologies (apart from anecdotal records of installation risk or in-service failure) available to assess which side of the balance general practice lies for different types of site investigation (SI) data, seabed conditions and infrastructure.

Recent improvements in off-the-shelf computational capability have seen growing interest in the application of data-centric methods to analyse and use measured data, with recent publications highlighting advances in the interpolation, and in some cases extrapolation, of data via statistical and analytical approaches (e.g. Zhao et al. 2020, Cai et al. 2018, Rahman et al. 2021, Shi & Wang 2021, Wang et al. 2021). Such approaches provide a tool which can be used to question how design profiles are selected from various types of SI data and quantify whether these profiles result in appropriate installation and operational reliability when incorporated into code-based design.

1.2 Purpose of study

This paper describes a study to investigate the potential benefits and consequent challenges of using advanced statistical methods (that considers proximity of SI data to the designed infrastructure) to select inputs for geotechnical design. One particular method (Zhao et al. 2020) uses a two-dimensional (2D) Bayesian compressive sensing-Markov Chain Monte Carlo (hence termed 'BCS') approach, which is compared to a simpler 'standard' approach using an offshore field PCPT dataset.

The study incorporates the BCS and standard analysis results into a simple geotechnical design assessment of a representative foundation. By comparing the findings of the foundation assessment, the study highlights the benefit an advanced statistical approach provides in addressing uncertainty (risk) in the estimation of soil strength for foundation design.

2 FIELD PCPT DATA

2.1 *Overview*

The field PCPT data were obtained at a deep-water site offshore north-western Australia. The sediments across the site comprised high plasticity carbonate muddy silts and silty muds. For this study the five PCPTs located along the example survey line (PCPT1 to PCPT5) highlighted on Figure 1 were considered. The tests were conducted at approximately regular intervals along the line, with a horizontal distance (x) of 142 m separating PCPT5 from PCPT1. Data were recorded at regular depth increments (Δz) of 0.02 m
Figure 1. PCPT locations.

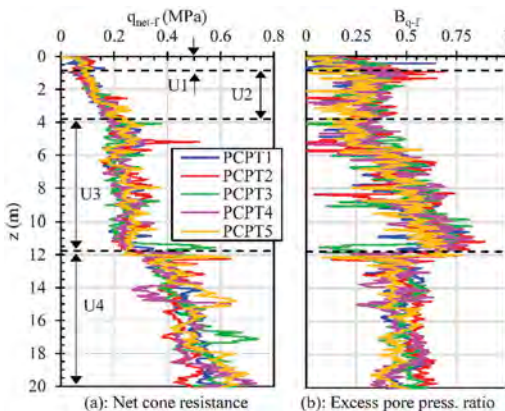
Profiles of the measured (field) net cone resistance (q_{net-f}) and excess pore pressure ratio (B_{q-f}) versus depth below mudline (z) obtained at the five PCPT locations are presented on Figure 2 down to z = 20 m. A cursory review of the data indicates four soil types (units; U1 to U4) exhibiting similar overall trends with depth across the survey line down to 20 m depth, as illustrated on Figure 2. It is noted that across the survey line (relative to x) q_{net-f} is reasonably uniform with no significant 'outliers'. For sites with higher variability the estimation of soil strength would require a greater amount of input (measured) data.


Figure 2. PCPT measured net cone resistance & excess pore pressure ratio.

2.2 *Sampled data case scenarios*

For this study three 'sampled data' case scenarios were assessed:

- Case 1 considered q_{net-f} from all five PCPTs as input;
- Case 2 considered q_{net-f} from PCPT1/3/4/5 as input and excluded PCPT2 (x = 38 m);
- Case 3 considered q_{net-f} from PCPT1/3/5 as input and excluded PCPT2 (x = 38 m) and PCPT4 (x = 108 m).

For Case 2 and Case 3 the excluded PCPTs were considered to be unsampled (unseen) data.

3 BCS ANALYSIS OF FIELD PCPT DATA

The BCS method proposed by Zhao et al. (2020) for assessing sparse geotechnical data allows for the formal treatment of uncertainty in the estimation of geotechnical parameters at unsampled locations. The method is relatively fast, computationally efficient and well suited to non-stationary data (i.e. multi-layered soil stratigraphies with spatially varying soil properties and soil layer boundaries).

3.1 *BCS analysis parameters*

A 2D BCS analysis was undertaken for each case, extending across the 142 m long survey line and down to 20 m depth, using horizontal and vertical spatial increments of Δx = 1.0 m and Δz = 0.02 m respectively. The analysis adopted natural log values of the input q_{net-f} data to avoid negative estimated net cone resistance (q_{net-e}) values and to reflect the generally log-normally distributed nature of the sampled q_{net-f} data (see Lacasse 1994, Griffiths et al. 2009).

Each BCS analysis comprised 10,500 iterations. Results from the first 500 iterations were discarded, as these were assumed to represent the numerical stabilisation phase of the analysis. In order to ensure the final results were statistically independent, the results from every 20th iteration (from the remaining 10,000 iterations) were saved while those from the other iterations were also discarded. Hence, each BCS analysis comprised 500 independent q_{net-e} sets across the full 20 m by 142 m z-x cross-section.

The study did not account for measurement uncertainty in the PCPT data (this will be addressed as part of future/ongoing development of the approach).

3.2 *BCS analysis results*

Results from the Case 1 BCS analysis are presented on Figure 3 as z-x heat maps showing the mean and coefficient of variation (COV) of the estimated net cone resistance (q_{net-m} and $q_{net-cov}$ respectively) determined from the 500 independent q_{net-e} cross-sections, with the PCPT locations (input q_{net-f} data) high-lighted. The q_{net-m} map shows a similar soil unit structure across

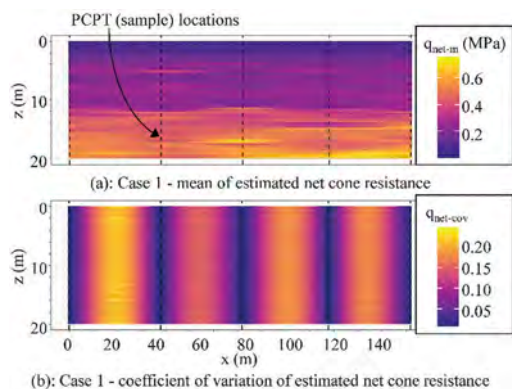
the survey line as that inferred from the measured data (see Figure 2). The $q_{net-cov}$ map provides an informative illustration of the predictive functionality of the BCS method. The COV at the PCPT locations is near-zero; this is to be expected, since at these locations q_{net} is measured (known; i.e. q_{net-f}) and the corresponding estimated values are considered to be reliable. Conversely, in between the PCPTs the COV is relatively high, since at these locations no information on q_{net-f} is available. Note the COV increases as the horizontal distance from the nearest sampled location also increases.


Figure 3. Case 1 BCS analysis – mean & COV of estimated net cone resistance.

Figure 4 provides a useful demonstration of the overall structure of the BCS analysis results. The figure shows plots of q_{net-m} and the 10th and 90th percentile ([P10, $q_{net-p10}$] and [P90, $q_{net-p90}$] respectively) estimated net cone resistance versus horizontal distance along the survey line (x) at a depth (z) of 8 m for the three cases. On each plot the locations of the PCPT measured q_{net-f} included in the respective analysis input are highlighted. The q_{net-m}, $q_{net-p10}$ and $q_{net-p90}$ profiles essentially represent near-smooth continuous functions of x. At the PCPT locations the q_{net-f} values constrain the range of q_{net-e}, while as the horizontal distance from the nearest PCPT increases the q_{net-e} range also increases (as reflected by the widening range between $q_{net-p10}$ and $q_{net-p90}$).

Further insight into the BCS analysis functionality may be obtained by interrogating estimated net cone resistance versus depth profiles at specific locations along the survey line. Figure 5a shows the measured (q_{net-f}) profile for PCPT2 (x = 38 m), together with the mean, P10 and P90 estimated profiles from the Case 2 BCS analysis at x = 38 m. In this scenario where the PCPT2 measured q_{net-f} was excluded from the BCS analysis input, we can assess the performance of the BCS method in predicting q_{net-f}. The mean estimated q_{net-m} profile shows generally reasonable agreement with the measured profile, although locally there is some mismatch. Comparing the mean estimated and measured profiles, the Case 2 average normalised
Figure 4. Case 1, Case 2 & Case 3 BCS analyses – mean estimated & P10-P90 estimated net cone resistance at 8 m depth.
Figure 5. Case 2 & Case 3 BCS analyses – measured, mean estimated & P10-P90 estimated net cone resistance at PCPT2.

prediction error for PCPT2 (expressed as the average absolute value of [q_{net-m} − q_{net-f}]/q_{net-f}) was 16.9 %. Furthermore, with the exception of a handful of specific abrupt changes in the measured q_{net-f}, the $q_{net-p10}$ and $q_{net-p90}$ profiles bound the q_{net-f} profile well.

A similar set of profiles at x = 38 m are presented on Figure 5b for the Case 3 analysis. The overall agreement between q_{net-m} and q_{net-f} is similar to that observed for Case 2. For Case 3 the average normalised prediction error for PCPT2 was 17.1 %.

4 FOUNDATION DESIGN ASSESSMENT

A simplistic design assessment of a representative foundation was undertaken which utilised the results of the BCS analyses (in the form of estimated soil strength along the survey line z-x cross-section), in addition to an alternative estimate of soil strength based on a more standard approach.

4.1 Standard assessment of field PCPT data

A 'standard' assessment of field PCPT data across a specified survey area or line for the purpose of foundation design often involves assuming that the seabed forms a single soil zone in the area of interest (covering the planned infrastructure and investigated locations). The available data is compiled and simple percentile (or quantile) profiles of the data versus depth are generated. These profiles are normally independent of horizontal location and apply right across the survey area or line.

For this study the standard assessment was based on the quantile regression (QR) 'zonation' approach (Uzielli et al. 2019). An example of this approach is illustrated on Figure 6, which shows the Case 1 (five PCPTs) measured q_{net-f} versus depth data. Included on the same figure are the corresponding 10th and 90th quantile (Q10 and Q90 respectively) representative design profiles of the Case 1 q_{net-f} data. The QR profiles were generated considering the same soil units inferred from the field PCPT data (see Figure 2).

4.2 Foundation design scenario

The simple deterministic foundation design scenario considered a circular caisson foundation with nominal outer diameter (D) values of 2 m and 10 m, an embedment length (L) ranging between 5 m and 20 m, and a skirt wall thickness (t) defined by D/t = 50.

The design considered the foundation in-place vertical capacity and installation resistance. The capacity (V_{cap}) was simplistically assumed to comprise the sum of end bearing across the full caisson base ($q_b = N_c\, s_{u-b}\, A_b$, N_c = bearing capacity factor, s_{u-b} = average undrained shear strength across the caisson base, A_b = caisson base area) and skin friction across the outer caisson wall ($f_o = \alpha\, s_{u-o}\, A_o$, α = adhesion factor, s_{u-o} = average undrained shear strength across the outer caisson wall, A_o = outer caisson wall area).

The installation resistance (V_{inst}) was simplistically assumed to comprise the sum of end bearing across the caisson wall tip area ($q_t = N_c\, s_{u-b}\, A_t$,

where A_t = caisson wall tip area), friction across the outer caisson wall (f_o) and friction across the inner caisson wall ($f_i = \alpha\, s_{u-i}\, A_i$, where s_{u-i} = average undrained shear strength across the inner caisson wall, A_i = inner caisson wall area). In all cases it was assumed $N_c = 9$ and $\alpha = 0.6$, while s_{u-b}, s_{u-o} and s_{u-i} were determined assuming $s_u = q_{net}/N_{kt}$ where N_{kt} = cone factor = 15.

4.3 Foundation design example

A set of foundation design assessment results is presented on Figure 7 in terms of V_{cap} and V_{inst} versus L for D = 2 m and a caisson centre horizontal location (x_c) of 38 m (coincident with PCPT2). The V_{cap} and V_{inst} values were calculated considering soil strengths based on the Case 1 and Case 3 BCS estimated q_{net} values (P10 for V_{cap}, P90 for V_{inst}) and Case 3 QR estimated q_{net} values (Q10 for V_{cap}, Q90 for V_{inst}). Since the PCPT2 q_{net-f} data was included in the Case 1 analysis input, the Case 1 BCS-estimated V_{cap} and V_{inst} values for D = 2 m at x = 38 m closely reflect the soil strength profile derived directly from the PCPT2 measured q_{net-f}.

Figure 7a shows for all values of L the Case 3 BCS-P10 V_{cap} is lower than the Case 3 QR-Q10 V_{cap}, which in turn is generally lower than the Case 1 BCS-P10 V_{cap}. For Case 3 at x = 38 m (midway between the closest PCPTs, PCPT1 and PCPT3) no information on q_{net-f} is available, and therefore the BCS estimated strength range is sufficiently wide (about the mean, reflecting higher uncertainty) such that the Case 3 BCS-P10 strength is less than the Case 3 QR-Q10 strength (and the Case 1 BCS-P10 strength, which is assumed to be similar to the PCPT2 q_{net-f}).

The opposite trend is shown on Figure 7b for V_{inst}, implying the Case 3 BCS-P90 strength is greater than the Case 3 QR-Q90 strength (and the Case 1 BCS-P90 strength, which again is assumed to be similar to the PCPT2 q_{net-f}).

Considering a scenario represented by Case 3 and a design requirement to select an appropriate L for a D = 2 m caisson at x = 38 m, the results presented
Figure 6. Case 1 – Q10-Q90 design net cone resistance.
Figure 7. Case 1 & Case 3 – example foundation vertical capacity & installation resistance versus embedment length.

on Figure 7 highlight the implications of the decision on if the caisson sizing should adopt an estimated soil strength based on the available (in-hand) data, or whether additional data (in the form of a PCPT) should be acquired at x = 38 m. If it were decided not to acquire additional data, the design may adopt the relatively conservative Case 3 BCS estimates for V_{cap} and V_{inst} as these account for the relationship between location (x) and uncertainty in the estimated soil strength. Conversely, if the additional PCPT was performed, the designers could adopt the less conservative Case 1 BCS V_{cap} and V_{inst} estimates. If no extra PCPT was performed and the designers adopted the simpler traditional approach, the resulting QR-based estimate of soil strength would underrate uncertainty and lead to a design that may be unconservative (by an amount represented by the difference between the Case 3 QR and BCS estimates for V_{cap} and V_{inst}).

4.4 Overview of foundation design assessment

A summary of the foundation design assessment findings is provided in Table 1 in terms of the capacity ratio (R_{cap}) equal to the BCS estimated V_{cap} divided by the QR estimated V_{cap}, and the installation resistance ratio (R_{inst}) equal to the BCS estimated V_{inst} divided by the QR estimated V_{inst}. By normalising the BCS-based capacity and installation resistance values against their QR counterparts, the R_{cap} and R_{inst} results highlight the ability of the BCS method to account for location-specific confidence in soil strength. Note the R_{cap} and R_{inst} values contained in Table 1 are average values for 5 m ≤ L ≤ 20 m. Results are presented for x_c = 72 m, 55 m and 38 m, D = 2 m and 10 m, and for the three different cases.

The same results are plotted on Figure 8 in terms of average R_{cap} and R_{inst} values versus the corresponding representative horizontal separation distance of the caisson centre from the nearest PCPT locations ($s_{rep} = [s_1\ s_2]/[s_1^2 + s_2^2]^{0.5}$, where s_1 and s_2 = horizontal distance from the caisson centre to the immediately adjacent PCPTs situated each side of the caisson centre location; values of s_{rep} are listed in Table 1). Included on the plots are approximate trendline fits to the results.

The results indicate a general trend of R_{cap} decreasing and R_{inst} increasing with increasing s_{rep} (i.e. greater separation between the caisson and known soils data). For caissons centred about a PCPT location (s_{rep} = zero), the BCS estimated capacity is shown to be higher than the corresponding QR estimated value (R_{cap} > 1.0), while the BCS estimated installation resistance is lower than the corresponding QR estimated value (R_{inst} < 1.0). Hence, these results suggest for s_{rep} = zero the QR approach tends to overestimate the level of soil strength uncertainty.

Conversely, for caissons situated some distance away from the closest PCPT locations (high s_{rep}), the BCS estimated capacity is shown to be slightly lower than the corresponding QR estimated value (R_{cap} < 1.0), while the BCS estimated installation

Table 1. Foundation design assessment results.

	2	16.2	0.96	0.96	1.06	1.06
	3	16.2	0.95	0.95	0.98	0.98
38	1	0.0	1.20	1.14	0.86	0.88
	2	25.3	0.95	0.95	1.10	1.10
	3	25.3	0.87	0.86	1.09	1.09
Figure 8. Foundation average capacity & installation resistance ratios versus representative horizontal separation distance from nearest PCPTs.

resistance is generally slightly higher than the corresponding QR estimated value (R_{inst} > 1.0). Hence, this suggests for high s_{rep} the QR approach tends to slightly underestimate soil strength uncertainty.

The results listed in Table 1 also show that for caissons centred about a PCPT location (s_{rep} = zero), as the caisson outer diameter (D) increases R_{cap} decreases slightly while R_{inst} increases slightly. This reflects the increasing level of uncertainty in the BCS estimated strength across the caisson footprint as it expands beyond the PCPT location. For caissons situated away from the closest adjacent PCPT locations (relatively high s_{rep}) the opposite trend is expected, although the results indicate minimal change in R_{cap} and R_{inst} with increasing D. This suggests the foundation must be situated within some limiting distance from the nearest adjacent PCPT for D to influence R_{cap} and R_{inst}.

5 CONCLUSIONS

5.1 *Interpolation of PCPT data and impact on foundation design*

The study outlined in this paper provides a demonstration of the application of an advanced statistical approach to interpolating sparse field PCPT data (specifically net cone resistance) to improve geotechnical design inputs for a representative foundation. The findings of the foundation design assessment (summarised in Table 1 and Figure 8) provide a concise quantitative example of the benefit offered by such approaches in addressing the spatial variation in soil strength uncertainty caused by the layout of an SI. This benefit encapsulates both the opportunity to rationally reduce foundation size requirements when soil strength uncertainty is low (near SI locations), and the need to fully account for risk by increasing foundation size requirements when soil strength uncertainty is high (further from SI locations).

5.2 *Next steps – interpolation of data*

As part of future/ongoing development of the application of advanced statistical approaches to interpolate sparse data, a near-term goal will be to investigate options for incorporating additional sources of geodata into approaches such as the Zhao et al. (2020) BCS method featured in this paper. One potential source is geophysical data which may inform the spatial alignment of soil unit boundaries and the identification and selection of soil unit types and possibly soil classification properties.

The BCS approach may also be expanded to a three-dimensional (3D) spatial framework. Such analyses would require significantly more computational time and resources. However, in situations where data is available over a specific spatial footprint or survey area, and for the scenario where the position of future infrastructure within the footprint changes, such a capability would be beneficial.

5.3 *Next steps – applications of interpolated data*

As demonstrated by the foundation design assessment, the potential geotechnical engineering applications of statistical analysis methods which consider spatial distribution of seabed uncertainties are significant. A possible future application involves using predicted soil properties at unsampled locations as input to a suite of forecasting-costing-optimisation tools, which may be used to facilitate planning of future geotechnical SIs and inform real-time decision-making for current SIs. Similarly, in the context of an offshore setting the tools may be employed in the optimisation of infrastructure design (e.g. pipelines, cables, platforms, offshore wind turbines and subsea structures). The goal will be to use these tools in a project setting to undertake quantitative cost-benefit assessments in order to provide answers to questions such as "do we need to acquire additional geo-data?", "where should we locate our infrastructure?" and "what size does our infrastructure need to be?".

Use of CPT as a soil mixing verification tool: Some practical observations

A. O'Brien & I. Murray

GE Solutions Consulting Ltd., Whitburn, UK

ABSTRACT: Mass soil mixing is a versatile ground improvement technology for marginal and brownfield sites. Dry soil mixing is relatively common in the UK for the improvement of ground with very wet and/or organic materials. Wet mixing is less commonplace and involves introduction of a fluid grout with simultaneous rotavating of the soil with a mixing tool. This paper presents the results of CPT investigations into wet mixed soils with a view to use the results as a means to verify the strength and consistency of the mixed materials. A high volume of data has been extracted from two active sites. CPT soundings are found to be purposeful in terms of demonstrating the overall improvement effect and integrity of the mixed soil volume spatially and with depth. Existing CPT testing of mass mixed soil is very limited and this testing has allowed the mixed soil to be compared to existing CPT soil behaviour indexes to give an insight into their usefulness for characterising mixed material and its behaviour.

1 INTRODUCTION

Mass wet soil mixing involves disaggregation over large areas / volumes of soil using a rotavating tool. Mixing usually takes place within discrete "cells" and the mixing depth is typically limited up to 5-7m depending on the application and native soil conditions. The rotavating tool spins at high revolutions per minute (in the order of 80-90rpm) and grout is injected under medium pressure (typically up to 50bar). The result is a completely fluidised cell, homogenising the native soils and engendering the required strength with curing time.

Post-construction behaviour is usually assessed via limited in situ testing, such as plate bearing tests supplemented with laboratory strength testing of samples recovered during construction, typically to establish a specified unconfined compressive strength. However, because of the nature of the mixing process, there is scope for small inclusions of unmixed material to remain where mixing effort is not adequate. Cone penetration testing is a practical means to establish the strength and consistency of the mixed soil body, particularly where pre-construction and post-construction soundings are undertaken to allow quantification of the improvement effect.

The use of the cone penetration test for these purposes needs careful consideration if the data is to be used for anything more than a comparison of pre-construction and post-construction conditions. The nature of the soil mixing process is such that the entire matrix of the soil is de-structured with hydration & cementation subsequently forming an entirely new macro- and microscopic condition. The mixed materials would fall outside of the normal soil behaviour type / index categorization, which is obviously limited to natural materials. However, if found to be reliable, the use of CPT to re-parameterise the mixed material would have significant technical and commercial benefits including spatial quality control, estimating spatial variability of the mixed area and development of geotechnical parameters for the mixed soil, thereby mitigating the need for high-frequency laboratory testing.

It is noted that the use of CPT in soil mixing applications is currently typically limited to deep columns (e.g., Puppala et al., 2005; Ilander et al., 1999), which are necessarily more focused and higher intensity mixing efforts and this is a distinction which must be made for mass mixing, which attempts to productively improve larger soil volumes, typically to a lower strength than deep soil mixed columns.

2 THE SITES

Two sites have been examined in this study, denoted as BWB and JSR – both are active sites in western Scotland. Site BWB was predominantly firm non-organic lightly overconsolidated horizons of sandy, silty clay or sandy silt with occasional

lenses of silty sand. The groundwater regime is ill-defined on this site and is potentially subject to a hydraulic gradient, but is known to be within the mixed horizon. The minimum mixed depth for the BWB site is 6m.

Site JSR was characterised by very soft silty clay with inclusions of organic materials and occasional bands of organic materials up to 1m in thickness. The organic materials are nominally described as amorphous peat. The site is low-lying between glacial drumlins. The groundwater table is, again, ill-defined but typical equilibrium water level is within the mixed horizon. The minimum mixed depth for the JSR site is 4.0m.

2.1 Mass mix procedure

For both sites, a target mixing depth was established and achieved. Cement was added via a neat cementitious grout (CEM I only) with added cement proportions measured between 12-15% of the bulk unit weight of the native soil. This is a typical proportion for this type of mixing in order to control both material bulking and overall injected volume. Curing time post-mixing varied in a narrow range of 25-35 days when the CPTs were undertaken at both sites.

3 COMPARISON OF PRE- AND POST-CONSTRUCTION CPT DATA

All CPT data in this study was collected using 15cm^2 subtraction piezocones manufactured by Geomil Equipment B.V. The data procedures were consistently in accordance with EN ISO 22476-1:2012 and all CPTs achieved Application Class 2, noting that the soil type prohibited achievement of Application Class 1 as a practical matter.

Porewater pressure measurements were measured at the cone shoulder (u2) position.

3.1 Tip resistance

Corrected cone tip resistances for both sites are presented in Figures 1 & 2 for the BWB and JSR sites respectively. Based on mean corrected tip resistance, post-construction improvement in tip resistance was estimated as a multiplier of 6.11, with a standard deviation of 2.71 for the BWB site (mean pre-construction tip resistance of 1.16MPa, standard deviation of 0.518MPa). The equivalent multiplier for the JSR site is 4.86 with a standard deviation of 2.27 (mean pre-construction tip resistance of 0.30MPa, standard deviation of 0.11MPa).

3.2 Sleeve friction

Sleeve friction for both sites are presented in Figures 3 & 4 for the BWB and JSR sites respectively. Based on mean sleeve friction, post-construction improvement in sleeve friction was estimated as
Figure 1. BWB site tip resistances.
Figure 2. JSR site tip resistances.

a multiplier of 5.33 with a standard deviation of 1.94 for the BWB site (mean pre-construction sleeve friction of 50.5kPa, standard deviation of 17.93kPa). The equivalent multiplier is 4.55 with a standard deviation of 2.17 for the JSR site (mean pre-construction sleeve friction of 12.77kPa, standard deviation of 5.08kPa). A statistical summary of the primary measured parameters are presented in Table 1.

3.3 Dynamic porewater pressure

Dynamic porewater pressure profiles are presented in Figures 5 & 6 for the BWB & JSR sites respectively. A rational statistical examination of these profiles is not possible; however, a number of observations can be made. Pre-construction dynamic porewater pressure, noting that cone saturation was tightly controlled and dissipation tests were run in order to assure saturation of the cone where appropriate, is invariably negative/approaching cavitation pressure or inconsistently and modestly positive (u_2 where positive is typically less than 50kPa).

Post-construction, large dynamic porewater pressures are generated, particularly for the BWB site. The large porewater pressures are generated generally towards the middle of the mixed horizon and are observed to revert towards pre-construction behaviour at the base of the mixed horizon. Cavitation pressures were established over some of the mixed horizon at the BWB site and more consistently towards the base of the mixed horizon at the JSR site. There are no noted operational reasons for this occurrence.

3.4 Friction ratio

Comparison of pre- and post-post construction friction ratio observes a degree of inverse proportionality. Figure 7 presents a comparison of friction ratio pre- and post-construction based on average values. It is observed that where the pre-construction friction ratio is initially low (<4%), there is a tendency for post-construction friction ratio to be elevated. Where the

Table 1. Statistical summary of measured parameters for BWB & JSR sites.

Measured parameter	Stat.	Site BWB		Site JSR	
		Pre	Post	Pre	Post
Corrected cone resistance (MPa)	Mean	1.160	6.469	0.301	1.298
	Median	0.990	7.066	0.294	1.221
	St. Dev.	0.518	2.331	0.105	0.441
	COV	0.447	0.360	0.350	0.340
Sleeve friction (kPa)	Mean	50.502	258.010	12.766	49.394
	Median	47.346	273.448	12.264	47.356

	COV	0.355	0.340	0.398	0.210
Figure 3. BWB site sleeve friction.
Figure 4. JSR site sleeve friction.

pre-construction friction ratio is >5%, there is a tendency for the post-construction friction ratio to be reduced. Between 4% and 5%, there is a transition zone where friction ratio could be either reduced or elevated when compared to pre-construction levels.

3.5 Soil behaviour index / type

Normalised soil behaviour indexes (I_c), calculated based on the work of Robertson (2009), for both sites are presented in Figures 8 & 9 below for the BWB & JSR sites respectively using routine procedures for normalising the input parameters. The soil behaviour indexes are observed to undergo a marked shift post-construction.

Examining soil behaviour type more broadly, the shifts are in the main from normally to lightly over-consolidated fine-grained soils towards very stiff fine-grained soils, capturing the cemented structure. More recent soil behaviour index methods (e.g., Robertson, 2016) would have categorised the mixed soil as *Clay-like / Dilative* or *Transitional / Dilative* with estimates of the lower B_q parameter indicative of increasing microstructure (cementation, bonding). The SBT charts for the BWB & JSR charts are presented respectively in Figures 10 & 11, while the mean shift in soil behaviour type is shown in Figure 12.

4 OBSERVATIONS

The direct measurements of cone tip resistance and sleeve friction are observed to increase post-mixing. Mean tip resistance increased by between 558% (site BWB) and 430% (site JSR) for respective mean pre-construction tip resistances of 1.16MPa and 0.3MPa. Similarly, mean sleeve friction increased by between 511% and 387% for respective mean pre-construction sleeve friction of 50.5kPa and 12.8kPa. The CPT is observed to be purposeful in demonstrating that achieved improvement is less at the base of the mixed horizon at the time of the measurements.

The naïve coefficient of variation (noting that mean values were used in these calculations on the basis of consistent sample sizes) reduces for the measurement of tip and sleeve resistance over both sites, though not markedly, mainly owing to the lack of stratification over both sites i.e., there are no dominant horizons in the pre-mixed zone. The magnitude of the reduction in variation is most pronounced in the measurement of sleeve friction for the JSR site where the pre-construction variation was greatest of the parameters measured (0.398 pre-construction, 0.210 post construction).

There is marked facility to set up high excess pore-water pressures post-construction. Pre-construction soils expressed dilative behaviour and cavitation resulting in negative u2 measurements. However, post-construction, and most pointedly at the BWB site, very high excess porewater pressures were measured.
Figure 5. BWB site dynamic porewater pressure (u2).
Figure 6. JSR site dynamic porewater pressure (u2).
Figure 7. Pre- / post-construction friction ratio comparison.

Figure 9. I_c for JSR site.

extract from this chart is the trajectory of the soil behaviour type which is towards a very stiff and fine-grained categorisation which is indicative of the cemented nature of the material. As noted, more modern SBT methods would identify the materials as cohesive or transitional and dilative. However, the magnitude of dynamic porewater pressures established

Figure 8. I_c for BWB site.

As noted, the friction ratio measurements appear to show a trend of inverse proportionality with the presence of a transitional zone of between 4%-5% where post-construction estimate has been observed to be both higher and lower than pre-construction estimates.

Soil behaviour index/type were found to markedly shift post-construction using traditional methods (see Figure 12). The SBT chart shows indicatively the average shift pre- to post-construction. The main point to

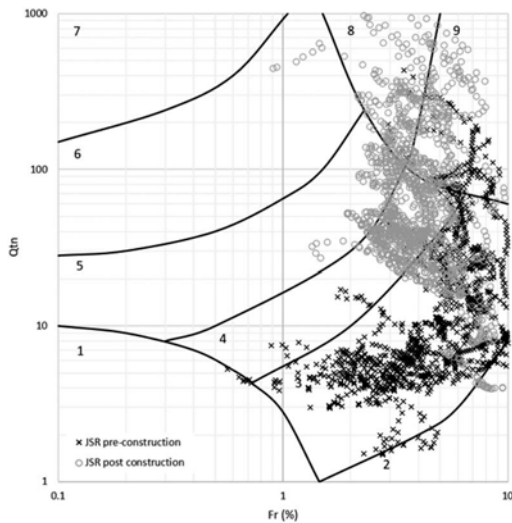
Figure 10. Soil behaviour type chart for BWB site.


Figure 11. Soil behaviour type chart for JSR site.
Figure 12. Soil behaviour type chart for both sites showing trajectory of mean shift in behaviour.

post-mixing is not consistent with dilative material categorisation.

While sub-optimal as a categorisation tool, soil behaviour index may have some utility as a measure of the integrity of the mixed soil, particularly where the expected behaviour of the soil pre-construction is well defined. This is because the soil behaviour index takes into account both tip and sleeve resistance and can be stress-normalised. With regard to stress normalisation, variation in the bulk density of the mixed material when compared to the native soil bulk density, should be accounted for.

5 RECOMMENDATIONS FOR FURTURE WORK

It is clear that current SBT methods are effective in capturing the effect of the mixing effort, however, even with more modern methods which consider soil fabric / microstructure more actively, current SBT methods are not optimal for a final categorisation. Key to this is the observation regarding the contractive / dilative behaviour and the marked facility to set up substantial excess porewater pressures. It appears justified that the assumption of undrained behaviour is reasonable for design incorporating wet soil mixing of this nature and to that end, extraction of undisturbed samples for more detailed laboratory (triaxial) testing would be purposeful to establish an appropriate N_k factor for mixed soil.

As noted, the efficacy of the mixing toward the base of the mixed horizon is less than through the main body of the mixed horizon. However, there are a number of other effects that should be investigated as contributory here. For example, the oscillation of the mixing tool, which is typically excavator-mounted in mass mix applications, could yield small unmixed inclusions which would distort CPT results at the base. Also, the exothermic effects of curing merit further consideration in strength achievement in particular, how the ambient ground temperature can be contributory to suppression or acceleration of curing rate which would be most pronounced at the native soil interface. CPT (with thermal measurement capability) would be purposeful in investigating this in situ as extracted samples can be subject to storage and temperature variations that are not representative of the in-situ condition.

Liquefaction damage assessment using Bayesian belief networks

L. Paolella, A. Baris & G. Modoni
University of Cassino and Southern Latium, Italy

R.L. Spacagna & S. Fabozzi
CNR IGAG, Area della Ricerca Roma 1, Italy

ABSTRACT: The seismic and liquefaction risk assessment implies introducing methods based on different hypotheses and dealing with different levels of uncertainty affecting the whole process from triggering to surficial manifestation. In this context, soft computing methods, like Bayesian Belief Networks (BBN) and artificial intelligence algorithms, provide the logic framework for cause-effect relationships and the statistical statement to manage uncertainties. Taking advantage of the significant amount of geotechnical data and post-earthquake surveys, an application of BBN versus the forecasting of liquefaction-induced ground damage is proposed considering three main shocks of the 2010 – 2011 Christchurch (New Zealand) Earthquakes Sequence. The BBN algorithms are firstly employed to identify significant variables and learn the relationships among them, then a direct and graphical link between input and target data is created. The quantitative validation of the built architecture enables to advantageously queried the net to predict the result of new datasets.

1 INTRODUCTION

The chain phenomena describing the liquefaction process involve numerous and complex relationships that rule the origin, propagation, surficial manifestation, and induced structural and infrastructural damage. In the field of Earthquake Engineering, the cause-effect relationships starting from the probability of occurrence of a predefined intensity measure have been translated into the PEER convolutive integral (Cornell and Krawinkler, 2000), which develops the performance-based earthquake engineering approach.

In recent years, the development of soft computing methods and the progress in artificial intelligence A.I. provide robust and reliable instruments capable of dealing with large amounts of data in a reasonable time, controlling the quality of results and quantifying uncertainties. Artificial Neural Networks (ANNs) and Bayesian Belief Networks (BBNs) have been advantageously used in various engineering applications to identify the most significant variables, learn the relationships and dependencies among them, and link the input data to the target. After scrutinizing the new data collection campaigns following the 2012 Emilia (Italy) Earthquake sequence, Paolella et al. (2019) developed artificial neural networks and Monte Carlo simulations to relate the Ishihara-based geotechnical model to the observed ground liquefaction in the municipality of San Carlo. Ching and Phoon (2017) developed a method based on the sparse Bayesian learning (SBL) approach to analyze

site-specific measurements like cone penetration test (CPT) data for probabilistic site characterization. A detailed study has been carried out by Tesfamariam (2013) about liquefaction risk that calibrates four different BBN structures and defines a procedure to assess the liquefaction risk at the regional and single building levels. Tang et al. (2018) compare ANN technology and BNNs in describing the liquefaction ground severity demonstrating that the Bayesian model achieves better accuracy for each damage state. Taking advances from previous experiences and the considerable amount of geotechnical data, a BN model for liquefaction prediction is proposed in this work. The best structure is obtained after the processing of ≈9′000 CPTs available from the New Zealand Geotechnical Database and testing each performance against three main events of the 2010-2011 Canterbury Earthquake Sequence. In a preliminary analysis, the back analysis enables the reconnaissance of the critical layer, *i.e.,* the sandy stratum most likely to undergo liquefaction during the 2010-2011 Christchurch earthquake sequence. The obtained results have shown that, if opportunely guided, the model can relate pre-defined representative variables to liquefaction ground evidence, the latter available from specific post-earthquake surveys. In a subsequent step, more detailed evaluations have been performed on such a critical layer, and a set of site-specific soil fragility functions is proposed. Uncertainties at different levels are accounted for through statistical and probabilistic terms, displaying

and controlling each variable. In conclusion, an alternative approach to large areas studies (Spacagna et al., 2021) and traditional liquefaction severity indicators often evaluated deterministically is presented by developing a set of fragility functions.

2 BAYESIAN BELIEF NETWORKS

A Bayesian Network falls in the category of probabilistic graphical modeling (PGM) technique that is to compute uncertainties by using the probability concept (Pearl, 1988). It is represented as a directed acyclic graph (DAG) which contains a set of nodes and links, arches, relating parent nodes to the children ones. A directed acyclic graph evaluates the uncertainty of an event occurring based on the conditional probability distribution of each random variable. A conditional probability table is used to represent this distribution of each variable in the network.

To understand the meaning, it is necessary to introduce the inference algorithm that is based on the Bayes theorem and conditional independence as follows:

$$P(B|A) = \frac{P(A|B)P(B)}{P(A)} \qquad (1)$$

It introduces joint probability, a measure of two events happening simultaneously *i.e., P(A|B)*, and the conditional probability of an event B, which is the probability that event B occurs given that an event A has already occurred. The Bayesian Networks satisfy the Local Markov Property, stating that a node is conditionally independent of its non-descendants, given its parents. In the example of Figure 1, *P(D|A, B)* is equal to *P(D|A)* because D is independent of its non-descendent, B. This property aids us in simplifying the Joint Distribution. The Local Markov Property leads us to the concept of a Markov Random Field, which is a random field around a variable that is said to follow Markov properties.
Figure 1. Scheme of a sample Bayesian Network.

Proven that the probability of a random variable depends on his parents, a Bayesian Network can be generalized as shown in Eqn. 2:

$$P(X_1, .., X_n) = \prod_{i=1}^{n} p(X_i|Parents\,(X_i)) \qquad (2)$$

2.1 Bayesian Networks for liquefaction hazard

In general, the assessment of liquefaction hazard moves from subsequent steps, which translate the soil propensity to liquefy, the triggering analysis, and the liquefaction-induced ground deformation (Bird et al., 2005). Therefore, a BN model for liquefaction hazard requires introducing three types of nodes: 1) input nodes that include soil parameters (e.g., relative density, plasticity, fine contents), site conditions (groundwater depth, thickness and position homogeneous layers, distance from geological features like rivers/paleochannels) and seismic intensity measures (peak ground acceleration, Magnitude, duration, epicentral distance); 2) state nodes which combine input into intermediate variables (*i.e.,* the classification of soil susceptibility, the probability of triggering the phenomenon), and 3) output nodes describing the severity of liquefaction-induced ground observations.

Hu et al. (2016) provided an example of a net that constructed a model for liquefaction potential evaluation considering 12 factors. In this study, a revised approach is proposed, to link geotechnical and geological susceptibility to free field liquefaction ground evidence via the Arias Intensity, without evaluating traditional liquefaction severity indicators, *i.e.,* simplifying an intermediate step that unavoidably introduces noises.

After selecting representative variables for liquefaction, several net models are automatically generated and tested. With this regard, updating the net calculates the probability of having a particular combination of input variables given the evidence, allowing to determine the size, position, and strength characterization of the most likely layer experiencing liquefaction during the considered Earthquake sequence. On this layer, more detailed studies are carried out. The development of a probability model for liquefaction occurrence considers different crust thickness, *Hc*, thick, *Hl*, and average resistance, mean *crr*, of the potentially liquefiable layer. The maximum likelihood criterion is applied to fit the histograms data to lognormal functions (Baker, 2013).

2.2 Management of uncertainty and Validation

Among the advantages of the proposed method there, is an immediate and reliable graphic tool that displays input variables and their relationships. Uncertainties in data estimates and the validity of basic assumptions (like the three-layer hypothesis) can be managed at different levels. In addition, the probabilistic model

allows practitioners to make predictions for future situations with a certain level of confidence. Validation criteria are required to assess the reliability of the obtained results. The metrics used in this study are borrowed from the binary validation methods Lusted (1971), which introduces the concept of Receiver Operative Characteristic Curves obtained by combining specificity and sensitivity; the Area Under the Curve (AUC) is a global proxy of the estimate quality. In addition, the Kappa statistics method is used to assess the agreement between the actual and expected results (Witten and Frank, 2005). Kappa statistics is defined in Equation 3: Pa is the fraction of agreement and Pe is the fraction of random agreement used to correct for values. Pa is a summation of the diagonal values of the confusion matrix.

$$K = \frac{Pa - Pe}{1 - Pe} \qquad (3)$$

3 THE CASE STUDY OF CHRISTCHURCH (NEW ZEALAND)

3.1 *The 2010-2011 Canterbury Earthquake Sequence*

The city of Christchurch (≈370′000 inhabitants in 2011), in the Canterbury Region of the South Island of New Zealand, was repeatedly struck by earthquakes during the 2010-2011 seismic sequence known as Christchurch Earthquake Sequence (C.E.S) The most noticeable were: the Mw 7.1 Darfield event of September 4th 2010, the (Mw 6.2) Christchurch Earthquake of February 22nd 2011, resulting in 185 fatalities and diffuse devastation to dwellings and infrastructures and the Mw 6.0 June 13th 2011. Liquefaction played a significant role in causing the removal of 900′000 tons of liquefied soil, the demolition of 8′000 buildings (Cubrinovski, 2013; Tonkin & Taylor, 2013), and an economic loss of NZ$30 billion only on the residential sector (NZ Parliament).

3.2 *Creation of databases and variables management*

Taking advantage of the significant amount of geotechnical data, a general framework to develop BBN is developed. The strategy to reach such goals include: i) database construction and preliminary processing of CPT data; ii) sensitivity and correlation analyses; iii) automated training of different nets and validation test. In addition, a probabilistic model is derived from the output of the structure showing the best performance.

The database creation includes the collection and homogenization into a standardized format of many CPTs from the New Zealand Geotechnical Database. Out of 30′000 stratigraphies available on the whole

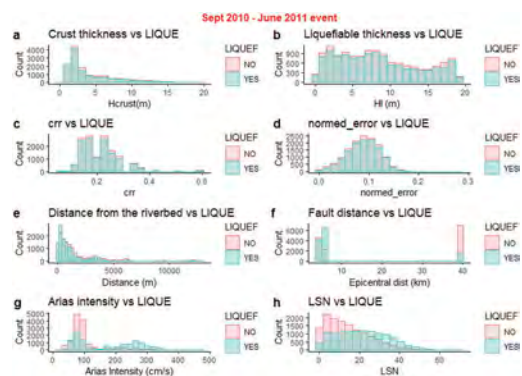
Christchurch area, around 9′000 CPT profiles with a depth greater than 10m have been considered. In a preliminary phase, the Equivalent Soil Profile (ESP) method defined by Millen et al. (2020) is applied to determine the liquefaction susceptibility. This criterion converts a CPT profile into a three-layered equivalent one, defined by Hc, Hl and crr of the potentially liquefiable layer, with an error term used to confirm the consistency with the hypothesis of three-layered profile. The following analysis include three variables (*i.e.,* crust thickness, liquefiable thickness, and resistance), which define 22 homogeneous soil classes for liquefaction susceptibility taken from Millen et al. (2020) criterion. The groundwater table is not explicitly accounted since it is already considered in evaluating the crust thickness. In addition, the ESP normed error representing a check factor for the consistency with the 3-layered profile hypothesis is considered. On the other hand, the distance from riverbeds is assumed as a proxy for geological susceptibility. Seismic hazard is characterized for three earthquakes among the main events of the 2010-2011 C.E.S., *i.e.,* the Sept 2010 Mw7.1 Darfield earthquake, the Mw6.2 Feb 2011, and the Mw6.0 Jun 2011 Christchurch Earthquakes. For each of them, the Arias Intensity is evaluated elaborating the records of Central Christchurch strong motion stations. These scenarios are modeled through the fault distance and the Arias Intensity selected in place of the pair PGA-magnitude since it embeds the intensity and duration of the shaking. On the other hand, the liquefaction ground observation is classified as "YES" and "NO". The subsequent diagnostic inference showing the correlation between each variable and the observed liquefaction is reported in Figure 2. Just as an example of traditional severity indices, the van Ballegooy et al. (2014) Liquefaction Severity Number (LSN) which combines triggering with a hyperbolic weight function, is presented in Figure 2.


Figure 2. Sensitivity analysis of selected variables versus liquefaction ground observations: a) non-liquefiable crust thickness (m); b) thick of potentially liquefiable layer (m); c) mean crr; d) normed error (Millen er al., 2020); e) distance of investigated profile from riverbeds (m); e) epicentral distance (km); g) Arias (1970) Intensity (cm/s); h) LSN (van Ballegooy et al., 2014).

Although each variable of Millen et al. (2020) method seems to correlate to liquefaction poorly, if considered alone, from Figure 2, it is intuitive to observe that liquefaction occurrence increases with proportionally with the seismic shaking (see Arias Intensity) and close to riverbeds. The herein analyzed seismic scenarios remark that the relationship between seismic moment magnitude Mw and observed liquefaction is here strongly affected by the epicentral distance that made the Mw6.0 (located at approximately 5km from the City Center) and Mw6.2 February event, whose epicenter was around 6-7km South of Christchurch, more severe than the Mw7.1 Darfield event (epicenter 45km West of Christchurch).

In the following analysis, the existing dependencies among input variables are evaluated by calculating the Pearson coefficient; the resulting correlation matrix is plotted in Figure 3, whose coefficient font size is proportional to the correlation found. The massive amount of raw data, the lack of a predefined standard in the format, in conjunction with a certain level of subjectivity connected to post-earthquake rapid surveys, results in a non-negligible noise affecting the whole dataset. Therefore, Figure 3 shows a partial moderate/strong correlation between parameters introduced to quantify liquefaction susceptibility, which can be merged into one variable (*i.e.,* the ESP soil class) and between Arias Intensity and liquefaction severity indicators like LSN. However, to reduce the intermediate steps resulting in error, in the following process Arias Intensity is directly assumed as Engineering Demand Parameter for a given soil configuration, providing an alternative approach to traditional liquefaction severity indicators. In addition, the preliminary classification of variables applied by Millen et al. (2020) has been increased to investigate other geometric configurations better.

Figure 3. Correlation matrix of the considered variables for liquefaction.

3.3 *Training and validation of Bayesian Belief Networks for liquefaction*

To generate a BBN for liquefaction assessment, the local score metrics are considered for structure learning. Following the typical steps in assessing the liquefaction-induced permanent ground deformation, seven structures of Bayesian Belief Networks are trained and tested comparing the performance versus the liquefaction prediction capability for the Sept 2010 Mw7.1 Darfield earthquake, the Mw6.2 Feb 2011, and the Mw6.0 Jun 2011 Christchurch Earthquakes. Bearing in mind the results displayed in Figure 3, these networks architecture is built in the "Genie Academy" environment (Genie, 2020 https://www.bayesfusion.com/) by introducing different search algorithms. PC (Spirtes et al., 1993) uses independences observed in data (established employing classical independence tests) to infer the structure that has generated them and is the most adequate for continuous datasets; Naïve Bayes and its improved version, *i.e.*, Tree Augmented Naïve Bayes (TAN) and Augmented Naïve Bayes (ANB), Bayesian search (BS), and Greedy thick thinning (GTT), respectively defined by Cooper and Herkovits (1992), and Cheng et al. (1997). Additionally, a background knowledge is provided to the PC algorithm to build an expert-guided network based on engineering judgment. The expert-guided model is displayed in Figure 4. The net is based on the PC algorithm customized on the phenomenon knowledge. In particular, the combination of *Hc*, *Hl*, and *crr* provides the equivalent soil profile class by introducing the normed error as the first control factor. The geological susceptibility is separately considered; therefore, the distance from the riverbed is considered and modeled as an independent variable. On the right side of the net, the epicentral distance and Arias Intensity can be observed; the net learned both a dependency among each other and liquefaction ground evidence. Conditional and prior probabilities are specified and, in turn, employed to perform belief updating and extract posterior beliefs. The quality measure can be judged with several criteria like the Bayesian approach or minimum description length (Bouckaert et al., 2011). The score of the whole network can be decomposed as the sum (or product) of individual node scores in a way that enables local scoring and searching methods. The performance of each algorithm is summarized in Table 1 that shows the result of the 5-fold cross-validation test, which splits the whole dataset into 5 panels and estimates how the model is expected to perform when used to make predictions on data not used during the training of the model. The AUC, in conjunction with the *K* statistics, is used to rank the best learning structure. Although a perfect match exists when *K* statistics is equal to 1.0, realistically, for a site investigation on a regional scale, a *K=0.5* match is more appropriate (Demshar, 2020).
Table 1. Summary of validation results for the above defined Bayesian networks.

| BBN | SCORE | | | |
	AUC	K-stat.	OSR	PRECISION
PC	0.81	0.442	0.72	0.70
Naïve Bayes	0.79	0.431	0.72	0.72
ANB	0.77	0.458	0.73	0.71
TAN	0.82	0.447	0.72	0.71
BS	0.81	0.421	0.72	0.56
GTT	0.81	0.460	0.73	0.69
Expert-guided*	0.81	0.461	0.73	0.70

* Ranked as the best structure because of the highest K-statistics and the physical accounting of cause-effect relationships governing the liquefaction phenomenon.

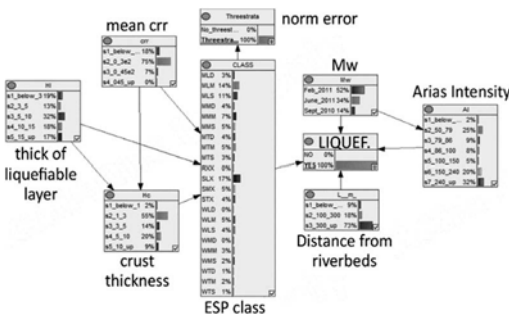
Once the general performance is evaluated through the AUC, the features of the Christchurch critical layer have been searched by setting the evidence of liquefaction and discarding those profiles not ascribable to the three-layered model (Paolella et al., 2020). It is found that, for the considered seismic scenarios, the critical layer for liquefaction is shallow ($Hc < 3m$ in 60% of cases), mid-size to large ($Hl > 3m$ in 81% of cases) and can be modeled with a $crr < 0.30$ (93% of cases) (Figure 4).


Figure 4. Back analysis of Christchurch earthquake scenarios with the selected expert-guided net.

3.4 A probabilistic model for liquefaction triggering analysis

The automated processing of such a number of CPT data and the availability of post-event damage surveys provides a unique chance to test the performance of current criteria and develop new models. About the latter task, the probability of observing liquefaction given the critical layer has been better investigated by splitting the liquefiable thickness range into three classes, i.e. $3 < Hl \leq 5m$, $5 < Hl \leq 10m$, $10 < Hl \leq 15m$

curves have been derived on these configurations. A fragility curve like the one shown in Equation 4 evaluates the probability of observing liquefaction given an intensity measure (IM) idealized by a typical lognormal distribution:

$$p(L|IM) = \phi\left(\frac{LN\left(\frac{IM_i}{IM_m}\right)}{\beta}\right) \quad (4)$$

where ϕ denotes the Gaussian cumulative distribution function, IM_m is the median distribution and β is the logarithmic standard deviation. Even though that minor literature exists about the modeling of soil liquefaction vulnerability with this approach (Geyin and Maurer, 2020), fragility curves are generally adopted in procedures to assess seismic and liquefaction risk on buildings (Fotopoulou et al., 2018), road and embankments (Syner-G, 2013) and pipelines (Liu et al., 2015; Baris et al., 2020). Fragility functions are developed as an extension of deterministic models, allowing practitioners to make previsions linked to probabilistic seismic hazard analyses. After the experience of Baker (2013) in structural modelling, the maximum likelihood method is here applied to reach the appropriate data fitting. Assuming that the number of liquefaction/no liquefaction observations from each experiment is independent of observations from other experiments, the probability of observing z_j liquefaction occurrence in nj motions having $IM = x_j$ is provided by the binomial distribution (Equation 5).

$$P\left(z_j \text{ evidence in } n_j \text{ experiments}\right) = \binom{n_j}{z_j} p_j^{z_j} (1-p_j)^{n_j - z_j} \quad (5)$$

where p_j is the probability that a ground motion with $IM = x_j$ will trigger liquefaction. The maximum likelihood is thus implemented to find the fragility function capable of predicting p_j with the highest probability of fitting experimental data. When analysis data are obtained at multiple IM levels, we take the product of the binomial probabilities (from Equation 5) at each IM level to obtain the likelihood for the entire data set.

$$Likelihood = \prod_{j=1}^{m} \binom{n_j}{z_j} p_j^{z_j} (1-p_j)^{n_j - z_j} \quad (6)$$

where m is the number of IM levels and Π is a product over all levels.

The pairs of IM_m and β obtained for each soil configuration by maximizing Equation 6 are reported in Table 2; in addition, the maximum observed value of

arias intensity is indicated, meaning that discretion should be used in using the obtained fragility functions out from the suggested range. Figure 5 displays both the suit of functions showed in Table 2 and the interpolated experimental points; a graphical comparison among each other is presented in Figure 5d. It reflects the positive correlation between thick of liquefiable layer *Hl* and liquefaction occurrence for a given shaking.
Figure 5. Probability of observing liquefaction manifestations given the AI, for each profile configuration: a) *3 < Hl ≤ 5m*; b) *5 < Hl ≤ 10m*; c) *10 < Hl ≤ 15m*; d) general comparison.

Table 2. Summary of fragility function parameters.

H1(m)	IMm	β	Arias Intensity (cm/s) range
3-5	142.3	1.03	< 350
5-10	123.8	1.02	< 350
10-15	102.6	1.06	< 350

4 CONCLUSIONS

After processing ≈30′000 CPTs, seven structures of Bayesian Networks are tested against the liquefaction ground evidence induced by three main shocks of the 2010 – 2011 Christchurch Earthquake Sequence. The validation criteria ranked the "expert-guided" Net as the best architecture. It accounts for the cause-effect relationships ruling the phenomenon introducing new variables that better describe the geological/geotechnical susceptibility (e.g., epicentral and riverbeds distances) not considered by traditional liquefaction severity indicators. The robustness of the proposed method herein is quantified by an AUC equal to 0.81, *i.e.*, ≈15% higher than traditional indices, which cannot manage all the uncertainties connected with

the randomness of seismic source, spatial variability, and error propagation (Paolella et al., 2020). The Bayesian Network-based back analysis located the Christchurch critical sandy layer at a relatively small depth (*Hc < 3m*), and a very low relative density is found on it (*crr < 0.3*). The following analysis defined a set of soil fragility curves that couple the liquefaction susceptibility of such a critical layer to the seismicity of the area via the Arias Intensity measure. Their applicability should respect the Arias Intensity range reported in Table 2, requiring additional analyses and judgment if this value is exceeded.

Geotechnical zoning of deltaic and alluvial soils of Guayaquil (Ecuador) using CPT and N_{kt} calibration based on FVT

J. Paredes & F. Illingworth
Subterra, Ecuador

R. Luque
Geosísmica, Ecuador

ABSTRACT: This document summarizes the results obtained from geotechnical zoning analysis in the city of Guayaquil and its surroundings, which stratigraphy consists mostly of alluvial and estuarine deltaic soils, by compiling over 600 CPTs and 800 boreholes. Products generated include a map of rigid stratum depth with high impedance contrast as well as spatial distribution of liquefaction susceptibility using a simplified methodology. Furthermore, shear strength s_u peak and remolded have been evaluated by comparing CPT-borehole pairs and 26 sites with CPT and electric FVT. It has been found that s_u peak from laboratory tests adjusts well to the FVT s_u remolded and f_s, suggesting sample disturbance. It has been verified that N_{kt} values measured with FVT are lower than average reported values in previews studies, possibly due to diatoms identified in scanning electron microscope (SEM). F_r based estimates appear to yield an upper limit of N_{kt} factor in Guayaquil soft clays, while s_u maps for 5 m soil segments are provided from CPT-based N_{kt} values.

1 INTRODUCTION

Guayaquil is located on the Ecuadorian coast, and has a flat relief in most of its extension. Geologically, the soils correspond to the Holocene with a large alluvial plain and estuarine deltaic deposit, located at the foot of the Chongón-Colonche Mountain Range. Due to the geological characteristics of Guayaquil, a large percentage of sites include soils susceptible to liquefaction or profiles with a thick upper layer of soft clay and organic material. Moreover, the tectonic environment rich in dissolved silica, favors the existence of diatoms, elements that provide a characteristic geotechnical behavior.

Geotechnical investigation in Guayaquil has been predominantly conventional drilling and sampling, from the 1950s to the present, but in the last decade, emphasis has been placed on in situ testing, especially through CPTu soundings. In this document, the experience from 615 CPTs in Guayaquil and the surrounding area is synthesized along with 143 electric field vane tests (FVT), carried out in an effective area of 450 km^2. In situ results have been integrated with existing boreholes.

The common state of practice in Guayaquil is to perform unconfined compression tests or use handheld devices (torvane, penetrometer) to determine undrained shear strength s_u in clays, and measure N_{60} (standard penetration number, corrected) in order to estimate liquefaction potential of granular soils. While considering testing procedures, CPT estimates provide a more accurate and efficient alternative. However, it is imperative to calibrate CPT geotechnical parameters in unconventional soils, with measurements obtained from other in situ and laboratory tests (Mayne, 2007b; Robertson, 2009; Robertson, 2012). Therefore, this report analyzes: 1) back-calculated N_{kt} values from FVT measurements and 2) a simplified geotechnical zoning of Guayaquil considering highly compressible top stratum, shear strength s_u, and susceptibility to liquefaction (LSN, LPI and settlements).

2 IN-SITU INVESTIGATION

The database considered for developing a compressible-top-layer zoning map consists of 1432 soundings: 615 CPTs (95% down to refusal conditions), and 817 boreholes from several companies. In addition, 26 FVT profiles were evaluated, delivering 143 s_u values (Figure 1). SEM images were taken at 14 sites to corroborate the existence of amorphous microstructures.

For CPTu tests, a standard 10 cm^2 cone, compression type, with 150 cm^2 sleeve was used. The pore pressure filter (u_2 position) is made out of bronze, and saturated with silicone oil. The piezocone is pushed at 2 cm/s with a 15-ton Pagani TG-63

equipment recording measurements every cm. FVTs have been carried out by pushing the vane housing with the same penetrometer and further advancing 50x100 mm vanes, 25 cm from penetrated depth. Torque is applied from the surface at one-meter intervals with Geomil GVT-100 tester. The data acquisition system records the resistance as a function of angular rotation of the vane from initial position until peak and remolded resistance is measured.
Figure 1. Location of soundings.

A preliminary classification of each sounding was necessary to determine profile types and potential geotechnical problems. It was found that 38% of profiles have a top soft clay stratum with variable thickness from 3 to 30 m, 24% presented susceptibility of liquefaction in the first 20 m and 11% of profiles include both conditions. Also, 10% of profiles presented organic material content or more than 30 m of soft clay while 10% of soils consisted of high impedance contrast within the top 25 m. This totals 93% of the profiles in which an exhaustive geotechnical analysis is required on most medium risk projects. In 83% of soundings where a thick soft clay layer or loose sand is present, is convenient to use CPTu for a better identification of sandy intercalations and suitable characterization of soft layers, both in terms of strength and compressibility.

3 N_{KT} MEASUREMENT

Piezocone, along with vane testing, was performed at 26 different sites, less than 1.5 m apart and in 7

cases, also near boreholes. Vane measurements were taken between 1 and 17 m (avg. 5.6 m) while recorded peak values vary between 10 and 240 kPa (avg. 64 kPa). Different CPT parameters at FVT depth location were compared for trend evaluation: corrected cone resistance (q_t), normalized cone resistance (Q_{tn}), normalized friction ratio (F_r), normalized pore pressure ratio (B_q), normalized SBT_n Index (I_c). Tip values of q_t range between 0.1 and 4.4 MPa, those of I_c between 2.1 and 3.8, B_q between -0.3 and 1.0, and F_r between 1% and 11%.

The bearing factor N_{kt} for cone tip resistance was back-calculated first, using a single q_t value at vane test depth and secondly, with an average q_t value ±25 cm from FVT depth, to consider lenses variability across the distance between both tests. The lower the standard deviation of q_t (σ_{qt}), the closer both N_{kt} values are. Hence, by filtering measurements with $\sigma_{qt} > 0.2$ MPa, 95% of N_{kt} values range between 3 and 12 ($N_{kt-avg} = 7.4$).

There are limitations regarding the procedure and interpretation of the vane failure mechanism, as explained by Bjerrum (1972), Ladd & Foott (1977), among others. Even when considering a correction factor $\mu = 0.80$, according to Bjerrum, for an plasticity index (PI) of 50% (conservative in most data points analyzed), estimated N_{kt} values are in the range of 4 to 15, with an average of 9.3. Thus, relatively low values of N_{kt} should be expected in the upper compressible stratum of Guayaquil.

While no correlation was detected with F_r, inversely proportional trends have been identified with I_c and B_q and directly proportional with Q_{tn} and OCR. However, none of the correlations provides an acceptable adjustment coefficient. Figure 2 illustrates the correlation between N_{kt} and Q_{tn}, which could be considered the best trend found among normalized parameters.
Figure 2. Back-calculated N_{kt} values as a function of Q_{tn}.

Furthermore, the N_{kt} range has been analyzed graphically among $FVTs_u$ and net cone resistance ($q_{net} = q_t - \sigma_v$) considering 136 measurements with $\sigma_{qt} < 1$ MPa. Three sub-datasets corresponding to

different geotechnical zones (106 values) have been compared: alluvial, deltaic-estuarine of Guayaquil and Durán. The q_{net}-s_u relation is shown in Figure 3 with slopes between 8 and 10, which corresponds to plausible Guayaquil N_{kt} values.
Figure 3. Correlation between q_{net} and s_u from field vane tests: (a) 136 measurements with $\sigma_{qt} < 1$ MPa; (b) three sub-datasets for geotechnical zones.

Based on evaluated trends the following can be concluded: 1) N_{kt} values are low compared to average values of conventional soils and 2) a correlation for N_{kt} with normalized parameters such as B_q or F_r (Mayne & Peuchen, 2018; Robertson, 2012), seem unfit for the available data from Guayaquil.

Although laboratory tests are commonly used to determine s_u in Guayaquil, sample quality is poor in many cases. According to Lunne et al. (1997) criterion, based on void ratio initial (e_o) and void ratio variation (Δ_e), 50 consolidation tests were analyzed resulting in 90% of samples having $\Delta_e/e_0 > 0.04$ and 60% > 0.07, so the quality of sampling is generally low or medium. In addition, when comparing CPTs and boreholes from 40 sites, laboratory s_u peak tends to adjust to CPT f_s, and similarly to in-situ remolded s_u at sites where FVT was also available. As an example, Figure 4 illustrates this matter in two profiles, suggesting resistance loss due to samples disturbance.

Hence, Robertson N_{kt}-F_r correlation has proven to be more appropriate than readily available laboratory

tests for preliminary and somewhat conservative estimates in Guayaquil alluvial and deltaic soils. In addition, an upper N_{kt} limit of 12 is proposed for the NC clay deposit, while site specific CPT-FVT pairing along with laboratory tests would be necessary for evaluating site specific behavior. Therefore, an

interpolation has been performed in ArcGIS for average values of estimated s_u in 5 m soil segments, except for segments which are predominantly granular soils (>55% SBTn 5-8). Figure 5 shows maps generated for 0-5 m and 5-10 m segments.

4 PRESENCE OF MICROFOSSILS

Diatom microfossils have been found in several marine and lacustrine deposits, such as those in Japan, Mexico and Colombia. The presence of diatoms in two estuarine locations in Guayaquil has been widely discussed (Vera, 2014).

Diatoms are eukaryotic unicellular algae, with a frustule composed of SiO_2 that fossilizes after the death of the microorganism. They are found in marine environments with dissolved silica, very common in places with high tectonic activity (Díaz-Rodríguez, 2011). Diatoms modify the static and dynamic response of soils. A higher diatom content increases porosity, compressibility and dilatation (Díaz-Rodríguez et al., 1998; Shiwakoti & Tanaka, 2002). Besides, s_u increases proportionally with diatom content (Wiemer & Kopf, 2017). Diatoms may cause a deviation from existing N_{kt} trends per normalized CPT parameters and also provide an explanation for encountered relatively low N_{kt} values.

Abundant presence of diatoms and framboidal pyrites has been found in sites with low N_{kt}. In 13 out of 14 sites, SEM images identified a wide range of diatoms from different species. Figure 6 shows the microstructure identified in three different sectors. As diatoms exist in soil microstructure, and consequently higher s_{u-peak} values are measured, it is reasonable to obtain higher sensitivity values ($S_t = s_{u-peak}/s_{u-rem}$) as well, compared to a diatom-free soil matrix. Although measured S_t values from FVT range between 1.1 and 12.8, with an average of 2.5, several tests show 5 to 10 kPa oscillation around remolded values. So, reported S_t average could be higher, perhaps close to 4 considering lowest measured values. At such low values it is difficult to accurately determine soil sensitivity. Besides, it is

worth noting that f_s values lower than 5 kPa have been reported in several CPTs, demonstrating the presence of very soft and possibly sensitive soils. Further research with additional testing is required to establish a more specific range of S_t by geotechnical zones.

Previous studies indicate that S_t is inversely proportional to N_{kt} (Robertson, 2012; Mayne & Peuchen, 2018), which would support the low range values of N_{kt} obtained in Guayaquil. Nevertheless, no relationship between measured sensitivity and N_{kt} has been observed, possibly due to the difficulty of determining the exact remolded value in highly sensitive soft soils or due to the need of precisely determining diatom content, which has not been the case.

5 GEOTECHNICAL ZONING OF COMPRESSIBLE STRATUM AND SOIL LIQUEFACTION

Other parameters evaluated from the database were: 1) thickness of top compressible layer or depth of rigid stratum, 2) liquefaction potential, 3) SBTn Index I_c, 4) relative density D_r of granular materials, 5) OCR and 6) coefficient of consolidation c_v (Paredes, 2020). This report illustrates zoning maps with regards to the compressible layer and soil liquefaction potential.

A preliminary qualitative and quantitative evaluation of the rigid stratum depth was performed to determine the first and foremost impedance contrast with the upper clay deposit. Supported by dozens of pile driving analyses, this stratum would correspond to a pile bearing capacity of 2500 kPa for a 50 cm square section. For defining such stratum, Q_{tn} must be greater than 100 (N_{60} greater than 45 blows in sands) and thickness greater than 2 m. If the identified layer was less than 2 m thick and located above a second soft clay layer, then the following layer with Q_{tn} and thickness greater than 100 and 2 m, respectively, was considered. The thickness variation of the upper compressible stratum has been calculated by means of a global interpolation process with local adjustment and iterative finite differences (topo to raster), which

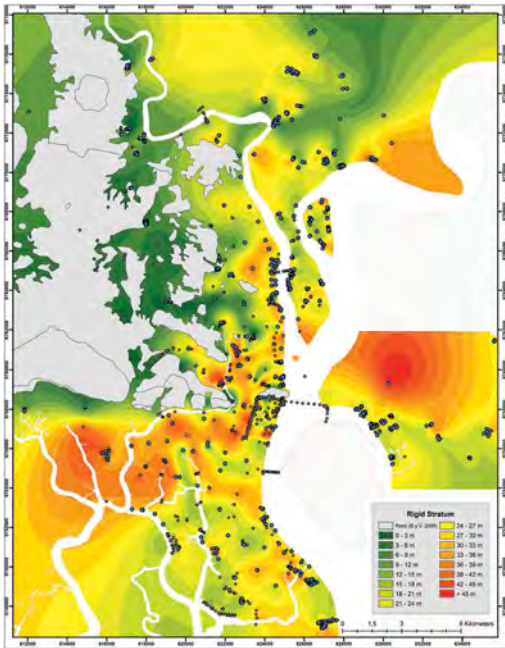
allows generating smooth curves and considering boundaries. Figure 7 illustrates the interpolation map, with depth contours between 0 and 50 m.


Figure 7. Rigid stratum depth map from 1432 soundings (615 CPTs). Rock outcrop (Benítez & Vera, 2006).

This map provides a rapid identification of depths in which pile installation may complicate if appropriate measures are not considered. Also, it constitutes a preliminary drainage or compressibility boundary with regards to settlements analyses. Although, the presence of soft to firm clays greater than 20-meter thick has been confirmed in most of the estuarine area, certain sectors south-west of the city are noteworthy, where dense soils have been identified at shallower depths as well as sandbars.

Due to the abundance of soft soils in Guayaquil, this map results beneficial for the construction industry and real state. Based on the map, an exploration campaign could be targeted towards potential geotechnical issues and project risks.

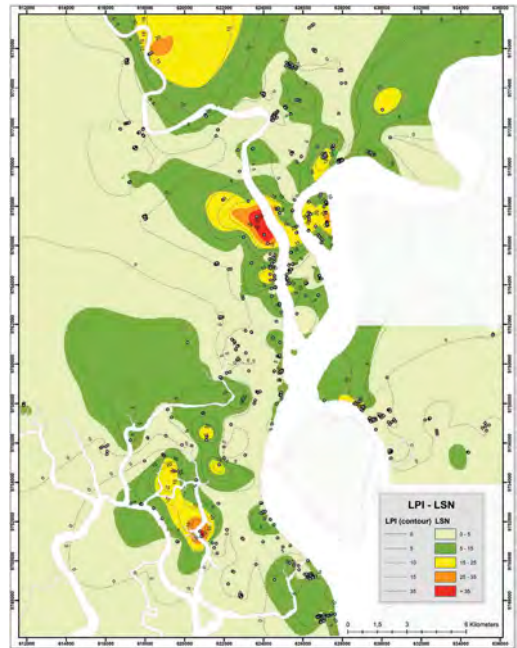
In an effort to develop liquefaction potential maps, the factor of safety FS was calculated for each sounding in Guayaquil database, considering a seismic demand of Mw=7.5 and PGA=0.4 g (according to the PSHA disaggregation carried out by Beauval et al., 2018). Subsequently, LPI (Iwasaki & Tokida, 1981) and LSN (Tonkin & Taylor Ltd, 2013) indices were calculated as well as post-liquefaction vertical free field deformations for the first 20 m (Sett @ 20m), and for the entire profile (Zhang, Robertson, & Brachman, 2002). Figures 8 and 9 illustrates the interpolated maps.


Figure 8. Spatial distribution of LPI and LSN.
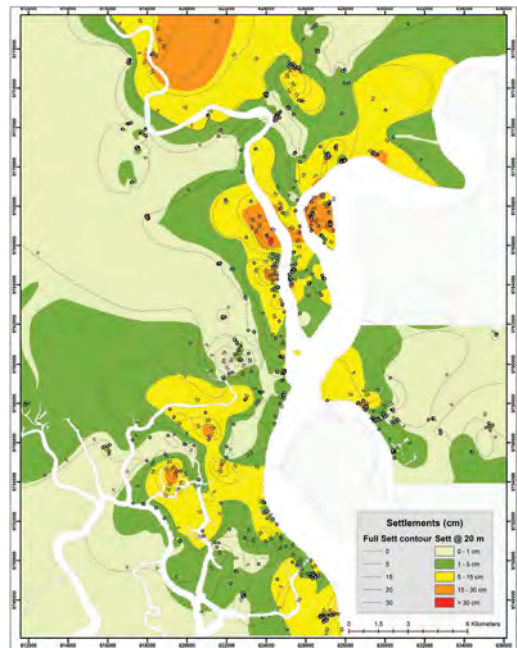

Figure 9. Spatial distribution of free field post-liquefaction settlements down to 20 m and complete profile.

Results indicate that 20% of CPTs have LPI > 10, 8% LSN > 20, 20% Sett@20m > 15 cm and 35% Sett in the entire profile > 15 cm. The low percentage of moderate LSN is due to the strong influence

of upper layers with high fines content that, in most cases mitigate damage at ground surface. Zones where estimated post-liquefaction deformations in the entire profile is greater than 15 cm, even though Sett@20m is lower, are especially relevant for pile design projects to ensure the neutral plane is below liquefiable layers.

According to LSN and LPI, sectors with highest risk and damage associated with liquefaction are those located north, in the alluvial zone. However, low LSN values south-east of Isla Mocolí and at the first five kilometers of Ave. Puntilla-Samborondón are notable, since before mapping a high liquefaction potential would have been expected due to its geotechnical location in alluvial zones. On the contrary, for estuarine deltaic areas where predominantly thick clayey layers are expected, some soil profiles are prone to liquefaction due to the presence of sandy layers in the top 20 m.

6 CONCLUSIONS

A database of 615 CPTs, 26 FVT profiles and 817 boreholes have been used to perform a geotechnical zoning of 1) top compressible stratum, 2) liquefaction potential, and 3) undrained shear strength s_u for the city of Guayaquil and surroundings.

Diatoms have been identified in the soils of Guayaquil, and the presence of these microstructures possibly relates to the low N_{kt} values measured in FVT. Although a valid trend is not observed between N_{kt} and F_r-B_q, there is a direct proportionality with Q_{tn}. Average values of N_{kt} varying between 8 and 10 have been found for different geotechnical zones.

There is high variability and heterogeneity in the alluvial and estuarine soil deposits from Guayaquil, based on different geotechnical zoning maps. Moreover, the database highlights the suitability of CPTu investigation in soft compressible soils given that drainage conditions are better determined when detecting a sandy intercalation that may have not been characterized while sampling. Likewise, CPT liquefaction analysis is more reliable since it would consider sandy or clayey lenses that might aggravate or alleviate foundation damage. Finally, pile driving analysis with CPT has been highly beneficial in several construction projects for Guayaquil soil deposits, by modeling with great precision intercalations of dense soils that hinders pile penetration while estimating shaft resistance accurately. Further research hopes to provide detailed field results from case studies.

Use of piezocone with dissipation tests CPTu_Δu, in tailings dams in Mexico: Case history

J.L. Rangel-Núñez
Universidad Autónoma Metropolitana, Plantel Azcapotzalco, Mexico

E. Ibarra-Razo & R. Flores-Eslava
inGeum Ingeniería, Mexico

ABSTRACT: This paper describes and analyzes several aspects observed during the exploration of mine tailings deposits in Mexico using the CPTu_Δu, test: high ground temperatures, interstratification, chemical reaction, dissipation curves with negative pore pressure, and S-wave profile. It was observed that the use of sensors with temperature compensation for the q_T and f_s measurements produces satisfactory results if temperature changes are not abrupt. For the case of the dynamic pore pressure sensor u_2, where no temperature compensation was made, the measurements are within the range mentioned in the standard except in the case when the temperature increases to values of 50°C or higher. The presence of high interstratification between thin layers of hard and soft soils, with different degrees of saturation, leads to errors in the measurement of the tip resistance and can produce deviations from the verticality of the cone, making it necessary to carry out corrections. The different types of dissipation curves observed in the tailings dams studied, where the soils are partially saturated, are generally the same as those described by Sully *et al.* (1999), with the particularity that in some cases, the equilibrium pressure reaches negative values. Finally, the S-wave profile obtained with correlations reproduces the general trend of the measured S-wave profile. Nevertheless, it was not possible to capture the variations in this type of deposit. In the case history described in this paper, the maximum values were not reproduced. Therefore, in this type of deposit, it is advisable the direct measurement of the shear wave and to use the smaller intervals of measurement according to the technique used.

1 INTRODUCTION

The design, execution and interpretation of an exploration campaign require experience and knowledge of both geology and exploration techniques to achieve satisfactory results. The case of tailings dams is a particular challenge because this type of deposit presents peculiarities, namely: they are very young, *i.e.*, compaction or consolidation is sometimes in the process; chemical processes may still be developing that can affect measurements, mainly in gold mines; the different sequences and forms of deposition using different types of debris induce a highly variable heterogeneity and anisotropy in the mechanical properties of the deposit.

All the mentioned aspects have an impact on the geotechnical exploration campaign. For example, the number of stages of the exploration campaign could increase, as well as, the field and laboratory tests. Undisturbed soil sampling is difficult, it is not possible to use the correlations commonly employed to estimate mechanical properties and it is often necessary to carry out modifications of the processes of execution of the field tests, such as increasing the rotation speed in shear vane tests.

One of the techniques used to characterize soils in tailings dams is the seismic piezocone with dissipation testings (sCPTu_Δu test); however, it has been observed that for this type of deposit there are factors that make it difficult to perform the test and their interpretation.

This paper describes and analyzes several aspects observed during the exploration of mine tailings deposits in Mexico using the sCPTu_Δu test, that is: high ground temperature, interstratification, chemical reaction with the soil and evaluation of the dissipation test and s-wave velocity profile.

In deposits where it is difficult to use any field exploration techniques, as in the case of tailings dams, the execution of a piezocone test requires to following procedures that ensure the quality of the tests in order to eliminate factors that hinder its interpretation and finally to reliably obtain both the stratigraphic profile and the geotechnical model of the deposit.

In order to validate exploration with CPTu_Δu in tailings deposits, it is advisable to observe the following aspects: verification of zeros at the beginning and end of the test, performing repeatability tests more frequently, changing filters and verifying their saturation, evaluating tip and shaft continuously,

measure verticality, measure temperature, control driving speed and in general carry out continuous maintenance of the equipment.

2 FACTORS AFFECTING THE INTERPRETATION OF THE PIEZOCONE TESTS

A variety of CPTu_Δu and sCPTu_Δu tests have been carried out in several Mexican tailings dams where aspects that have hindered the performance and interpretation of these tests have been observed. Some of them, which are particular aspects of exploration in tailings dams, are described below.

2.1 *High ground temperature*

During the exploration of a tailings dam of a gold mine in northern Mexico, where high ambient temperatures arise, the piezocone temperature before driving was 25°C, and during the test, it gradually increased to a maximum value of 50°C, in other words, twice the ambient temperature. High temperatures can affect the measurements of the parameters q_T and f_s when the equipment does not have compensating temperature sensors. If the cone has compensating temperature sensors, according to the manufacturer, the sensors can stabilize the measurements if:

- The temperature gradient should be uniform as the piezocone is driven, *i.e.* not present abrupt temperature changes.
- The compensation is performed for temperature variations or changes in the piezocone of up to 50°C (temperature variation in the piezocone with respect to that adopted at ambient temperature). For a temperature variation of up to 50°C, a change in the voltage output of the load sensor of up to 10 microvolts is compensated.
- The output voltage of the load sensor for the full-scale output (FSO=75 MPa) is 8.7 mV, so that 10 microvolts correspond to 0.115% of the output voltage for the full scale; in terms of stress, it represents a compensation of approximately 86.20 kPa for a maximum temperature change or variation of 50°C (1.72 kPa/°C), so that for the case studied where there was an increase of 25°C, there would be a compensation of 43.1 kPa.

However, for the pore pressure sensor, the equipment does not perform any temperature compensation, so that the measurements of u_2 and Δu may be erroneous. In this sense, two experiments were proposed to evaluate these effects using corrections for q_T and f_s.

The first experiment consisted of gradually increasing the temperature of the water in which the piezocone was submerged under controlled conditions, from 4°C to 45°C, while recording the variations in the zero readings of the tip, shaft and pore pressure sensors: the first parameters (q_T and f_s) were

registered to validate the temperature compensation already described and in the case of the pore pressure, the objective was to observe the influence of the temperature in their measurements.

Figure 1 shows the results obtained in the first experiment for each of the variables studied. it can be seen that for the q_c and f_s sensors, the measurement variations are very small, falling within the interval error indicated in ASTM D5778-12. Regarding the pore pressure, u_2, where the measurements were performed without compensating temperature, the results indicate variations of about 8kPa for low temperatures and 13kPa for high temperatures. Although, although they are small values, for a class 1 cone the value determined for high temperatures is in the limit according to the ASTM standard. On the other hand, this temperature effect can induce errors for the interpretation of dissipation tests, so it is advisable to provide the cone with compensating temperature in the tailing deposit are expected.
Figure 1. Effect of temperature on pore pressure (u_2), tip (q_c) and shaft (f_s) sensors.

The second experiment consisted of evaluating the repeatability of the piezocone testing under field conditions. To do this, two CPTs were executed, two meters apart for each other, in an area where variable temperatures between 41.5 and 44°C were recorded during the extraction stage. The temperature in the piezocone was measured with a digital thermometer. Figure 2 shows the results obtained in both boreholes

and it can be seen that this temperature gradient generated during the driving of the equipment does not affect the measurements, considering an ambient temperature of 25°C at the beginning of the driving.
Figure 2. Repeatability survey.

2.2 *Interstratification*

The presence of high interstratification between thin layers of hard and soft soils, with different degrees of saturation, causes sudden changes in the tip resistance. Moving from a hard to a soft stratum leads to errors, low values in the measurement of the tip resistance (Figure 3), making it necessary to carry out corrections (Boulanger and DeJong, 2018) and the instrumentation must guarantee low hysteresis in order to obtain trustworthy data.
Figure 3. Alternation between hard and soft lenses or layers produces reductions on q_T values.

Likewise, since the measurement of the parameters q_T and f_s is carried out at a given time but not at the same depth, and the alternation in the stiffness of the soil can produce deviations in the verticality of the cone, it is necessary to make depth corrections. Therefore, the interpretation of the records is not immediate since post-processing is required. In addition to this, interstratification makes it difficult to interpret dissipation tests because drainage and soil saturation conditions are often different, so it is common to observe that dissipation curves have different and unusual shapes.

2.3 *Dissipation curves*

Dissipation tests were carried out using piezocones with u sensor located at position 2 (u_2). The dissipation tests were executed at various sites of tailings dams, where there are clays and silty clays and no groundwater level. Figure 4 shows the main types of dissipation curves observed in the tailings dams studied:

a. With monotonic decay up to the equilibrium pressure, u_0, either positive or negative.
b. A maximum is present and the equilibrium pressure may be positive or negative.
c. With monotonic growth up to the equilibrium pressure.
Figure 4. Main types of dissipation curves observed in the studied tailings dams.

According to the criteria presented by Sully *et al.* (1999), monotonic decreasing curves with a positive value are of type I and II and occur in normally consolidated fine soils; those with a maximum value are of type III if the initial pressure is higher than the equilibrium pressure, but if the initial pressure is lower, they are of types IV and V. According to this classification, all types of curves are present in the tailings dams studied, with the particularity that there are negative equilibrium pore pressures, although with small magnitude, between 0kPa and -50kPa.

In the literature, methods have been proposed to determine the value of the pressure increase $\Delta u = u_i - u_0$ generated during piezocone driving and determined in dissipation tests following the nomenclature shown in Figure 5 (Burns and Mayne, 1998; Sully *et al.,* 1999; Paniagua *et al.,* 2016; Imre *et al.,* 2018), however, these methods are only applicable for type I to III curves. For the other cases, it is difficult to determine the value of Δu due to the number of factors involved: fastening of the driving rods, position of the sensor, drainage and saturation conditions of the soil, soil type, to mention the most important ones.
Figure 5. Nomenclature used for conventional dissipation curves.

Considering the hypothesis that the dynamic pore pressure u_2 is given by eqs 1 and 2 (Burns and Mayne, 1998), and given that the octahedric component produces only positive increases in pore pressure, the shear component, which depends on the dilative/contractive behavior of the soil, would be one of the factors responsible for the suction generated in the driving process for the dissipation curve types III to V. The decrease of the initial pore pressure in the dissipation test can also be caused by the abrupt stop of the driving (Kurup and Tumay, 1995), by the actual drainage conditions, by the saturation conditions of the soil, by the movement of the bars after stopping the driving, among other factors.

$$u_2 = u_0 + \Delta u \tag{1}$$

$$\Delta u = \Delta u_{oct} + \Delta u_{shear} \tag{2}$$

As previously mentioned, all the tests were performed in tailings deposits where there is no groundwater level, so the soils are partially saturated. For comparison purposes, Figure 6 shows dissipation tests carried out in the clays and silty clays of
Figure 6. Main types of dissipation curves observed in clayey soils in Mexico City.

Mexico City, where the groundwater level is superficial, and although the deposit is saturated, there are significant drops in pore pressures. Curves with behavior similar to that observed in the tailings dams are observed, but there is a case where u_2 starts at negative values.

2.4 Chemical reaction

It is common that after driving the cone, the probe gets dirty, mainly in fine soils, and has to be cleaned to start a new drilling, but a relevant aspect that was observed in drillings on mining deposits, was the generation of an impregnated oxide layer in the piezocone after the execution of a probe (Figure 7), which is difficult to remove with the process that is commonly done even using a brush with steel bristles. One of the important characteristics of the deposits where this aspect was observed was that there was a constant emanation of gaseous ammonia (NH_3) generated as a consequence of the leaching process. The most feasible and efficient solution to remove this oxide layer was to immerse the removable parts of the piezocone, such as the shaft jacket and the apex in acetic acid ($CH_3\,CO\,OH$), as well as to clean the fixed parts with the same compound and with the help of a toothbrush.

Figure 7. Piezocone with oxide induced by the minerals that make up the tailings deposit.

2.5 S-wave velocity profile

The tailings dams are formed by deposits of very young soils, some of them still in the process of compaction or consolidation, where the definition of the stratigraphic profile and the evaluation of the mechanical properties of each stratum is difficult, mainly because there is heterogeneity, both vertical and horizontal, and it is also difficult to obtain unaltered samples. Therefore, in this type of deposits, field techniques are used, especially sCPTu_Δu and VST tests, because it is possible to define the stratigraphic profile and determine, either directly or indirectly, the mechanical properties of each unit, particularly

parameters such as modulus of stiffness at small deformations (G_0), permeability coefficient (k) and undrained shear strength (s_u), in order to carry out stability analyses.

The velocity profiles obtained at one site from the sCPTu are presented in Figure 8. In this case, the determination of the S-wave velocity profile is performed with two procedures: direct measurement by means of the seismic modulus and by means of empirical correlations. It is observed that, although the correlation generates satisfactory results, it was not able to reproduce the alternation of values, especially the maximum values.
Figure 8. Determination of the S-wave profile by correlations and with the seismic modulus.

3 CONCLUSIONS

This paper describes and analyzes several aspects observed during the exploration of mine tailings deposits in Mexico using the CPTu_Δu test: high ground temperatures, interstratification, chemical reaction, dissipation curves, and S-wave profile.

High temperatures can affect measurements of the parameters q_T, f_s, u_2, and Δu when the equipment does not have compensators, but if they do exist, it is required that temperature changes are not abrupt so that the sensor can stabilize during the measurement. For this reason, experiments were carried out in this type of deposits using equipment with compensators, finding that the variations of q_T and f_s measurements were found to be within the error range indicated in the standards (ASTM D5778-12). Regarding the dynamic pore pressure, u_2, where the measurement was performed without a temperature compensator, the results indicate variations of about 13kPa, which, although small, can induce errors for the interpretation of dissipation tests.

The second factor analyzed was the presence of high interstratification between thin layers of hard and soft soils, with different degrees of saturation. Moving from a hard to a soft stratum leads to errors in the measurement of the tip resistance, making it necessary to carry out corrections (Boulanger and DeJong, 2018). Also, since the measurement of q_T and f_s parameters is performed at a given time, but not at the

same depth, and the alternation in soil hardness can produce deviations from the verticality of the cone, it is necessary to carry out depth corrections. Therefore, the interpretation of the logs in this type of terrain is not immediate, since post-processing is required.

The different types of dissipation curves observed in the tailings dams studied, where the soils are partially saturated, are generally the same as those described in Sully *et al* (1999), with the particularity that in some cases the equilibrium pressure has negative values.

A case is described in which a chemical reaction occurs in the piezocone during its driving, which may affect the readings. Ammonia generated as a consequence of the leaching process induces oxidation, so it is necessary to perform continuous maintenance of such equipment, and for the type of deposits studied vinegar proved to be the best substance for cleaning the cones.

Finally, velocity profiles are determined for two sites of tailings dams through correlations with the value of q_T and the one determined with the seismic modulus. It is observed that the profile obtained with correlations reproduces the general trend but it is not possible to capture the variations of the shear wave velocity in this type of deposits, in the particular case, the maximum values are not reproduced, therefore, in this type of deposits it is advisable the direct measurement of the shear wave and to use the smaller intervals of measurement according to the technique used.

University of Zagreb, Croatia

K.G. Gavin
Delft University of Technology, The Netherlands

ABSTRACT: Understanding how soil varies spatially is necessary in order to accurately quantify the reliability of geotechnical infrastructure. For long linear infrastructure such as flood embankments, incorporating vertical and horizontal scales of fluctuation can have a significant impact on stability assessments. This paper presents preliminary results and discussion from a field test designed to determine the vertical and horizontal scales of fluctuation of a Croatian flood embankment. A series of 15 CPTUs were carried out over a 200m length of the embankment with a Multi-channel Analysis of Surface Waves (MASW) survey done on the same section. CPT spacing was designed specifically to determine horizontal variation with multiple CPTs carried out in close proximity to each other. There was significant variation in soil stratigraphy over the embankment section with pockets of increased strength and stiffness showing up in the MASW and CPT results. This paper discusses dealing with horizontal correlation in challenging deposits and presents initial findings from the underlying sand layer.

1 INTRODUCTION

Soil properties vary as a function of space and time. Quantifying exactly how they vary is of upmost importance in determining the capacity of geotechnical structures(De Gast, Vardon and Hicks, 2020). This is particularly important for aged linear infrastructure, which underwent less rigorous design than its modern counterparts and has a lower safety margin as a result (Reale *et al.*, 2016; Reale, Xue and Gavin, 2017). It is infeasible and inadvisable to replace such infrastructure en-masse, moreover it is likely unnecessary given that the structures have remained stable so far. Instead, a better approach is to quantify the uncertainties present in the material in order to accurately assess the risk of failure. Such an approach could be applied consistently with a risk-based decision methodology to decide which assets to improve or replace (Reale, Xue and Gavin, 2016).

Random field theory considers soil properties at a given location as random variables. Within a zero mean stationary random field, the spatial variation between one point and another in the same structure can be described by their correlation structure. Statistically modelling spatial variability presumes a stationary random field. Such an assumption may be hard to achieve in reality given that soil is not really

stochastic but it is convenient to model it as such, as information is limited(Phoon, 2008). If a dataset is not stationary, then estimation of soil statistics may be subject to bias. To prevent this, the dataset should undergo transformation to achieve stationarity, data decomposition is frequently adopted to this end. Phoon et al (2003) describe a modified Bartlett hypothesis test that can be used to check stationarity.

If one is concerned about the average properties within some volume of soil (e.g. the average shear strength or average resistance of a material) then areas of high value balance areas of low value so that the variance of the average goes down as the volume of soil mobilised becomes larger. Point variations such as those listed by (Phoon & Kulhawy, 1999) are typically much higher than spatially averaged variations. Spatial averaging therefore reduces uncertainty. The net result of which is lower failure rates which are more consistent with those observed in reality (Phoon, 2008). Depending on the scale of fluctuations involved spatial averaging can have a significant impact on the stability of linear infrastructure.

Random field theory has been successfully used to generate one dimensional, two dimensional and three dimensional geological models (Zhu and Zhang, 2013; Lloret-Cabot, Fenton and Hicks, 2014) and applied to various geotechnical

problems such as bearing capacity of foundations (Fenton and Griffiths, 2003; Srivastava and Babu, 2009),water flow (Renato et al., 2006), two dimensional slope stability (Srivastava, Babu and Haldar, 2010; Santoso, Phoon and Quek, 2011; Tabarroki, Ahmad and Banaki, 2013; Li *et al.*, 2014), three dimension slope stability (Hicks and Spencer, 2010), scour (Prendergast, Reale and Gavin, 2018) and suction caisson design (Remmers *et al.*, 2019).

This study describes the initial findings from a series of CPTs investigating the horizontal and vertical variability of a flood embankment in Croatia, the findings will be utilised in a wider study to investigate the stability of the flood defenses and to assess their potential for liquefaction.

2 METHODOLOGY

Decomposition can be used to investigate a CPTs underlying spatial correlation structure where a trend function is fitted to and extracted from a dataset using least squares or some similar approach. This removes any underlying trend from the data leaving behind some fluctuating component. The correlation structure of this fluctuating component can then be determined.

After removing any discernible trend, the soil property (in this case q_c) for a normal distribution can be described by Equation 1.

$$q_c = \mu + \sigma \, \mathbf{G} \qquad (1)$$

where μ is the mean value described at some depth z using Equation 2, σ is the standard deviation at the same depth and $\mathbf{G}$ is a matrix containing n spatially correlated normal random processes of zero mean and unit variance which account for the spatial correlation structure of the soil.

$$\mu(z) = a_i + b_i z \qquad (2)$$

where a_i is the mean trends value at the beginning of the *ith* layer, b_i is the slope of the trendline in question and z is the depth.

After removing the linear depth trend of each q_c profile in the dataset, the standard deviation of the detrended tip resistances can be calculated. Dividing an individual detrended tip resistance by its respective standard deviation transforms the tip resistance variation into the standard normal space. i.e. it produces normal random fields with a mean of zero and a standard deviation of 1. Variations within these normal random fields can be used to estimate the spatial correlation structure $\widehat{\rho}(\tau_j)$ of the tip resistance with depth or horizontal distance, see Equation 3.

$$\widehat{\rho}(\tau_j) = \frac{1}{\sigma^2(n-j)} \sum_{i=1}^{n-j} (X_i - \mu)(X_{i+j} - \mu) \qquad (3)$$

where $j = 0,1,..., n\text{-}1$ with n being the number of data points, $\tau_j = j\Delta\tau$ is the lag distance between the two points in question where $\Delta\tau$ is the distance between two adjacent points, μ is the estimated mean, σ is the standard deviation and X is the random soil property in this case tip resistance. A Markov correlation function (Lloret-Cabot, Fenton and Hicks, 2014; Kasama and Whittle, 2015) was used to approximate the spatial correlation structure, see Equation 4. It is important to note, that many correlation functions exist and the choice of correlation function will depend on the goodness of fit achieved with the underlying correlation structure. The scale of fluctuation θ, is varied until the correlation structure obtained from Equation 3 is described by the correlation function i.e. until the difference between $\hat{\rho}(\tau)$ and $\rho(\tau)$ is negligible.

$$\rho(\tau_j) = \exp\left(\frac{-2|\tau_j|}{\theta}\right) \qquad (4)$$

For horizontal spatial variation the Equation 4 holds except there is a greater distance between measurement points and the spacing between points is unlikely to be uniform. In practice this complicates the process as it becomes difficulty to determine when like is being compared with like. The authors compared the top of the sand layer in each CPT as if they occurred at the same depth and determined horizontal correlations across CPT using a 1m moving window therein.

3 TEST SITE

The CPT test location is located next to a embankment in central Croatia, in Orle Municipiality, around 25 km from Zagreb. The embankment is part of a flood defence network which protects the wider area from the influence of the Odra and Sava rivers. CPTs were performed over a 200m length at the following spacings [0 m, 2 m, 5 m, 10 m, 25 m, 50 m, 75 m, 100 m, 125 m, 150 m, 175 m, 190 m, 195 m, 198 m, 200 m], see Figure 1, to a depth of 15 m. The first soil layer at the site was a clay of variable thickness, with deeper deposits of between 7m and 8m found on either end of the 200m test length. Layer thickness reduced to approximately 2m in the middle of the test length. Underneath the clay was a dense sand deposit to great depth. The full set of CPT traces demonstrated a lot of variability, particularly within the sand layer and at transition depths, see Figure 2.
Figure 1. CPT traces and MASW were performed along the blue line adjacent to the embankment.
Figure 2. 15 CPT traces across the site.

Multi-Channel Analysis of Surface Waves (MASW) was also performed at the site, see Figure 3, which corroborated the assumed stratigraphy showing deeper deposits of low shear wave velocity at either end of the test length. The presence of localized deposits of increased stiffness can also be seen within the sand layer, demonstrating the variability of the material.

Due to the complex layering present in the upper clay layer the initial spatial variability interrogation is focused in the lower sand layer from a depth of 10 to 15m where the soil behaves more consistently across the site, see Figure 4.
Figure 3. Shear wave velocities from MASW performed at the site, demonstrating the variability in the depth of the sand layer across the site.
Figure 4. CPT traces from 10 to 15m with the mean qc profile shown in red.

4 RESULTS

The CPT traces in the lower sand layer were detrended, normalised and the underlying correlation structure was determined using the procedure described in section 2. Equation 4 was then fitted to the underlying structure by optimizing the scale of fluctuation. The vertical scale of fluctuation θ_V was found to be 0.82 m with the 95% confidence intervals ranging from 0.78 m to 0.85 m. A strong goodness of fit with achieved using the Markov correlation function with an R-square of 0.9358 and an RMSE of 0.0528.

The same procedure was followed for horizontal correlation with intermediate points interpolated to facilitate curve fitting. Initial results indicated that the horizontal scale of fluctuation was approximately 8.39 m with a 95% confidence interval range of 7.45 m to 9.33 m.
Figure 5. Vertical correlation structure found in the lower sand layer.
Figure 6. Initial horizontal correlation structure found in the lower sand layer.

5 DISCUSSION AND CONCLUSIONS

This paper presents initial results from a site investigation to investigate spatial variability in Croatia. Initial work was focused on the underlying sand layer which behaved more consistently than the finer surface deposits. Initial results suggest than horizontal variability is an order of magnitude greater than the vertical variability. However significant uncertainty exists in determining the horizontal correlation structure. One issue stems, from the variability in layer depth across the site, as the boundary of the sand layer is inclined. This makes it difficult to correlate "like with like" across the site as merely correlating CPTs at the same depth could result in correlating across layer boundaries. To overcome this the authors considered the top of the sand layer in each CPT as the start point of the analysis and used a moving window of 1m to determine horizontal correlations below those point. As there is no continuous measurement in the horizontal direction, there needs to be a methodology to ensure that the correct data is being used to determine the mean autocorrelation behavior horizontally. Different averaging procedures will be investigated, while different window sizes to determine the effect of sample size on scales of fluctuation. The analysis will also be rerun to consider the start point at intermediate CPT locations to check consistency across the site. Some consideration also needs to be paid to stationarity. This is difficult to ensure in the vertical direction, but much more so in the horizontal direction where there are much more limited discrete measurement points which makes the implementation of stationarity checks such as Bartlett statistics challenging. This will be investigated moving forward.

Prediction of bearing capacity and settlement using penetrometer design method for shallow foundation and load transfer curves

P. Reiffsteck & F. Szymkiewicz
GERS-SRO, Université Gustave Eiffel, IFSTTAR, Marne la Vallée, France

M.A. Benz Navarrete & T.A. Luong
Research and Development, Sol-Solution, Riom Cedex, France

ABSTRACT: This paper presents a simple, economic, and sound design method that could be easily implemented worldwide, based on a new generation version of Dynamic Cone Penetrometer Test (DCPT) devices giving access to the whole cone resistance versus penetration depth of the cone curve, to predict the bearing capacity, as well as to estimate the load – settlement curve of a shallow foundation which is partly inspired from the French Penetrometer design method. A methodology is then proposed in this study for the conception of shallow foundation based on load transfer curves obtained from DCPT.

1 INTRODUCTION

Spread foundations are the most extensively used geotechnical structures in civil engineering world, as they are simple to construct and the most cost-effective choice for support of a building furthermore. These foundations are implemented for all kinds of structure from small individual buildings to bridges.

For the conception of shallow foundations including the evaluation of bearing capacity and its settlement, the conventional methods such as c and φ method (Skempton, 1951) (Terzaghi, 1943) and the one-dimensional approach often overestimate limit load and underestimate settlement, which leads to a non-conservative design or differential settlement, both being detrimental to the structures (Poulos & Carter, 2001).

Static and dynamic cone penetration tests (respectively, CPT and DCPT) are the techniques in the ground investigation and foundation design, which are widely used in many countries around the world. However, in conventional procedures, these tests only allow a fairly assessment of soil deformation since no direct relationship between load and settlement (stress strain relation) is obtained during the test. Thus, the development of a new test protocol and equipment of Cone Penetrometer Test in its dynamic version are improved not only to ensure the advantages of economy and simple operation, but also improve the measurement capacity to derive various soil parameters and increase their reliability.

The dynamic cone loading test (DCLT), developed very recently in France (Benz, et al., 2013) (Escobar Valencia, et al., 2013), consists of analyzing the measurements made during the dynamic penetrometer driving to obtain a dynamic cone load-penetration curve at cone-soil interface, which is qualitatively comparable to the expansion curve obtained by the pressuremeter as well as settlement curve obtained during shallow foundation loading test.

This paper then introduces a methodology for the calibration of the transfer curves from the DCPT tests, therefore, to predict the load – settlement curve for the conception of the shallow foundations.

2 DYNAMIC CONE LOADING TEST (DCLT)

2.1 Description of DCLT apparatus

The instrumented dynamic cone penetrometer (DPT) has been designed and based on the same functional principle as the P.A.N.D.A. (*from French Pénétromètre Autonome Numérique Assisté par ordinateur*).

It is an instrumented lightweight DPT which is driven with variable energy (Gourvès & Barjot, 1995) provided by the operator by means of a hand-hammer mass. For each blow, the energy supplied as well as total penetration is directly measured (Benz Navarrete, 2009).The new version of P.A.N.D.A. used in this work, includes new sensors and the general principle is based on wave equation solution. A general description of the device as well as the theoretical implemented approach is presented by (Benz Navarrete, et al., 2021).

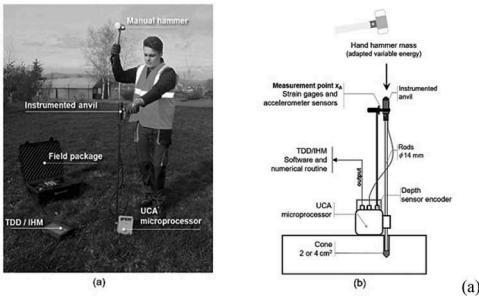
After each hammer blow, instrumented anvil records strain, acceleration, and displacement. An example of raw measurements performed during the test is shown in Figure 1.b.


Figure 1. (a) Dynamic penetrometer P.A.N.D.A.3 (Benz et al. 2013 and (b) raw measurements (acceleration, force, and displacement).

Penetrometer is composed of rods with a diameter of 14 mm and 500 mm in length and of overflowing conical tips with a cross-section of 2 or 4 cm^2 (respectively, 15.9 or 22.5 mm in diameter). In accordance with the ISO-22476-2 Standard (2005), the apex angle of cones is 90°. To avoid the effects of skin friction on the rods, the use of overflowing conical tips (having a larger diameter than that of the rods) has proved to be sufficient. However, jacking or mud injection can be implemented in necessary (ISO 22476-2).

2.2 *Getting DCLT curves*

The derivation of mechanical parameters is based on pile dynamic, rapid shocks, Split Hopkinson Pressure Bars (SPHB) as well as rock percussion borehole tests (Rausche, 1970; Karlsson, et al., 1989; Bussac, et al., 2002; Omidvar, et al., 2014; Omidvar, et al., 2015).

Figure 2 shows for each blow, by supposing no skin friction along the rods and from measurements carried out in the upper end of rod string (close to the anvil), elementary downward and upward waves are decoupled. From that, force $F_p(t)$, velocity $v_p(t)$ and settlement $s_p(t)$ are then computed at cone/soil interface (Benz, et al., 2013) (Escobar Valencia, et al., 2013) and (Tran, et al., 2019). Dynamic Cone Load-penetration (DCLT) curves are obtained by plotting cone resistance $q_d(t)$ as a function of its settlement $s_p(t)$ (Figure 3).

Cone resistance $q_d(t)$, shown in Figure 3, represents the total soil resistance under dynamic loading. DCLT

Figure 2. Example of (a) force decoupled waves in measurement point x_A, and reconstructed cone signals (b) velocity and displacement; and (c) cone stress.
Figure 3. Field Dynamic Cone Loading (DCLT) curves (Jossigny, France).

curve can be modelled by a perfectly elasto-plastic and dashpot model, where total soil resistance $q_d(t)$ is the sum of pseudo-static q_{ps}, damping $q_{dyn}(t)$ and inertial q_{in} resistances (Eq. (1)) which can be neglected due to the low mass of penetrometer. Pseudo-static resistance q_{ps} is displacement dependent and modelled by a non-linear elastic perfectly plastic law

while $q_{dyn}(t)$, is penetration rate dependent and modelled with a radiation dashpot (Eq. (2)).

$$qd(t) = q_{ps} + q_{dyn}(t) + q_{in} \qquad (1)$$

$$qd(t)Ap = Qd = k_b u + c_b \dot{u} + m_p \ddot{u} \qquad (2)$$

In Eq. (2), $\ddot{u}$, $\dot{u}$, and u are, respectively, acceleration, velocity, and displacement at penetrometer's cone/soil interface. Qd is the total strength and A_p the cone section. c_b and k_b are the dashpot and spring constant (El Naggar & Novak, 1996), defined by:

$$k_b = \frac{4 G_s R_{(H)}}{(1 - v_s)} \qquad (3)$$

$$c_b = \frac{3.4 R_{(H)}^2 \sqrt{G_s \rho_s}}{(1 - v_s)} \qquad (4)$$

Where, $R_{(H)}$ is equivalent radius introduced by (Holeyman, 1988) and computed according to (Novak & Beredugo, 1972; El Naggar & Novak, 1994). G_s, ρ_s and v_s are respectively shear modulus, density, and Poisson's ratio of soil.

Plastic resistance or soil limit resistance q_{lim} is obtained from velocity, displacement, and strength signal according to the Unloading Point Method proposed by (Middendorp et al. 1992; Hölscher et al. 2012) and explained by (Brown 1994, 2016).

Moreover, spring constant or dynamic stiffness k_{dyn} is determined from DCLT experimental measurements by mean of FRF transfer functions (Davis 1975; Paquet and Briard 1976; Tran et al. 2019). For the case of a rigid embedded foundation subject to transient dynamic loading, it is assumed that at low frequencies, k_{dyn} is close to k_b. Knowing k_b and assuming Poisson's ratio v_s, shear modulus G_s can be obtained from Eq. (3). Moreover, Elastic modulus (E_s) can be then obtained by applying the theory of elasticity. Other elastic parameters can be deduced.

In practice, DCLT curves are analyzed as follows:

– Assessment of dynamic stiffness k_b from FRF curves,
– Determination of shear modulus G_s (Eq. (3)).
– Elastic modulus (E_s) assessment from G_s and v_s.
– Determination of soil limit resistance q_{lim} from DCLTs curves and Eq. (2) according to UPM method:
  ○ From cone velocity signal $v_p(t)$, find the moment (t_0) where $v_p(t)$ is zero after the blow.
  ○ Confirm that the t_0 moment coincides with maximum tip displacement $s_p(t)$ is at its maximum.
  ○ From strength signal $F_p(t)$, computed average value $F_p(t)*$ at ($t_0 \pm dt$) moment (with dt ≈0,1ms).

○ Limit resistance assessment is obtained after inertial correction, $q_{lim} = F_p(t)* - m_p.a(t_0)$; where m_p is the mass of penetrometer and $a(t_0)$ is average acceleration at t_0.

In this way, knowing E_s and q_{lim}, DCLT curves can be modeled by a nonlinear elastic plastic model as the Simplified Hyperbolic one presented below.

2.3 Simplified hyperbolic model adjustment to DCLT

The possibility to establish the cone resistance–penetration curve of DCLT is to fit a predetermined curve type suitable for reproducing the test from the experimental curves, with the choice set on the characteristic features of the curve which are the modulus E_s and the limit resistance q_{lim}. A similar development has been proposed by (Elhakim, 2005).

To reproduce the curves in a systematic way based on the parameters that are the cone resistance and the dynamic modulus, we will use a hyperbola formulation. The final version homogenizes the terms of the formula and systemizes the determination of the A_i parameters, closer to the method proposed by (Baud & Gambin, 2008), the deformation ε:

$$\varepsilon = \frac{s}{h_e} = A_1 + A_2 q + \frac{A_4}{A_6 - q}$$

$$A_1 = -\frac{A_4}{A_6} \qquad A_2 = \frac{\beta}{E_{dyn}} \qquad (5)$$

$$A_4 = \frac{(\alpha - \beta)(1 - x)}{E_{dyn}} q_d^2 \quad A_6 = q_d = q_{lim}$$

Where, $x = \frac{q_2}{q_d}$ a non dimensional term, where q_2 is the inflection point at the end of the linear part, corresponding to the conventional definition of $p_{LM} = 1.7 p_{fM}$. We can therefore estimate x with a value around 0,6 to 0,7.
$\alpha = \frac{s_2 E}{q_2 h_e} = (1 - \nu^2) \frac{b}{h_e} C_f$, a non dimensional term, with $C_f = 0.79$ corresponding to the form coefficient of the rigid circular cone of P.A.N.D.A, an influence depth $h_e = \frac{\pi R}{4}(1 - \nu^2)$ (Butterfield & Banerjee, 1971), b and R being respectively diameters and radius of the cone.
β is equal to 0.95α, this ratio allowing to decrease the initial slope, in order to guide the hyperbola with an upward concavity.

Figure 4 shows the adjustment curves modelled by this version, based on data of DCLT tests that are the tip resistance, q_d and the dynamic modulus, E_{dyn} at the depth from 1 m to 1.25 m, in Jossigny site and at the depth from 1.75 m to 2 m, in Cran site.
Figure 4. Curve adjusted in (a) Jossigny from 1 to 1.25 m and (b) Cran from 1.75 to 2 m.

3 PROPOSED DESIGN METHOD

3.1 *Bearing capacity*

Bearing capacity of the foundation is computed using the French penetrometer design direct method with slight modification (AFNOR, 2013).

$$q_{net} = q_0 + k_d \cdot q_{de} \qquad (6)$$

$$k_d = k_{d0} + \left(a + b. \frac{D_e}{B} \right) \cdot \left(1 - e^{-c \cdot \frac{D_e}{B}} \right) \qquad (7)$$

With the q_{net} the net pressure under the foundation, q_0 the total vertical stress at the base of the foundation after construction, k_d the penetrometer bearing capacity coefficient, q_{de} the equivalent cone resistance, D_e and B respectively, the equivalent embedment depth and the width of foundation and k_{d0}, a, b, c and d the coefficients tabulated according to the type of soil and the shape of the foundation.

3.2 *The load-settlement curve approach*

As shown in Figure 5, a similar approach to the Load Settlement Curve Method proposed by Briaud has been developed to access the full load settlement curve (Briaud, 2007). The principle is based on the similarity of the cone resistance – penetration curve acquired by the DCLT at each hammer blow with the loading – settlement curve of the shallow foundation.

This transformation based on full-scale tests and numerical simulations is achieved using the equation

5 and real load pressure anticipated up to q_{net} obtained with equation 6. Results obtained with the proposed method are compared with settlement predicted by Schmertmann method as proposed by Eurocode 7 part 2.
Figure 5. Principle of the similitude between shallow foundation loading test and DCLT.

4 FOUNDATION LOADING TESTS

4.1 *Loading procedure*

Several loading tests of B = 1; 0.71 m square and 0.6 m circular footings have been performed on several sites. Ground investigation using P.A.N.D.A (DCLT), PMT, CPT, SPT and other techniques helped to define the ground model.

Foundations were loaded, using load steps of a 30-minutes duration, until failure occurred, with an average number of 10 steps. The Figure 6 and 7 show schematically the equipment used for shallow foundation loading tests.
Figure 6. Schematic shallow foundation loading test.
Figure 7. Foundation loading test in Cran.

4.2 Sites presentation and tests performed

Table 1 summarizes information on two sites of different soil types where foundation and DCLT tests have been performed. Based on the results of several shallow foundation load test for each site, a mean curve can be fitted (by least-squares method).

Table 1. Sites and number of DCLT test.

Site	Soil type	DCLT test	
		Quantity	DCLT curves /ml
Jossigny	Silty	6	130 c/ml
Cran	Marine clay	9	128 c/ml

Figure 8 presents the mean loading – settlement curve for Jossigny site for the case of 1m square foundations and two experimental curves for Cran site for the case of a 0.6 m circular footing.

4.3 Tests results and comparison to prediction

The bearing capacity prediction using the pressuremeter and penetrometer methods, proposed in the French national application standard of Eurocode 7 NF P94-261 for shallow foundation design, is presented in Figures 9 and 10.
Figure 8. Mean curve of foundation load tests performed on Jossigny (Square 1x1m) and Cran (Circular D = 0,6m) sites.

The cumulative distribution curves of ratios between calculated and measured bearing capacity coefficients are compared with Normal law distribution function.

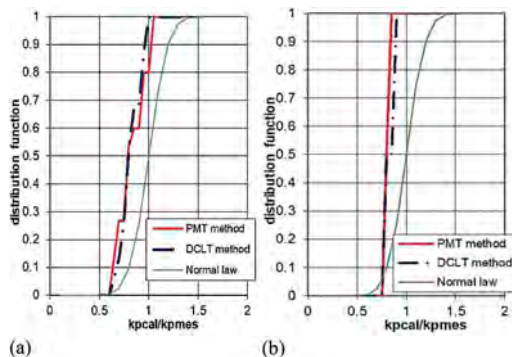
The DCLT method results superimposed well on the ones obtained using pressuremeter method as proposed by NF P94-261. The safety level of the bearing capacity is represented by the deviation from an average value of 1. Figure 9 shows that the prediction of these methods tends to a conservative


Figure 9. Distribution curves of the experimental and computed bearing capacity ratio for (a) square 1x1m footing in Jossigny and (b) circular D = 0.6 m footing in Cran.

prediction of bearing capacity, for Jossigny as well as Cran sites, especially the results from DCLT method.

Figure 10 shows settlement prediction, by four design methods: the French Application Standard of EC7 (NF P94-261), the Load
Figure 10. Comparison of experimental and predicted settlement curves. For (a) 1x1 m square foundation on silt in Jossigny and (b) D = 0,6 m circular foundation on marine clay in Cran.

Settlement Curve Approach (LSCA) proposed by (Briaud, 2007), the Simplified Hyperbolic (SH) model for PMT and the Schmertmann method, for a square footing in Jossigny and circular footing in Cran. We also note that the values of the respective conventional bearing capacity of soil in Jossigny and in Cran are respectively about 36 and 6 tons.

Figure 10a, compares the mean experimental curve (Figure 8) to computed settlement. The predicted settlement obtained with NF P94-261 and Schmertmann methods and the SH model for PMT well match the experimental mean curve, in the first half the loading phase. However, the LSCA method underestimates the settlement. One drawback of this method is the non-zero settlement for a loading close to zero.

Figure 10b shows the case of marine clay in Cran. The NF P94-261 method gives an acceptable settlement prediction while the two others present a non-conservative result.

When the loading is over 50% of bearing capacity, the four methods all underestimate the settlement of the real foundation. The calculated curve of the LSCA method is always farthest from the experimental mean curves while NF P94-261 method is the closest prediction.

5 CONCLUSIONS

This paper presents a method to predict bearing capacity of shallow foundations from the cone resistance and dynamic modulus of the newly developed Dynamic Cone Loading Test. A database of tests has been collected to validate the proposed design method whose results show a good agreement with the real foundation loading test results. However, the enrichment of more data from dynamic penetrometer and foundation loading tests in different sites is needed to better define the model factor of this method.

Probabilistic analysis of gyttja undrained strength from CPTU data for slope stability analysis

S. Rios, L. Sousa & A. Viana da Fonseca
CONSTRUCT-GEO, Faculty of Engineering, University of Porto, Porto, Portugal

ABSTRACT: The design of an artificial peninsula near Copenhagen led to an extensive experimental campaign where a significant number of CPTU tests were performed. The CPTU data presented a significant dispersion due to material heterogeneity, which motivated a probabilistic analysis of the soft soil undrained strength. For that purpose, a probabilistic density function of the undrained strength ratio was estimated and introduced as input in a limit equilibrium slope stability analysis. This enables the evaluation of the probabilistic density function of the factor of safety, the probability of failure and the reliability index instead of a single deterministic factor of safety. This information can be used by the designer or project owner to choose between different solutions based on the required level of risk.

1 INTRODUCTION

1.1 *Probabilistic analysis in geotechnical engineering*

The main concern of an engineer when designing a certain structure is its safety. In geotechnical engineering, designers have to deal with the uncertainties related to the geological materials, the variability existing in nature, and simplified models. The conventional way of coping with these uncertainties, is to use a deterministic factor of safety. A factor of safety of 1.5, for example, is often used to account for the combination of uncertainties in the ground, in the analysis parameters and the calculation method. There is the general perception that a design with a safety factor higher than 1.5 has to be safe. However, a factor of safety of 1.5 represents a spectrum of failure probabilities, which depend on the uncertainties in the analysis. As shown by Lacasse and Nadim (1996) a design with a high factor of safety can have higher failure probability than another with a lower factor of safety, if the involved uncertainties are large. This means that a higher factor of safety does not imply a smaller risk, because it is affected by the uncertainties in the analysis (Lacasse et al., 2019).

At present, Eurocodes (Eurocode 0, CEN, 2002) are based in the statement that"a structure shall be designed and executed in such a way that it will,

during its intended life with appropriate degrees of reliability and in an economic way sustain all actions and influences likely to occur during execution and use, and remain fit for the use for which it is required".

As the deterministic scenario may underestimate the risk, it is recommended to adopt a reliability-based-design instead of the usual factor of safety. Basic reliability measures include probability of failure and reliability index. These can be used to verify the margin of safety defined as the difference between resistance and load. Reliability index refers to the number of standard deviations between the mean safety margin (M) and failure, being defined as:

$$\beta = \frac{M_{mean}}{SD} \qquad (1)$$

where SD is the standard deviation of the safety margin.

The reliability index, β, can be related to the failure probability (p_f) by the expression:

$$p_f = \Phi(-\beta) \simeq 10^{-\beta} \qquad (2)$$

where Φ represents the cumulative distribution function of the standardised normal distribution.

This work presents an attempt of applying a probabilistic approach to describe the undrained strength ratio in a slope stability situation.

1.2 Lynetteholmen project

The case study presented in this work concerns the construction of an artificial peninsula, built outside the Copenhagen harbor, in an area called Lynetteholm. This artificial peninsula will span over 282 hectares over the North of Refshaleøen and will be delimited to the north by Nordhavn and to the west by the Trekroner. The main purpose for its construction is to prevent the city of Copenhagen from the occurrence of floods and storm surges. In fact, it is predicted that by the end of 2100, the sea level will rise between 54 cm (under the "Paris agreement") and 74 cm ("business as usual" scenario), according to the Geological Survey of Denmark and Greenland. Lynetteholm is expected to be completed in 2070. The hope is that the first homes can begin building in 2035.

The artificial peninsula will be mainly built with hydraulic fill contained by earth supporting structures such as sheet pile walls and embankments. Then perimeter design layout will be arranged with sand and rock in the front to form beaches.

2 SITE CONDITIONS

2.1 Site geology

Formerly below the Scandinavian Ice Shield, the area has now an upper layer of filling material resulting mainly from dredging, although ashes, slags, rubble, concrete rubble and other man made components can be included. Mixed with the fill or immediately below, post-glacial marine deposits are found consisting mainly in gyttja. On top of the gyttja layers, slag that was thrown overboard from steamships is frequently found. Gyttja is a very soft and odorous soil that originates from remains of plants and animals rich in fats and proteins. The material consists of both organic matter and inorganic (clay, silt, fine sand, shells or limescale). During its formation, varying quantities of inorganic material are mixed with the organic and when examined, a lower loss of filament and water content is found which is common for peat (Larsson, 1990).

2.2 Geotechnical data

COWI carried out extensive geotechnical studies in order to obtain factual geological, geotechnical and hydrogeological data for the area. The geotechnical studies included 301 CPTU tests and 191 boreholes. Based on boreholes and CPTU, a thickness map was developed (Figure 1) indicating the thickness of soft postglacial deposits, including gyttja, peat and clay. The thickness of the organic post-glacial deposits is greatest in the former meltwater valleys, where up to 6-9 m thick layers of gyttja and peat were taken.

CPTU data (Figure 2) revealed low values of the corrected cone resistance (q_t) defined as follows:
Figure 1. Gyttja thickness map.
Figure 2. Corrected cone resistance (qt) evolution with depth for all CPTU data.

$$q_t = q_c + u_2(1 - a) \qquad (3)$$

where q_c is the tip cone resistance, u_2 is the pore pressure measured behind the cone, and a is the area factor calculated as the ratio of the cross sectional area of the load cell, A_n, by the projected area of the cone, A_c, ($a = A_n/A_c$). In this case, two different cones were used for the CPTU campaign. A number of 193 tests were conducted by a piezocone with $a = 0.6$ and 106 tests with $a = 0.8$.

Figure 2 plots q_t values with depth, ranging in the interval of 0 to 0.6 MPa, where a significant dispersion is observed. To better understand the type of material present, the results were analysed by the unified approach proposed by Robertson (2009) which have indicated a clayey/silty behavior with no relevant sensitivity (Figure 3)
Figure 3. CPTU data plotted in the Robertson (2009) soil behavior chart.

3 UNDRAINED STRENGTH

3.1 Laboratory data

Based on 5 boreholes, 15 valid anisotropically consolidated undrained triaxial compression tests (CAUC) were conducted to determine the gyttja undrained shear strength (Table 1).

From that data summarized in Table 1, the evaluation of the undrained shear strength ($C_{U,TC}$) was plotted against the vertical effective stress after the consolidation, σ'_v, obtaining the following linear regression:

$$C_{U,T,C} = 0.26 \cdot \sigma'_V + 5.4 \ (kPa) \qquad (4)$$

Table 1. Undrained strength obtained in the triaxial tests.

Triaxial N0.	$C_{U,TC}$ (kPa)	σ'_{v0}	C_u/σ'_{v0}
BH_P_34_1	4.2	12.1	0.35
BH_P_34_2	14.3	41.0	0.35
BH_P_34_3	58.5	186.3	0.31
BH_P_33_1	16.3	28.3	0.58
BH_P_33_2	21.8	58.3	0.37
BH_P_33_3	60.5	205.4	0.29
BH_P_25_3.1	6.5	12.0	0.54
BH_P_25_3.2	16.5	44.0	0.38
BH_P_25_3.3	60.5	185.0	0.33
BH_P_25_8.1	16.0	33.0	0.48
BH_P_25_8.2	84.0	217.0	0.39
BH_P_25_8.3	63.5	214.0	0.30
BH_P_84_1	13.5	29.3	0.46
BH_P_84_2	22.0	44.0	0.50
BH_P_84_3	47.5	195.0	0.24

3.2 Undrained strength from empirical correlations

Mayne and Peuchen (2018) have proposed an empirical correlation to obtain the parameter N_{kt} from the Bq parameter of the CPTU interpretation (equation 5)

$$N_{kt} = 10.5 - 4.6 \cdot \ln(B_q + 0.1) \qquad (5)$$

Bq being given by equation (6) where q_{net} is the net cone resistance ($q_{net} = q_t - \sigma_{vo}$),

$$B_q = \frac{(u_2 - u_0)}{q_{net}} \qquad (6)$$

N_{kt} can then be used to calculate the undrained strength using the following well-known relation:

$$C_u = \frac{q_{net}}{N_{kt}} \qquad (7)$$

Considering only the CPTU tests performed near the boreholes where the samples for the triaxial tests were retrieved and the CPTU data at the depths at which those samples were taken, the following results were obtained (Table 2).

It is clear from this data that much higher undrained strength ratios (C_u/σ'_{v0}) were obtained from the CPTU data interpreted with Mayne and Peuchen (2018) correlation (Table 2) in comparison with the laboratory data presented in Table 1. These values are also very high taking into account that the soil under study concerns a normally consolidated material where an undrained strength ratio between 0.2 and 0.4 was expected. This might be explained by two main reasons: i) this empirical correlation has not been developed for gyttja; ii) the site is very

Table 2. Undrained strength obtained in the CPTU tests by the Mayne and Peuchen (2018) correlation.

N_{kt}	C_u (kPa)	C_u/σ'_{v0}
14.3	9.5	0.91
15.6	8.3	0.77
15.7	8.3	0.86

13.1	15.4	0.59
13.8	15.9	0.60
11.7	23.7	1.04
12.0	21.4	1.02
12.2	23.3	1.05

heterogeneous where it is possible that gyttja is mixed with other man-made materials.

3.3 Proposed approach

In these conditions, an average N_{kt} value was adopted considering only the five CAUC tests performed with lower effective stresses (<60 kPa) considered more representative of the effective stresses acting at gyttja according to Figure 1. To avoid differences between effective stresses of CPTU tests and the effective stresses of CAUC test, the undrained strength coming from CAUC tests was calculated with equation (4) for the depth at which the CPTU data was taken. The results are presented in Table 3 from where an average N_{kt} value of 19.2 was taken (Sousa, 2020).

Table 3. N_{kt} values obtained in 5 CAUC tests.

Borehole	$c_{u,TC\ avg}$ (kPa)	CPTU	$q_{net,avg}$ (MPa)	N_{kt}
BH_P_25	7.7	CPT_A_235	0.133	17.2
	12.5		0.208	16.6
BH_P_33	11.2	CPT_A_193	0.237	21.2
BH_P_34	8.1	CPT_A_179	0.135	16.7
BH_P_84	11.3	CPT_P_84	0.277	24.5

Then, the undrained strength obtained in all the 80 000 CPTU measurements was calculated with this N_{kt} value using equation (7). The results are plotted in Figure 4, which represents the histogram of all the undrained strength ratio values.

It is clear that, even using a quite high N_{kt} value, there are still a significant number of undrained strength ratios above 0.4. This may be associated to the
Figure 4. Histogram of all the undrained strength ratio values.

heterogeneity of the material and the presence of man-made materials, namely slag, mixed with the soft soil.

4 PROBABILISTIC ANALYSIS

For the data presented in Figure 4, a probabilistic density function was fitted using a Lognormal distribution (equation (8)),

$$f(x) = \frac{e^{-(\ln((x-\theta)/m))^2/2\sigma^2}}{(x-\theta)\sigma\sqrt{2\pi}} \qquad (8)$$

where σ is the Lognormal standard deviation (or shape parameter), m is the Lognormal mean (or scale parameter) and θ is the offset of the Lognormal mean (or the location parameter). This case, the following estimates of the parameters were obtained to adjust the histogram of Figure 4: $\sigma=0.852$, $m=0.720$ and $\theta=0.04$, as presented in Figure 5.
Figure 5. Lognormal fit to the undrained strength ratio.

5 SLOPE STABILITY ANALYSIS

The probabilistic distribution of the undrained strength as described above was included in a slope stability analysis using the limit equilibrium software SLOPE/W from GEOSTUDIO®. The aim of this work was to analyze the gyttja stability during its excavation. The retaining support structures built in the perimeter of the area to contain the hydraulic fill, will be founded in the layers below gyttja. For this reason, the gyttja will be excavated in those areas. Slope stability analysis are needed because submarine landslides caused by failures in the gyttja layer can cause tsunamis and/or disturbances in the submarine environment with impact on its biodiversity.

In these conditions, limit equilibrium analysis using the Morgenstern-Price method were performed considering the gyttja undrained strength as a random variable whose distribution is the one indicated in equation (8). The probabilistic procedure used herein was the Monte Carlo method, integrated in SLOPE/W, considering a total amount of 500 MC samples. This was applied to a slope of 9 m high and 45º of inclination, as illustrated in Figure 6.
Figure 6. Slope used in the gyttja stability analysis.

The results of the probabilistic distribution of the factor of safety (FS) are indicated in Figure 7, where a minimum FS of 1.43 and a maximum FS of 9.40 were obtained with an average of 2.64. In addition, a reliability index of 1.45 was obtained for this case.
Figure 7. Probabilistic density function of the factor of safety.

6 CONCLUSIONS

Geotechnical engineering design is progressively moving from a deterministic approach to a probabilistic approach. This enables the consideration of natural variability and the uncertainties associated to geotechnical parameters. It also enables to quantify the probability of failure and the reliability index associated to a certain design, which can be used by designers or project owners to decide upon different options depending on the required level of risk. In this work, the large amount of CPTU data performed for the construction of an artificial peninsula close to Copenhagen was used to perform a probabilistic analysis of the soft soil undrained strength ratio. The probabilistic density function of this variable was then introduced in a slope stability analysis by the limit equilibrium method. The results indicated that for a slope of 9 m high and 45º of inclination, the reliability index associated to the probability of failure was 1.45, which is quite low. This means that although a deterministic factor of safety of 1.4 was obtained, the reliability associated with the studied design is low.

ABSTRACT: The present work describes the use of the seismic dilatometer test (SDMT) and the piezocone test (CPTu), to assess the effects of ground improvement at a wastewater treatment plant in Guayaquil, Ecuador. The ground improvement consisted of 15 m-long, 0.55 m-diameter and 2 m-spacing stone columns built with vibro-replacement technique. The tests were carried out both in natural and in treated soils to compare the variation of the geotechnical parameters in the analyzed deposits. The results show specific sensitivity of the DMT over the CPTu tests to the ground improvement into the layer composed of sands and sandy silts, while VS values show a limited increase in the treated area.

1 INTRODUCTION

Ground improvement involves different techniques to modify soil response under different conditions. Ground modification performance is based on assessing problematic soils, liquefaction potential, soil instability, insufficient bearing capacity and excessive settlement, seepage. U.S. Army Corps of Engineers (1999).

Mitchell (2008) discussed the applications and limitations of these densification methods, and the author noted that the degree of improvement given by the deep dynamic compaction, vibro-compaction and blasting is greater in clean sands since it decreases as the fines content (FC) increases. Nevertheless, several studies have documented mitigation works using various FC values (including rather high percentages), highlighting an improvement given by the vibro-replacement stone columns, Mackiewicz & Camp (2007) used an improvement index (I_i), given by the ratio between the cone resistance (q_c) after and before the treatment minus one, to provide an improvement of $0.3 < I_i < 2.8$ for FC < 5%, and of $0 < I_i < 1.6$ for 15% < FC < 40%. (Luehring et al. 2001) showed an increase of 95% for the corrected SPT blow count $(N_1)_{60}$, and 180% for the normalized corrected cone

resistance q_{c1N}, using vibro-replacement stone columns in combination with vertical drains in deposits with FC < 65%. Mitchell & Wentz (1991) showed a 100% increase for the corrected cone resistance for overburden stress, (q_{c1}), and a 45% increase for the SPT corrected penetration resistance, $(N_1)_{60}$, when comparing pre and post-treatment results in soil layers with FC < 55%. Vibro-replacement stone columns installation may have the double beneficial effect to cause densification of the surrounding soil during installation and facilitate the dissipation of the excess of pore water pressure developed during an earthquake, by providing a shorter path of drainage, Adalier & Elgamal (2004).

Therefore, the effectiveness verification of the improvement using in situ tests becomes relevant since these investigations allow a quick assessment, which compares selected geotechnical parameters obtained before and after the treatment. Numerous authors (Schmertmann 1986, Mackiewicz & Camp 2007, Mitchell 2008, Monaco et al. 2014, Bałachowski & Kurek 2015, Wotherspoon et al. 2015, Massarsch & Fellenius 2019, Massarsch et al. 2020) evaluate the change of the soil characteristics using different in situ tests and their parameters: SPT blow count N_{SPT} in the standard penetration test (SPT),

horizontal stress index K_D and constrained modulus M in the flat dilatometer test (DMT), corrected cone resistance q_t in the piezocone penetrometer test (CPTu). Other studies (e.g., Wotherspoon et al. 2015, Hwang et al. 2017, Comina et al. 2021) have applied shear wave velocity V_S in the geophysical measurements provided by invasive or non-invasive tests (e.g., seismic piezocone SCPTu, seismic dilatometer SDMT, down-hole DH, cross-hole CH, multichannel analysis of surface waves MASW). Moreover, several research discusses the change in the at-rest lateral earth pressure coefficient K_0, the overconsolidation ratio OCR and the ratio M/q_t when monitoring the densification effectiveness and the lateral stress increase. A combination of CPT and DMT tests is performed to estimate the parameters mentioned above, as suggested in previous studies (e.g., Baldi et al. 1986, Marchetti et al. 2001, Amoroso et al. 2018, 2020, Massarsch et al. 2020)

The present study describes the effects of ground improvement using SDMT and CPTu tests. In this regard, CPTu and SDMT tests and V_S measurements were executed in natural and treated soils, to compare the geotechnical parameters, to assess liquefaction before and after treatment.

2 COMBINATION OF SDMT AND CPTU FOR MONITORING GROUND IMPROVEMENT

Single-parameters derived from SDMT and CPTu tests can detect the modification in soil characteristics due to improvement works. As stated by various authors (e.g. Schmertmann 1986, Bałachowski & Kurek 2015, Amoroso et al. 2018, 2020, Massarsch & Fellenius 2019, Massarsch et al. 2020), these parameters can be identified in the horizontal stress index K_D and the constrained modulus M from DMT, the corrected cone resistance q_t (or the cone resistance q_c) and the relative density D_R from CPT. K_D is directly derived from the corrected DMT membrane lift-off pressure reading and contains information about the stress history of the soil. Concurrently M is a function of the three DMT intermediate parameters (horizontal stress index K_D, dilatometer modulus E_D and material index I_D). q_t (or q_c) is a direct measurement from CPT, while D_R is usually based on correlations as a function of the cone resistance and effective stress, Juang et al. (1996). According to previous ground improvement studies related to densification techniques (e.g. Massarsch & Fellenius 2002, 2019, Massarsch et al. 2019), the horizontal stress also increases after compaction, making K_D (and therefore M) more sensitive than q_t (and consequently D_R) to detect the modifications induced by the treatment.

Moreover, the coupled CPT-DMT parameters, such as K_0, OCR, can help identify the treatment effectiveness in sandy soils. The present research estimated K_0 using the more recent relationship proposed by Hossain & Andrus (2016):

$$K_0 = 0.72 + 0.456 \log OCR + 0.035 K_D - 0.194 \log^{q_c/\sigma'_{v0}}$$

$$(1)$$

where σ'_{v0} is the vertical effective stress.

To estimate OCR in sands the approximation by Monaco et al. (2014) was used:

$$OCR = 0.0344(M/q_t)^2 - 0.4174(M/q_t) + 2.2914 \quad (2)$$

3 IN SITU TESTS

The results presented in this study belong to a trial site located within a wastewater treatment plant (WTP) in Guayaquil, Ecuador. Figure 1, shows the location where CPTu and SDMT tests were performed before the stone columns (SC) installation, natural soil (NS), and after SC installation, treated soil (TS), up to 16-20 m depth. NS soil testing is identified as CPTu1_NS and SDMT1_NS, while surveys after SC installation are detected as CPTu2_TS and SDMT2_TS. The SC were in a staggered arrangement with 2 m spacing. Additional information regarding the NS condition was obtained from the borehole, SPTs (SPTP3_NS) and CPTu tests (CPTu14_NS) performed during the WTP construction.
Figure 1. Location of the water treatment plant at "Las Esclusas", in-situ tests and stone columns.

For the execution of CPTus and SDMTs, the shallow compacted fill layer ($\approx$ 0.6-0.8 m thick) was removed, to prevent damage to the geotechnical

equipment. Table 1 summarizes the basic information of the in-situ tests used for verifying the ground improvement effectiveness. The ground-water table (GWT) fluctuations, at the trial site, were strongly influenced by the Guayas river tide, following the Navy Oceanographic and Antarctic Institute measurements, INOCAR (2021).

Table 1. Summary information of the in situ tests at the trial site.

Field test	Depth (m)	GWT depth* (m)
SPTP3_NS	19.0	2.0
CPTu14_NS	20.8	2.7
SDMT1_NS	20.4	3.4
SDMT2_TS	20.6	3.4
CPTu1_NS	17.6	3.8
CPTu2_TS	19.0	3.8

* Note: Measured from the ground surface post filling.

3.1 Geotechnical description

Figure 2 summarize the soil profile in both soil conditions using CPTu and SDMT tests at the Guayaquil trial site. Beneath the shallow fill, the soil is variable, but four clearly defined layers can be observed. The first layer is approximately 2 m thick and varies from silt to clay, as described by: the soil behavior index (I_c) profile that intercalates between 2.6 and 3.4, the material index (I_D) values which are between 0.2 and 1.1. Underlying this layer, loose to medium dense sand mixtures ($2 MPa < q_t < 8$ MPa; $2 < K_D < 9$) are present with a maximum depth of ≈ 10 m. These nonplastic sands and silty sands are mainly characterized by $I_c < 2.6$ and $I_D > 1.2$. A lens of variable thickness, comprised of silt mixtures ($2.6 < I_c < 3.0$, $0.6 < I_D < 1.1$) is present within the sandy layer between ≈ 7 and 10 m depth. Finally, below 10-11 m depth, normally to moderately overconsolidated clays are encountered, according to OCR approximation by Marchetti et al. (2001). This finding associates the following DMT and CPTu parameters: $2.2 < K_D < 3.3$, with $3.1 < I_c < 3.9$, $0.2 < q_t < 2.0$ and $0.2 < I_D < 0.6$.

4 GROUND IMPROVEMENT

Figures 2 and 3 show the variation of the CPTu, DMT and combined (CPTu and SDMT) parameters in natural soil (NS) and treated soil (TS), estimated according to Robertson & Cabal (2015). The relative density (D_R) estimation is based on the correlations proposed by Kulhawy & Mayne (1990). I_c profiles present a very slight variability of the soil before and after treatment, which makes quite comparable the data within the depth of the SC improvement where

the silty sand to sandy silt layer ($I_c < 2.6$) is located. However, for some depth intervals between 4 and 10 m, q_t ($\approx 4.2-6$ m, 8-9 m, 9.6-10.4 m depth), and D_R ($\approx 4.5-6$ m, 8-9 m depth) values in the NS are somewhat higher than in TS. This rise is observed when the I_c increases in the TS, and it behaves more like fine-grained soil. Figure 3 also compares the CPTu-D_R values with the ones evaluated from SPT, Skempton (1986). The D_R SPT-based values in the NS are in good agreement with the related CPTu ones from ≈ 6 to 8 m depth, while between 8 and 11 m depth, the SPT-based method overpredicts the relative density. The SPT-based overestimations of D_R can be attributed to the lens of silt mixtures detected only by CPTu and SDMT.

The DMT parameters, were calculated using the Marchetti et al. (2001) formulae. The equilibrium pore pressure, u_0, obtained from the third DMT pressure reading (p_2) into the sandy layers, well determined the GWT location. The effectiveness of the treatment is noticeable from ≈ 2 to 6 m depth, by looking at K_D and M and profiles (Figures 2, 3); in this depth range, $I_D > 0.6$ predominate in both soil conditions. The increase in K_D profile is clearly defined in this depth interval and a 52% increment is observed after the treatment. The shear wave velocity V_S (Figure 3) also provides some increase after improvement, but limited between 4 and 6 m. A specific lateral soil heterogeneity is distinguishable in the NS and TS, I_D profiles between ≈ 6 to 8 m depth: the TS exhibits a fine-grained soil behavior, considering the lower I_D values ($0.3 < I_D < 1.2$ corresponding to silty clay to silt), while the NS of the same layer results mostly silty-sandy ($1.2 < I_D < 2.3$). This response helps to understand why for the same depth interval, the horizontal stress index K_D and the constrained modulus M are much lower despite the SC installation. The analysis of CPTu and DMT combined parameters is displayed in Figure 3 to monitor ground improvement effectiveness. The OCR and K_0 estimations were performed both in fine-grained and incoherent soils. Specifically, for $I_D < 1.2$, OCR and K_0 were estimated by DMT using Marchetti et al. (2001) formulae, while for sandy layers ($I_c < 2.6$ and $I_D > 1.2$) the combined CPT-DMT approach was used according to Equation 2 from Monaco et al. (2014) for OCR and to Equation 1 from Hossain & Andrus (2016) for K_0. The OCR and K_0 profiles detect the effectiveness of the SC treatment between ≈ 2.6 and 6.6 m depth. Below 6.6 m, the NS and TS trend remains unchanged despite the SC installation.

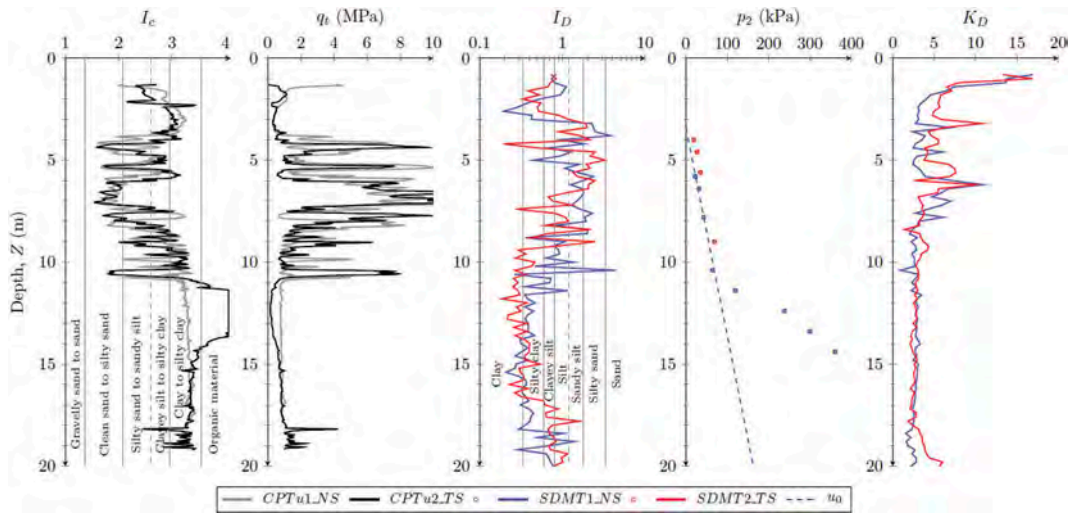
Table 2 summarizes the average test results of the single and combined parameters in the layer where the increase was better noticed for $I_c < 2.6$ and $I_D > 1.2$, approximately between 3.2 and 6.6 m depth. The improvement was calculated by relating the difference between TS and NS to NS results, expressed as a percentage. The CPTu conventional indicators of improvement show an increment of 6% for q_t and 7% for D_R, while for


Figure 2. CPTu and SDMT basic parameters in both soil conditions (natural and treated soil) at the Guayaquil trial site.
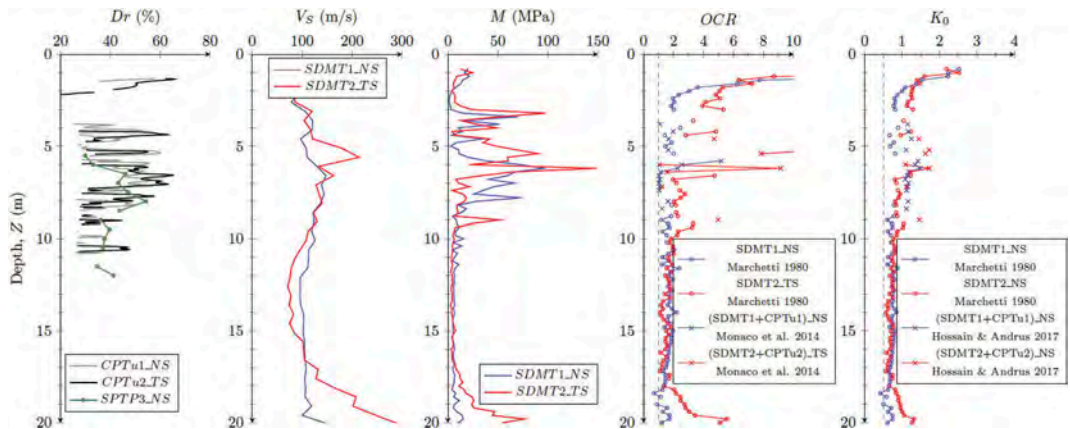

Figure 3. CPTu and SDMT estimated parameters in terms of D_R, V_S, M, OCR and K_0 at the Guayaquil trial site.

Table 2. Summary of average parameters (pre and post treatment) between 3.2 and 6.6 m depth: q_t, D_R, K_D, M, V_S, OCR, K_0.

	q_t (MPa)	D_R (%)	K_D	M (Mpa)	V_S (m/s)	OCR	K_0
NS	5.0	42.5	5.0	43.6	121.2	3.1	1.3
TS	5.3	45.7	6.2	61.9	152.8	6.1	1.5
Inc. (%)	6.0	7.6	22.4	42.0	26.1	98.4	15.8

the SDMT parameters, K_D increased 22%, M 42% and V_S 26%. For the combined CPTu and SDMT parameters, K_0 increased just 16%, while OCR increased 98%

5 CONCLUSIONS

Despite the length of the SCs, the effectiveness of the treatment resulted noticeable only between 3.2 to 6.6 m depth, where the sand mixtures where detected by in situ tests. Below this layer a lens of silt mixtures, with higher FC (up to 46%) approximately between 7 to 10 m depth, and of a cohesive soil layer, from 10-11 m depth, were identified.

The evaluation of the soil improvement between 3.2 to 6.6 m depth was mainly detected by using the combined CPTu and SDMT parameters, with a 98 % increment in OCR and 15% increment in K_0. The relatively low increment in K_0 can be attributed to the high initial K_0 condition in NS ($K_0 \approx 1.27$), as already noticed by Schmertmann (1985). In the CPTu based effectiveness assessment, q_t and D_R

have a similar increase (6% and 7.5% respectively), although the NS and TS were related to quite homogeneous subsoil, as detectable looking at I_c. Furthermore, SDMT single parameters, K_D, M, V_S, provided a more evident SC improvement, even still limited, 22%, 42% and 26% respectively. Therefore, at the Guayaquil trial site the densification provided by the SCs resulted merely perceived by the CPTu tests probably also due to the lateral soil variability.

Plate anchor capacity estimation through CPT tip resistance in sand

A. Roy & S.H. Chow
Department of Infrastructure Engineering, the University of Melbourne, Australia

ABSTRACT: Reliable estimation of plate anchor uplift capacity in sand through analytical and empirical equations is often complicated due to uncertainties in estimation of soil properties required in the equations. In order to address this uncertainty, this study proposes a correlation to estimate plate anchor vertical uplift capacity in sand based on cone tip resistance measured from cone penetrometer tests (CPT). The correlation was established using a database of reported centrifuge experiments on circular, rectangular and strip anchors in loose and dense silica sand at various embedment depths and *g*-levels, along with the corresponding centrifuge CPTs performed in the same testing boxes. The centrifuge cone tip resistances were also depth-corrected to remove the effect of shallow embedment. Through regression analyses, the correlation between plate anchor capacity and cone tip resistance in dimensionless form was developed, with different coefficients fitted for circular, rectangular and strip anchors respectively.

1 INTRODUCTION

Plate anchors are routinely used onshore as foundations for structures subjected to high uplift or lateral loads. With a recent global thrust in harnessing energy from cleaner renewable energy sources, plate anchors are also likely to find increased application in mooring offshore renewable energy devices owing to their cost- and capacity-effectiveness relative to other anchors and piles. Such renewable energy devices are likely to be located in much shallower water where the seabeds of interest include coarser-grained deposits. Hence, reliable estimation of plate anchor uplift capacity in coarser-grained soils will be of interest for geotechnical practitioners.

One of the most widely used soil exploration methods in coarser-grained offshore deposits is cone penetration tests (CPT). As undisturbed core sample collection for coarser-grained soils requires specialised equipment and becomes expensive for offshore sites, CPT data is often the only source of geotechnical information available during the early planning stages for offshore projects. Considering that behaviour in sands is highly dependent on initial fabric, stress levels and relative density (R_D) (Been et al. 1991, Gajo & Wood 1999), a continuous CPT profile can macroscopically capture such effects with respect to the change in soil stratigraphy. As compared to a traditional 'operational' friction angle (φ) based approach, there is great value in direct application of cone tip resistance (q_c) profiles in design approaches, because it will significantly improve reliability in prediction by eliminating uncertainties in estimation of a back-analysed φ. Such q_c based design approaches have been reported for bearing capacity problems on footings and spudcans (Lee & Salgado, 2005, Liu & Lehane 2020,

Pucker et al. 2013) and pile foundations (Schneider et al. 2010) over the last two decades, but is yet to be explored in uplift capacity problems.

This paper explores the test results from an elaborate set of reported centrifuge experiments (vertical uplift tests) on circular, rectangular and strip anchors with companion cone penetrometer tests in different densities at various embedment depths, *g*-levels and OCR levels. The cone tip resistance (q_c) measured in the centrifuge were depth-corrected to remove the effect of shallow embedment. A correlation between plate anchor capacity and cone tip resistance is then developed using a regression analysis on the database of centrifuge anchor tests.

2 EXPERIMENTAL DATABASE DETAILS

The anchor database comprised of 91 uplift tests across 20 sand samples reported from two different centrifuge studies:

- Tests reported by Roy et al. (2021a,b) on strip, rectangular and circular plate anchors in silica sand of relative density, $R_D \sim 70\%$ and $R_D \sim 45\%$ (details in Table 1 and Table 2). These tests were conducted at gravitation accelerations ranging between 20*g* and 100*g*, and embedment ratios (*H*/*B* or *H*/*D*, where *H* is depth of the plate anchor, *B* is the anchor width and *D* is the anchor diameter) of 2 to 6 to investigate the behaviour of plate anchors under different stress levels (hence at different *g*) and load inclination. For the current study, only vertical uplift tests from the respective samples are included in the database.

- Tests reported by Hao et al. (2018) on circular plates and single helices in sand of R_D = 85-95% at 20g(details in Table 3) at anchor embedment ratios (H/D) in the range 2 to 10;

(R) with aspect ratio 2:1, circle (C), helix (H)) as listed in Tables 1-3 and Figure 1. All these tests were conducted in a fine sub-angular silica sand, commonly identified as the UWA Silica sand with properties as summarised in Table 4. The samples for the centrifuge tests were prepared using air pluviation technique and anchor testing setup can be found in the respective papers.

These uplift tests involved anchors with different geometry (strip (ST) with aspect ratio 8:1, rectangular

Companion cone penetrometer tests were also conducted in these reported studies at 20g using a 10 mm diameter cone penetrometer (d_{cone}).

Figure 2 presents q_c profiles measured across: (a) the 13 sand samples reported in Roy et al. (2021) at 20g performed at the start of testing, and (b) q_c profiles from the 13 sand samples in Hao et al. (2019). These q_c profiles are used to estimate the relative density (R_D) of the samples using a q_c - R_D relation proposed by Roy et al. (2019) for the UWA silica sands, that accounts for effective vertical stress(σ'_v), relative density and normalised penetration depth (z_m/d_{cone}):

$$q_c = C_0 P_a(\sigma'_v/P_a)^{C_1+C_3(1-f_D)+f_D\Delta C_{1oc}} (e)^{(C_2+f_D\Delta C_{2oc})R_D} \tag{1a}$$

$$f_D = \exp(-C_4(z_m/d_{cone})^{-C_5}) \tag{1b}$$

where the constants for UWA Silica sand were obtained as $C_0 = 8.5$, $C_1 = 0.89$, $C_2 = 3.3$, $C_3 = 0.36$, $C_4 = 1049.2\ R_D^{7.25}$, $C_5 = 3.7$ respectively. ΔC_{1-oc} and ΔC_{2-oc} are constants that account for the decreased compressibility of the sands under OC condition, the details of which are explained in Roy et al. (2019). It is worth noting that the effect of shallow embedment on q_c for centrifuge CPTs are incorporated through a varying depth factor (f_D) in Equation 1. Using Equation 1, relative density at the anchor locations was back-analysed as $R_D = 41 – 51\%$ for the loose sand and $R_D = 69 – 76\%$ in the dense sand reported by Roy et al. (2021a). For the tests reported by Hao et al (2019) on circular plates, the R_D was ~ 85 - 96%.

Table 3. Anchor database in very dense sand at 20g and OCR = 1 (after Hao et al., 2019).

Relative density (%) (unit weight) (kN/m³)	Anchor code	H/D	q_a (kPa)	N_γ
96.2 (17.07)	H	3	182.29	8.9

85.8 (16.84)	C	9	1879.34	31.0

For anchor tests conducted at different g-levels or OCRs within the same sample (see samples D1-D7, D9 in Table 1 and L1-L7 in Table 2), a q_c profile at the respective g-level or OCR was required to generate the correlate to anchor capacity. However, CPT tests at all g-levels as those of the anchor tests were

not possible due to the space constraints in the strong-boxes; as such Equation (1) was subsequently used in such cases to establish the respective q_c profile. The validity of such an approach is confirmed by the good agreement between the measured and simulated q_c - z_m/d_{cone} profiles using Equation (1) at two different R_D and g-levels in a separate CPT study as shown in Figure 3.

3 ESTABLISHING N_Γ - q_c CORRELATIONS

3.1 Anchor capacity factor

The mobilised peak anchor capacity (q_a) in this paper is reported in dimensionless form as peak anchor factor ($N_\gamma = q_a/\sigma'_{vo}$, where σ'_{vo} is the effective overburden stress). The q_a and N_γ for each anchor test is tabulated in Tables 1-3. The N_γ is typically attained within normalized displacement (δ/B or δ/D) of 15% in medium dense ($R_D = 48\%$) and 7-12% % in dense sand ($R_D = 70\%$), as reported in Roy et al. (2021a,b). At a given H/B, the highest N_γ is observed from circular plates whereas the least is observed from strip anchors.
Figure 3. Comparison of measured and simulated q_c - z_m/d_{cone} profiles at different R_D and g-levels.

3.2 Correcting q_c for shallow embedment effects

The q_c profiles from centrifuge samples undergo shallow penetration and need to be corrected for effects of shallow embedment (Bolton *et al.* 1999). For example, if the results for a prototype anchor having D = 0.6 m at H/D of 2 was to be simulated, a model anchor plate with diameter of 30 mm (as reported in the database) would have to be embedded at a sample depth of 60 mm at 20g. With centrifuge penetrometers having d_{cone} = 10 mm, the anchor placement depth would be located within a penetrating distance of 6d_{cone}, resulting in a shallow failure mechanism for the penetrometer. For corresponding prototype anchors having D = 0.6 m, it would have to be embedded at a depth of 1.2 m in field (for H/D = 2); a penetrometer in such conditions would have penetrated by ~33d_{cone} (considering a standard cone diameter of 35.8 mm) to reach embedded depth for the anchor, resulting in a deep failure mechanism. As per reported studies by Bolton et al. (1999) and Liu & Lehane (2020), the critical normalised depth governing the transition from shallow to a deep mechanism for a cone penetration test usually ranges between 5 and 15. So, cone profiles from centrifuge samples would produce a smaller q_c value at shallow depths than the corresponding prototype samples at similar stress and density levels. Hence, correction is necessary to obtain an equivalent q_c value under the effect of similar stress and density levels but independent of penetrating distance. This can be readily worked out using the correlations by use of depth factor $f_d = 1$.

The depth-corrected q_c profiles simulated using f_d = 1 in Equation (1) is shown in Figure 4 for two different densities at two different stress levels. These profiles show that the effect of depth correction on q_c is more pronounced as the g-level and the R_D increases. For the measured (uncorrected) centrifuge $q_c$profiles in Figure 4, a shallow failure mechanism results in an increased concave upwards curvature at the shallower penetration depths. In contrast, the simulated (depth-corrected) profiles are convex-shaped at the shallow penetration depths. The simulated and measured profiles tend to merge with each other at z/d_{cone} value greater than 8.

3.3 Obtaining average q_c values

The anchor tests reported in Table 1-3 were conducted at stress levels ranging from 20g to 100g. In order to obtain a correlation between N_γ and q_c, a representative q_c value in the influencing domain was necessary at the corresponding g level of the anchor test. Numerical studies have confirmed that (Al Hakeem and Aubeny, 2019, Hao et al. 2014), for plate anchor uplift under drained conditions, the failure mechanism significantly mobilises a soil on top of the anchor plate up to a distance of 2D or 2B. Based on this evidence, a representative q_c value (termed as $q_{c,avg}$) was taken as the average over a distance of 2D or 2B over the top of the anchor using the depth-corrected simulated q_c profiles obtained by correlations in Equation 1. This zone encompasses the distance required to mobilise peak N_γ for all anchor types and embedment ratios.

3.4 Correlation for anchors

Figure 5 presents the average cone tip resistance ($q_{c,avg}$) vs. mobilised peak anchor capacity (q_a) data at all g levels for circular anchor. The data shows q_a linearly with an increase in $q_{c,avg}$ for all anchor types. However, at a particular value of $q_{c,avg}$, q_a values from loose sand are observed to higher than those in dense sand. Now, in order to inter-compare q_a at similar $q_{c,avg}$ values in loose and dense sand, an anchor would have to be located at a much deeper depth (or higher σ'_v) for the loose sand than for the dense sand. This suggests that there appears to be a significant contribution of σ'_v in governing peak N_γ. This hints that a stress normalised $q_{c,avg}$ value would be necessary to reliable correlation.
Figure 4. Comparison of measured cone profiles and simulated cone profiles using $f_D = 1$ at different g-levels in loose and dense sand.

In order to capture the effects of stress on the penetration resistance, Sharp et al. (2010) suggested the use of a normalised tip resistance term q_{c1N}:

$$q_{c1N} = (q_c/P_a)(P_a/\sigma_v')^m, \qquad (2)$$

where P_a is the atmospheric pressure, σ_v' is the effective overburden stress and m is a stress exponent term ranging from 0.3 to 0.8 that better accounts for the effects of σ_v' for a given problem. Trial iterations with using $m = 1$ across all densities (i.e. without using any R_D dependent normalisation), showed that insufficient overlap across all datasets, thus hindering the development of a unique correlation. This suggested that a density dependent m value needs to be used to ensure sufficient overlap between the datasets.
Figure 5. Variation of peak anchor capacity with average cone tip resistance in loose and dense sands for circular anchors.
Figure 6. Correlation of N_γ with q_{c1N} in loose and dense sand for (a) strip anchors, (b) rectangular anchors and (c) circular anchors.

The value of m was therefore evaluated using an optimisation routine to produce the greatest overlap in loose and dense sand data by a relative shift in the abscissa of the N_γ - q_{c1N} plot. This was achieved iteratively resulting in a value of $m = 0.6$ in loose sands (R_D ~45%), 0.4 in dense sands (R_D ~70%) and 0.39 in very dense sands (R_D ~90%). More anchor experimental data at $R_D < 40\%$ would be required to draw an unambiguous conclusion on the precise values of m in very loose sand. In absence of such data, it is assumed that m would take an upper bound of 0.8 at very low R_D values, therefore the exponent m used to obtain q_{c1N} can be expressed as:

$$m = 0.41(R_D(\%)/100)^{-0.24} \qquad (3)$$

Applying the optimized m in Equation (2), the correlation between q_{c1N} and N_γ is established as shown in Figure 6 and presented in Equation (4):

$$N_\gamma = 1 + f_u\, q_{c1N} \qquad (4)$$

where f_u is a coefficient dependent on anchor shape and is equal to 0.0396, 0.0784 and 0.2 for strip, rectangular and circular plates respectively. The R^2 values for the respective correlations for strip, rectangular and circular plate anchors are 0.776, 0.26 and 0.881 respectively. The significantly lower R^2 of 0.26 for the rectangular anchors is due to greater scatter in the experimental dataset at lower q_{c1N} levels and suggests that more experimental data would be required to obtain a reliable correlation. The f_u values also indicate that the anchor capacity increases in the order of strip, rectangular and circular anchors, which agree with existing studies (e.g. Murray and Geddes 1987).

4 CONCLUSIONS

A correlation between anchor capacity factor (N_γ) and normalized cone tip resistance (q_{c1N}) has been established based on a collected database of centrifuge tests on strip, rectangular and circular anchors at varying g-levels in loose and dense sands. The centrifuge cone profiles were depth-corrected to remove the effect of shallow embedment and make them inter-comparable with prototype tests. The results indicated that a varying stress exponent factor is necessary to account for the effect of overburden stress in loose and dense sands and to establish a unique correlation. It is desired to validate the proposed N_γ -q_{c1N} correlation using field anchor and companion CPT data. The results can also be used to readily compute anchor capacity through CPT profiles when the soil fabric has been disturbed due to installation effects, which is a distinct advantage when compared to other methods relying on in-situ inputs of density and friction angles.

ABSTRACT: A large number of bored CFA piles was installed during the construction of a big treatment plant in Poggiomarino (Naples), where the subsoil is formed by sub-horizontal strata of alluvial soils of pyroclastic origin interbedded with organic silt layers, overlying the pyroclastic base formation. The installation parameters of CFA piles (rate of revolution, rate of penetration, torque, etc.) have been recorded during construction. In the paper the statistical correlation between CPT results and monitoring data of CFA piles installation was analysed. The statistical correlation allowed evaluating the bearing capacity of each CFA pile based on the monitoring of installation data. The correlation was developed by considering different pile groups located around the CPT verticals, in order to analyse the sensitivity to the spatial variability of geotechnical subsoil properties. The statistical based prediction of bearing capacity was validated by considering two load tests on pilot CFA piles at the study site.

1 INTRODUCTION

The CFA or Continuous Flight Auger pile is a rather widespread pile type in USA also called auge cast piles. They are installed by first inserting an auger under the combined action of a torque and an axial force. The auger retrieval is carried out while concrete is pumped through the central stem.

With this technology is possible and is more and more frequent the monitoring of installation parameters during the pile construction. These parameters are connected to the step of auger insertion and to the final stage of auger retrieval and concrete downwards pumping.

In the drilling phase, the tube advancement takes place with an intermediate mechanism between that of a screw and that of a *coclea*. Named v the speed of advancement, n the speed of rotation and l the pitch of the auger, in a time Δt there is a volume of displaced soil:

$$V_d = \frac{\pi}{4} d_0^2 \, v \, \Delta t \qquad (1)$$

and a volume of soil removed from the auger and taken to the surface:

$$V_a = \frac{\pi}{4} \left(d^2 - d_0^2 \right) (nl - v) \, \Delta t \qquad (2)$$

If $v=nl$, the volume removed is null, the auger advances into the ground without any removal of the surrounding soil.

If $v=0$, the auger turns without advancing and works as a an archimedean coclea screw by continuously removing soil. To obtain an overall compression effect, it should be $V_d \geq V_a$, and therefore:

$$v \geq nl \left(1 - \frac{d_0^2}{d^2} \right) = v_{crit} \qquad (3)$$

The second member of the equation (3) represents the critical penetration speed v_{crit}, of the auger into the ground.

The paper is dedicated to determine a statistical correlation between CPT results on one side and installation parameters of the CFA piles recorded during the pile construction at the site of the large treatment plant in Poggiomarino (Napoli, Italy) on the other side.

A further correlation aimed at the prediction of the bearing capacity of piles on the basis of the installation recorded parameters has been developed and tested using the results of statical design load tests on several piles instrumented with strain gauges along the pile shaft

2 GEOTECHNICAL INVESTIGATIONS AND SUBSOIL CONDITIONS

The whole area has been investigated between 1998 and 1999, the available in-situ tests include n. 5 boreholes (20-50m) with undisturbed/disturbed samples for laboratory tests, 19 CPT (14-30m), 7 CPTU (16-51m), 4 SCPTU (16-39m).

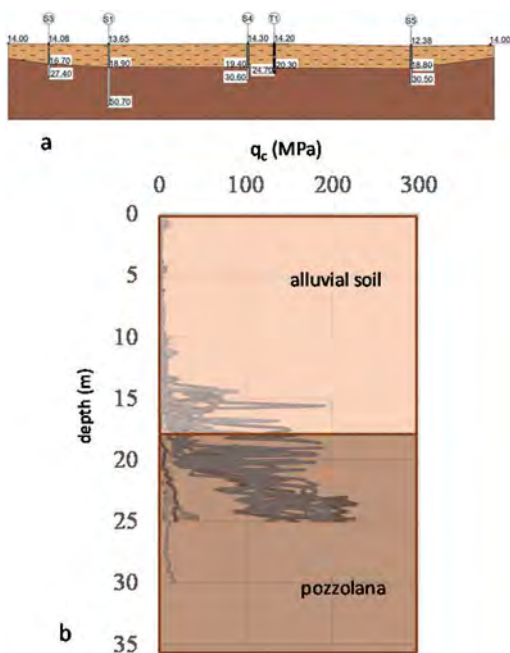
Two main lithotypes, whose main physical and mechanical characteristics are reported in Table 1, characterize the site (Figure 1): a lacustrine/alluvial soil constituted by pyroclastic sand and silt with organic or peat levels, with a thickness of 15÷18 m is found above the *Ignimbrite Campana* formation, made of pozzolana (silty sands) and grey tuff levels, that extends down to 50 m (max. borehole depth). Cone penetration resistance q_c is between $2 \div 3$ MPa in the mostly silt, organic levels while $q_c = 50 \div 70$ MPa in the sandy levels; in the pozzolana layer, qc ranges between $5 \div 200$ MPa.


Figure 1. Subsoil profile (*a*) and CPT results (*b*) of the investigated area.

Data referring to the alluvial soil are scattered, with grain size distribution ranging from sandy silt to silty sand; the unit weight γ ranges between 14 and 20 kN/m³, the water content w=20-60%, with corresponding value of the porosity n=40-60%. Some thin levels with high organic content have been detected at various depths, with lower values of γ (11-12 kN/m³) and higher values of w and n (respectively 80-200% and 65-80%). The base formation of pozzolana (silty sand) is more uniform: the unit weight γ ranges between 14 and 16 kN/m³, the water content w is

generally higher than 40%, the porosity n ranges between 55% and 65%. The few available lab data on the shear strength and estimation deriving from the interpretation of CPT tests lead to an overall value of the friction angle $\varphi' = 28°$ for the alluvial soils, $\varphi' = 35°$ for the base formation of pozzolana.

Table 1. Main physical and mechanical parameters of subsoil layers.

Layer	depth [m]	γ [kN/m³]	ϕ' [°]	c' [kPa]	E_{ed} [MPa]
Alluvial soil	0.0÷18.0	15.8	28	0	0.5÷5.0
Pozzolana	18.0÷50.0	15.6	35	0	20.0

3 INSTALLATION PARAMETERS OF CFA PILES AND IN SITU LOAD TESTS

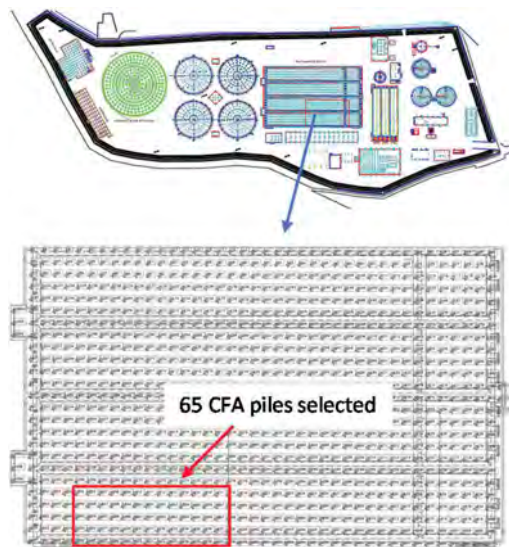
In this study a group of 65 piles with 27 m length and 0.8 m diameter belonging to the biological treatment tank have been considered, as reported in Figure 2.


Figure 2. Investigated area with details of biological treatment tank foundation; the red square evidences the set of 65 CFA piles selected for this study.

The drilling machines were equipped with Jean-Lutz recording system that allowed for continuous monitoring of installation parameters. Rate of revolution, rate of penetration and torque with depth were recorded every 8 cm. Conversion of operating pressure in torque (kNm) was performed with reference to a specific relationship for the drilling machine provided by the manufacturer. Torque has been considered as the most relevant installation parameter in this study, for its close relation with the subsoil characteristics. An increase of

soil resistance along the depth results in increase of torque applied for continuing the pile installation and *vice versa*. Profiles of average values of torque and box-plots of statistical parameters with depth for the n. 65 piles considered in the study are reported in Figure 3.
Figure 3. Measured values of torque along depth: average values and boxplot representation.
Figure 4. Results of piles load tests: axial loads *vs.* settlements and axial loads *vs.* depth curves.

Load tests to failure on three instrumented CFA piles belonging to the foundations were conducted (Mandolini at al., 2002). Vertical displacements were measured by means of four dial gages and precision levelling. All the test piles were equipped with the removable tape extensometers (Bustamante and Jezequel, 1991) whose results were also compared with vibrating wire gages installed in a central pipe (Russo, 2005). The main results of the load tests are listed in Table 2, while the axial load-settlement curves (total load Q, shaft load, S and base load P) and the axial load distributions along the pile shaft as an example are reported for all the tested piles in Figure 4. In Figure 5 is shown the torque registered during the tested piles.
Figure 5. Measured values of torque along depth for test piles.

Table 2. Load tests results.

Load test	d	L	Q_{max}	w_{max}	P_{max}	S_{max}
	[m]	[m]	[MN]	[mm]	[MPa]	[MPa]
		a*	b*	c*		
pile n.1	0.8	24.0	4.08	75.6	1.55	2.81
pile n.2	0.6	22.5	3.26	81.9	0.89	2.59
pile n.3	0.8	24.1	5.30	22.8	1.36	3.94

d = diameter; L = length; Q_{max} = maximum axial load; w_{max} = maximum settlement; P_{max} = maximum tip resistance; S_{max} = maximum shaft resistance.

4 STATISTICAL ANALYSIS

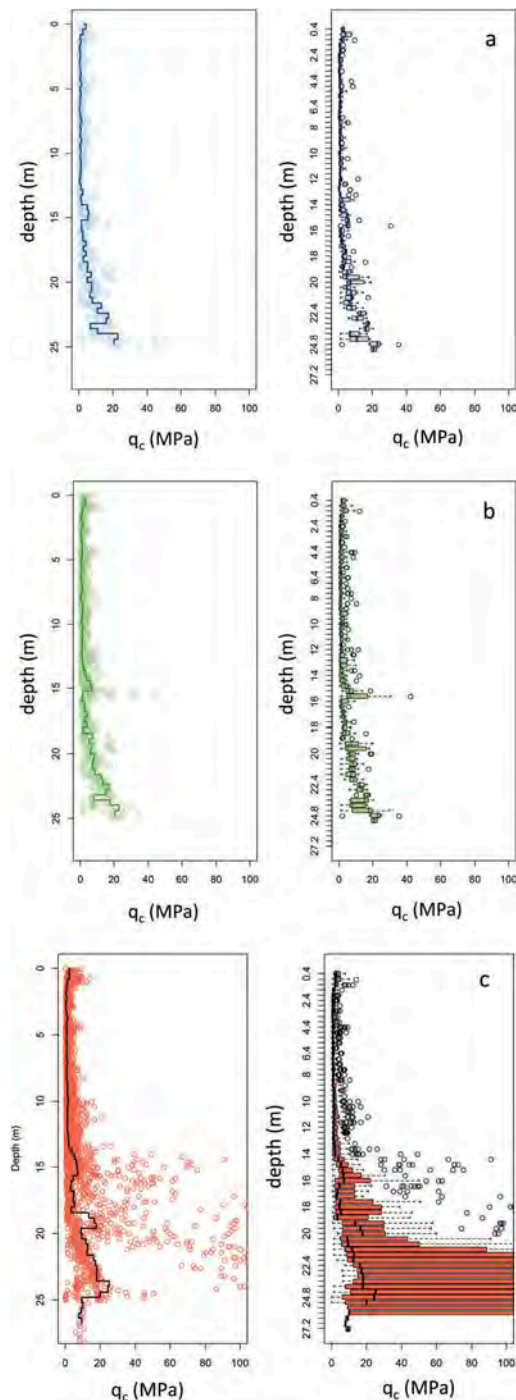
Statistical correlations between the relevant parameters were investigated with R numerical code (R Core Team, 2013). CPT tip resistance q_c and torque M_t recorded during the drilling of 65 piles of the biological treatment tank and CPT results in the proximity of the area were first considered. A sensitivity analysis was performed, aimed at investigating correlations at difference distances scales, considering three ranges,


Figure 6. CPTs tip resistance q_c *vs.* depth: average trends and boxplots for a) n.4 CPTs, b) n.7 CPTs, c)n.29 CPTs.

from the nearest CPTs around the selected piles up to all available CPTs in the investigated area (namely n.4 CPTs located close to the selected piles, n.7 CPTs
Figure 7. CFA piles: regression functions of $q_c = f(M_t)$ for the three selected set of CPTs.

located within the biological tank foundation, n. 29 CPTs performed within the plant perimeter). For each group of selected CPTs, the tip resistance q_c varies with depth as shown in boxplots of Figure 6, highlighting similar trends of q_c with depth regardless the number of data selected, thus confirming the homogeneity of subsoil profile in the considered area.

Regression analyses of average values of M_t and q_c with depth confirmed that correlation coefficients ρ for each set of selected CPTs were similar (namely $\rho = 0.63$ for n.4 CPTs set, $\rho = 0.66$ for n.7 CPTs set, $\rho = 0.71$ for n. 29 CPTs set), denoting a positive, moderate correlation between the two variables. The function $q_c = f(M_t)$ was determined by means of non-linear regression analysis. Polynomial regression models were used with the constrain that $q_c = 0$ for $M_t = 0$. The three functions are reported in Figure 7. The assessment of the "goodness of fit" was provided through the absence of trends of residuals (not shown), and a close relation between measured q_c and fitted q_c trends with depth for the three levels of analysis.

The statistical correlation between M_t and the unitshaft resistance s of test piles was also analyzed. The distribution of s with depth was evaluated from the measured variation of axial load along the test pile shaft. The function $s = f(M_t)$ derived by the non-linear regression analysis between $s(z)$ and measured $M_t(z)$ is reported in Figure 8.
Figure 8. Test piles: regression function of $s = f(M_t)$ from the results of load tests.

1086

5 PREDICTION OF UNIT SHAFT RESISTANCE

To assess the suitability of inferring CFA pile shaft resistance form installation parameters, the derived relations from statistical analysis were used for calculating the shaft resistance of selected CFA piles and compared with the results of load tests.

The average shaft resistance of the selected CFA piles was evaluated following the relation (Viggiani et al., 2012):

$$s(z) = \alpha q_c(z)$$

where a is a coefficient varying from 0.02 (qc < 2 MPa, very loose soil) to 0.07 (qc > 25 MPa, dense soil) and the tip resistance q_c was evaluated as function of the average torque $M_t(z)$.

The shaft bearing capacity of test piles has been calculated by integrating along the pile length the function $s = f(M_t)$ obtained through the statistical analysis.

The shaft resistance inferred from load test results was considered as benchmark for the predictions of shaft resistances based on the regression functions with installation parameters. Only test piles n.1 and n.3 were considered, having those piles the same diameter of CFA piles set considered in the study (i.e. d = 0.8 m). In Table 3 the calculated shaft resistances of CFA piles (both ordinary and test piles) and the shaft resistance inferred from load tests are reported.

Table 3. Comparison between calculated and measured pile shaft resistances.

Load test	S_{max} [MPa]	$S [s = f(q_c(M_t))]$ [MPa]			$S [s=f(M_t)]$ [MPa]
		a*	b*	c*	
pile n.1	2.52	3.17	3.19	3.90	3.51
pile n.3	3.54	3.73	3.50	3.95	2.95

* a = n.4 CPTs; b = n.7 CPTs; c = n.29 CPTs

With reference to the integral shaft resistance S calculated referring to the function s=f(q$_c$(Mt)), the results highlight an overestimation of the shaft resistance for pile test n.1, whereas for pile n.3 the estimate can be considered as satisfactory, whenever the level of the analysis performed. As shown by Mandolini et al. (2012), test pile n.1 is characterized by a rate of penetration v_P along the pile shaft lower than the critical value v_{crit}, whereas for test pile n. 3 the rate of penetration is higher than v_{crit}. The effects of the installation procedure of test piles n.1 on the soil mass, closer to the effects of bored piles, may explain the overestimation of shaft resistance based on the correlation function s=f(q$_c$(Mt)).

The correlation function s=f(M_t) seems to be less effective in the estimation of both test piles shaft resistance, probably due to the limited number of Mt data on test piles available for the statistical regression.

6 CONCLUSIONS

CFA piles are generally considered as replacement piles because there is a rather large volume of soil removed during the construction. It has long been recognized however that the careful control of the installation parameters via monitoring tools on board of the equipment used to install the pile may positively influence the performance of the pile under live loading. Particularly the comparison between the advancement velocity, v, of the auger and the critical velocity v_{crit} allow to evaluate at least qualitatively the net effect of the installation of the auger on the surrounding soil.

In this paper following the path already outlined by the authors in previous published works (Mandolini & Russo, 2008, Mandolini et al. 2012,) a correlation between CFA installation parameters and soil response during the widely used CPT investigation tool has been outlined. The best correlation has been found between the tip resistance q_c of the CPT and the torque M_t. A direct statistical correlation between this last value and the shaft unit friction of piles load tested to failure has been also established. Finally it is also well known that CPT is a valid tool to directly obtain bearing capacity of piles at the design stage. In this paper the load tests available carried out on instrumented CFA piles have allowed to compare shaft capacity derived by statistical correlations with installation parameters and that one directly measured during loading tests on three CFA piles. Two comparisons have been carried out: one based on direct correlation with the measured torque on tested pile and the other based on undirect correlation between the torque and the shaft capacity passing via the correlation with the CPT tip resistance. The comparison is indeed rather satisfactory, particularly for the second type of correlation, showing that another step has been done in the direction of reliable pile performance prediction on the basis of a careful controlled installation process.

Validation of CPT-based methods for estimation of footing settlement in sand

V.A. Sakleshpur, M. Prezzi & R. Salgado
Lyles School of Civil Engineering, Purdue University, West Lafayette, IN, USA

ABSTRACT: A variety of design methods have been proposed to estimate the settlement of footings in sand using cone penetration test (CPT) results. Yet, due to the limited number of well-documented, high-quality footing load tests, efforts still need to be made to assess the performance of these methods. This paper presents two case histories of full-scale, instrumented load tests performed on axially loaded, square footings in silica sand reported in the literature. The performance of the traditional Schmertmann method and more modern CPT-based methods are evaluated through a detailed comparison between the predicted footing load-settlement curves and those obtained from footing load test measurements. For the case histories considered, these modern methods are shown to generally produce more accurate, reliable, and consistent predictions of footing response in sand than the traditional Schmertmann method.

1 INTRODUCTION

Schmertmann's method (Schmertmann 1970, Schmertmann et al. 1978) is widely used in foundation engineering practice to predict the settlement of footings in sand using cone penetration test (CPT) data. The method is based on the following observations: (1) footing settlement results from vertical strains that start at some value at the base of the footing, peak at some depth below the footing base, and then approach zero below a certain depth, and (2) the representative elastic modulus of each sublayer within the influence zone of the footing is determined from the representative cone resistance for that sublayer. The genesis and shortcomings of Schmertmann's method have been critically reviewed by Pantelidis (2020). The main shortcoming of the method is that it is based on linear elasticity and does not account for modulus degradation with increasing footing settlement level.

Over the past two decades, several methods have been proposed for estimation of footing settlement in sand using CPT results. These methods may be broadly classified into three categories: (1) methods based on Schmertmann's approach but with some modifications and improvements (Lee et al. 2008, Lee & Salgado 2002, Mohamed et al. 2013, O'Loughlin & Lehane 2010), (2) methods that fit an equation to load test data after normalizing the unit load and settlement of the footing with respect to cone resistance and footing size, respectively (Mayne et al. 2012, Mayne & Dasenbrock 2018, Mayne & Illingworth 2010), and (3) methods that approximate the shape of the footing load-settlement curve by an initial linear component followed by a nonlinear (parabolic) component (Gavin et al. 2009).

The reliability and accuracy of design methods in predicting the settlement of footings in sand can be assessed by comparing the predictions with measured results from instrumented footing load tests. In this paper, two case histories (Briaud & Gibbens 1997, Lehane et al. 2008) comprising a total of nine instrumented, full-scale load tests performed on square footings in sand at Perth, Australia (four footings), and Texas, USA (five footings), are documented. The footing load-settlement curves predicted by four CPT-based design methods (Schmertmann et al. 1978, Lee & Salgado 2002, Gavin et al. 2009, and Mayne et al. 2012) were compared with the data obtained from the footing load tests.

Of these, the method by Mayne et al. (2012) is a purely direct CPT-based method, i.e. the method relies only on CPT data (e.g. cone resistance q_c) to the exclusion of other variables. The other three methods are indirect or soil property-based methods; for example, the method by Schmertmann et al. (1978) requires the estimation of a representative Young's modulus E from q_c and the calculation of a strain influence factor I_z; the method by Lee & Salgado (2002) accounts for the dependency of the ratio E/q_c on footing settlement level w, footing size B, and relative density D_R; while the method by Gavin et al. (2009) requires the small-strain Young's modulus E_0 as input in addition to q_c. A summary of the equations involved in these design methods can be found in Sakleshpur et al. (2021a).

2 CASE HISTORIES

2.1 UWA footing load tests (Lehane et al. 2008)

2.1.1 Site description and cone resistance profiles

Lehane et al. (2008) reported the results of four, instrumented, footing load tests performed at the University of Western Australia (UWA) test site at Shenton Park, Perth, Australia. The soil profile at the site consists of 5–7 m of poorly graded, medium-dense, siliceous dune sand overlying weakly cemented Tamala limestone. The sand layer is of Holocene age and was formed from the chemical weathering (dissolution) of limestone with subsequent erosion, transportation, and re-deposition by wind (Lehane et al. 2008, Schneider 2007). The presence of small quantities (< 5%) of remnant carbonates from the parent limestone provides the potential for very light cementation and bonding between the sand particles (Lim & Lehane 2014). The groundwater table is typically located at a depth of about 5.5 m, just above the limestone layer. The degree of saturation S of the sand layer is typically less than 15% and varies seasonally by up to about 5% (Lehane et al. 2004, 2008, Lim & Lehane 2014). Table 1 summarizes the properties of Shenton Park sand; the sand particles are sub-angular to sub-rounded in shape.

Table 1. Properties of Shenton Park sand (Lehane et al. 2004, Schneider et al. 2008).

Property	Unit	Value
Particle sizes D_{10}, D_{50}, D_{60}	mm	0.21, 0.42, 0.47
Coefficient of uniformity C_U	—	2.24
Fines content	%	< 5
Unit weight γ_m*	kN/m³	16.14–16.63
Minimum void ratio e_{min}	—	0.45
Maximum void ratio e_{max}	—	0.81
Relative density D_R	%	35–55
Critical-state friction angle ϕ_c**	(°)	32

* Based on *in situ* sand replacement density tests.
** Based on isotropically-consolidated ($p' = 100$ kPa) triaxial compression tests performed on specimens reconstituted to $e_0 = 0.60$ ($D_R = 58.3\%$).

Figure 1 Shows the cone resistance profiles obtained from four CPT soundings performed at the site. Based on self-boring pressuremeter test (SBPMT) results, Lehane et al. (2008) stated that the coefficient of lateral earth pressure at-rest K_0 decreases from 0.70 at a depth of 1.3 m to a relatively constant value of 0.43 below a depth of 2.3 m. Using this information, we considered a constant K_0 value of 0.70 between 0–1.3 m depth, a linear decrease in K_0 from 0.70 to 0.43 between 1.3–2.3 m depth, and a constant K_0 value of 0.43 for depths greater than 2.3 m (Sakleshpur et al. 2021b).
Figure 1. Cone resistance profiles obtained from four CPT soundings performed at Shenton Park [digitized from Schneider (2007)].

2.1.2 Footing dimensions and loading details

Table 2 summarizes the width, thickness, and embedment depth of four square footings constructed inline at the site. The center-to-center distance between the footings is about 5.5 m for footings 1 and 2, 5.2 m for footings 2 and 3, and 4.1 m for footings 3 and 4 (Schneider 2007). The four CPT soundings, CPT-1 to CPT-4, were performed at a horizontal distance of about 3 m from the centerline of footings 1–4, respectively (Schneider et al. 2008). The soundings were performed about nine days after the footings were constructed and six days before they were tested (Schneider 2007). The footings were loaded up to a maximum value of about 200 kN in increments of 15–20 kN using the reaction provided by a 25-tonne CPT truck; each load increment was maintained for about 10 minutes (Lehane et al. 2008).

Table 2. Dimensions of Shenton Park footings (Lehane et al. 2008).

Footing	Width B (m)	Embedment depth D (m)	Thickness t (m)
1	1.5	1.0	1.0
2	1.0	1.0	1.0
3	1.0	0.5	0.5
4	0.67	1.0	1.0

2.1.3 Comparison between predicted and measured load-settlement curves

Figure 2 compares the load-settlement curves of footings 1–4 obtained from the footing load tests at Shenton Park with those predicted using the methods of Schmertmann et al. (1978), Lee & Salgado (2002), Gavin et al. (2009), and Mayne et al. (2012). For aged, normally consolidated silica sand, the parameter λ in

the Lee & Salgado (2002) method was set to a value of 0.53 (Sakleshpur et al. 2021b), while the E/q_c ratio in the Schmertmann et al. (1978) method was set to a value of 3.5 (Robertson & Campanella 1989). The following points should be noted for the Gavin et al. (2009) method: (1) The normalized yield settlement level w_y/B and small-strain Poisson's ratio v_0 were set to values of 0.03% and 0.15, respectively, (2) The depth profiles of small-strain shear modulus G_0 obtained from the results of two seismic cone penetration tests performed at the site were averaged to obtain a representative G_0 profile, and the small-strain Young's modulus E_0 was then determined using the relationship $E_0 = 2G_0(1 + v_0)$, and (3) The effect of time-dependent settlement (creep) was considered by setting the values of parameters t and t_R as 600 seconds and 100 seconds, respectively; t = time elapsed since the application of the load increment, and t_R = reference time corresponding to the onset of creep settlement.
Figure 2. Comparison between predicted and measured load-settlement curves at Shenton Park for (a) Footing 1, (b) Footing 2, (c) Footing 3, and (d) Footing 4.

Although unload-reload tests were performed on the footings, the unload-reload loops of the measured load-settlement curves were not included in Figure 2 for simplicity. According to Lehane et al. (2008), some of these loops were unplanned and arose due to on-site difficulties with the pump for the hydraulic jack. It can be seen from Figure 2 that the load-settlement curves obtained using the Lee & Salgado (2002) method are either in good agreement (e.g. footings 2 and 4) or slightly conservative (e.g. footings 1 and 3) with respect to the UWA footing load test data than those obtained using the other methods considered in this study.

2.2 Texas A&M footing load tests (Briaud & Gibbens 1997)

2.2.1 Site description and cone resistance profiles

Briaud & Gibbens (1997) reported the results of five, instrumented, footing load tests performed at the National Geotechnical Experimentation Site on the Texas A&M University Riverside Campus near College Station, Texas, USA. The soil profile at the site consists predominantly of medium-dense, silty fine silica sand of Pleistocene age up to a depth of 11 m. The fines content at the site generally varies from about 8% near the ground surface to 35% at a depth of 9 m; the fines are nonplastic. The silty sand layer is overconsolidated due to the desiccation of the fines and the removal of 0.5–1.5 m of overburden prior to the construction of the footings. Below the silty sand layer, there is a very stiff, marine clay deposit of Eocene age extending down to a depth of about 33 m. The liquid limit LL and plasticity index PI of the clay layer are 40% and 21%, respectively. The groundwater table was observed at a depth of 4.9 m from the ground surface. Table 3 summarizes the properties of the silty sand layer at the site.

Table 3. Properties of silty sand layer at Texas A&M (Briaud & Gibbens 1997).

Property	Unit	Value
Specific gravity G_s	—	2.64–2.66
Mean particle size D_{50}	mm	0.15–0.20
Coefficient of uniformity C_U	—	1.8–2.4
Unit weight γ_m	kN/m³	15.28–15.65
Minimum void ratio e_{min}	—	0.62–0.65
Maximum void ratio e_{max}	—	0.91–0.94
Relative density D_R	%	55
Critical-state friction angle ϕ_c*	(°)	34.2

* Based on consolidated, drained triaxial compression test results.

Figure 3 shows the cone resistance profiles obtained from five CPT soundings performed at the site. It can be seen that the cone resistance q_c obtained from sounding CPT-7 is very low (≈ 300 kPa) at a depth of 3 m. The corresponding values of sleeve resistance f_s and friction ratio f_s/q_c were also reported to be very low at this depth (Briaud & Gibbens 1997). However, results obtained from adjacent CPT soundings (CPT-2 and CPT-6) reveal that the cone resistance at a depth of 3 m is about 6 MPa, which is 20 times greater than that obtained from sounding CPT-7. In addition, results obtained from an SPT boring (SPT-1) adjacent to CPT-7 show that the SPT blow count at a depth of 3 m is equal to 22 (Briaud & Gibbens 1997). Therefore, we believe that the very low q_c values observed for sounding CPT-7 near a depth of 3 m may not reflect the true soil state below footing 3. Accordingly, for a depth of about 2.0–3.5 m, instead of using the q_c profile obtained directly from sounding CPT-7, we considered the cone resistance to increase linearly from 4.2–6.5 MPa within this depth range.
Figure 3. Cone resistance profiles obtained from five CPT soundings performed at Texas A&M [digitized from Briaud & Gibbens (1997)].

2.2.2 Footing dimensions and loading details

Table 4 summarizes the as-built dimensions and embedment depths of the footings. The footings were loaded using the reaction provided by four 0.91-m-diameter, 21.3-m-long, belled drilled shafts (with 60° under-reamed bells of 2.7 m base diameter) and one 0.91-m-diameter, 5-m-long, cylindrical drilled shaft. The footings were loaded in increments equal to $1/10^{th}$ of the footing capacity estimated by Briaud & Gibbens (1999) using traditional bearing capacity calculation methods. Each load increment was typically maintained for 30 minutes. The layout of the footings and CPT soundings at the site can be found in Briaud & Gibbens (1997) – CPTs 1 and 2 correspond to footings 5 and 4, respectively, while CPTs 5–7 correspond to footings 1–3, respectively.

Table 4. As-built dimensions of Texas A&M footings (Briaud & Gibbens 1999).

Footing	Length L × width B [as-built (m)]	Embedment depth D (m)	Thickness t (m)
1	3.004 × 3.004	0.762	1.219
2	1.505 × 1.492	0.762	1.219
3	3.023 × 3.016	0.889	1.346
4	2.496 × 2.489	0.762	1.219
5	0.991 × 0.991	0.711	1.168

2.2.3 Comparison between predicted and measured load-settlement curves

Figure 4 compares the load-settlement curves of footings 1–5 obtained from the footing load tests at Texas A&M with those predicted using the methods of Schmertmann et al. (1978), Lee & Salgado (2002), Gavin et al. (2009), and Mayne et al. (2012).

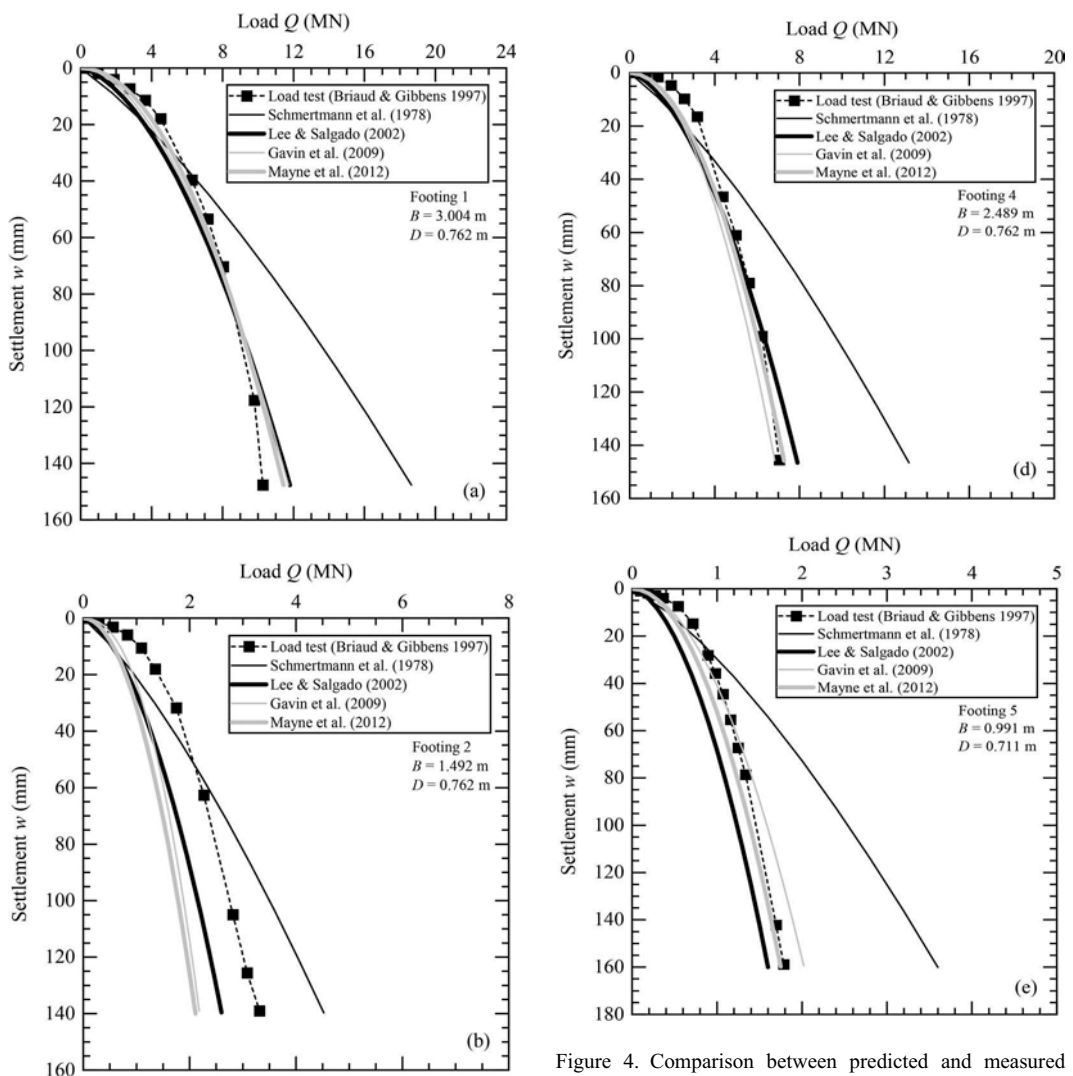
For overconsolidated silica sand, the parameter λ in the Lee & Salgado (2002) method was set to a value of 0.91 (Sakleshpur et al. 2021b), while the E/q_c ratio in the Schmertmann et al. (1978) method was set to a value of 6.0 (Robertson & Campanella 1989). The following points should be noted for the Gavin et al. (2009) method: (1) The values of w_y/B and v_0 were set to 0.03% and 0.15, respectively, (2) The depth profiles of small-strain shear modulus G_0 obtained from the results of *in situ* cross-hole tests performed at the site were averaged to obtain a representative G_0 profile from which the values of the small-strain Young's modulus E_0 were obtained, and (3) The effect of time-dependent settlement (creep) was not included in the analysis of this case history because the equation to model the creep response was developed by Lehane et al. (2008) primarily for the Shenton Park site.


Figure 4. Comparison between predicted and measured load-settlement curves at Texas A&M for (a) Footing 1, (b) Footing 2, (c) Footing 3, (d) Footing 4, and (e) Footing 5.

1093

The data points on the measured load-settlement curves shown in Figure 4 correspond to the footing settlements obtained at the end of each load increment during the load tests; for simplicity, all unload-reload cycles have been removed from these curves. It can be seen from Figure 4 that the load-settlement curves obtained using all the methods, except that of Schmertmann et al. (1978), are in fairly good agreement with the Texas A&M footing load test data over a wide range of settlement levels. The load-settlement response obtained using the Schmertmann et al. (1978) method tends to be unconservative when the load or settlement level increases beyond the range to which the representative Young's modulus applies.

The method by Gavin et al. (2009) is sensitive to the value of relative settlement w_y/B up to which the small-strain Young's modulus E_0 is assumed to operate. For example, in the UWA case history, if the value of w_y/B is decreased from 0.03% [the value suggested by Gavin et al. (2009)] to 0.005% (Lehane et al. 2008), the footing load-settlement curves obtained using the Gavin et al. (2009) method would be in better agreement with the load test data. In contrast, the method by Mayne et al. (2012) was developed based on statistical (regression) analysis of a footing load test database; both the UWA and Texas A&M footings were a part of this database.

3 CONCLUSIONS

The paper presents two case histories of axial load tests performed on full-scale, instrumented, square footings in silica sand. The load-settlement curves obtained from the test results for each of the nine footings were reported. Four CPT-based footing design methods were used to predict the load-settlement curves of the test footings in both case histories. The estimated load-settlement curves were compared with those obtained from the footing load tests to assess the performance of the design methods. Among the four footing design methods, the Lee & Salgado (2002) method generally provides the most accurate load-settlement estimates for the case histories considered in this paper. Finally, from a practical standpoint, the paper demonstrates the applicability of CPT data and CPT-based methods for estimation of footing settlement in sand.

Derivation of SRD for driven piles from CPT data

J.A. Schneider

ABSTRACT: Measurements from the cone penetration test are analogous to parameters used in assessing the static component of the soils pile driving resistance. This paper presents comparisons of pile driving data from 610 mm open ended pipe piles driven through lake clays into underlying glacial till, with estimates of driving resistance using the web-based software, IMPACT. IMPACT uses a continuum-based soil model that explicitly separates internal and external shaft friction in the soil-pile model. CPT based expressions for evaluating the static resistance to driving include factors that account for end condition, friction fatigue and differences in the diameter of the CPT and the pile. Evaluation of static tension load test results requires additional estimates of setup and relative contribution of driving resistance from the soil plug.

1 INTRODUCTION

Data from cone penetration tests (CPT) are ideal for assessing the 'static resistance to driving' (SRD) of a pile as well as for evaluating long-term axial capacity after installation and equalization. Pile-soil interaction parameters can be derived from the cone data, including values of end-bearing resistance and maximum values of shaft friction relevant in the current vicinity of the pile tip.

The sleeve friction measurement, while conceptually similar to pile shaft friction, has complications in application to assessing both long-term static resistance and short-term pile driving resistance. This is illustrated in Figure 1 by comparing average long term shaft friction from pile load tests $(\tau_{f,avg})$ in clay to average CPT sleeve friction ($f_{s,avg}$). The ratio of $\tau_{f,avg}/f_{s,avg}$ ranges from over three to approximately 0.5. For low values of $f_{s,avg}$, setup, or the increase in capacity with time due to equalization of pore water pressures tends to control the ratio. For high values of $f_{s,avg}$, the ratio is less than unity, implying that friction fatigue, or the reduction in local friction with continued pile penetration, tends to dominate long term pile friction when compared to CPT sleeve friction.

For the case of pile driving, evaluation of pile shaft friction from CPT sleeve friction would seem to be simpler than attempting to assess setup for evaluating the long-term capacity. However, viscous rate effects and separating the contribution of internal as compared to external shaft friction for open ended piles still require additional analysis and interpretation. This paper presents interpretation of pile drivability, stress

wave analysis, and pile load testing for a case history of an open-ended pile in clay. The stress waves are analyzed systematically to provide insight into the derivation of the SRD from CPT parameters.

Dynamic analysis of piles, including drivability studies and stress-wave analysis following a dynamic test, is presented in this paper, using the web-based software, IMPACT. The software allows input of CPT data as the basis for assessing relevant pile-soil interaction parameters, with several published recommendations for estimating pile SRD from CPT data being included as options. However, the web-app allows the user to input their own algebraic expressions relating, for example, maximum shaft friction to cone tip resistance for any given soil behaviour type, and similarly for the friction degradation functions and the end-bearing resistance. Application of the web-app is illustrated with an example field study where dynamic stress-wave data were measured during driving of an open-ended pile in lake clay overlying glacial till.

2 SITE CHARACTERIZATION, FARGO, ND

Data discussed in this paper were collected as part of a load test program at the Diversion Inlet Structure, in Fargo, ND, USA. Site characterization included piezocone penetration tests (CPTU), prebored pressuremeter tests (PMT), standard borings and index testing, as well as laboratory triaxial and oedometer tests.

Figure 2 shows results of a CPTU performed adjacent to the pile driving locations, along with PMT and index test results collected in the area. The site
Figure 1. Comparison of ratio of average pile shaft friction to average CPT sleeve friction (database used discussed in Schneider 2010).

consisted of approximately 13 m of lake clays underlain by glacial till. Most CPTs were terminated at the top of the till. The CPTU shown had the deepest penetration in the till, of about 2.5 m. CPT refusal in the clay till was typically associated with sharp changes in cone inclination which exceeded 1 degree over a 1 m push length.

3 PILES AND DRIVING DATA

Two 18.3 m long, 610 mm diameter x 19 mm wall thickness (D/t = 32) open ended pipe piles were driven with a Delmag D46-32 hammer to a depth of approximately 16.2 m. Each pile was monitored with a pile driving analyzer (PDA) during installation. One pile (TP-7) was statically load tested after a setup time of 120 days. The second pile, TP-8, was restruck at 125 days after installation.

Figure 3 shows the collected pile driving data (blowcount, stroke, and transferred energy) adjacent to the CPTU cone tip resistance. In addition to the measured CPTU data, the geometric mean of tip resistance taken either from 4 equivalent diameters (D_{eq}) above the cone tip to 2 D_{eq} below the cone tip, or from 4 diameters (D) above the cone tip to 2 diameters below, are shown. The equivalent pile diameter of 210 mm represents a solid circle with the same area of steel as the pile annulus. Average cone tip resistance and sleeve friction were used in analyses.

The Delmag D46-32 hammer has a rated energy of 165 kN-m. Hammer efficiencies ranged from 35% in the lake clays to 45% in the glacial till for TP-7 and from 40% to 55% for TP-8.

4 DRIVABILITY ANALYSIS

The background and workflow for an IMPACT pile drivability analysis is discussed by Randolph (2008)

and Doherty et al. (2020). Equations based on the Alm & Hamre (2001) drivability method were used in this paper to account for friction fatigue. The method includes friction fatigue that leads to a reduction in local shaft friction (τ_s) with height (h) above the pile tip (in m) according to

$$\tau_s = \tau_{min} + (\tau_{max} - \tau_{min}) \exp(-hk) \qquad (1)$$

The rate of friction fatigue (k) increases with normalized cone tip resistance according to

$$k = \left(q_t/\sigma_v'\right)^{0.5}/80 \qquad (2)$$

The soils at the site are predominantly clayey. The maximum shaft friction is evaluated from CPTU sleeve friction, and the minimum shaft friction is related to normalized cone tip resistance by

$$\tau_{max} = f_s\left(\sigma_v'/100kPa\right)^{0.13} \qquad (3)$$

$$\tau_{min} = \frac{q_t}{250}\left(1 - \frac{q_t/p_0'}{400}\right) \qquad (4)$$

The end bearing in clays is taken as 60% of the cone tip resistance.

Soil stiffness was based on secant unload-reload modulus from pressuremeter tests. This resulted in ratios of G/q_b of approximately 30 and G/τ_s of 200. Poisson's ratio was taken as 0.5. Viscous rate effects were used to evaluate dynamic shaft friction (τ_d) using a power law function of

$$\tau_d = \tau_s\left[1 + \alpha\left(\frac{\Delta v}{v_{ref}}\right)^\beta\right] \qquad (5)$$

where v_{ref} is 1 m/s and Δv is the relative velocity between the pile and the soil. The parameter β was taken as unity for all soils. Softer clays used an α of 0.2, while heavily overconsolidated clays (Till) used an α of 0.06.

Comparisons between measured and calculated blowcounts using impact and a continuum soil model are shown in Figure 4. Two cases were analyzed: (1) with the plug friction taken as 1 percent of the external friction, and (2) with the plug friction equal to the external friction. The small amount of friction for the first case was primarily to maintain numerical stability. Minimal to zero plug friction is often used for drivability studies of open-ended piles.

Both cases overpredict blow counts in the upper lake clays, but show good agreement in the glacial till at the end of driving.

Figure 4. Comparison of Impact predictions of blowcount based on CPT data to measured results using Alm & Hamre (2001) method, and $\tau_{f,in} = 0.01\tau_{f,out}$ and $\tau_{f,in} = \tau_{f,out}$.
Figure 5. Comparison of measured and calculated wave up for TP-7 assuming resistance distribution from Alm & Hamre (2001) and $\tau_{f,in} = 10$ kPa.

5 SIGNAL MATCHING

Signal matching was undertaken using the downward travelling stress-wave as input and comparing the calculated and measured upward travelling stress waves (see, for example, Randolph 2003). The upward travelling wave is

$$F_u = 0.5(F - Zv) \qquad (6)$$

where F is the force, v is the velocity, and Z is the pile impedance, EA/c. EA is the cross-sectional rigidity and c is the wave speed in the pile.

Stress wave measurements are presented for three cases: (i) the end of driving for TP-7 (300th blow); (ii) the end of driving for TP-8 (350th blow); and (iii) the beginning of restrike collected 125 days after driving on TP-8 (6th blow).

The first comparison in Figure 5 for TP-7 uses the recommended end bearing and shaft friction based on the Alm & Hamre (2001) method. The match between the measured and calculated upward traveling wave is good. However, the method assumes no internal shaft resistance for a coring case. This has historically been a reasonable assumption, since commercial wave equation analysis software does not explicitly model the soil plug. To logically step through the relationship between CPT and pile SRD parameters, modeling the soil plug explicitly becomes more useful.

A series of four analyses of upward traveling stress waves are shown in Figures 6 through 9 for pile TP-8 at the end of driving (EOD). Details of the analyses are:

1. Assume CPT parameters apply directly to the pile driving analysis with full internal friction, $\tau_s = f_s$, $q_b = q_t$, $\tau_p = \tau_s$ (Figure 6).
2. Essentially remove internal pile plug friction $\tau_p = 0.01\tau_s$ (Figure 7).
3. Reduce external friction using friction fatigue, increasing internal friction over lower two diameters of the pile (Figure 8).
4. Improve fit, increasing end bearing (Figure 9).
Two more (5th and 6th) analyses are presented for the TP-8 beginning of restrike (BOR) blow to explore setup mechanisms, the results of which
Figure 6. Comparison of measured and calculated wave up for TP-8 assuming $q_b = q_c$, $\tau_f = f_s$, and $\tau_{f,in} = \tau_{f,out}$ (Step 1).

are compared to static load test response in the next section.

5. Increase external friction to account for setup (Figure 10).
6. Increase internal friction to account for different pile response during restrike (Figure 11).

Figures 6 and 7 show a calculated up wave force greater than the measured up wave force, for a normalized time between approximately 4 and 5. This indicates overprediction of soil resistance to driving using CPT parameters, even when no internal friction from the plug is assumed.

Friction fatigue was used to reduce external friction. A greater rate of degradation (k) was needed for the till soils as compared to the softer lake clays. Some internal friction was needed for an acceptable match. A constant internal shaft friction of 700 kPa, approximately equal to the CPT sleeve friction, was used over the lower two diameters near the pile tip. A reasonable match for this case is shown in Figure 8.

The match was slightly improved in Figure 9, by increasing the annular base resistance from q_t to $1.4q_t$. The higher q_b is considered reasonable since

Figure 7. Comparison of measured and calculated wave up for TP-8 assuming $q_b = q_c$, $\tau_f = f_s$, and $\tau_{f,in} = 10$ kPa (Step 2).
Figure 9. Improving fit from Step 3 by increasing $q_b = 1.4$ q_c (Step 4).

Figure 8. Comparison of measured and calculated wave up for TP-8 assuming $q_b = q_c$, but reducing τ_f for friction fatigue and adding some internal friction at bottom of pile (Step 3).
Figure 10. Matching TP-8 restrike blow through increasing external friction.
Figure 11. Improving restrike match for TP-8 by increasing internal friction.

interpretation of the external shaft capacity from the restrike blow was approximately 10% less than the load test capacity.

Table 1. Summary of soil resistance inferred from dynamic measurements and static load tests.

	TP-7 EOD[1]	TP-8 EOD[2]	TP-8 RS[2]	TP-7 SLT
External Shaft (kN)	3899	2883	3794	4200
Internal Shaft (kN)	36	811	2988	
Base (kN)	257	581	581	
Unplugged (kN)	4192	4276	7364	
Plugged (kN)	6025	7704	8614	

[1] Assumed minimal internal friction
[2] Analysed using progressive CPT procedure

CPT refusal was met (following increased inclination) prior to the termination tip elevation of the pile. It is likely that higher resistance layers exist in the till.

A restrike blow performed on TP-8 was recorded 125 days after pile installation, as shown in Figure 10. Compared to Figure 9, a significant increase in measured up wave resistance is shown. A two-step procedure was used to match the restrike blow:

1. The external friction was increased to match the peak up force.
2. The internal friction was increased to improve the overall fit.

The first estimate of external friction was based on using CPT sleeve friction directly, with no friction fatigue degradation. The match in Figure 10 was surprisingly good. This is not to imply that CPT sleeve friction is always a good match for long term pile capacity (see Figure 1). However, the comparison was reasonable for this pile. Increasing the plug length to 20D, and keeping the internal friction equal to the external friction leads to the best match using this technique, as shown in Figure 11.

6 LOAD TEST COMPARISON

A static load test was performed on TP-7 120 days after pile installation. The load-displacement curve is shown in Figure 12. The contributions of internal and external shaft friction, as well as annular base resistance and total plugged and unplugged capacity are shown in Table 1. The restrike blow for TP-8 showed an increase in capacity by a factor of approximately 1.3 compared to TP-8 at the end of driving. The

Figure 12. Comparison of external shaft friction from PDA signal matching to tension load test results on TP-7.

A point of interest from Table 1 comes from looking at the internal shaft friction. For TP-7, the analysis assumed that essentially all shaft friction is external. This is a common assumption for analysis of open-ended pipe piles, leading to three follow-on effects: (i) the effects of friction fatigue are underestimated; (ii) the effects of soil setup are underestimated; (iii) if plug resistance is ignored when interpreting restrikes, tension capacity could be significantly overpredicted.

7 CONCLUSIONS

This paper focused on analyses that highlight the mechanisms controlling the relationship between

soil-pile resistance and CPT parameters. Insights related to both soil resistance to driving and static capacity highlighted effects of friction fatigue and setup at this clayey site. The CPT is an excelled tool to constrain parameters used in pile analyses. However, additional mechanisms need to be included such that rational decisions can be made during installation as well as in relation to long term capacity.

New method for assessing soil liquefaction resistance using a cyclic cone penetrometer

ABSTRACT: This paper introduces a new methodology and machinery to extract soil properties and assess its liquefaction susceptibility. A mechanical Gouda tip cone penetrometer is used to apply a cyclic load on the soils. This test aims a load closer to real world liquefaction events, more robustness and a cheaper cost than a conventional CPTu. Since the cone tip used for the test does not have a pore pressure sensor, nor a friction sleeve and electrical or optical cables, it is of low maintenance, easy to operate and can be used to drill through gravel or any dense layer to reach layers of interest without digging a borehole, saving time and money. The liquefaction resistance is found using the response of soils to cyclic loading on the cone tip. The methodology also involves measuring the change of tip resistance before and after applying a cyclic load and correlates it to the volume changes that took place during it. For this, an experimental campaign was carried out in a new calibration chamber using a mini cone with stress and pore pressure changes measured independently in the soil during the cyclic load. The different response to cyclic load of clean Fontainebleu GA39 sand under different vertical stresses, saturation conditions and created by different sample preparation methods is studied. In turn, the pore pressure increase and the corresponding number of cycles during the cyclic cone penetration tests are compared with similar results from cyclic compressive triaxial tests. This allows us to find a relation between the loading applied in the two methods to cause a similar increase of pore pressure. Hence, a method is suggested to compare the loading applied by the cone penetrometer to the Cyclic Stress Ratio(CSR) expected in a liquefaction event. Eventually, using the CSR and CRR defined, the liquefaction susceptibility of the soils can be calculated.

1 INTRODUCTION

A new cone penetration testing methodology is introduced to predict liquefaction and extract soil properties. The cone we use for our tests is a mechanical Gouda tip (Figure 1) which lacks any sensors inside the tip. Instead, the tip resistance is measured using the force transmitted by the internal rods and recorded by a force sensor on the surface. The test uses a cone of standard 10 cm^2 surface area for the field experiments, while for the laboratory experiments, we use a miniature cone of 4 cm^2 to minimize boundary effects.

The loading devices, both at the site and in the laboratory, involves two different driving mechanisms. One for the constant penetration, to measure the tip resistance against penetration at a constant speed and to reach the desired depth for the cyclic test. The other is a cyclic jack capable of applying the cyclic load to the internal rod of the Gouda tip without moving the external rods. This jack is constrained in its total drive length (6 cm for laboratory and 10 cm for field experiments). For the laboratory experiments, a calibration chamber has been newly

developed in the 3SR laboratory to facilitate better placement of independent pore pressure and total stress sensors and for better control of saturation con-
Figure 1. The schematic(top, sizing in mm) and image of the Gouda tip used for the field test.

ditions. The boundary conditions applied are fixed lateral and bottom boundaries, while the vertical stress is applied from top using a pressurized membrane with a hole in the center to allow the cone to enter the calibration chamber. The tip opening is measured using the internal measurement of the cyclic

jack and using a LVDT attached to a frame at the head of the cyclic jack. Under normal driving, the length of internal rods are chosen to ensure that the tip is slightly open (<0.5 cm) and all the tip force is transferred to the force sensor attached at the piston of the cyclic jack. The cyclic jack acts as a rigid frame for the internal rods and the force sensor during static driving. During the cyclic loading, the cyclic jack applies the load directly on the internal rods, which moves the front end of the tip without moving the external rods.

2 METHODOLOGY

The traditional CPTu relies on empirical relationships that use the pore pressure, the friction sleeve readings and the cone penetration resistance for predicting liquefaction resistance (Idriss & Boulanger 2006, Robertson 1990). These empirical relations are developed from comprehensive databases of tests done in-situ and in calibration chambers.

However, the dependency on empirical relationships, the complexity of use and susceptibility of the sensors to damage and malfunction leads to uncertainties in CPTu tests. Also, these tests are relatively expensive to perform, involves equipment with high maintenance cost and may also require boreholes to traverse through hard strata. As such, the CPTu test becomes an unpractical solution for a large number of geotechnical problems. Besides, the empirical relations used to predict liquefaction susceptibility and other soil properties may need to be adapted for local soil conditions.

Our novel approach tries to overcome a few of these shortcomings and provide a cost effective and reliable method to find liquefiable layers under all field conditions.

We use a mechanical Gouda tip to apply stress-controlled cycles on depths of interest. For each test, the outer rod of the cone penetrometer will be fixed, and the tip of the cone will be used to apply a cyclic load in accordance with the patented loading mechanism on the tip using the internal rods. The maximum displacement of the tip during each cyclic CPT test is 6 cm in the lab and 10 cm on the field. It is limited by the dimensions of the Gouda cone or/ and the maximum displacement of the jack applying the cyclic load. As such, in each cyclic test, we measure the properties of a layer of depth around 10 cm while the zone of influence of each test may be as high as 72 cm as is the case in conventional CPTu (Rogers 2006). The loading applied to the soil can be divided into eight steps which involve two pushes at a constant speed for 1 cm penetration, waiting times after each push while applying a constant force, and uniform stress cycles after the waiting time. The frequency used for the cyclic loading was 1 Hz, and the amplitude of cycles was decided based on the tip resistance measured during the initial push.

The number of cycles required for a given displacement, the displacement of tip during the waiting time, the rate of displacement during cycles, and the change of tip resistance before and after cycles are a few significant results being looked into to distinguish between different soil types and extract soil properties, especially the liquefaction susceptibility. The density of the soil, the stress state the soil exists in, are a few of the parameters that can affect the response of the soil and vary these results.

3 CHARACTERIZATION OF SAND

All the tests were performed on clean Fontainebleau GA39 sand whose main properties are summarized in Table 1.

Table 1. GA39 sand properties, from the supplier SIL-BECO, France.

SiO_2 (%)	G_S (-)	d_{10} (mm)	d_{50} (mm)	d_{60} (mm)	C_u	e_{max}	e_{min}
>99.1	2.56	0.087	0.113	0.122	1.1	1.01	0.56

The sand grain shape is sub-angular, sub-rounded (Rimoy 2013). The grain size distribution of this sand falls directly under soils that are traditionally prone to liquefaction.
Figure 2. Grain size distribution for sand prone to liquefaction and Fontainebleau GA39 sand.

A number of laboratory experiments were performed to characterize the sand properties, its interaction with the cone, and the effect of sample preparation. Direct shear interface tests between smooth steel used to make the cone and the sand at constant normal stress resulted in a friction angle of 13.1°. We also performed constant head permeameter tests to study the effect of the sample preparation method on permeability. Moist tamping specimen created more permeable samples than those created by dry pluviation, which were more permeable than those created by dry tamping. In all cases, the order of magnitude of permeability was similar (10^{-5} m/s) and corresponded to those expected from fine sand.

However, the values varied between 3.4 to 7.1* 10^{-5} m/s. These permeability values correspond to conditions of completely drained conditions during normal cone penetration. (McNeilan and Bugno, 1985).

Also, as a part of this study 20 tri-axial tests (6 drained, 14 un-drained) were performed to study the effect of sample preparation, back pressure, initial confining stress on very loose(Relative density<15%) or loose sand specimens (Relative density<35%). For the drained tests in Figure 3, we see a clear distinction
Figure 3. Varying drained behaviour for different sample preparation methods at 200 kPa confining stress.

in volumetric strain for tests done at similar confining stresses (200 kPa) based on sample preparation method even when all the samples fell in loose or very loose category. The relative density for the two air poured sample was 25% (±2.5%) and was the minimum the authors could achieve with this method of
Figure 4. Varying behaviour of samples during undrained triaxial tests.

sample preparation. The moist tamped sample resulted in much looser samples. The samples discussed in Figure 3 had a relative density of -13.3% (±0.3%) We observed that moist tamped loose sample contracted while shearing but the air poured sample dilated.

These effects can be caused due to the density difference as well as the difference of method of sample preparation. However the shear stress were quite close at high axial strain as expected at critical state.

Also, the effect of back pressure is quite small for samples prepared by same method and having simi-
Figure 5. Difference of behaviour of moist tamped sample based on initial confining stress.

lar initial density. As such the specimen in the calibration chamber which is saturated without a back pressure should behave similarly as the one saturated using a high back pressure.

For undrained tests too, the initial density of the air poured sample shown in Figure 4 was higher (27% & 35%) for air poured samples as compared to moist tamped samples (-7% & -1%). The behaviour of the specimen even under the same initial confining pressure (200 kPa) varied depending on the method of sample preparation and the resulting relative density. It was observed that even loose air poured samples dilated (negative pore pressure) hence showing no tendency to liquefy. While very loose moist tamped sample had a development of pore pressure as the axial strain increased, as such may be prone to liquefaction.

Therefore, we will be able to control the initial state of the soil sample in the calibration chamber by either preparing the sample by moist tamping or air pouring. In particular the control of initial relative density can be used to create samples that are susceptible to liquefaction or not for this sand.

Lastly, in Figure 5 we can observe the undrained response of four moist tamped samples with relative density of -4.5±3% when initial confining stress is changed. We can observe a change of behaviour when initial confining stress changes from 200 to 300 kPa giving us an indication as to what depths on the field and what vertical stresses in the calibration chamber can be used to differentiate between liquefiable and non-liquefiable cases for these kinds of samples.

4 CYCLIC CPT TESTS IN LABORATORY

For preliminary tests, we performed cyclic penetration tests on the same Fontainebleu GA39 placed in a cylindrical container (35 cm Ø and 40 cm depth) at a depth
Figure 6. The difference of behaviour of saturated and dry sand to cyclic penetration test.

of 15 cm without applying a confining pressure. We created the sample by air pouring and observed a relative density of 28±2% and performed tests in dry and saturated state. We observed that the total tip penetration caused by the cyclic CPT test is less in the dry state than in the saturated state (Figure 6). However, the tip resistance measured during static penetration at
Figure 7. Similar behaviour of the two saturation conditions to static penetration.

constant speed (normal CPT) were very close for the dry and the saturated sample (Figure 7). (drained penetration – as expected from permeability values). Also, the response of the soil to a second penetration, after applying the cyclic load, is different in the two saturated conditions. We saw a distinct increase of penetration resistance after applying the cyclic load in saturated sand (Figure 8). This increase may be due to the compaction of the saturated soil due to the cyclic

loading. Thus the test can play a major role in distinguishing the saturation condition of the soil without a pore pressure measurement and this is an useful information for calculating the liquefaction probability.

It can also be observed that the penetration of the tip in dry sample continues for the second round of cycles almost with the same rate as during the first round of cycles. However, in the saturated sample, the rate of displacement continuously decreases during the first round (between ~20 to ~150 seconds in Figure 6) and reduces drastically for the second round of cyclic loading. This occurs even when the maximum and the minimum amplitude of the two sets of cycles remain similar. This decrease of the penetration rate is an indication of densification of the saturated sample due to the first cyclic loading and the second 1 cm push. This effect is more pronounced in the saturated sample.
Figure 8. Different behaviour of the two saturation conditions to static penetration after the cyclic load.

5 FIELD EXPERIMENTS

During the initial investigation, we have performed cyclic tests next to a CPTu test. The CPTu tests were performed at a building site at *Le Bourget du Lac*, France. This CPTu test was used to find the Soil Behaviour Index (I_c) (Robertson 1990). The test indicated a compacted layer for 1.8 m depth and a predominantly saturated clay like soil till a depth of 8.5 m. However, a sand like layer was observed between a depth of 3.8 and 4.2 m. We performed the cyclic CPT tests just outside and inside of this layer. In two of these tests, performed at 3.2 m (clay like soil- I_c value of 3.1) and at 4 m depth (sand like soil - I_c value of 2.3) we observed two different behaviours. Figure 9 shows the results of two cyclic CPT tests.

It was observed that the tip resistance during the initial static push of 1 cm is higher for the sand like layer and as such the cyclic load applied was also higher (compared to clay like layer). In the clay like soil we observed rapid tip opening during the stress controlled cycling loading while the same in sandy soil is much
Figure 9. Field tests done on soil of two different type at similar depths.

slower. Also, the total tip displacement in the sandy soil remained less than 5 mm even after 180 cycles, while 35 cycles of lesser amplitude resulted in almost 40 mm of the tip opening in clay like layer. These results are encouraging as with this cyclic test, different responses for soils with different I_c values can be observed. As such, the cyclic CPT may be used to identify different soil types.

6 CONCLUSION

A new cyclic cone penetration test is presented and the benefits are listed. Primary results indicates its effectiveness in differentiating between different saturation state of the soil and also to differentiate soils at almost identical depth but different soil behaviour index. This can add to the information from existing geotechnical tests and help engineers better predict soil properties and also liquefaction susceptibility of soil. The laboratory experiments provide us with the framework to differentiate liquefiable and non-liquefiable conditions of the Fontainebleau GA39 sand and provide us with variable to be tested during the calibration chamber testing.

7 PERSPECTIVE

The laboratory equipment became functional only a week before the final submission of this paper. The preliminary results are encouraging and motivating to study the effect of vertical stress, the density of the sand on the response of soil to cyclic CPT. The results obtained from the laboratory testing regarding the effect of the sample preparation method, max effective stress to permit liquefaction etc., can be used to decide parameters for experiments in the calibration chamber. The evaluation of pore pressure around the tip in different cases and the corresponding tip displacement will be studied to differentiate between liquefiable and non-liquefiable cases. Field experiments are limited by a max cyclic force of 3500 N on a 3.57 cm dia cone. Thus only shallow depths could be investigated till now and leaves scope for improvement. Comparison of CPTu test results and our cyclic CPT test on similar specimens performed in identical conditions will further help us validate our method to predict soil properties, including liquefaction susceptibility.

Evaluation of deformation modulus during Cone Loading Tests (CLT) and settlement of shallow foundations

A. Teyssier, M. Rispal & C. Jacquard
Fondasol, Avignon, France

P. Reiffsteck

ABSTRACT: The static loading of a piezocone is one of the only in-situ tests leading to a measure of compression of soil under the cone, shear stress on the shaft and pore pressure between these two points. These three load-deformations curves give valuable information usually impossible to reach with another ground investigation technique. The incremental loading of the cone up to failure, called Cone Loading Test (CLT), provides the vertical loading/unloading soils curve. From this curve, an estimation of deformation modulus, which is a key parameter in structure design such as foundations, is possible. CLT's deformation modulus will be compared to modulus obtained from traditional investigation methods (Menard pressuremeter tests). An experimental survey, including pressuremeter tests (PMT), Cone penetration test (CPT) and shallow foundation loadings tests, was undertaken to compare the results with CLT moduli measurements. A calculation procedure, based on CLT's deformation modulus, is proposed to design shallow foundations settlement. The article presents prediction of long-term foundation settlements (i.e. effect of time) both with the conventionnel methods and the new CLT method.

1 INTRODUCTION

The common ground investigation methods provide many parameters to characterize soils.

Each method measures different parameters relative to resistance and/or deformation. However, the variability of soils and the costs of the tests, represent limits, all parameters cannot be directly measured in-situ, and some are obtained from empirical correlations, with limited validity.

The Cone Penetration Test with pore water pressures measurements, or piezocone (CPTu) is worldwide used (EN ISO 22476-1). It is highly documented and known as a reliable method to measure soils mechanical parameters of fine-grained soils and coarse soils up to a maximal diameter of 20 mm. It provides the static cone resistance (q_c or q_t the total cone resistance with piezocone), the sleeve friction (f_s), and the pore pressure (u_2). From these parameters, the soil resistance, the permeability and the liquefaction potential can be obtained. Though the CPT does not allow a direct soil nature identification, the Robertson and Cabal correlations (2014) permit an estimation of the lithology encountered during the test.

As all penetration methods, the CPT does not provide a measurement of the deformation modulus, needed to calculate ground settlements and to consider their impact on structures. The Cone Loading Test (CLT) was developed (Arbaoui, 2006; Ali, 2010), in this aim. The CLT is an hybrid test combining the classical probing and an incremental loading of the cone, to obtain resistance and deformability parameters.

The test consists in interrupting the penetration at a chosen depth, and then applying an incremental load on the cone up to failure. Once the yield point is reached, an incremental unloading is performed. This allows the drawing of a loading/unloading curve giving settlements beneath the cone from the applied pressure (Figure 1 and Figure 2).
Figure 1. Cone Loading Test principles (Reiffsteck, 2017).
Figure 2. Determination of deformation modulus $E_{0;CLT}$, $E_{50;CLT}$ and $E_{d;CLT}$ according to the pressure versus deformation curve (Ali., 2010).

The limit cone resistance from the CLT is named q_{CLT}. This is the maximum loading reached at the yield point during the CLT test just before the soil collapses. This load is generally smaller than the classical cone resistance (q_c) because it is measured with an almost zero penetration rate.

Three different values of deformation modulus are calculated from the curve:

- $E_{0;CLT}$: the initial tangent modulus, estimated with the slope of the first linear part of the loading curve.
- $E_{50;CLT}$: the modulus at 50% loading, calculated with P_{50} which is half of the limit cone resistance (q_{CLT}) and with h_{50} the associated deformation.
- $E_{d;CLT}$: the unloading modulus, estimated from the slope of the unloading curve.

According to Ali (2010), every modulus is affected by a coefficient of 0,7.R, where R is the conical radius and 0.7 is a coefficient taking into account the conic driving, its geometry, and the disturbed soil.

2 THE CONE LOADING TEST

2.1 *The CPT penetrometer*

The test is performed with a heavy static penetrometer vehicle, at a constant speed of 2 cm/s. The thrust can reach 200 kN.

The cone penetrometer, in compliance with the EN ISO 22476-1 standards, allows independent measurements of the cone resistance (q_c), the sleeve friction (f_s), the pore pressure (u_2) and the vertical inclination. These measurements are collected in real time inside the CPT truck by a connecting cable that is threaded inside the push rods.

The data acquisition system is located at the surface and synchronized in real time to store the cone resistance and depth measurements at the same time.

2.2 *The loading system*

The additional thrust device consists in an hydraulic cylinder placed between rods and the thrust head of the penetrometer. This jack, controlled by a pressure limiter, is powered by a hydraulic power pack. It allows to apply a controlled thrust on rods independently from the evolution of the soil reaction force.

2.3 *Instrumentations and measures*

At the beginning of a CLT test, a dissipation test is done and recorded by the data acquisition system of the penetrometer. At the same moment, the thrust device at the surface allows the measurement of the pressure in the hydraulic jack, and so the total thrust force on rods corresponding to the q_c value expected. The displacement is measured at the top of rods as it is represented in Figure 3.

In this study, CLT tests has been performed at shallow depth (1, 2 and 3m), allowing to neglect the effect of rods compression.
Figure 3. Schematic representation of CLT Test equipment.

3 EXPERIMENTAL SURVEY

To meet the objectives (and allow comparisons), conventional investigations (PMT, CPT, shallow foundation loading tests) were needed.

The data is issued from the "Jossigny-France" site, located on Figure 4:

Figure 4. Location of Jossigny site (Google Earth).

3.1 Site description and in situ tests performed

The Jossigny site is located along the A4 highway, East of Paris ("Aire de Ferrières"). The area is relatively flat and horizontal, and composed of homogeneous clayey silts on the top 6 meters.

The in-situ tests undertaken were:

- 5 pressuremeter boreholes (PMT) down to 3 and 6 m
- 6 mechanical cone penetration tests with "Gouda cone"down to 3 and 6 m
- 17 shallow foundation loading test, using a 1 m × 1 m footing and a axially centered force.

The results of measured cone resistance (q_c) are given in Figure 5.

The results of measured Menard Modulus (E_M) are presented in Figure 6, together with the representation of the harmonical mean calculated for each meter using the results of the different boreholes.
Figure 5. Cone resistance (q_c) measures for Jossigny site.
Figure 6. Ménard pressuremeter modulus (E_M) results for Jossigny site.

The Figure 7 shows the results of the different shallow foundation loading tests. The experimental foundations are one-meter squares and are directly laid on the ground (no embedding).
Figure 7. Vertical shallow foundations loading tests for Jossigny site.

3.2 Cone loading tests and results

This study considers three CLT tests (CLT1, CLT3, CLT4), from the Jossigny site.

The CLT tests were performed and interpreted in compliance with the operating procedure defined by Ali (2010). The test starts after a 10 min waiting time, for pore pressure dissipation. The cone is loaded following different stages; every loading stage is maintained during 1 min. Displacements are measured at 30 and 60 sec.

Figure 8 shows a result of a CLT test. Figure 9 shows the results of the different CLT tests realized at the Jossigny site. The different values of CLT moduli obtained are represented in Figure 10.
Figure 8. Example of a CLT test interpretation – Jossigny-CLT1-1m.
Figure 9. CLT tests for Jossigny site.
Figure 10. CLT moduli for Jossigny site.

The CLT moduli measured on the the Jossigny site are in the same order of magnitude as the pressuremeter moduli at the same depths. The $E_{0;CLT}$ average value at 1 m is slightly higher; this average value is probably affected by a stiffer soil encountered beneath the surface on the CLT4 test.

3.3 Synthesis of Jossigny site

In this study, several metric layers are distinguished in clayey silts (0-1, 1-2, 2-3 and 3-6m). Table 1 summarizes the geotechnical characteristics:

Young moduli are derived from the relation (1), (2) and (3) from NF P94-261-J.2.2:

$$E_y = \alpha_E(q_c - \sigma_{v0}) \qquad (1)$$

If $I_c < 2.2$:

$$\alpha_E = 0.015.10^{0.55I_R+1.68} \qquad (2)$$

If $I_c > 2.2$:

$$\alpha_E = \frac{Q_T}{1.2} \text{ for } Q_T < 14 \qquad (3)$$

$$\alpha_E = 11.7 \text{ for } Q_T > 14$$

A mean Young modulus of 18.7 MPa and a mean initial tangent CLT modulus of 10.2 MPa are considered for the top three meters of clayey silts.

Table 1. Geotechnical characteristics of Jossigny site.

Depth	q_c	E_M	I_c *	α_E **	E_y	$E_{0;CLT}$
(m)	(MPa)	(MPa)	(-)	(-)	(MPa)	(MPa)
0-1	1.3	6.2	2.35	11.7	15.1	15
1-2	1.7	10	2.75	11.7	19.7	8.9
2-3	2.0	10.2	3.02	11.7	23.1	8.6
3-6	4.1	21	2.80	11.7	47.3	-

* I_c: Soil behavior type index
** α_E: Correlation coefficient on penetrometer method

4 DISCUSSION

4.1 CLT loadings and shallow foundations loading tests

CLT loadings (red envelope curves) and shallow foundations loading tests curves are compared, in normalized axis (values divided by maximum values), in Figure 11.

At 1 m depth, and for small values of load, there is a good match between shallow foundation loading tests and CLT loading tests. Then, the initial tangent CLT moduli can be considered as similar as the initial tangent moduli for shallow foundation loading tests.
Figure 11. CLT loadings and shallow foundation loading tests (red) for Jossigny site.

4.2 CLT moduli and settlement calculations

Settlement results with different methods based on penetrometer and pressuremeter data are compared to the settlement measured during shallow foundation loading test n°1, which is almost an average of all the foundation loading tests realized:

– Method 1: Boussinesq method, NF P94-261-J.4.1
– Method 2: Homogeneous soil (mean moduli on 3 meters), NF P94-261-J.3.1
– Method 3: Schmertmann method, NF P94-261-I
– Method 4: Multi-elastic method, according to Steinbrenner (1934) and Bowles (1996)
– Method 5: Pressuremeter method, NF P94-261-H

Then the initial tangent CLT moduli are used in these calculation methods instead of Young moduli.

Calculations are realized with small loading stages (V_d), between 0 and 204 kN, to remain in the elastic domain of deformations.

The results are presented in Figure 12 and in Table 2.

Table 2. Settlement predictions with the five methods using E_Y moduli and $E_{0;CLT}$ moduli.

V_d (kN)	1 (mm)	1_{CLT} (mm)	2 (mm)	2_{CLT} (mm)

159.1	6.2
181.8	7.0
204.5	**7.9**
Figure 12. Settlement predictions with different calculation methods and with $E_{0;CLT}$ moduli.

First, we can note a good match of values between the loading observed for foundation n°1 and the settlement obtained with the homogeneous soil method (2), the multi-elastic method (4) and the pressuremeter method (5)

For the four different methods, settlement predictions using the CLT moduli are always higher than predictions using the Young Moduli.

To consider the initial tangent CLT moduli in calculation methods, a coefficient named ψ must be determined. This coefficient is applied to the initial tangent modulus to obtain the same deformation than with elastic moduli, according to equation (4). Only penetrometer methods are considered for the determination of these coefficients.

$$E_{calc} = E_{0;CLT} \times \psi \qquad (4)$$

This coefficient is calculated for each method with the ratio of settlement predictions between elastic moduli and CLT moduli, for every loading case. For all methods, the ratio remains constant for all loads. The mean is calculated for each method.

Results of ψ coefficients are given in Table 3:

Table 3. ψ coefficient applied to $E_{0;CLT}$ modulus, for each penetrometer settlement prediction method.

Method	1	2	3	4
ψ	1.54	1.84	1.27	1.37

Using this coefficient, for clayey silts, it is possible to consider CLT moduli for different calculation procedures.

However, it is necessary to consider the context.

The penetrometer calculation method presented here was used only in the elastic domain in clayey silts.

The incidence of the Soil Behavior Type index on the determination of the Young modulus is preponderant, linked to the lithological nature.

5 CONCLUSIONS

The Cone Loading Test is a loading/unloading test than can easily be coupled with a static cone penetration test campaign to measure a soil deformability parameter at different depths.

This study, based on Jossigny's clayey silts proposes a method to consider CLT moduli in traditional method of settlement predictions from penetrometer data. This method requires the use of a coefficient ψ which applies to CLT moduli. This coefficient varies depending on the calculation method but also on the stiffness and the lithological nature of soils.

In the future it would be necessary to carry out new surveys, firstly in clayey silts to confirm the ψ coefficient table, then in other type of soils (sands, …) to complete the table of ψ coefficient for every method of settlement design of shallow foundations. Indeed, a complete table will allow the use of CLT moduli measurements for every calculation procedure.

Assessment of the potential for liquefaction using CPTu in the tailings dam I – Feijão

M. Tincopa
Universidad de Ingeniería y Tecnología - UTEC, Peru

G. Carnero-Guzman
Golder Associates Pty. Ltd., Australia

ABSTRACT: In Brazil in 2019, the failure of the tailings dam I - Feijão costed a total of 7 billion dollars in civil and environmental reparation. The report of the expert panel that evaluated the failure of dam I concluded that the failure was due to static liquefaction, which is one of the most common dam failures in the world. However, the identification of the liquefaction potential has challenges such as identifying the behavior of the tailings (contractive and dilative behavior) and extracting undisturbed samples for sophisticated laboratory tests. CPTu is a fast and reliable field test, and, through empirical relationships, the liquefaction potential of soil can be estimated using the state parameter (ψ). The objective of this article is to present the results of piezocone (CPTu) in the different in situ geotechnical campaigns in Feijão Dam with focus on the state parameter (ψ) data used to determine the liquefaction potential. The methodology used herein is that $\psi > -0.05$ means contractive behavior or high change of potential for liquefaction. The results show that the CPTu tests in dam I - Feijão showed that there was high liquefaction potential during the geotechnical campaigns (2005, 2016, and 2018) by using this procedure.

1 INTRODUCTION

Tailings dams are structures made up of mining waste coming from mineral processing (Vick, 1990). Unfortunately, some significant failures in tailing dams occurred in recent years. In this regard, static liquefaction has been one of the most damaging failure modes for tailings facilities as shown in Table 1.

Particularly, a recent failure in tailings dam No. 1 of Vale's external link Córrego do Feijão iron ore mine near Brumadinho (Minas Gerais – Brazil) triggered the urgency for a global tailings management standard. This conclusion was drawn from the official expert panel report (Robertson et al. 2019), where the causes of the disaster were assessed.

The Expert Panel looked in detail at available monitoring, laboratory, field data and undertook a back analysis of historical InSAR data. The upstream construction method deployed by Vale at Brumadinho and the lack of adequate drainage were found responsible for the dam failure.

The mechanisms involved in the dam failure were creep and static liquefaction (sudden loss of soil strength). Specifically, static liquefaction can be assessed by the state parameter. As shown in Been (2016), this parameter is defined as the difference between the in-situ void ratio and critical state locus

(CSL) void ratio (defined in Figure 1). The value indicates if the soil is whether contractive (loose) or dilatant (dense). Commonly, this evaluation is conducted during the characterization of tailing dams which is a difficult and overestimated problem in geotechnical engineering. However, extremely relevant to prevent failure of the structure, which can lead to significant negative impacts on the economy, surrounding properties, and lives of the population (Draves & Fox 1998; Hudson-Edwards et al. 2003).

Characterization of tailings dams is needed to minimize the risk of failure. For instance, liquefaction potential is a crucial analysis that requires a tailings characterization. The pressure to minimize geotechnical characterization costs without a consistent approach for assessing the tailings material means that empirical methods derived from sand and clay research work are often inappropriately applied (Been 2016; Macedo & Vergaray 2021). Nevertheless, the empirical methods still used on the industry.

This article focuses on the evaluation of static liquefaction using the state parameter. A similar study on fundão tailings dam failure was conducted by Reid (2019). Nevertheless, the current paper focuses on the state parameter (ψ) from the CPTu data presented in the panel expert report (Robertson et al. 2019).

The paper concludes that using the CPTu test (ASTM 5778-20) to measure the state parameter is

an excellent practical approach applicable to other case scenarios.

Table 1. Summary of recent tailings dam failures.

Description	Location/ Year	Consequences
Aberfan	UK/1968	144 dead from static liquefaction caused by increased groundwater pressure
Aznalcollar	Spain/ 1998	Brittle foundation failure causing dam failure and widespread downstream contamination
Kingstong Fly ash	USA/ 2008	Static undrained failure of fine-grained volcanic ash, causing significant environmental pollution
Mt Polley	Canada/ 2014	Rapid foundation failure resulted in the dam rupture and one of the most significant environmental disasters in modern Canadian history
Fundão	Brazil/ 2015	Static liquefaction with at least 17 deaths and estimated damage of billions of dollars
Brumadinho	Brazil/ 2019	It triggered the urgency for a global tailings management standard which ICMM published in 2020
Figure 1. Definition of state parameter (retrieved from Been 2016).

2 DETERMINATION OF THE STATE PARAMETER

2.1 *Field data*

The raw CPTu data available previous of the failure dam included 28 CPTu tests completed as part of geotechnical investigations in 2005, 2016 and 2018 (see Annex B, Robertson et al. 2019). Figure 2 shows the locations of the CPTu tests in dam I, Feijão.

The field test data presented in this paper were obtained from the results of tests performed during the following geotechnical field explorations:

- CPTu tests performed by In Situ Geotecnia Ltda. in 2005;
- CPTu tests conducted by Fugro In Situ Geotecnia Ltda. in 2016; and
- CPTu tests performed by Fugro In Situ Geotecnia Ltda. in 2018.

For this paper, three CPTu, namely CPTu2005-07, CPTu2016-04, and CPTu2018-19 were selected by considering the executed year and close location as shown inside the red circle on Figure 2.

To obtain the usable set of data from these probes, the tip resistance (q_t), pore pressure (u) and friction ratio (R_f) records provided in graphical form in the panel Appendix B were transferred into AutoCAD version 2022 software and scaled, and then data from the probes were extracted at 0.25 m intervals. By doing so, the range of relevant CPTu calculations to estimate various engineering properties could be made in particular to analyze ψ. It is worth mentioning that the three CPTu could not reach more than 50 m although there are commercial push rigs capable of reaching around 100 m depth. Deeper investigations are relevant because the potential failure mechanism of a tailings dam may be found on the foundation or nearby.

2.2 *Subsurface conditions and state parameter estimation using CPTu data*

The subsurface soil conditions at the site were characterized by using normalized soil type behavior (SBT) charts to interpret the soil type encountered during testing. SBT charts group soils that exhibit similar engineering behavior properties allowing interpretation of soil type based on the normalized tip resistance and friction ratio results. Fine (I_c>2.6) and Coarse (I_c<2.6) tailings were assumed by using the SBT charts.

Various methods are available to calculate the in-situ state parameter from CPTu data. The methods of Robertson (2009), Plewes et al. (1992) and Jefferies and Been (2016) were used in this assessment.

The Robertson (2009) and Plewes et al. (1992) methods are empirical and do not require laboratory testing or numerical analysis but rely on relationships developed from a database of mainly silica-based sandy soils. The method developed by Jefferies and Been (2016) is a more site-specific approach that relies on numerical simulations and incorporates index and laboratory testing data.

The next section discusses the three methods examined to characterize the in-situ state parameter of Fine and Coarse Tailings.

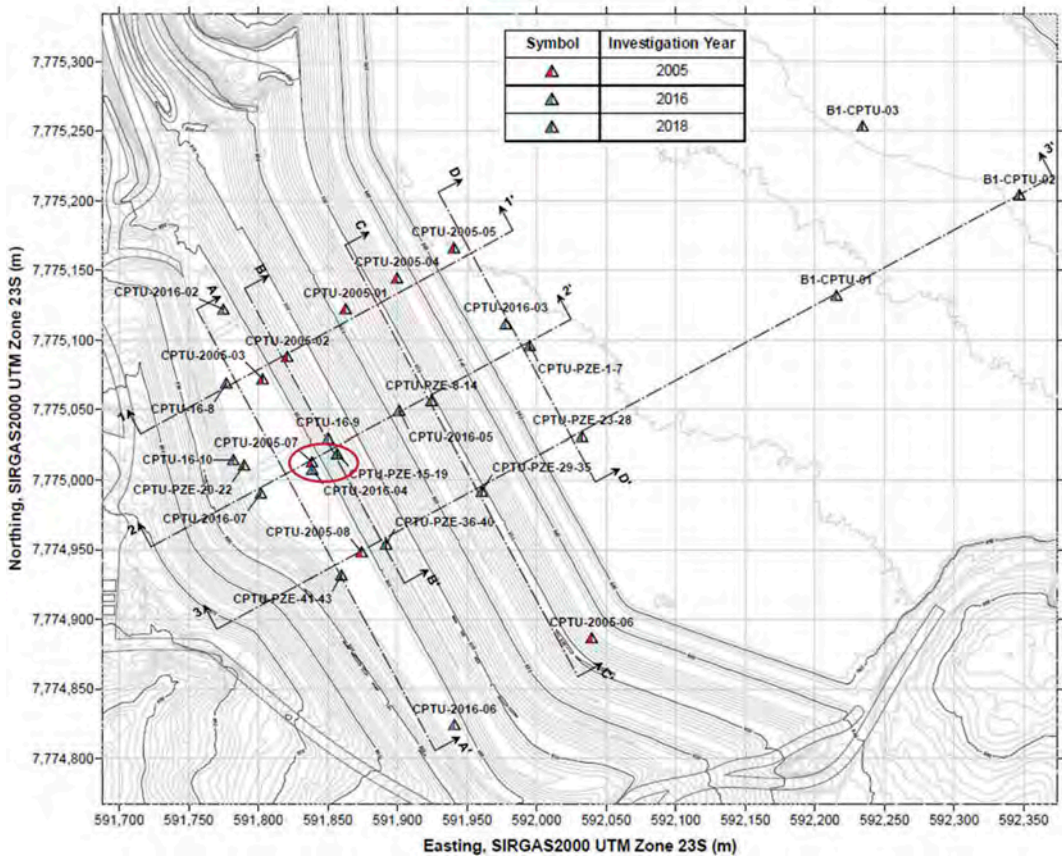
2.2.1 *Robertson (2009) method (PKR)*
The Robertson (2009) method uses corrected tip resistance (q_t) and sleeve friction (f_s) from CPTu


Figure 2. Location plan of CPTu tests (modified and retrieved from Robertson et al. 2019).

data to calculate a stress-normalized tip resistance (Q_{tn}) using Equation 1.

$$Q_{tn} = \left(\left(\frac{q_t - \sigma_v}{p_a} \right) \right) \left(\frac{p_a}{\sigma_v'} \right)^n \tag{1}$$

Where,

σ_v = in-situ total vertical stress
σ_v' = in-situ effective vertical stress
p_a = atmospheric pressure
n = stress exponent ($n \leq 1$)

The stress-normalized tip resistance (Q_{tn}) is adjusted to account for fines content, mineralogy and plasticity using the correction factor K_c, to calculate an equivalent clean sand value ($Q_{tn,cs}$), as shown in Equation 2.

$$Q_{tn,cs} = K_c Q_{tn} \tag{2}$$

Where,

$K_c = 1.0$, if $I_c \leq 1.64$
$K_c = 5.581 I_c^3 - 0.403 I_c^4 - 21.63 I_c^2 + 33.75 I_c - 17.88$, if $I_c > 1.64$

The in-situ state parameter (ψ) is then calculated using Equation 3.

$$\psi = 0.56 - 0.33 \log(Q_{tn,cs}) \tag{3}$$

2.2.2 Plewes Et Al. (1992) method (Plewes)

The Plewes et al. (1992) method normalizes q_t using mean effective stress and dynamic pore water pressure and relates it to (ψ) using Equation 4, 5, 6 and 7.

$$Q_p(1 - B_q) + 1 = \bar{k} \, exp(-\bar{m} \, \psi) \tag{4}$$

$$B_q = \Delta u / (q_t - \sigma_{v0}) \tag{5}$$

$$\bar{k} / M_{tc} = 3 + 0.85 \lambda_{10} \tag{6}$$

$$\bar{m} = 11.9 - 13.3 \lambda_{10} \tag{7}$$

$$Q_p = (q_t - p_0) / p_0' \tag{8}$$

Where,

Q_p = tip resistance normalized by mean effective stress

B_q = normalized exceed pore pressure
M_{tc} = critical state friction ratio
λ_{10} = slope of the critical state line
$\bar{k}$ & = semi-empirical parameters for estimating ψ
p_0 = mean total stress
p_0' = mean effective stress
Δu = exceed pore pressure

While the method provides empirical relationships for estimating λ_{10} and M_{tc}, it also indicates that development of the soil's CSL through triaxial testing on intact or reconstituted soil samples can be used to refine estimates of λ_{10} and M_{tc} and provide an estimate of (ψ) that is more soil specific. The calculation of (ψ) was completed using a λ_{10} value of 0.09 and a M_{tc} value of 1.38. These values were calculated by laboratory testing. Additionally, the later stress coefficient (K_0) of 0.5 was selected as reported by Robertson et al. (2019).

2.2.3 Cavity expansion method - Jefferies and Been (2016)

Jefferies and Been (2016) method uses the critical state parameters discussed in Plewes et al. (1992). However, this method uses numerical simulations of the spherical cavity expansion treated as an analogue to the CPTu technique. These simulations are used to develop site-specific values of $\bar{k}$ and m (see method of Plewes, et al. (1992)), to calculate $\bar{k}$ from CPTu data. These analyses used the NorSand constitutive model with the inputs of laboratory tests (Robertson et al. 2019). Jefferies and Been (2016) method was not used in the current paper since it is an extension of Plewes et al. (1992).

3 RESULTS AND DISCUSSION

A histogram represents a frequency distribution. Figure 3 shows histograms of the state parameter during field exploration stages. Two range of (ψ) can be identified, namely dilatant range (from -0.3 to -0.05) and contractive range (from -0.05 to 0.2). The tendency of the state parameter in each year showed an increased on the range values highest than -0.05. Consequently, this range meant a contractive tailings that was liquefaction susceptibility. Robertson's and Plewes' methods presented a similar contractive trend on the CPTu2018-19, but not in the CPTu2005-07 and the CPTu2016-04. It can be noted that CPTu2018-19 presented Fine tailings along with the depth profile. Consequently, Robertson's method results for such layers might not be as accurate as for the Coarse tailings encountered in the profile.

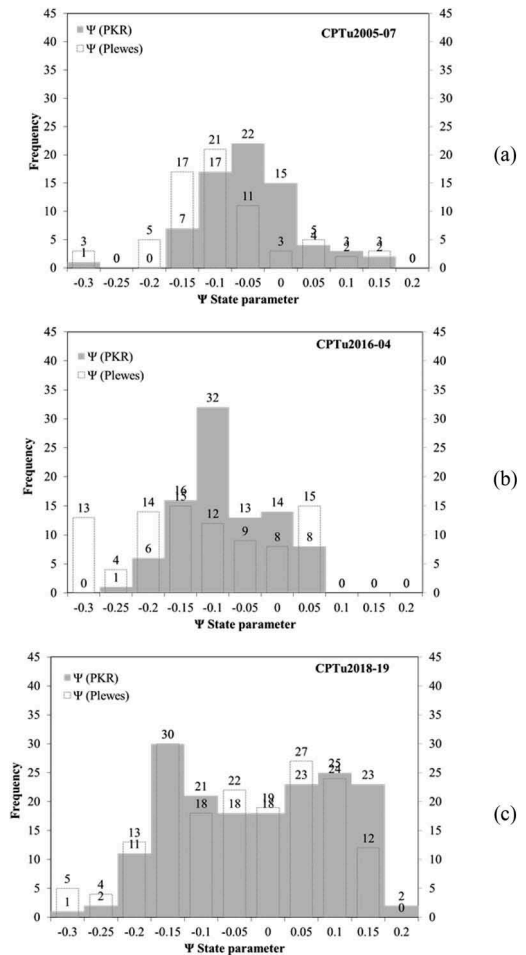
Both methods showed that the distribution of state parameter moved to the contractive range over time (i.e. 2005, 2016 and 2018). The observed behavior in Figure 3 is consistent with the range of states parameters often seen on tailings dam (Reid and Jefferies 2017).


Figure 3. Histogram of the state parameter estimation based on Robertson (2009) and Plewes et al (1992) (a) CPTu2005-07, (b) CPTu2016-04, (c) CPTu2018-19.

Using the Robertson's and Plewes' methods described above, estimates of (ψ) were calculated for both fine and coarse tailings at each CPTu location, as shown in Figure 4.

The analysis of ψ shows that CPTu2005-07 presented contractive range (ψ >-0.05). Over time, the analysis of ψ for CPTu2016-04 and CPTu2018-19 showed an increment in areas with a high value of ψ which translate into high liquefaction potential. Therefore, the results herein point out that liquefaction potential increases as time goes. Consequently, the results should have been a warning during the operation of the dam.

Interestingly, the CPTu2018-19 presented the highest depth (~45 m) between the three CPTu. Conversely, CPTu2005-07 and CPTu2016-04 presented a shallow depths (around 25 m). The relevance of deep CPT data relies on identify the layers for liquefaction potential. This was clearly found on CPTu2018-19.
Figure 4. State parameter based on PKR and Plewes methods (a) CPTu2005-07, (b) CPTu2016-04, (c) CPTu2018-19.

For the three CPTu selected, a state parameter greater than -0.05 is identified at different depths, which was established as zones susceptible to liquefaction (Plewes 1992), as presented in Figure 4. Most of the tailings dam failure showed a high value of state parameter before the failure (contractive behavior).

Additionally, histograms of the 28 CPTu data from Feijão were reproduced in the expert panel report. The histograms were overlain for the Coarse and Fine Tailings in Figures 5a and 5b, showing the distributions of these data used in the analyses. In this analysis, Robertson (2009) method was ultimately not used for the Fine Tailings because the method is not appropriate given the similarity in the slope of the CSL for the Coarse and Fine Tailings. Fine tailings showed a high frequency on the higher range of state parameter (Figure 5b) which should have been a warning for operation purposes.

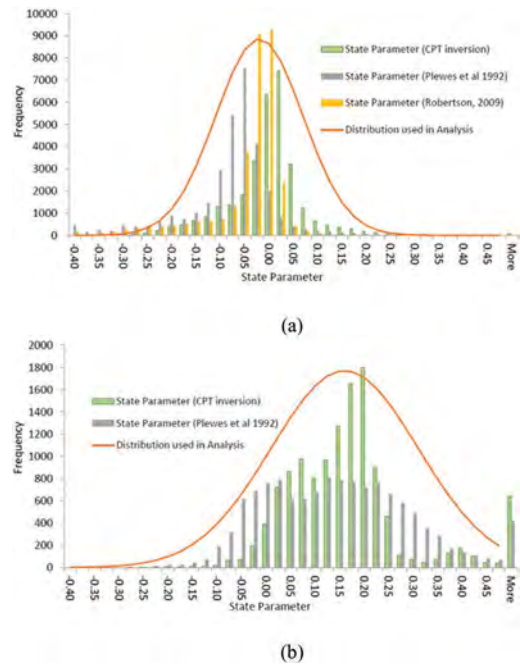
Overall, the main trend of the Feijão dam is that the fine tailings were mainly contractive and the state parameter were captured by using the two methods as discussed in Figure 3, 4 and 5. Moreover, the contractive tailings was identified at high depth and increased the frequency over time.


Figure 5. State Parameter (Ψ) Distribution for (a) Coarse Tailings and (b) Fine Tailings (Retrieved from Robertson et al. 2019).

4 CONCLUSIONS

In general, the results indicated that the three methods agree well with the state parameter for coarse tailings.

For fine tailings, Plewes' method and Jefferies and Been's method resulted in a similar state parameter ψ.

However, Plewes' method was more even. Both methods show that the state parameter (ψ) of fine tailings was significantly higher than coarse tailings. Therefore, both fine and coarse tailings are likely to exhibit potential flow liquefaction.

The three CPTu selected showed that the liquefaction potential is high as time goes by. As a recommendation, designed makers should be considering this key indicator in their decision for the physical stability of the tailing dams.

The histograms of state parameter illustrated a tendency for high-frequency values of ψ (right side of the gauss curve) which can be an indicator for contractive behavior of tailings body.

Is CPT a suitable in situ test for characterizing gravely sands?

G. Togliani
Geologist, Massagno, Switzerland

ABSTRACT: A recent study (Han et al, 2019) showed that CPTs performed in sandy soils with a variable but sometimes significant gravel content, despite special operational measures (alternating drilling and CPT), frequently provide unrealistic q_c values which adversely affect the piles capacity predictions even using the most representative CPT-based design methods. However a series of SPT verticals are also available and the conversion of N_{30} into q_c values has allowed, via a number of steps, the development of four virtual CPTu, two of which were then used for the pile capacity predictions This procedure has proven to be effective, so that, even employing far less authoritative methods, were obtained sufficiently approximate shaft and toe resistances.

1 INTRODUCTION

This paper is based on the study of Han et al. (2019) concerning the load response of two pipe piles driven in a gravelly sand alluvium (Lafayette, Indiana, USA), one open-ended and the other closed-ended (D=0.61 m and L=17.3 m) but only the last one is debated because it is affected by fewer unknowns.

The variable but frequently significant gravel content has made CPTs execution problematic, so much so that, for CPT3, it was necessary to refer to a drill-and-push procedure in order to go deeper than 30m.

It is precisely for this reason that to obtain a complete test it was necessary to combine CPT2 and CPT3, via digitizing both with the result shown in Figure 1 (CPT2-3).

Anyway, the most serious problem was created by the gravel dragging effect that made the q_c values poorly reliable, increasing them, randomly, in an unlikely manner.

Nevertheless, the q_c values, albeit with a few local corrections, were likewise used to calculate the piles capacities applying five of the most representative methods known to date, logically with poor results.

In contrast, some SPT verticals, one of which is represented in Figure 1 (SPT2), were not considered for the same goal maybe fearing similar results due to a ratio [(qc/Pa)/N] close to 10 as suggested by lit-erature for gravelly sands or, again, to the generally accepted SPT limitations, surprisingly emphasized, however, only in recent years although innate.

Some grain size analysis, which results are summarized in Table 1, complete the soils description.
Figure 1. q_c and N_{SPT} plots.

Table 1. Geostratigraphy at test site.

Depth m	Soil Type	Gravel Content (%)	D50 mm	USCS
0.0-5.5	Clayey silt	-	-	-
5.5-8.2	Sand with gravel	4	0.4	SP
8.2-10.4	Sandy Gravel	49	4.5	SP
10.4-19.1	Sand with gravel	10	0.9	SP
19.1-22.6	Gravely sand	43	4.1	SP
22.6-32.6	Gravely sand	28	1.1	SP

2 CPT AND SPT MATCHING

Comparing the two curves in Figure 1, it is rather singular to note that with q_c values, over 6 m depth, almost always above 30 MPa and with frequent peaks of 40/50 MPa, the SPT has only two N_{30} values above 50, both, moreover, at depths greater than 29 m when the energy is decidedly declining.

Considering that, anyway, also the SPT values despite the more favorable scale effect (cone section of 20 cm^2 against 15 cm^2 for CPT), are influenced by the gravel presence, it is reasonable to assume that the poorly graded sandy matrix has a density index that, barely, achieves the medium dense state.

The author, noting the above, then thought to verify what results were provided by some of the most known methods for the piles design via SPT (Shariatmadari et al., 2008), summarizing them in Table 2 together with the measured one, corrected for residual load, and those obtained by Han et al. (2019) using CPT based methods described by themselves.

Table 2. CEP capacities.

Static Loading Test & Design Methods	Toe (kN)	Shaft (kN)	Capacity (kN)
Measured (corrected)	2403	2157	4560
Purdue (CPT)	4350	2825	7175
ICP05 (CPT)	3616	2055	5671
UWA05 (CPT)	5026	2624	7650
NGI05 (CPT)	3817	3665	7482
Fugro05 (CPT)	4204	3167	7371
Meyerhof (SPT)	3000	1082	4082
Decourt (SPT)	3465	2135	5600
Bazaara (SPT)	1843	2164	3998
Shariatmadari (SPT)	3101	1389	4490

By examining the table contents, it is evident that the approximation of the predictions obtained using SPT methods is better than those produced via CPT, so justifying the attempt to generate more likely q_c values by creating virtual CPTu starting from the N_{30} values of SPT2, even knowing their limits.

On the matter, remembering that Jefferies et al. (1993) claim that the best SPT is the one obtained by suitably processing a CPTu, then the author assumed that, in specific, the opposite could also be true

However in developing this procedure within sandy-gravel alluviums, the q_c values derived via D_{50} (Robertson et al., 1983), or using I_c [Lunne et al. (1997), Robertson (2012)], or $f(I_c)$ according to Ahmed et al. (2013), were ignored because with a mean value around 1 for D_{50}, I_c anyway ≤ 1.50 and consequently $f(I_c) > 550$, we always get too high q_c values.

Instead, new q_c profiles were obtained using for the conversion four different approaches [Jefferies et al., Bustamante, Dutch modified, Togliani (2016)].

The next Table 3 and Table 4 are helpful in understanding the way followed to carry out the mentioned conversions over the pile whole length.

Table 3. Conversion coefficients guides.

α (Guide)	Zone (Ic Guide)
1.2 (GW, GP, GM, GP)	7 Ic<1.25
1.1 (GM-ML, GC-CL)	7 Ic<1.25
1.0 [SW, (GW)]	6 1.25<Ic<1.80
0.9 [SW (SM), SP]	6 1.25<Ic<1.80
0.8 (SC, SM-ML)	5 1.80<Ic<2.40
0.7 (SC-CL)	5 1.80<Ic<2.40
0.6 (ML. CL-ML)	4 2.40<Ic<2.67
0.5 (CL)	3 2.67<Ic<3.22
0.4 (OL, OH, MH)	2 Ic>3.22
0.3 (Pt)	2 Ic>3.22

Table 4. Conversion coefficients application.

Depth (m)	N30	USCS	α	Zone	Ic
1.3	2	SC, SM-ML	0.8	5	2.20
2.2	3	SC, SM-ML	0.8	5	2.20
2.9	12	SP[SW (GW)]	1.0	6	1.50
3.4	3	SC, SM-ML	0.8	5	2.20
4.3	4	SC, SM-ML	0.8	5	2.20
5.1	1	SC, SM-ML	0.8	5	2.20
5.8	3	SC, SM-ML	0.8	5	2.20
6.6	18	SP[SW (GW)]	1.0	6	1.50
7.4	19	SP[SW (GW)]	1.0	6	1.50
8.1	15	SP[SW (GW)]	1.0	6	1.50
8.9	30	SP[SW (GW)]	1.0	6	1.50
9.6	30	SP[SW (GW)]	1.0	6	1.50
11.1	10	SP[SW (GW)]	1.0	6	1.50
12.5	20	SP[SW (GW)]	1.0	6	1.50
14.2	28	SP[SW (GW)]	1.0	6	1.50
15.8	30	SP[SW (GW)]	1.0	6	1.50
17.3	25	SP[SW (GW)]	1.0	6	1.50

Based on previous suggestions, the q_c values, for the Jefferies et al. approach, were obtained solving the original equation (1993), just according to q_c instead of N_{30}, choosing for I_c a value compatible with the results of the grain size analyses (Table 1):

$$qc(bar) = 8.5N30\,(1 - Ic/4.6) \qquad (1)$$

Instead, using Bustamante et al. (1993), q_c values were derived according with nomogram in Figure 2.

The Dutch modified method already described by Togliani et al. (2004) and Togliani et al. (2015), is based on the following equation:

$$qc(bar) = \alpha(M^2H)/[Ae(m + M1) \qquad (2)$$
Figure 2. Bustamante et al. (1993) Nomogram.

where: α =conversion coefficient (Table 3)
M=63.5 kg, H=76 cm, A=20 cm^2
e=set per blow, m= 6kg/m, M1=70 kg

Finally, the Togliani method, created for personal use in 2016, refers to equation below:

$$qc(MPa) = \alpha[N30/\log(\sigma'v)] \qquad (3)$$

where:$\sigma'_v v$ is in kPa

Subsequently, pertinent f_s values were estimated via q_c elevating it to 0.4 (if q_c < 1.5 MPa), to 0.55 (if q_c > 30 MPa), to 0.47 for intermediate q_c values as illustrated in the graph below, which serves also as check involving the well-known Euripides Project.

For the study by Han et al., 2019 (Lafayette) a change was introduced to mitigate the gravel impact [if q_c >1.5 MPa, $f_s=q_c^{0.45}$ (with f_s and q_c in kPa)].
Figure 3. Virtual f_s.

At last, the virtual CPTu were completed equalizing the u_2 to u_0 values (soils classified as SP assume that their permeability is high), processing which via CPeT-IT interpretation software (supervised by P.K. Robertson), new N_{30} values were derived to compare with those measured, thus closing the loop.

3 VIRTUAL AND REAL N_{30}, q_c VALUES

Applying the procedure suggested in the previous paragraphs, the four curves relating to both q_c and N_{30} values were determined and compared with the measured ones in Figure 4 and in Figure 5.

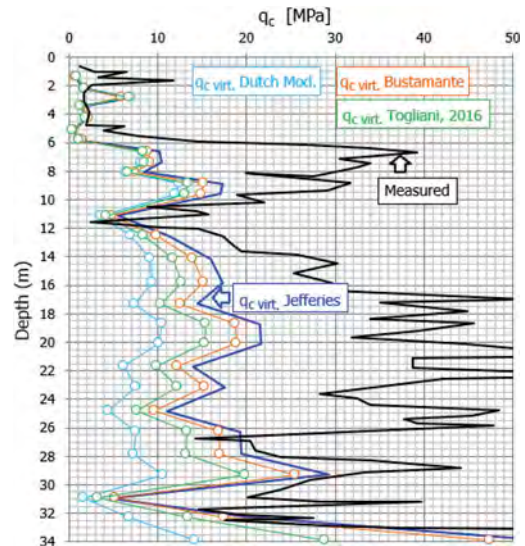
In this regard, we highlight the amazing match of the curves referred to N_{30} values both measured and predicted according to Togliani, 2016.


Figure 4. q_c Synoptic plots.
Figure 5. N_{30} Synoptic plots.

The above synoptic graphs show that the approach of Jefferies et al. (1993) for q_c and the one of Togliani (2016) for N_{30}, are those closest to the measured values and, for this reason, were chosen for the piles capacity prediction, applying the methods below:

1. ICP05 selected, as reference and comparison, among those used by Han et al.(2019);
2. Décourt (1995) by employing the N_{30} values obtained from the two virtual CPTu;
3. LCPC (1982) method, being the precursor among those using only the q_c values;
4. Togliani 2008 (q_c&R_f) and 2018 (q_c&$K*_G$).

4 CPT/SPT-BASED DESIGN METHODS

ICP05, LCPC and Décourt methods are well-known and widely used and therefore do not need any explanation.

For ICP05, however, it should be noted that, in the specific case, the q_c values used have not been subjected to any filtering, that those of the natural unit weights γ_n were obtained from virtual CPTu processing (CPeT-IT), as well as the interface fric-tion angles ($\delta_c = \phi_{peak}^{0.95}$, arbitrarily decided in this case where q_c is only virtual and specific measured values are missing).

With this option, δ_c, at least in gravely sand, is ranging anyway between 29° and 32° and so in agreement, with the suggestion of Salgado et al. (2011), by which $\delta_c = 0.9\phi_c$.

Both Togliani methods, are usually updated according to new experiences especially related to international piles capacity prediction events, which is why we report below their latest version.

1 q_c&R_f Method (2008): Unit Friction (q_s)

$$qs = \beta qc^{0.4} \quad if\ f_s \le 20\ kPa \qquad (4)$$

$$qs = \beta\{qc^{0.52}[0.9(0.4lnRf)]\} \quad if\ R_f \ge 1.5 \qquad (5)$$

$$qs = \beta\{qc^{0.51}[0.8 + (1 - Rf/8)]\} \quad if\ 1 \le R_f < 1.5 \qquad (6)$$

$$qs = \beta\{qc^{0.53}[0.8 + (1.1 - Rf/8)]\} \quad if\ R_f < 1 \quad (7)$$

2 q_c&$K*_G$ Method (2018): Unit Friction (q_s)

$$qs = \beta(qc^{0.3+x}) \quad if\ 3 < SBT < 7 \qquad (8)$$

$$qs = \beta(qc^{0.2+x}) \quad if\ SBT \ge 7(q_c < 30MPa) \qquad (9)$$

$$qs = \beta(qc^{0.2+x}) if\ SBT \le 3 \qquad (10)$$

where SBT= Soil Behavior Type

$$x = \log(K^*G^\alpha)$$

$\alpha = 0.11$ (driven precast and pipe piles)
$\alpha = 0.10$ (cast in situ piles)

3 Both Methods (2018): Unit Base (q_b)

$$qb = qctoe[\lambda + 0.05Lpile/Dpile] \qquad (11)$$

where: $q_{c\ toe}$ goes from +8 d_{toe} to -4d_{toe}, range considered for homogeneityreasons also for ICP05 predictions

Table 5 summarizes the correspondent pile type co-efficients.

Table 5. Pile type coefficients.

Pile Type	β	λ
Driven/Jacked (precast, pipe closed-ended)	1.00	0.30
Drill Displacement	0.90	0.25
Pipe (open-ended)	0.70	0.20
CFA, Bored (cased-cohesionless)	0.60	0.15
Bored (polymer, bentonite-upper bond)	0.60	0.10
Bored (cased-cohesive)	0.50	0.10
Bored (bentonite-lower bond)	0.40	0.05

About λ we note that at least doubles if SBT < 3, when the whole length "+8 dtoe to -4dtoe" develops in a dense/consistent soil without gravel or an Expander Body is present, while it reduces to 1.5λ in gravelly soils.

5 CEP: CPT/SPT-BASED METHODS RESULTS

The first group of results is that of the already known representative methods (Han et al. 2019), none of which fall within ± 20% of the generally admitted tolerances (red lines), where especially the toe resistance is overestimated in a remarkable amount while, among all the methods, only ICP05 correctly evaluates the shaft resistance (Figure 6).
Figure 6. Pile capacity by representative methods.

When using q_c values derived by Jefferies et al. (1993) conversion approach, three methods are within the accepted tolerances not only for pile capacity (ICP05, LCPC, Togliani 2018) but also for its toe and shaft components while Togliani 2008 suffers from a notable overestimation of the latter that extends, for Decourt, also to toe resistance (Figure 7).
Figure 7. Pile capacity using q_c by Jefferies et al (1993).

The circumstance that, for ICP05, in the face of much lower q_c values (Jefferies et al., 1993) we obtain a higher shaft resistance than Han et al. (2249 kN vs. 2055 kN, respectively), is probably due to the different evaluation of the interface friction angles.

Lastly, applying the method of conversion from N_{SPT} to q_c developed by Togliani in 2016, only Togliani 2008 and 2018 meet the requirements for pile capacity but it is exclusively Togliani 2018 that satisfies both components.

Among other methods, the approximation is sufficient for shaft resistance for both ICP05 and Decourt while LCPC is underestimating both components (Figure 8).
Figure 8. Pile capacity using qc by Togliani (2016).

6 PILE UNIT FRICTION DERIVED FROM VS

The author has only at the last moment known the outcome of three dynamic loading tests performed on bored piles with a diameter of 1.5 m and a length of 16 m placed in sandy gravel with cobbles, for the first 6-12 m consisting of medium-dense, dense fill followed by dense, very dense alluvial deposit.

This is the reason why the matter is treated in a concise way making visible first, in Figure 9, the grain size of the soils of interest (at 9 m and 10 m bricks are still present while GWT is at depth of 15 m)
Figure 9. Samples collected during a pile execution.

The deep foundations were necessary for the cover-ing of the Swiss Federal Railways Maintenance Cen-ter in Biasca.

The piles are distributed on two rows for a length of about 500 m for whose geotechnical characterization were available a continuous coring borehole with punctual SPT each 2-3m and a tomographic seismic profile that covered the entire length.

In this way it was possible to have a vertical log of the shear waves per meter depth at each pile that allowed to try a correlation between Vs and unit friction (qs), finally applied and proving promising so as to be tested for our pile after the appropriate modifications (in comparison, in fact, there are a cast in situ bored pile and a driven closed ended steel pipe whose capacity prediction comes, for more, from pa-rameters found in a virtual CPTu).

The proposed equation is:

$$qs = Vs^{0.95 - Ic/10} \qquad (12)$$

where: q_s is in kPa, Vs is in m/sec and I_c is the Soil Behavior Type Index

Despite being totally improvised, the above equation predicts a shaft resistance close to that measured, then showing a good potential (Figure 10).
Figure 10. Shaft resistance prediction vs measure.

7 CONCLUSION

The above leads to the following final remarks:

1. if an alluvial sand is frequently gravelly, a CPT is not a suitable in situ test to propose, being the static penetration often problematic and the q_c values too frequently unrealistic especially due to dragging gravel effect. Always applying the rule that "garbage in, garbage out", any pile capacity prediction where such values are directly used, is then condemned to failure whatever the representativity of the methods used;

2. fortunately, in this case, SPTs were also available, processing which made it possible to create alternative qc values that proved valid even when applying pile design methods derived from personal experiences and therefore mainly intended for practical use, such as those of the author, that, in the 2018 updated version (qc&K*G), proved to be the most performing;

3. in sandy soils with a variable but sometimes significant gravel content, punctual SPTs, carried out in continuous core drilling, would be more effective by replacing the standard sampler, useless in this case, with a conical point thus allowing to extend the test well beyond the zone remolded by the decompression/structural change that frequently affects the values recorded in the standard length of 0.45 m. Alternating the recovery of samples to SPTs, in incoherent soils even several meters long, we are able to obtain a sort

of continuous and reliable DPSH and also, in cohesive soils, to bypass the casing requirement that should characterize the dynamic continuous penetration tests of better quality. This way of performing SPTs, already described (Togliani et al., 2004), has never been disappointed the author which, on the contrary, has often benefited from it and in any case obtained information that has allowed him to make better-informed decisions. Of course, in cohesionless sands without gravel, it should be remembered that when interpreting the results, the replacement of the standard sampler with a conical point will generate different and greater values as we go from small displacement to full displacement conditions;

4. the lesson learned, especially for the practitioners, is that SPT, which is still the most popular and used in situ test although its validity is being questioned more and more, in certain contexts is providential and therefore, where present, should always be considered at least as a comparison.

5. last but not least, the use of Vs for the pile unit friction prediction seems to be able to help in predominantly gravelly soils with cobbles in which the usual in situ tests are difficult to perform and their outcome uncertain as well as questionable and, for this reason, other tests, in different scenarios, would be beneficial.

A CPT-based diameter-dependent m-θ spring model for lateral pile analysis

J. Tott-Buswell & L.J. Prendergast
Department of Civil Engineering, University of Nottingham, Nottingham, UK

ABSTRACT: Offshore Wind Turbines (OWT) are a successful renewable energy solution; however, emerging turbine sizes require pile geometries beyond the calibration range of existing design standards. This necessitates soil sampling and rigorous finite element modelling, which is problematic for quick design estimates. Cone Penetration Test (CPT)-based *p-y* methods can provide preliminary deflection estimates, although their applicability becomes increasingly uncertain as pile slenderness ratios, length normalized by diameter (L/D), reduce. This is due to the increase in diameter incurring additional resistances that *p-y* models alone cannot account for. To incorporate the additional resistance, this paper defines a CPT-based moment-rotation (*m-θ*) model by rescaling empirically derived axial capacity functions (known as *τ-w* curves). Various monopile dimensions are simulated and pile-head displacements are compared for CPT-based *p-y* models with and without *m-θ* springs. The net effect of incorporating *m-θ* springs increases as monopile diameters (and rigidity) increase and diminishes as piles increase in slenderness.

1 INTRODUCTION

1.1 *Current monopile design process*

There are two fundamental solutions to the increasing demand in renewable energy within the offshore wind sector. These are; increasing the radius of the blade-swept area to generate more energy per OWT, and optimizing the windfarm construction process. However, the foundation geometries required to facilitate the large moments induced by emerging wind turbine dimensions extend beyond the applicability of current design practices, requiring advanced 3D finite element modelling (Doherty and Gavin, 2011; API, 2014; Burd et al., 2017). Such design methodologies call for soil sample investigations which are often difficult to undertake in offshore environments and are impractical for preliminary design estimates. It would therefore be beneficial to develop a model which takes advantage of early measurements for soil strength properties, such as the Cone Penetration Test (CPT) (Reale et al., 2021), to gain a preliminary performance evaluation of OWT monopiles, optimizing the design process.

1.2 *The p-y model using CPT data*

The *p-y* method for piles simplifies the physical system to one-dimension using a series of discretized nonlinear springs that represent the lateral soil pressures *p* as a function of lateral pile displacement *y*. Each spring is linked through linear-elastic Euler-Bernoulli beam elements. For sands, the API

design methodology recommends curves empirically derived from piles with slenderness ratios (L/D) much greater than the geometries expected for emerging monopiles (Reese et al., 1974; Murchinson and O'Niell, 1986), therefore their applicability in the design of OWT foundations is increasingly questionable.

CPT-based *p-y* curves have been developed based on taking the cone tip end resistance (q_c) and empirically deriving exponential functions for the *p-y* relationship (Dyson and Randolph, 2001; Li et al., 2014; Suryasentana and Lehane, 2014). However, it has been demonstrated that their effectiveness at encapsulating lateral soil resistance decreases as L/D reduces, and their suitability for the problem relies on the range at which they were empirically calibrated (Li et al., 2014). This notion limits the traditional model configuration to lateral springs that employ *p-y* curves calibrated for specific pile size configurations; however, they are unable to fully account for all resistances. Therefore, further modifications must be made to traditional *p-y* methods to account for the presence of these additional resistance mechanisms induced by the increased rigidity of monopiles.

1.3 *Distributed moment resistance*

It is becoming apparent that the lateral resistance of piles with stockier geometries are not solely dependent on lateral soil pressures (Lam, 2013; Murphy et al., 2018; Burd et al., 2020; Fu et al., 2020). The

increase in diameter size introduces a distributed moment along the shaft as well as additional lateral and overturning resistances at the pile tip. These additional resistances are termed "diameter effects". The distributed moment stems from the interface shear friction acting at a distance from the cross-section's center of rotation, generating a - moment m along the pile shaft proportional to its rotation θ. This is outside of the modelling capabilities of a lateral spring element and can be effectively modelled through rotational spring elements in tandem with the distributed p-y springs. Larger diameters additionally lead to base resistances, which are not considered in this paper.

The aim of this paper is to define an appropriate m-θ spring function to describe the distributed moment impeding global rotation using q_c only, improving current CPT-based p-y models and enhancing geometric versatility. Such a model can provide the first step towards a strong preliminary evaluation of OWT monopile performance due to the convenience of CPT extraction in offshore environments.

2 METHODOLOGY

2.1 P-y function

The monopile's embedded length L and the CPT q_c profile are both discretized into lengths L_{inc} such that the q_c values can be averaged over length L_{inc} (giving $q_{c,avg}$). This informs evenly discretized points along the monopile, thereby characterizing the p-y and m-θ springs (Figure 1). The p-y springs used in this paper are informed through Equation 1 which were empirically derived by Suryasentana and Lehane (2014) for low L/D monopiles in sand.

$$\frac{p}{\gamma z D} = 2.4 \left(\frac{q_c}{\gamma z}\right)^{0.67} \left(\frac{z}{D}\right)^{0.75}$$
$$\times \left\{ 1 - \exp\left[-6.2 \left(\frac{z}{D}\right)^{-1.2} \left(\frac{y}{D}\right)^{0.89} \right] \right\} \quad (1)$$

where γ is the unit weight of the soil (assumed 20 kN/m^3 for dense sand applications), z is the spring depth and D in the diameter of the monopile. The initial stiffness of the p-y spring is determined based on a correlation to small-strain shear modulus, see Suryasentana and Lehane (2016).

2.2 M-θ function

The m-θ spring model is derived from principles based on the axial capacity design for monopiles. τ-w vertical springs represent the uniform soil-pile interface friction when loaded vertically as shown in Figure 2a. The τ-w
Figure 1. (a) Soil resistances on a monopile under lateral load and (b) the one-dimensional discretised model (neglecting base diameter effects).

relationship is described through a quadratic equation defined by Randolph (2003) in Equations 2 and 3.

$$\tau(w) = G_0 \left(\frac{w}{2D}\right) \left[1 - \frac{w}{2w_f}\right] \quad (2)$$

$$w_f = \frac{4D\tau_f}{G_0} \quad (3)$$

Where w is the vertical displacement, w_f is the maximum vertical displacement at which the shear resistance is fully mobilized, and G_0 is the initial stiffness which can be approximated from q_c using the relationship $G_0 \approx n q_{c,avg}$ (Schnaid et al., 2004). n is taken as 6 for dense soils (Prendergast et al., 2013). The maximum shear stress τ_f is shown in Equation 4 as defined in UWA-05 (Lehane et al., 2005).

$$\tau_f = \frac{f_t}{f_c} \tan \delta_f$$
$$\times \left[0.03 b \, q_c \, A_{re}^{0.3} \left[\max\left(\frac{H}{D}, 2\right) \right]^{0.5} + \Delta\sigma'_{rd} \right] \quad (4)$$

where $f_t / f_c = 1$ and $b = 1$ for piles in compression, H is the distance from pile tip to a given soil horizon, and $A_{re} = 1 - \text{IFR}(D_i / D)^2$ is the effective area ratio. IFR (Incremental Filling Ratio) is taken as 1. For the present study, the angle of friction δ_f is assumed 35° and the change in radial stress due to dilation $\Delta\sigma'_{rd}$ is assumed negligible.

A pile section under rotation experiences varied shear resistance magnitudes proportional to the distance from the axis of rotation. The origin of this varied shear resistance due to an overturning moment is recognized to be related to the uniform friction due to vertical loading as shown in Figure 2b.
Figure 2. Pile section under (a) vertical uniform friction and (b) vertical varied friction.

It is therefore possible to scale the original τ-w function and transform to m-θ form. Figure 3 illustrates the scaling theory. This model assumes that the axis of rotation is at the center of the pile cross section for all depths and the p-y and m-θ springs remain uncoupled.
Figure 3. Derivation of total moment about a pile's cross-section (adapted from Fu et al. (2020)).

The vertical displacement w for any point around the rotating pile section in Figure 3 is given by Equation 5.

$$w = \frac{\theta D}{2} \cos \phi \qquad (5)$$

where ϕ is the radial coordinate within the pile cross section. The total moment per meter m caused by incremental force $\mathrm{d}F$ on the lever arm $0.5D\cos\phi$ is given by the integral defined in Equation 6.

$$m = 2 \int_{-\frac{\pi}{2}}^{\frac{\pi}{2}} \frac{D}{2} \cos \phi \, \mathrm{d}F \qquad (6)$$

Substituting $\mathrm{d}F = \tau \mathrm{d}A$ (where $\mathrm{d}A = 0.5D\mathrm{d}\phi$) into Equation 6 gives m as a function of $\tau(w)$.

$$m = \frac{D^2}{2} \int_{-\frac{\pi}{2}}^{\frac{\pi}{2}} \tau(w) \cos \phi \, \mathrm{d} \phi \qquad (7)$$

Further substituting Equation 4 and 5 into 7, then solving the integral gives the total moment m as a quadratic function in terms of θ (Eq. 8).

$$m(\theta) = \begin{cases} a\theta - b\theta^2, & \theta < \theta_f & (8a) \\ m_f, & \theta \geq \theta_f & (8a) \end{cases}$$

$$a = \frac{G_0 D^2 \pi}{16}, \quad b = \frac{G_0^2 D^2}{96\tau_f} \qquad (8c)$$

Where m_f and θ_f are the maximum moment per meter and maximum rotation, respectively. m_f is computed based on taking advantage of the parabolic properties of Equation 8a. The function is illustrated in Figure 4 and the key parameters are highlighted in Table 1.
Figure 4. Parabolic relationship of m-θ.

Table 1. m-θ function key parameters.

Parameter	Definition
Maximum moment, m_f	$\frac{a^2}{4b} = \frac{3}{32}\pi^2 D^2 \tau_f$
Failure rotation, θ_f	$\frac{a}{2b} = 3\pi\tau_f/G_0$
Initial stiffness, k_θ	$a = \frac{1}{16}\pi D^2 G_0$

Note that the failure moment m_f, failure rotation θ_f and initial stiffness k_θ are in some scaled form that is reflective of the soil's conventional properties, enabling a quick specification of the moment-rotation interaction. The described methodology for deriving the m-θ function is not limited to the CPT τ-w curves derived by Randolph (2003) and can be replaced with any τ-w definition. The initial stiffness k_θ can also be used for small-strain dynamic analysis to determine natural frequencies (Prendergast and Gavin, 2016).

The numerical model implementing the above procedure is developed in MATLAB using its proprietary programming language to compute the monotonic lateral response of a series of piles with varying L/D. The secant stiffness of the springs defined in Equations 1 and 8 characterize the global stiffness matrix and the displacements are iterated until convergence to compute pile deflections using the Direct Stiffness method. Diameter effects induced at the pile tip are neglected.

2.3 CPT profile

An idealized CPT profile is generated based on the formulations derived by Lunne and Christoffersen (1983) as follows:

$$q_c = 60\left(\sigma_v'\right)^{0.7}\exp(2.91D_r) \qquad (9)$$

where D_r is the relative density and is taken as 0.8 for dense sand and σ_v' is the vertical effective stress. The vertical effective stress was calculated by assuming a bulk unit weight of 20 kN/m³ and dry soil conditions. Equation 9 is used to inform spring characteristics in Equations 1 and 8.

It is noted that the current iteration of the model does not account for monopile tip effects, which can have a significant influence on the lateral displacements when the diameter size is substantially large (Murphy et al., 2018). The currently proposed framework is therefore an iteration towards an all-encompassing versatile resistance model informed through preliminary offshore soil data.

3 RESULTS AND DISCUSSION

Two models are developed to observe the influence of the m-θ springs for various monopile geometries. The py-$m\theta$ model includes $n = 100$ lateral and rotational spring elements defined by Equations 1 and 8, respectively, to capture the monotonic soil-structure interaction, whereas the py-only model is simply the traditional p-y methodology with $n = 100$ lateral spring elements. An independent study showed that an increase in n had negligeable effects on the model's performance. Both models implement the same CPT profile derived from Equation 9.

The embedded length of the pile is 24m and the outer diameter is set to 8m, 4m, 2m and 1m to investigate model performance with various L/D ratios ($L/D = 3$, 6,

12 and 24, respectively). A horizontal force is applied at the mudline and the pile head displacements are calculated. The results are shown in Figure 5.
Figure 5. Comparison of pile head displacement between py-$m\theta$ and py-only models.

It is clear from Figure 5 that the increase in slenderness ratio results in the py-$m\theta$ model converging towards the traditional p-y model, as the rotational spring elements exhibit negligeable influence for lateral monotonic loading. This is due to the distributed moment m being proportional to D^2 as described in Equation 8. Conversely, a decrease in L/D amplifies the effect of the m-θ springs, which is indicative of the physical behavior of a monopile experiencing a distributed moment along its embedded depth. Therefore, the proposed model has demonstrated adaptability towards monopile modeling when the dimensions are varied. Further, the model's inherent modular framework allows for alternative spring functions and is not limited to the expressions used in this paper. Thus, defining m-θ functions does not require quantifying m-θ relationships experimentally, but instead selecting an appropriate axial resistance model.

An alternative approach to the problem is to calibrate p-y functions that are specifically tailored for a given range of pile dimensions, which would include contributions of the distributed moment in the lateral springs. However, this restricts the model to a specific range of slenderness ratios and would incorporate physical resistances that the mechanical analogy is not intended for. It is therefore important to note that it would be preferable to use a p-y function appropriate for slender piles in this proposed framework to ensure that only lateral resistances are considered in the lateral spring (as best as possible).

4 CONCLUSION

With demand outpacing research in the offshore wind sector, the need for an efficient preliminary design tool for laterally loaded monopiles is apparent. CPTs can provide initial strength profiles for offshore sites where soil sampling can be impractical for initial

performance estimates of OWTs. This paper presents an elegant method to include the distributed moments that arise from the increased cross-sectional dimensions for monopile foundations. The rotational springs are included with the traditional p-y methodology that should be already familiar to practicing engineers. The m-θ function is derived from CPT-based τ-w relationships due to the similarity in the origin of their resistances. The vertical soil-pile stresses τ mobilized from vertical displacements w are rescaled to define the relationship between the distributed moment m mobilized by pile rotation θ.

A series of monotonic pushover simulations were undertaken for various slenderness ratios of p-y models with and without m-θ springs. It was demonstrated that the increase in diameter resulted in a larger contribution from the rotational spring elements, accurately representing the likely resistance behavior of monopiles with low L/D values. Increasing the slenderness resulted in the model converging towards the p-y only model, highlighting the versatility of such a modular framework.

Defining the m-θ relationship has been simplified to selecting an appropriate τ-w function informed through q_c data. The next stage for this framework is to include a model for pile tip diameter effects that can be characterized by CPT data. Additionally, the initial rotational stiffness of the rotational spring facilitates a potential improvement to the evaluation of natural frequencies via small-strain analysis.

An investigation into the use of the Vibdrive and β-methods for calculating the SRV of offshore piled foundations

M.P. Trubshaw & T. Joseph
Ramboll, London, UK

G. Giuliani
COWI, London, UK

ABSTRACT: Offshore piled foundations are typically installed using an impact hammer. Increasingly, more attention is being given to use of vibratory hammers due to added benefits of prolonged pile life, reduced installation noise, and reduced risk of observing pile-run. This paper considers a case study in the North Sea, consisting of six positions where piles are installed in layered sands and clays. The Cone Penetration Test (CPT) data for the positions have been used in calculating the Soil Resistance to Vibratory Driving (SRV) as part of the Vibdrive method, from Holeyman (2002). This method has been compared with the SRV calculated using the non-CPT based β-method, from Jonker (1986). By varying the SRV used in driveability predictions, the results can be compared with the available driving records. It was found that the CPT based Vibdrive method consistently produced more representative results while still maintaining a conservative prediction.

1 INTRODUCTION

The foundations of offshore wind farms represent approximately 25% of the construction cost. Currently, the predominant type of offshore windfarm foundations are monopiles, which accounted for 88% of foundations installed in 2016, Moscoso (2018). The traditionally used installation technique is impact driving. Adopted worldwide, it is the preferred method and considered the lowest risk approach. However, there is increasing interest in vibratory driving as this technique surpasses many of the inherent problems of impact driving. This includes the generation of lower stresses into the pile thereby increasing its design life, it is 3-4 times faster at pile installation than impact driving and can be combined with faster handling procedures allowing for serial installation.

There is currently a lack of driving data for vibro installed piles in the public domain. This lack of available data prevents the development of more reliable methods of predicting the installation resistance of vibro-installed piles. As vibro-driving predictions are better understood, there is greater potential for this method to be more widely used. This paper will provide a case study of the application of two SRV calculation techniques, and how the subsequent analysis compares to the driving records. This work adopts the current industry approach to determine the driveability of impact driven piles and makes amendments to the soil input, accounting for liquefaction

induced by vibro-driving. Using this process a link is made between the two installation methods.

The SRV is calculated using the industry standard β-Method and the CPT-based Vibdrive method. There are other methods used to predict the vibro-driveability of offshore piles, some of these consist of advanced numerical models that aim to account for the forces involved, Viking (2002).

The case study is located in the southern North Sea and consists of monopiles with transition pieces. Vibro-driving was initially used until refusal, after which the impact hammer was used to achieve target penetration. The vibro-driving records, pile geometry, and hammer information were made available for six positions, along with corresponding CPT data.

2 SITE CHARACTERISATION

The soils at the investigated site are known to be dominated by medium dense to extremely dense sand with two large formations of medium plasticity clays.

The Friction Ratio (R_f) and Cone Tip Resistance (q_c) for the six positions considered in this investigation are presented in Figure 1. It can be observed that Location 4 is a significant outlier with R_f values of generally greater than 4 % from 4 m to 26 m depth. Likewise, Location 5 exhibits an R_f of greater than 4 % between 2 m and 12 m depth. At these locations, the q_c values are generally less than
Figure 1. Measured R_f and q_c values for each location.

5 MPa within these depth ranges, and overall, less than 20 MPa. Indicating predominantly cohesive soils.

In contrast for Locations 1, 2, 3, and 6, the R_f values predominantly vary between 0.5 % and 4 %, and the q_c values are generally higher. These indicate a more silty to increasingly sandy material. The significant variability of the R_f values also indicates there is a large amount of interbedding present in the soil column.

3 METHODOLOGY

The SRV calculation for the β-method and Vibdrive method are described below:

3.1 *β-method*

Unit Shaft Resistance (τ)

$$\left(k_0 \cdot \sigma_v' \cdot tan\delta\right) \cdot \beta \tag{1}$$

Unit End Bearing (q)

$$\left(N_q \cdot \sigma_v'\right) \cdot \beta \tag{2}$$

where k_0 = the lateral earth pressure at rest; σ_v' = the vertical effective stress; $\delta = \varphi - 5$ degrees; φ = angle of internal soil friction, β = factor applied to account for residual yield stress of the soil and N_q is an end bearing factor (DNV-GL, 2019).

β values are expected to range from 0.1 to 0.45 based on the soil type, as shown in Jonker (1987), however for this assessment it was observed that a β value of 0.6 for both the shaft and end bearing resistances was considered more appropriate.

3.2 *Vibdrive method*

Unit Shaft Resistance (τ)

$$\tau_d = (1 - e^{-\alpha})\tau_l + \tau_s \cdot e^{-\alpha} \tag{3}$$

$$\tau_l = \tau_s \left[(1 - \psi)e^{\frac{-1}{FR}} + \psi\right] \tag{4}$$

$$\tau_s = \frac{1}{2}(2III) \tag{5}$$

$$\alpha = \frac{me \cdot \omega^2 \sin(\omega t)}{M_{dyn}} \tag{6}$$

where τ_d = vibratory shaft resistance; τ_l = liquified shaft resistance, τ_s = static shaft resistance; α = acceleration ratio, me = eccentric moment, ω = angular frequency, M_{dyn} = dynamic mass ψ = empirical liquefaction factor, FR = friction ratio; III = the average sleeve friction resistance between the level of the

sleeve and an equal distance ($III = b/2$) below and above the sleeve, and b= the diameter of the pile.

Unit End Bearing (q)

$$q_d = (1 - e^{-a})q_1 + q_s \cdot e^{-a} \qquad (7)$$

$$q_l = q_s\left[(1 - \psi)e^{\frac{-1}{FR}} + \psi\right] \qquad (8)$$

$$q_s = \frac{1}{2}(I + II) \qquad (9)$$

where q_d = vibratory toe resistance; q_l= liquefied toe resistance; q_s = static toe resistance; I = the average cone penetration resistance between the level of the base and a distance ($I = b/4$) above the base, b = pile diameter; II = the average cone penetration resistance between the level of the base and a distance ($II = 3b/4$) below the base.

The toe SRV can be seen for four locations in Figure 2. It can be observed that a significantly greater SRV is calculated using the Vibdrive method than the β-method.

3.3 *Dynamic factors*

The values of maximum elastic deformation corresponding to the maximum elastic force (quake) and the dynamic loading effect of the soil (damping) for the purpose of driveability predictions are summarised in Table 1. Both quake and damping values are based on information from Sinke (2020) and WEAP (2010).

Table 1. Dynamic factors used for analysis.

Quake (mm)		Damping (s/m)	
Toe	Shaft	Toe	Shaft
2.5	2.5	0.5	0.15

3.4 *Software*

The driveability analysis was carried out using the software GRLWEAP 2010, Offshore Version. This analysis is based on the stress wave theory and uses a lumped mass approach developed by Smith (1960). The pile is divided into discrete masses, interconnected by springs, and each interacting with the soil through a series of springs and dampers. The motions and forces within a foundation pile when driven by a specific hammer are simulated by the software. It carries out a dynamic analysis that represents the stress wave propagation (inclusive of reflection) throughout all sections of the pile.

The program computes the following for a vibro-driving case:

- The penetration rate (sec/m) for the pile to reach design penetration;
- Frequency (Hz) over the length of the pile;
Figure 2. Calculated Toe SRV using the β-Method and the Vibdrive Method.

- The axial stresses in the pile over its cross sectional area;
- Max power (kW).

3.5 *Hammer properties*

The vibro-hammer analysed here is made up of four separate vibrators. The combined properties of the hammer are summarised in Table 2.

Table 2. Hammer Properties.

Hammer Property	Value
Eccentric moment (kgm)	920
Dynamic Mass (kg)	76188
Max Frequency (Hz)	23.3
Clamp Weight (kN)	1494.5
Maximum Power (kW)	3552

3.6 *Driving records*

Driving records were available for each foundation location and typically included:

- The start and end time of each period of operation;
- The cumulative penetration [cm];
- The centrifugal force for each period of operation (MN);
- The revolutions per minute (RPM) of the eccentric moments;
- The hydraulic driving pressure (bar);
- Hydraulic clamp pressure (bar).

The refusal criteria for the vibro hammer are considered as below:

- Penetration speed < 2.0 mm/s is calculated for 1.5 consecutive meters;
- Penetration speed < 1.0 mm/s is calculated for 0.5 consecutive meters;
- Maximum movement of 250 mm in 300 seconds of operation at full frequency.

3.7 *Pile geometry*

The pile design comprised non-uniform, open-ended, large diameter steel piles. The general pile geometry and key properties assumed are summarised below:

- Gain/loss factors - taken as 1 for this study;
- Pile lengths between 54 m and 71 m;
- Varying diameters between 4700 mm and 6500 mm from the pile head to pile tip;
- Wall thickness between 57 mm to 110 mm;
- Steel yield stress of 355 MN/m^2;
- Steel elastic modulus of 210 GN/m^2.

The pile geometry varies slightly for each position.

3.8 *Available data*

To be able to undertake this assessment, four key pieces of information are required:

- Driving data;
- Soil information (CPT data);
- Pile geometry;
- Hammer make and model.

For this case study the full driving data was available for four locations. Two locations (Location 5 and Location 6) had partial driving data consisting of the self-weight penetration (SWP), average penetration speed, and refusal depth. The q_c and sleeve friction (f_s) data was available for all locations, however, the measured porewater pressure was not available which limited the soil characterisation undertaken.

4 RESULTS

Plots for four locations showing the predicted driving time with depth using the β-Method and the Vibdrive method compared with the driving record are shown in Figure 3. Locations 1, 2 and 3 are from the more granular material whereas Location 4 represents the more clay dominated material. The two locations which formed part of the study but only have partial driving records are included in Table 3.

Table 3. Summary of results for Location 5 and Location 6.

Driving Data	Location 5	Location 6
SWP (m)	4	1
Average Penetration Speed (s/m)	166.7	88.5
Refusal Depth (m)	37.7	31.7
Vibdrive		
SWP (m)	2	3
Average Penetration Speed (s/m)	138.8	27.2
Refusal Depth (m)	7	9
β- Method		
SWP (m)	16	6
Average Penetration Speed (s/m)	9.2	53.8
Refusal Depth (m)	37.7	11

4.1 *Self-weight penetration*

The SWP is the penetration into the seabed prior to driving. Dynamic soil resistance is therefore not active during this stage of pile installation. Under- or over-predictions of SWP affects the accuracy of the remaining driveability estimate.

Generally, the SWP was underpredicted using the Vibdrive method, with Location 1 and 2 predicting no SWP and Location 3 predicting 1m of SWP. This compares to the driving records which showed 4 m, 2 m, and 5 m respectively of SWP. For Location 4, the Vibdrive method predicted 2 m SWP which

compares to 3 m from the driving record. The β-method significantly overpredicted the SWP for all locations with 9 m predicted for Locations 1 and 2, 8 m for Location 3 and 14 m for Location 4.

4.2 *Penetration rate*

It can be observed that for all locations, the β-method underpredicts the driving record suggesting a faster penetration speed will be achieved. In contrast, the Vibdrive method generally overpredicts the driving record suggesting a slower penetration speed. Prior to refusal, the Vibdrive method matches reasonably well with the driving records.

For Location 1 there is a good match until 12 m, where the pile is predicted to refuse. This coincides with a slight spike in the q_c and a drop in the R_f. The transition to a relatively more sandy layer may be the cause of the refusal.

Location 2 is a generally more sandy and granular profile. The Vibdrive method shows two points of refusal at 5 m and 8 m. From 12 m it underpredicts the driving record. The Vibdrive method has not been found to best capture the installation resistance very well at this location.

Location 3 consists of predominantly silty material. The Vibdrive method showed an early refusal when it encountered a particularly sandy layer at 3 m. It then showed another theoretical refusal at 11 m following a gradual rise in penetration rate.

At Location 4, which has a notably higher R_f value indicating clay material, the Vibdrive method predicts a good match to about 6 m, and then an early refusal at 7 m.

5 DISCUSSION

The Vibdrive method has been shown to consistently predict a more conservative result in terms of the SWP, penetration speed, and refusal depth while the β-method is shown to underpredict the result.

The refusal of the Vibdrive method occurs predominantly in the more cohesive soil profiles. This could suggest that the method overpredicts the soil resistance in cohesive material. For the β-method, the dynamic effect is incorporated by the β-factor and considered during the SWP, before the actual vibro-driving starts. This assumption may lead to an overprediction of the SWP. Therefore, based on the results observed, it is suggested that a combination of both methods may provide a representative range of SWP when undertaking vibro-installation assessments.

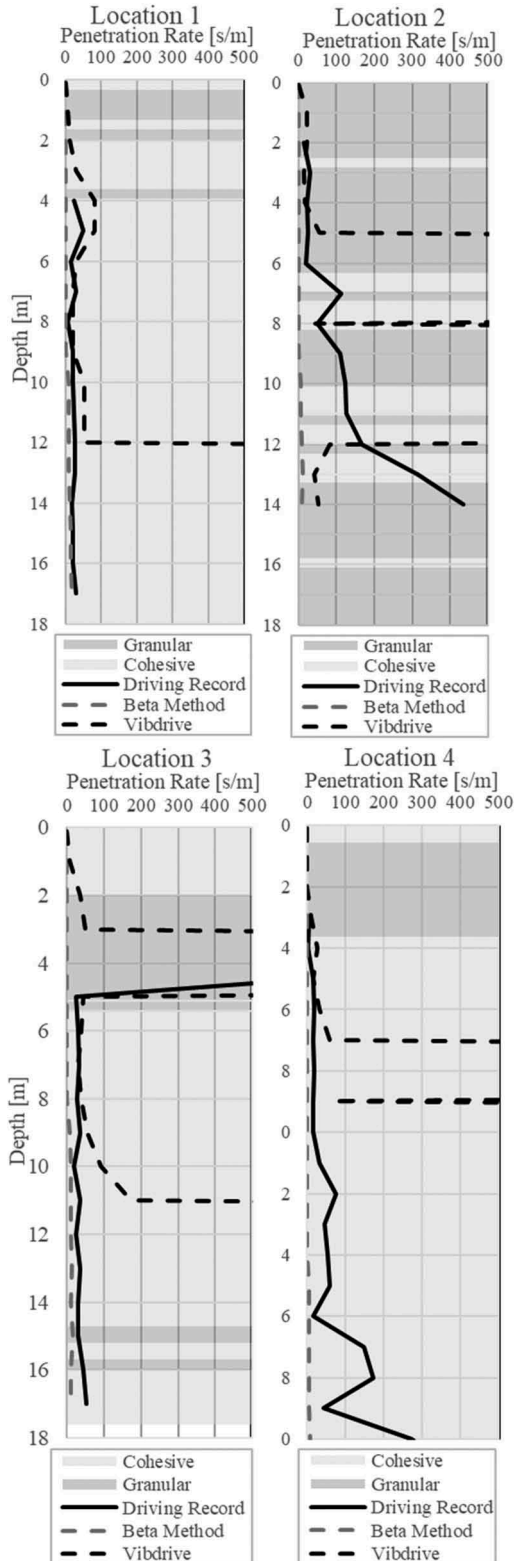
The results show that for both the granular and cohesive profiles presented in this study, the CPT based Vibdrive method generally produced a better match to the measured results and a more conservative prediction. However, the Vibdrive method also predicted refusal depths that may not always be realistic. This may be due to limitations of the


Figure 3. Results of the driveability predictions compared to the driving records of four locations.

method in capturing the actual variability of the process or other phenomena that need to be accounted for.

The β-method, on the contrary, predicts a much lower penetration rate than shown by the driving records. This can be due to a combination of factors such as the derivation of the geotechnical parameters and the selection of β-factors in determining the shaft and end bearing resistances. These would benefit from site-specific calibration through further back-analysis.

Further refinement of the Vibdrive method is required to produce a less conservative result. The associated research will require greater information on the soil conditions, which should include such details as the porewater pressure, unavailable for this study, but would give better insight into the liquefaction potential of the soil under vibratory loading. Using this information, in addition to the CPT data, a more complete ground model can be derived, and it will be possible to identify under which conditions the method best performs and what are its limitations. It should also be emphasised that the results from this study represent a small sample size and further work is required using different sites to gain more reliable conclusions and recommendations.

While appreciating the existing limitations, the current work does demonstrate that the existing methods can give acceptable estimates of the vibro-installation effort required. Based on the predictions of SWP, SRV and penetration rates, the CPT-based Vibdrive method consistently produced better results while still maintaining a conservative prediction. This method is therefore recommended to be taken forward for further improvement.

6 CONCLUSION

The results of this case study show there are still discrepancies between the current methods used to predict the vibro-driving behavior of offshore monopile installations and the actual driving records observed. The results have proven that many unknowns are not adequately captured by the methods analysed and further work needs to be done.

The misalignment shown by the two methodologies in respect of the driving record suggests that this is an area in which more research should be undertaken to remove more of the variations in predictions.

The Vibdrive method applied to this site was found to overpredict the driving record while the β-Method was found to underpredict the driving record. The use of both the β-Method and Vibdrive method provides an envelope of probable driving behavior.

The Vibdrive method, based on CPT data, was found to predict early refusal. This was often triggered when the pile progressed into a different soil type.

Further work is needed to understand the impact that both methods have in calculating SRV in different soil types. However, based on the case studies assessed, the Vibdrive method predicts a more representative driving behavior while maintaining conservativism. Once further driving records and back analysis data has been gathered from other sites, more robust conclusions can be made and inform advances in the application of the methods. This will enable greater certainty in the design of vibro-driven monopiles, and greater savings to be made in their design.

7 RECOMMENDATIONS FOR ADDITIONAL WORK

Further work into this field is required to improve the database of case studies with more driving records and soil data made available to allow research to be undertaken and improve the prediction of vibro driveability in a variety of soil conditions.

CPT data is still considered a valid starting point to investigate even further the performance of pile driving through a vibro hammer.

M. Taylor
In Situ Site Investigation

ABSTRACT: The piezocone (CPTU) offers a quick and repeatable investigation tool with instantly available high-resolution data. For these reasons it is both technically and commercially attractive to further instrument the CPTU to acquire additional measurements with more sensors either within the cone itself or as add-on modules behind the cone. Many ideas for further instrumentation of the CPTU have been conceptualised or tested but one that could offer direct benefit for offshore wind turbine foundation design is the Cone Pressuremeter (CPM). This in situ tool includes a pressuremeter module behind the standard cone that can measure ground displacement or expansion as a function of pressure applied during the loading, unloading and reloading of the surrounding soil when penetration is paused. From these measurements a number of soil parameters may be interpreted including the stiffness degradation (G/G_0) of the soil when combined with reliable in situ or laboratory measured G_0 values. With increasingly larger wind turbines being used and deeper water sites selected for construction, soil stiffness is an increasingly critical input for the design of many offshore wind turbine foundations. CPM testing has been trialed in the field onshore at a glacial till site and a medium to very dense sand site. The results of the CPM are compared in this paper to site specific results for the self-boring pressuremeter and advanced laboratory-based alternatives. The practical considerations of using the CPM offshore in seafloor mode are also reviewed.

1 INTRODUCTION

The piezocone (CPTU) is the main in situ tool for offshore geotechnical site investigations related to the design of offshore wind turbine foundations. It is a relatively fast test to perform and process, particularly in seafloor (non-drilling) mode, that provides continuous data for the entire investigation depth. These advantages inspire continuous development of the CPTU where many add on modules are considered and developed to investigate specific soil properties.

Following the general trends in offshore wind of increasing turbine sizes and larger water depths the soil stiffness becomes increasingly important for laterally loaded foundation design, for example the initial stiffness (G_0) and the stiffness degradation (G/G_0) required for the PISA design method (e.g. Byrne et al, 2017).

Current practice allows determination of initial stiffness in situ by seismic cone piezometer (SCPTU) and P-S logging and in the laboratory by use of advanced tests like the resonant column test and the bender element add on to triaxial tests. The knowledge on stiffness degradation can be derived from in situ pressuremeter tests and testing in the laboratory by use of resonant column tests and direct simple shear tests.

An onshore research campaign has been carried out to investigate the use of a cone pressuremeter (CPM), a CPTU with a pressuremeter module, with the objectives of investigating its practical application and benchmarking its results to the self-boring pressuremeter (SBP) and advanced laboratory tests. With the assumption that G_0 is known from other in situ tests (e.g. SCPTU) the applicability of the CPM for offshore use is explored. This assessment also assumes the requirement to deploy the CPM in seafloor mode to maximise the associated operational benefits.

2 BACKGROUND

The concept of mounting a pressuremeter module behind a cone penetrometer was first applied in the early 1980s. Jezequel et al. (1982) developed

a pressio penetrometer for shallow offshore surveys. The device had a diameter of 89 mm and was installed using a vibrating hammer device. Robertson et al. (1984) placed a 60° solid cone on to the base of a 75 mm diameter SBP. Due to the large diameter of these devices, special equipment was required for their installation. The pressuremeter data proved to be successful for the design of laterally loaded piles.

These early devices were superseded by smaller diameter devices known as CPMs, which comprised of a pressuremeter module mounted behind a standard electrical cone penetrometer. These devices could be installed by CPTU jacking equipment, either cone truck or seafloor frame, and enable pressuremeter tests to be performed as part of the CPTU operations. The first CPM, for which the most results have been published, was designed and built by Cambridge In Situ, originally to a specification of Fugro Netherlands. This device was described by Withers et al. (1986) and has been slightly modified afterwards to improve the operation.

Considerable research and development was carried out on the use of the CPM and the interpretation of the results in the late 1980s and the 1990s. Work was carried out by Powell & Shields (1995) and others. Over the last 20 years the CPM has not been used so much but its use may prove useful in the near future with an application in offshore wind foundation design.

3 TESTING

3.1 *Equipment and method*

The CPM considered here (Figure 1) comprises of a cylindrical 47 mm diameter pressuremeter module placed behind either a 46.7 mm diameter (15 cm²) or a 36 mm diameter (10 cm²) instrumented CPTU cone. This configuration can record live data during penetration through the soil, as well as being able to undertake a pressuremeter test and dissipation test when pushing is temporarily paused.

Figure 1. CPM equipment.

The combined CPM module is approximately 1.30 m in length. It has a central expanding section which is covered by a tough rubber membrane 250 mm in length and its centre point being 630 mm behind the instrumented cone tip. The expanding section can be pressurised internally by oil using a manual hydraulic pump or compressed air using cylinder stored gas and a manual control unit. Oil is typically only used for marine surveys, whereby the

complex internal electronics are more protected from the ingress of saltwater in the event of a membrane burst.

Testing is generally carried out in accordance with ISO 22476-6. Pressure applied to the inside of the instrument forces the membrane to expand against the test pocket wall. The radial displacement of the inside boundary of the membrane is measured at three points equally distributed at 120° around the centre of the expanding section by free moving arms. This displacement and the pressure necessary to cause the movement is continuously monitored by electronic transducers contained within the instrument.

Testing trials were performed in the field with the CPM either by pushing the instrument in from ground level, or by undertaking a pre-push using a 63 mm diameter dummy cone to approximately 1.00 m above each pressuremeter test depth. The CPM was inserted using a 20 tonne track mounted CPTU rig with 36 mm diameter push rods. The rods were then released from the top drive hydraulic pushing clamps at which point a pressuremeter test was simultaneously initiated. The pressuremeter tests were carried out in a nominal stress-controlled manner using a manually operated gas control box to pressurise the instrument at an appropriate rate for the ground conditions.

During the tests a number of pressuremeter unload-reload loops were performed in order to provide data for determining shear modulus. Loading was continued until uneven expansion around the probe occurred such that the operator deemed the risk of damage to the probe via a membrane burst too high if loading was continued, or the strain capacity of the CPM was approached, typically around 60 %. Upon full unloading and deflation of the membrane, the dissipation test was terminated, and the CPM was either pushed to the next pressuremeter test depth further down or withdrawn from the ground.

The CPM is classed as a full displacement pressuremeter as it increases the state of stress in the test material as it is inserted. The early stages of the pressuremeter test should therefore always be treated with a degree of caution as the material has already been partially disturbed from its original state.

The SBP used (Figure 2) for comparison purposes to the CPM comprises of a cylindrical instrument with an integral cutter, of the same diameter as the main body of the instrument, that is drilled into the ground using a top drive rotary drilling rig. The rotary rig provides rotation to the SBP cutter through RW size 27.8 mm diameter inner rods and thrust to advance the pressuremeter via non-rotating 50.8 mm diameter outer rods. Water or drilling mud is flushed by the rig pump down the inner rods and returns up through the annulus between the inner and outer rods to remove the cuttings and provide lubrication and cooling to the cutter. The outside of the pressuremeter remains in contact with the ground relatively undisturbed during insertion.

Figure 2. SBP equipment.

The SBP probe is approximately 1.20 m in length. It has a central section 493 mm in length covered by a rubber membrane. Pressure applied to the inside of the instrument, via compressed air, forces the membrane to expand against the test pocket wall.

The larger diameter of the SBP (63.1 mm) compared to the CPM (47 mm) means that the radial displacement of the inside boundary of the membrane can be measured by six free moving arms, equally distributed at 60° around the centre of the expanding section. Analysis using a greater number of measured points generally increases the reliability of pressuremeter test results. The radial displacement and pressure necessary for the expansion of the membrane are continuously monitored by transducers contained within the instrument body.

The SBP is also equipped with pore water pressure transducers, which are opposite facing, positioned at the midpoint of the membrane.

3.2 Site details and scope

Trials were performed with the CPM at two test sites with ground conditions similar to some commonly encountered at offshore wind farm developments.

The first site was located in Cowden, England and was selected to test overconsolidated clays within glacial tills. Groundwater level was estimated to be at 3.0 m below ground level (bgl) based on piezometer readings and CPTU dissipation tests. In total seven pressuremeter tests were performed using the CPM at three locations between 6.7 m bgl and 18.2 m bgl. For comparison purposes, a further seven pressuremeter tests were performed using the SBP at two locations between 7.0 m bgl and 18.7 m bgl. In addition, borehole samples were taken to perform a suite of laboratory testing for classification of the site and further comparison to the CPM.

The second site was located in Cuxhaven, Germany and comprised mainly of medium dense to very dense fine to medium sands. Groundwater level was estimated to be at 2.75 m bgl based on falling head tests in standpipes with time (slug tests). At this site six pressuremeter tests were performed using the CPM between 3.0 m bgl and 7.0 m bgl at three locations. A further six SBP tests were performed at three locations between 3.0 m bgl and 7.5 m bgl.

4 RESULTS AND ANALYSIS

4.1 Reliability of test data

The maximum distances between CPM and SBP test locations at both sites are summarised in Table 1.

Table 1. Maximum distance between CPM locations, between SBP locations and between all (CPM and SBP) locations.

Site	CPM only	SBP only	All
Cowden (CO)	2.8 m	1.5 m	5.0 m
Cuxhaven (CU)	1.5 m	3.0 m	5.0 m

For each site, the cone resistance (q_c), sleeve friction (f_s) and penetration pore water pressure (u_2) profiles with depth at each CPM location were compared to evaluate the similarity of soil conditions, as shown in Figure 3 and Figure 4. Pre-pushing was performed using a dummy cone, at Cowden to 15.1 m bgl and 15.5 m bgl for Tests CO-CPM-1A and CO-CPM-2A respectively and at Cuxhaven to 3.9 m bgl for Test CU-CPM-1, so it was not possible to compare these CPTU profiles to the others. Overall the ground conditions were comparable for the two sets of tests and hence not considered a major uncertainty for evaluating the repeatability of the CPM test results.
Figure 3. CPTU profiles with depth at CPM positions for the Cowden site.
Figure 4. CPTU profiles with depth at CPM positions for the Cuxhaven site.

For the interpretation of stiffness degradation, average arm displacements from the CPM and SBP data were used as per standard practice. A review of the datasets confirmed that average arm displacements were generally representative of the response for each individual pressuremeter arm with applied pressure. Examples of this are shown in Figure 5 for the CPM and Figure 6 for the SBP for Cowden.
Figure 5. Comparison of individual and average arm displacements for a representative CPM (CO-CPM-1A, 15.5 m bgl).
Figure 6. Comparison of individual and average arm displacements for a representative SBP (CO-SBP-1, 15.5 m bgl).

The repeatability of the applied pressure versus average arm displacement plots was reviewed to further evaluate the reliability of the data. Examples from Cowden are shown for pairs of CPM tests and pairs of SBP tests at similar depths in Figure 7 and Figure 8 respectively.

The 'lift off' pressures at the start of the CPM tests in Figure 7 were within approximately 10 % of each other. This was also found to be the case for the other pair of CPM tests available at Cowden. The difference in maximum pressure at the end of the two pairs of CPM tests were 3 % and 8 % respectively. For Cuxhaven, three pairs of CPM tests were available for comparison and the difference in 'lift off' pressures typically differed by approximately 200 kPa to 300 kPa and maximum pressures differed by between approximately 10 % and 35 %.

The only pair of SBP tests available from Cowden were within 7 % of the maximum pressure of each other while there was a nominal difference in 'lift off' pressures. Unfortunately, the SBP tests performed at Cuxhaven were significantly influenced by disturbance of the test pocket.
Figure 7. Comparison of applied pressure versus average arm displacement for CPM tests.
Figure 8. Comparison of applied pressure versus average arm displacement for SBP tests.

An additional comparison was made for CPM tests from Cowden with historical CPM tests at similar depths performed by Building Research Establishment (1996) where ground conditions were broadly similar enough for comparison purposes. It was found that plots of applied pressure versus average arm displacement were consistent between the two sites.

Finally, applied pressure versus average arm displacement plots for CPM tests were compared to SBP tests at the same depth to benchmark the CPM data against the SBP data. An example from Cowden is shown in Figure 9.
Figure 9. Comparison of applied pressure versus average arm displacement for CPM and SBP tests.

It was consistently observed across both sites that the CPM recorded a higher 'lift off' pressure and maximum applied pressure than the SBP, as was reported by Powell & Shields (1995). As the CPTU displaces

the surrounding soil during penetration before the pressuremeter test is performed, the applied pressure at a given displacement is higher than would be expected for the in situ conditions. In theory the SBP insertion method does not displace any soil and hence in situ conditions should not be disturbed, however in practice this requires a high degree of operator control, and so may be considered a disadvantage compared to the CPM. It was observed from the results of Cuxhaven that inserting the SBP in coarser grained soils is very challenging. These differences in measurements between the CPM and SBP may influence the reliability of other interpreted parameters but not the G/G_0 curves.

4.2 Stiffness degradation

Shear modulus was interpreted from the average gradient of the unload-reload loops performed during each CPM and SBP test using Bolton and Whittle (1999).

At Cowden interpreted shear modulus with shear strain was very similar for unload-reload loops from the same CPM test, and for pairs of CPM tests at the same depth. Figure 10 shows three stiffness degradation curves per pressuremeter test derived from the three corresponding unload-reload loops performed (loop 1-3). Very good repeatability was seen for loops from three pairs of CPM and SBP tests at similar depths. A fourth pair at 15.5 m bgl (CO-CPM-1A and CO-SBP-1), had very similar stiffness degradation profiles to CO-CPM-1A at 17.0 m and CO-SBP-1 at 17.7 m bgl. The only instance with poor repeatability was at 7.0 m bgl comparing CO-CPM-1 to CO-SBP-1, where the latter experienced leakage of the pressuremeter membrane.
Figure 10. Comparison of shear modulus versus shear strain for CPM and SBP tests at the Cowden Site.

Figure 11 shows that at Cuxhaven the repeatability of unload-reload loops from the same CPM test was still good, except for CU-CPM-2 at 5.5 m bgl. However, repeatability between loops from different CPM locations at the same depth and between loops from CPM and SBP locations at the same depth were comparatively poorer than at Cowden, with stiffness at a given strain differing by up to a factor of two approximately. The difference in performance at the two sites was deemed to be influenced by the quality

of the CPM test pocket that could be achieved in this instance, where considerable disturbance was observed for the coarser soils.
Figure 11. Comparison of shear modulus versus shear strain for CPM and SBP tests at the Cuxhaven Site.

For use in the design of laterally loaded foundations, shear modulus versus shear strain is normalised by G_0. As an example, data from Cowden was normalised using G_0 values from laboratory bender element and resonant column tests. The outcome was compared to historical pressuremeter and laboratory data presented by Powell & Butcher (2003) as shown in the example in Figure 12. Good agreement was found between the Cowden CPM data and the historical pressuremeter data. Relationships proposed by Vucetic & Dobry (1991) and Hardin & Drnevitch (1972) were not found be good fits.
Figure 12. G/G_0 from CPM and resonant column tests at 15.5 m bgl compared with data from Powell & Butcher (2003).

In practice the sensitivity of the measurement by the pressuremeter arms are considered accurate only to 0.01 % shear strain. However, the interpreted curve has been presented to 0.001 % shear strain for information and does not appear unreasonable compared to resonant column data. Verification work is needed to confirm if the method for establishing the

G/G$_0$ curve is representative of the lateral deformation experienced by the monopile.

5 APPLICABILITY FOR OFFSHORE USE

The CPM pressuremeter module is primarily designed for testing in superficial deposits, such as loose to medium dense sands and soft to very stiff clays. The CPM was found to be easily susceptible to damage if pushing through dense granular material or till deposits containing coarse gravel or cobble size fragments. In general, it is not recommended to advance the instrument in its current design through granular material that is dense to very dense (q_c > 18 MPa), or very high strength cohesive material (typically q_c > 4 MPa), as there is increased risk of damaging the membrane, or in the worst case bending the instrument body. Pre-pushing using a dummy cone was often required to advance the instrument to the required test depths, however this will not be practical for offshore testing.

For deployment offshore in seafloor mode, the body of the instrument would require strengthening and the electronics module made more robust with improved watertight sealing. The deployment and operation of the instrument would also need careful consideration if it is to be combined with currently available seafloor pushing systems, especially the control umbilical and instrument inflation system.

6 CONCLUSIONS

CPM tests have been carried out at two very different sites to investigate the use of the add on tool.

Analysis of the obtained stiffness results for over-consolidated clays showed very good repeatability in the CPM tests, and a direct comparison of the results from CPM and SBP tests showed good compliance for the unload-reload loops.

CPM testing in medium to very dense sands showed a fair repeatability for stiffness based on unload-reload loops from the same CPM test but much less so when loops were compared from different locations. The granular nature of the soils presented operational challenges with forming the test pocket which affected test quality and generally being able to insert the CPM in these soils.

The two sites that were tested represent the typical range of fine to coarse soils encountered offshore. The equipment presently available for CPM testing appears to be susceptible to damage in these soils and measures to ease the penetration (i.e. use of dummy cone) would not be compatible in seafloor mode. Thus, there is potential for further exploring the instrument and its development, including increasing its robustness.

A G/G$_0$ curve has been established from CPM and laboratory tests at Cowden and comparison with historical data shows a very good compliance, though deviating from the general relationships proposed in literature. Overall, the results show the potential of the CPM for offshore wind turbine foundation design. Further investigation and validation of reliable G/G$_0$ curves from the CPM when combined with other in situ tests used to estimate G$_0$ may help mature the CPM for this application in the future.

ABSTRACT: The *p-y* load transfer method is the most widely used for the design of monopile foundations. Recently, many CPT based *p-y* models were proposed experimentally or numerically to overcome the uncertainty in deriving stiffness and strength parameters of soil from in-situ testing. This paper aims to evaluate the performance of existing CPT based *p-y* models for predicting the monopile behavior, by conducting a series of centrifuge tests in dense Geba sand. Four different diameter (D = 0.9 m, 1.8 m, 1.25 m and 2.5 m) monopiles with two aspect ratios (L/D) of 3.6 and 5 were studied. The lateral load was applied at two different loading eccentricities of 0.67L and L above the ground surface. It was found that the model of Novello (1999) model gave the best overall prediction (at both small and large deflection) for the tests in this study, while the model of Dyson and Randolph (2001) model always underestimate the pile response. Compared with the Novello (1999), the model of Suryasentana and Lehane (2014) and Li et al. (2014) will overestimate the pile response at large deflection, but, can well predict the pile response at small deflection. In all cases, the API *p-y* model significantly overestimates the response with a factor more than 2. The experimental observations in this study proves the feasibility and reliability of developing CPT based *p-y* model for monopile.

1 BACKGROUND

For a typical wind farm, the foundations can take up more than 30% of the total cost and play an important role in the economic feasibility of the whole project (Byrne et al. 2015). Due to large horizontal forces and overturning moments from the wind, wave and currents, the lateral response of foundations is the key factor in the design. Among all the foundation types, monopiles are the most preferred for supporting offshore wind turbines (OWTs) and have been used in around 80% of total installations in Europe (Ramírez et al. 2020). The loads on OWT's in typical water depths of 10 to 40 m and in the dense sands found in offshore areas of Europe can be effectively resisted by large diameter (D) monopiles with low aspect ratios (L/D, where L is embedded length of monopile). The diameters of monopiles installed in Europe are usually larger than 6 m and the aspect ratios are less than 8. Meanwhile, monopiles with diameter of 10 m and aspect ratio of 3 are under consideration for the turbine with larger capacity in deeper waters (Kirkwood 2016, Negro et al. 2017).

Among all the existing methods for the design of a laterally loaded pile, the *p-y* load transfer method is

the most widely used. In this method, the monopile is modelled by a series of beam elements while the soil is represented by a series of non-interacting, non-linear springs distributed along the pile. The *p-y* curves are used to represent non-linear relationships between the net soil resistance (p) at a given depth per unit length and the lateral deflection of a pile at that depth (y) (Suryasentana & Lehane 2014).

The *p-y* model in current design guidelines API (2011) and DNV GL (2014) was originally proposed by Reese et al. (1974) based on a series of field tests and has been used successfully in the oil and gas industry for many decades. However, extensive studies have reported that the API *p-y* model is not suitable for the design of large diameter monopiles (Doherty & Gavin 2012). Furthermore, the API (2011) uses the friction angle (ϕ') of a soil as the only input to define the *p-y* curves. In real projects, empirical correlations with in-situ test results (e.g. CPT, SPT) are used to determine the sand friction angle. The uncertainties in those empirical correlations will further exacerbate the method's already high sensitivity to the chosen ϕ', leading to the unsafe design of the foundation.

To avoid difficulties in selecting appropriate strength parameters and to properly model in-situ

soil complexity, several researchers have suggested ways of using the tip resistance (q_c) from the cone penetration test (CPT) to determine the relationship between the soil resistance and the lateral deflection of a pile. Such approaches have the advantage that they are direct methods that are not susceptible to the subjectivity associated with the inference of friction angle values (Suryasentana & Lehane 2014).

Although many CPT based p-y models were proposed for the laterally loaded piles in sand, no systematic studies were performed to quantify the accuracy of the models for predicting the response of monopiles. In this study, a series of centrifuge tests in dense Geba sand were performed on monopiles with a wide range of configurations. The newly developed mini-CPT at TU Delft centrifuge lab was used to obtain the q_c profiles of the test samples. Beam simulations were performed using the existing CPT based p-y models and the API model. The performance of existing CPT-based p-y models is systematically evaluated.

2 CPT BASED P-Y MODELS

Salgado & Randolph (2001) performed a series of numerical analysis and concluded that the cone tip resistance depends both on horizontal stress, the sand friction angle and the sand's stiffness characteristics. Similarly, the behaviour of laterally loaded pile is also governed by the horizontal soil stress, the sand friction angle and the sand's stiffness characteristics. Therefore, it is possible to correlate the p-y curve of laterally loaded monopile with the measured in-situ cone tip resistance (q_c) of cone penetration test (CPT) (Suryasentana & Lehane 2014).

Novella (1999) and Dyson & Randolph (2001) performed a series of centrifuge tests on piles driven in calcareous sand and proposed the first power-law CPT based expression for p-y curves. Although the proposed formulation provided reasonable fits to the experimental data from which they were derived, the applicability of these expressions to the large diameter monopile is not clear. Li et al. (2014) performed six static lateral loading field tests and proposed an updated power-law model for piles driven in siliceous sand. Recently, Suryasentana & Lehane (2014) performed systematically analysis on monopile in homogeneous soil by three-dimensional finite element model. A nonlinear elasto-plastic soil model was adopted to simulate the behavior of sand. The corresponding cone tip resistance of CPT profile was derived numerically using a cavity expansion simulation. Parametric studies were conducted to investigate the influence of cross section shape, pile diameter, pile bending stiffness and soil non-homogeneity. An exponent CPT-based p-y formulation was then proposed and validated by full-scale field tests.

Compared with the power-law model, the exponent function can capture the ultimate limit resistance of pile at large deflection. Details of each CPT based p-y model are summarized in Table 1. As shown in the table, except Suryasentana & Lehane (2014), all the other p-y models adopted the power-law function, which means that the soil resistance (p) will keep increasing with pile deflection (y). Furthermore, it can be seen that in all the models, the soil resistance (p) is related to the q_c by a power of around 0.7 (0.67-0.72).

Table 1. Existing CPT-based p-y models.

Reference	CPT-based p-y model
Novello (1999)	$p = 2D(\sigma_v')^{0.33}(q_c)^{0.67}\left(\frac{y}{D}\right)^{0.5}$

Suryasentana and Lehane (2014)	$p = 2.4\sigma_v' D\left(\frac{q_c}{\sigma_v'}\right)^{0.67}\left(\frac{z}{D}\right)^{0.75}$ $\left(1 - exp\left(-6.2\left(\frac{z}{D}\right)^{-1.2}\left(\frac{y}{D}\right)^{0.89}\right)\right)$
Li et al. (2014)	$p = 3.6D(\gamma'D)\left(\frac{q_c}{\gamma'D}\right)^{0.72}\left(\frac{y}{D}\right)^{0.66}$

3 CENTRIFUGE MODELLING

All of the centrifuge model tests in this study were carried out at the Geo-engineering Section of TU Delft using the beam centrifuge with a nominal diameter of the rotating arm of 2.5 m. The centrifuge is capable of performing tests at a maximum acceleration of 300g with the maximum carrying capacity of 30 kg (Zhang & Askarinejad 2019).

A total of seven monotonic lateral loading tests were performed in this study at two different centrifugal accelerations of 50g and 100g. Two model piles with diameter of 18 mm and 25 mm were used to model the prototype monopile foundations with diameters of 0.9 m and 1.25 m at 50g and 1.8 m and 2.5 m at 100g, respectively. The two model piles were made of aluminum pipe with the elastic modulus and a poison's ratio of 71.7 GPa and 0.33, respectively. The wall thickness of 18 mm and 25 mm diameter piles are 1 mm and 1.5 mm, respectively, so as to meet the equivalent section bending stiffness of typical monopile in offshore wind projects (Negro et al., 2017). Most existing monopile foundations in offshore wind farms have an aspect ratio of less than 5. Therefore, two aspect ratios of 3.6 and 5 were investigated in this study. Considering the large overturning moment on offshore wind turbines, the lateral load was applied at two eccentricities of $0.67L$ and L above the ground surface. Details of the test program are summarized in Table 2.

Table 2. Centrifuge test program.

NO.	Acceleration	D^* (m)	L/D	e/L
1	50	0.9	5	0.67
2	50	0.9	5	1.0
3	100	1.8	5	0.67
4	100	1.8	5	1.0
5	50	1.25	3.6	0.67
6	100	2.5	3.6	0.67
7	100	2.5	3.6	1.0

Note: * denotes the pile diameter at prototype scale.

All the tests were performed in dry Geba sand with a relative density of 80%. The sand is sub-angular to sub-rounded, with a median grain size (d_{50}) of 0.11 mm. The maximum and minimum void ratios are 1.07 and 0.64, respectively. The sample seabed was prepared by first "raining" the sand from a sand bucket with holes at a pre-calibrated height and then vibrate to densify it to the target density. To obtain the q_c profile of the test sample, a mini-CPT was developed at TU Delft. Figure 1 shows a sketch of the developed mini-CPT at TU Delft centrifuge lab. As shown in the figure, the penetrator has a diameter of 7.5 mm with a standard 60 degrees cone tip. The cone tip is made of steel and connected with a steel inner rod. The inner rod has a diameter slightly smaller than the outer tube. A Teflon ring is installed between the inner rod and the outer tube, allowing to constrain the verticality of the rod without applying additional friction force.
Figure 1. Sketch of the mini-CPT.

During the test, the soil pressure acting on the cone tip will be transferred to the inner tube and measured as a total force by the load cell connected with the inner tube. The load cell has a measurement range of 2.65 kN, which is equal to a tip resistance (q_c) of 60 MPa. The whole penetrator is designed in a modular mode, which allows for changing the component independently based on the requirement of the tests. The penetrator has a maximum depth of 150 mm, which is equivalent to a depth of 7.5 m and15 m in prototype at a centrifuge acceleration of 50g and 100g, respectively. The mini-CPT can be easily installed on the 2D loading actuator. Photos of the mini-CPT installed on the actuator and the sample surface after the penetration are presented in Figure 2.
Figure 2. Photo of the mini-CPT.

In lateral loading tests, the two-dimensional (2D) servo actuator is used to apply lateral loads on the pile head. A specially designed loading head was designed to allow loading the model pile without inducing any rotational fixity. The loading head is connected with a beam-type loading cell, which monitors the applied force. Displacement potentiometers were also installed to calculate the pile deflection at loading point.
Figure 3. A typical model setup for the lateral loading test.

4 INTERPRETATION OF RESULTS

In the following sections, all results are interpreted in prototype scale, unless stated otherwise.

4.1 Q_c profiles from mini-CPT

Figure 4 shows the typical q_c profiles of the test sample at the centrifugal acceleration of 50g and 100g. In each sample, CPT tests with different distances between two penetrations and different penetration velocities were performed. It was found that a distance of around $13D_{CPT}$ (D_{CPT} is the diameter of the mini-CPT) is required to eliminate the boundary effect or any interaction between penetrations. In addition, since the tests are in dry sand, no rate effect is observed. The q_c profiles in Figure 4 are from tests in the same sample but at different locations. Based on the excellent consistency of the results, it can be concluded that the sample preparation method used in this study is reliable and repeatable. The prepared sample is very uniform.
Figure 4. q_c profiles from mini-CPT: (a) tests at 50 g; (b) tests at 100g.

4.2 Measured and computed pile response

Figure 5 presents measured load-deflection curves at the loading point for all the tests in this study. As shown, the reaction force of model pile increases with the pile deflection with no sign of reaching the ultimate capacity. This hardening response of monopile in sand has been widely reported in other studies. In the same figure, the computed response with the API p-y model and the existing CPT based p-y models were also included. It can be seen that in all the cases, the API model will significantly

overestimate the pile response, especially at small deflection. According to the DNV GL (2014), the maximum allowable rotation of the offshore wind turbine is 0.5 degrees, which equivalent of a pile head deflection of around 0.14 m for the
1.8 m diameter pile tests in this study. As shown in Figure 5a and 5b, in this deflection range, the pile response can be overestimated by a factor of more than 2 for the API model. However, it should be noted that due to the hardening behaviour of mono-pile, as shown in Figure 5a-5g, the API p-y model tends to underestimate the ultimate lateral capacity of the monopile.
Figure 5. Measured and computed pile response.

Compared with the API model, the CPT based p-y models generally give better prediction of pile response, except for the model of Dyson & Randolph (2001), which will always underestimate the pile response. This may be caused by the way of incorporating the vertical stress in the model. As shown in Table 2, in the model of Dyson & Randolph (2001), the q_c is normalized by the vertical effective stress (σ'_v). Compared with the power coefficient of around 0.33 in Novello (1999)'s and Suryasentana & Lehane (2014)'s model, p-y curves in Dyson an&d Randolph (2001) is related to the vertical effective stress (σ'_v) by a power coefficient of -0.72, which will cause the reduction of soil resistance compared to Novello (1999) and Suryasentana & Lehane (2014).

Among all the CPT based p-y models, the Novello (1999)'s model gave the best overall prediction for the series of tests in this study at both small and large pile deflection. On the contrary, the model of Suryasentana & Lehane (2014) and Li et al. (2014) can capture the pile behaviour at small deflection, but will overestimate the pile response at larger deflection. It is believed that the inaccuracy of Li et al. (2014)'s model should be related to the insufficient consideration of the influence of vertical stress and depth. As shown in Table 2, Li et al. (2014)'s model is defined mainly by pile diameter without considering the vertical effective stress (σ_v'). As for the Suryasentana & Lehane (2014)'s model, the overestimation may be attributed to the inaccurate input of the ultimate soil resistance used in the model, since the pile deflection in simulations of Suryasentana & Lehane (2014) are less than 10%D. The ultimate soil resistance was not reached in most cases.

Although the model of Novello (1999) gave best prediction in this study, it should be noted that the power-law function used in the model will eventually overestimate the pile ultimate capacity since the soil resistance (p) will keep increase with pile deflection (y) in the power-law function. On the other hand, the exponent function used in Suryasentana & Lehane (2014) has the feature to reach an ultimate value at large deflection. Based on the experimental observation from this study, it is recommended to combine the Novello (1999)'s model into the Suryasentana & Lehane (2014)'s model in the future study or even using a different function as the back-bone curve, for example, the hyperbolic function and hyperbolic tangent function.

5   SUMMARY

A series of centrifuge CPT tests and monotonic laterally loaded pile tests in dense Geba sand were performed in this study. Performance of the API p-y model and the existing CPT based p-y models were systematical evaluated. Based on the experimental observation, following conclusions were drawn:

1. The newly developed mini-CPT at TU Delft centrifuge lab can provide reliable q_c profile of the test sample. For the Geba sand used in this study, a distance of $13D_{CPT}$ (D_{CPT} is the diameter of the mini-CPT) is required to eliminate any boundary effect or interaction between penetrations.

2. The API p-y model significantly overestimate the pile response in all the tests, especially at the small pile deflection with a factor more than 2. But at large deflection, due to the hardening response of monopile in sand, the API p-y model tends to underestimate the ultimate lateral capacity of monopile.

3. All the CPT based p-y models, except Dyson & Randolph (2001)'s model, can give better prediction than the API model. The model of Dyson & Randolph (2001) underestimate the pile response due to the inaccurate consideration of the vertical stress (σ'_v).

4. The Novello (1999)'s model gave the best overall prediction for the series of tests in this study at both small and large pile deflection. On the contrary, the Suryasentana and Lehane (2014)'s and Li et al. (2014)'s model can only capture the pile response at small deflection. The inaccuracy of Li et al. (2014) may be caused by the insufficient consideration of the vertical effective stress in the model, while the overestimation of Suryasentana & Lehane (2014) is attributed to the inaccurate input of the ultimate soil resistance.

5. The experimental results in this study proved the feasibility of using the CPT based p-y model in monopile design.

However, it should be noted that the experimental observation is only limited to the specific pile configurations and the uniform dry sand in this study. More studies should be performed in the future on additional model piles and in different sands or layered soils to develop the CPT based p-y models with general applicability.

ABSTRACT: A series of CPT and skirt penetration tests have been conducted in carbonate silty sand in a range of drainage conditions ranging from fully drained to fully undrained. The drainage transition response for each has been quantified in order to provide guidance in how to use the results from field CPTs to predict soil resistance during the installation of skirted foundations.

1 INTRODUCTION

1.1 *Background*

Skirted foundations are a type of shallow foundation featuring vertical plates ('skirts') that extend up to beneath the underside of the foundation. They are frequently used offshore to secure subsea infrastructure to the sea floor. They are popular because they are installed by being simply craned onto the seabed where the self-weight of the structure pushes the skirts into the seabed. The skirts provide higher foundation capacity by contributing to sliding resistance (through the additional passive resistance that develops at the skirt face) and by moving the failure mechanism deeper in the soil, often mobilising higher soil strength. Reviews of their role in increasing foundation capacity are provided in Murff & Millar (1977) and Bransby et al. (2017). The skirts can also add some addition scour protection to the structure by delaying undermining. In carbonate silty sand conditions the skirts are kept short (e.g. often 200-300 mm long) because of the high seabed strength gradient.

Ease of installation leads to short installation durations and consequently a cheaper foundation solution because it requires less vessel time, but relies on the self-weight of the structure being sufficient to install the skirts. However, the approach requires confident prediction of maximum likely seabed resistance to skirt penetration whereby an overestimation of the resistance may result in unnecessary ballast increasing project outlay, whereas an underestimation may pose a risk of early refusal during installation requiring expensive mitigation (Bransby et al., 2015).

The most common design method utilises inputs direct from cone penetrometer tests (CPTs) in the depth range of the skirt length (which may be as small as 0.2 m in coarser-grained seabeds). In particular, skirt tip resistance, q_b (= total base resistance, Q_b divided by skirt base area, A_b) is linked empirically with net cone resistance, q_{net}, so that $q_b = \beta \, q_{net}$ although there is some dispute on the particular value of scaling factor, β, to use, particularly in carbonate soils. This uncertainty is further exacerbated when the soil drainage conditions during cone penetration may be different to those during installation of the skirted foundation. In addition, skirt skin friction, q_s (= total skirt resistance through interface shear, Q_s divided by skirt area, A_s) can be either related directly to CPT sleeve friction, q_s or empirically to net cone tip resistance, q_{net}.

The aim of the work reported here is to improve understanding of the relationship between skirt tip resistance and net cone resistance for a carbonate silty sand. This was achieved through a series of laboratory tests in which model scale CPTs and skirt penetration tests were undertaken using a carbonate silty sand taken from the North West Shelf of Australia. Samples were prepared at a density typically found on the seabed and probed with cones and skirts at a range of velocities from virtually drained to undrained (spanning an approximately four order of magnitude velocity range). Because of the shallow depth of interest (say 0.2 m) and the small thickness of typical skirts (say 8 – 12 mm), the skirt tests were conducted at full-scale. Furthermore, the size of the skirts allowed skirt tip resistance to be measured separately from skin friction and thus permitted a comparison of each component to the CPT equivalents.

This paper first describes the soil, apparatus and testing performed before presenting the results from the experiments and describing their implications for design.

2 EXPERIMENTAL METHODS

2.1 Overview

Two samples of carbonate silty sand were prepared in sample containers ('strongboxes') of plan dimensions 650 by 390 mm and depth 325 mm. In these samples 10 mm diameter cone penetrometer and 2, 4, and 8 mm thickness skirt penetration tests were conducted at different rates.

2.2 Sample preparation

The soil used was a carbonate silty sand with a fines content of 44%, median grain size, d_{50} = 0.085 mm and a carbonate content of 92% (O'Beirne et al., 2020) and was sampled from the North West Shelf of Australia in approximately 100 m water depth. Sufficient material was available to make a sample of depth 220 mm in the selected strongbox.

A 20 mm layer of dense coarse sand was first placed at the base of the strongbox to create a drainage layer that was covered by multiple layers of geofabric to prevent loss of fines. The carbonate silty sand was mixed by hand to the targeted moisture content of about 45%), and placed in layers by hand into the strongbox. The strongbox was then moved to a large consolidometer and a vertical stress of 100 kPa was applied in one increment through a lid to the top surface of the sample and allowed to consolidate with the lid settlement monitored during consolidation. On reaching equilibrium the sample was unloaded to approximately 0 kPa and allowed to swell. This process was repeated twice, such that the sample experienced three cycles of loading to 100 kPa and back to 0 kPa before it was removed from the large consolidometer and equilibrated under self-weight ready for cone or skirt testing.

The above procedure generated a repeatable dense sample (of moisture content of approximately 36%) which is believed to be in a density state representative of wave-trafficked sediment on the North-West Shelf at about 100 m water depth. Consequently, skirt testing was performed at full scale, investigating the performance of the very short skirts which are typically used in carbonate silty sands and sandy silts on the North West Shelf.

2.3 Measurement of coefficient of consolidation

Measurement of the coefficient of consolidation of each sample is critical for generalising the results of the skirt penetration tests. Consequently, two different approaches were used to quantify the coefficient of consolidation. The first was interpretation of the oedometer-style results generated when loading and unloading the sample in the large consolidometer during sample preparation to obtain c_v, whereas the second was interpretation of u_2 pore pressure dissipation data during pauses in cone penetration to obtain c_h.

From the oedometer-type loading events the average value across the two samples was c_v = 84.5 m^2/yr. The CPT dissipation tests were conducted by penetrating the 10 mm piezocone described below at a rate of 64 mm/s to a depth of 120 mm and holding position whilst recording the u_2 pore pressure. Interpretation using the method of Teh & Houlsby (1991) gave an average value c_h = 100 m^2/yr.

2.4 Cone penetrometer tests

The cone penetrometer tests were conducted using a model scale (laboratory) cone penetrometer, with dimensions that are scaled down (by a factor of ~3.6) from the standard 10 cm^2 field geometry (ISO 2014). This resulted in cone diameter of 10 mm and sleeve length of 37.5 mm. The model cone measures tip and sleeve resistance through independent load cells, and pore pressure at the cone shoulder (i.e. at the u_2 position).

Tests were conducted using one of two electro-mechanical actuators. The first 'standard' actuator is capable of vertical penetration rates in the range 0.001 mm/s to 3 mm/s to reach a cone penetration depth of 185 mm, whereas the other 'high speed' actuator is capable of penetration rates up to 72 mm/s, but restricted, by travel limits, to a penetration depth of 120 mm.

The test programme included a range of different penetration rate CPTs from 0.003 mm/s with the standard actuator (which were conducted overnight) to
Figure 1. Instrumentation of the skirt tip. Strain gauges were placed on the webs.

64 mm/s with the high speed actuator (which took two seconds). The cone was extracted at 3 mm/s in all tests.

2.5 *Skirt penetration tests*

Skirts of four different thicknesses (2, 4, 8 and 12 mm) were fabricated from Grade 316 stainless steel, with dimensions listed in Table 1. These values were chosen to investigate the effect of thickness on installation resistance and cover practical skirt thickness ranges of 6 to 12 mm.

Table 1. Dimensions of the fabricated test skirts.

Skirt thickness t (mm)	2	4	6	8
Skirt breadth b (mm)	20	40	80	120
Skirt length L (mm)	400	400	400	400
Instrumented?	N	N	Y	N

Figure 2. Skirt testing apparatus.

The same roughness characteristics for all skirts was achieved by sand blasting each skirt. After treatment, an absolute roughness, R_a, of approximately 3 microns was measured for all skirts. Based on a series of 'sled' interface tests performed on the same soil by O'Brien et al. (2020), this interface roughness was expected to have a drained residual interface coefficient, μ between 0.55 and 0.6.

The 8 mm skirt features a strain gauged web zone immediately behind the skirt tip (see Figure 1), allowing direct measurement of skirt tip resistance. During testing, an S-shaped load cell was placed in-line between the actuator and skirt plate in order to measure the total soil resistance to skirt penetration (and so deduce the skirt friction alone by comparing this to the resistance measured by the skirt tip load cell).

Tests were conducted by starting the skirt tip immediately above the soil surface and penetrating the skirt into the seabed at a prescribed rate whilst logging the vertical load, vertical displacement and the skirt tip load cell (when relevant). The experimental apparatus during skirt testing is shown in Figure 2.

3 RESULTS: CONE PENETRATION RESISTANCE

Depth profiles of cone tip resistance for all the cone penetration tests are shown on Figure 3. Multiple tests were conducted at the faster velocities (> 1 mm/s) to investigate repeatability (which appears to be reasonable, see Figure 4), but only single tests were conducted at the slower rates of 0.003, 0.01, 0.03, 0.1 and 0.3 mm/s.

There is an approximately linearly-increasing tip resistance for the slowest (drained) tests so that q_{net}/σ'_v remains almost constant with a cone q_{net} gradient of about 2.2 MPa/m. This is a typical near-surface value in a medium dense carbonate sand deposit offshore.

In contrast, a maximum q_{net} is mobilised in about 3 or 4 cone diameters of penetration for the fastest tests and this resistance does not increase significantly with depth thereafter. This resistance was also associated with mobilisation of a maximum negative pore pressure, $u_2 = 30$ kPa after which the pore pressure did not decrease further. This limit may be due to an early mobilisation of a 'deep' mechanism in undrained conditions or because of generation of cavitation conditions.
Figure 3. Cone tip penetration resistance curves for CPTs conducted at a range of velocities.

The variation in cone tip resistance with penetration rate is examined in more detail in Figure 4, which plots the net cone resistance, q_{net}, divided by a reference net cone resistance, $q_{net,ref}$, (taken here as that during the slowest (0.003 mm/s) cone test) against the dimensionless velocity, vD/c_v (where $c_v = 84.5$ m^2/yr as noted earlier). Results are shown for a penetration depth, $z = 40$ mm (4D) and 100 mm (10D).

At both depths, results suggest that undrained conditions are achieved for all tests with $vD/c_v \geq 20$ (approximately consistent with Finnie and Randolph, 1994), Randolph & Hope (2003) and Silva & Bolton (2004), and there is no further change in net cone resistance with increasing velocity. A 10 cm^2 field cone conducted at 2 cm/s (as in the ISO standard condition) would generate $vD/c_v = 274$ in this soil sample and therefore measure undrained soil resistance.

The difference in q_{net} is small between the two slowest cone tests and suggests that close to drained conditions were achieved with $vD/c_v \leq 0.05$. This suggests a range of partially drained behaviour when $0.05 < V < 10$ giving a velocity range of 200 times.

The ratio of undrained to drained net cone resistance is approximately 12 and 6.5 at penetration depths of 4D and 10D respectively – both noticeably higher than for clays. A higher ratio at shallower depths is consistent with the previous observation that drained cone resistance is proportional to effective stress level (and hence depth), whereas undrained cone resistance reaches a maximum at shallow depth and then becomes approximately constant with depth.

The evolution of cone resistance with V can be described using a 'back-bone' curve of the form:

$$\frac{q}{q_d} = a - \frac{(a-1)}{\left(1 + (V/V_{50})^d\right)} \quad (1)$$

where $a = q_{ud}/q_d$, with the subscripts 'd' and 'ud' denoting drained and undrained resistances respectively. Eq. 1 adopts q rather than q_{net} to permit application to both the cone and skirt data. As applied to

the cone data, q denotes the net cone resistance, with the best agreement with the measurements obtained using $a = 12$, $d = 0.8$ and $V_{50} = 1.5$ at $z = 40$ mm, and $a = 6.5$, $d = 0.8$ and $V_{50} = 1.0$ at $z = 100$ mm.

4 RESULTS: SKIRT PENETRATION

Figure 5 shows depth profiles of total and tip resistance for the three skirt thicknesses from tests involving penetration velocities in the range 0.003 to 18.75 mm/s. For clarity, total and tip resistance for the 8 mm instrumented skirt is shown separately on Figure 5a, whereas only total resistance is available for the 2 and 4 mm skirts and so is plotted compared to the total resistance for the 8 mm skirts on Figure 5b.

For the slowest tests, the resistance is almost proportional to depth up to about $z = 160$ mm, beyond which the influence of boundary effects at the bottom of the box on the obtained results becomes apparent for the 8 mm skirt. Furthermore, for the slowest tests, the total resistance measured by the load cell located at the top of the skirt is very similar to the load measured by the tip load cell, implying a very small skin friction. In contrast, for the fastest test (18.75 mm/s) the total resistance is larger, varies non-linearly with depth and

Figure 5. Skirt penetration resistance curves for skirt tests conducted at range of velocities (selected tests).

Figure 4. Evolution of normalised net cone tip penetration resistance with dimensionless penetration velocity at depths of 40 mm (4D) and 100 mm (10D).

the skirt friction is approximately 25% of the tip resistance (i.e. $Q_s/Q_t \approx 0.25$). Intermediate Q_s/Q_t values are observed for the tests at intermediate velocities.

Skirt tip resistance (from the 8 mm skirt penetration tests), normalised by the value for the slowest test, is plotted against dimensionless velocity, V ($=vt/c_v$, where t is the skirt thickness) on Figure 6 for depths, z = 40 and 100 mm (i.e. at the same depths as the cone data on Figure 4). The variation in normalised skirt tip resistance with V is approximately similar to the equivalent for the cone (Figure 4): the resistance maximises at V > 10 and appears to be close to drained at V = 0.01; and the ratio of undrained to drained resistance is approximately 11 and 5 at depths of 40 mm and 100 mm respectively.

Figure 6 also includes skirt tip backbone curves using Eq. 1, where the best fit to the data was obtained using a = 5, d = 1 and V_{50} = 0.3 for z = 100 mm and a = 12, d = 0.6 and V_{50} = 0.4 for z = 40 mm. These parameters are summarised together with those for the cone on Table 2, and suggest that higher velocities are required to ensure no drainage occurs for shallower depths.

Figure 7 compares tests with different skirt thicknesses using total rather than tip resistance as the 2 and 4 mm skirts were too thin to instrument to measure tip resistance independently. To investigate scaling, the data from the different skirt thicknesses are plotted against velocity (v; in mm/s) on Figure 7a, normalised velocity (vt/c_v; dimensionless) on Figure 7b, and in normalised movement time ($T = c_v \cdot (z/v)/t^2$; dimensionless) on Figure 7c. As expected, faster velocities are required to achieve undrained conditions for the 2 mm skirt, although the vD/c_v normalisation shown in Figure 7b does not appear quite sufficient to explain the trend. The normalisation using dimensionless travel time gives an interesting relationship which warrants further investigation, but is not believed to provide sufficient evidence to overturn the expected vD/c_v drainage scaling.

	100	5	0.3	1.0

5 IMPLICATIONS FOR DESIGN

The results from both the CPTs and skirt tests are presented in dimensionless velocity space showing the transition in resistance from undrained and drained soil response. By considering the field drainage conditions for the two devices (which

depends on the coefficient of consolidation of the soil and the foundation set-down velocity), improved advice is given about how to predict skirt installation resistance from CPT results in the field.

Calculations were performed to quantify the scaling between the skirt tip resistance, q_b and cone tip resistance q_c (i.e. $\beta = q_b/q_c$) for skirts of thickness, $t = 12$ mm penetrated in soils with different coefficient of consolidation values at different velocities (Figure 8). It was assumed that a 10 cm^2 cone was penetrated at 2 cm/s as in ISO (2014). For fully drained conditions, the cone gradient was approximated to 2.2 MPa/m as measured for the slowest conducted cone, and the skirt tip penetration resistance gradient approximated as 1.8 MPa/m. Equation (1) and the parameters for $z = 100$ mm listed in Table 2 were used to describe the drainage backbone curves. Consequently, for every skirt velocity and c_v combination, the vt/c_v value for the skirt and the vD/c_v for the cone and the above information could be used to calculate β.
Figure 8. Required scaling factor β for soils with different c_v values for a skirt of 12 mm thickness penetrating at different velocities ($z = 100$ mm).

For high c_v values (for a coarse-grained soil), both the skirt penetration and cone penetration is drained and the drained ratio is 0.8 (i.e. the ratio of the cone tip and skirt tip resistance gradients = 1.8/2.2). In contrast, if c_v is very low (for a clay or silt), the soil around both the penetrating skirt and the penetrating cone is undrained and the ratio becomes equal to a constant undrained ratio, $\beta \approx 0.62$. These ratios are broadly consistent with shape factors describing the difference in bearing resistance for plane strain versus axisymmetric shallow and deep foundations in drained and undrained conditions.

However, if the soil has intermediate c_v (such as with a silty sand or sandy silt – or for a fast-penetrating skirt in sand) the cone may be drained (generating less tip resistance), but the skirt would be partially drained (with more resistance).

Consequently, the cone resistance has to be scaled up for these conditions because of the drainage difference.

Figure 8 shows calculated values of scaling factor, β, for a likely range of set-down velocities (0.05 m/s to 0.2 m/s) for a typical skirt thickness (12 mm). The curve suggests that if the soil c_v is not well known (and it is normal to have some orders of magnitue of uncertainty in c_v for these types of soil), that there may be a need to use a β value larger than 1 in order to capture the largest likely skirt tip resistance from the CPT data. Interestingly, however, a curve for a slower velocity (0.02 m/s) reveals that the system may self-correct – increasing resistance from higher velocity may reduce installation velocity and therefore reduce installation resistance. This is true for the dilatant response observed for the soil investigated here, whereas for a contractant response the soil resistances will increase as the skirt penetration velocity reduces, which may lead to premature refusal.

6 CONCLUSIONS

A series of full-scale skirt penetration experiments were conducted in a carbonate silty sand sample, in a density state typically found offshore, to investigate how seabed resistance varies with penetration velocity due to changing soil drainage conditions. By comparing the drainage transition curve for the skirted foundations with a separately measured curve for a CPT, recommendations were generated for scale factors to obtain skirt tip resistance from cone tip resistance. The calculations revealed that a larger than currently recommended value (of larger than 1) may be required for some intermediate soils where standard cone penetration rates lead to almost drained soil response, whereas likely skirt penetration velocities provoke partially drained or undrained response. Further work is required to generalise this behaviour.

ABSTRACT: The cone penetration test is the preferred tool for measuring the in-situ soil conditions for offshore wind farm developments. This preference stems from the consistent and reliable data quality, low relative cost, and speed of data acquisition which enables developers to characterise large areas with numerous structure locations to support foundation concept feasibility studies, installation risk assessments and geotechnical engineering analyses to optimise the foundation design by reducing the uncertainty in soil input parameters. However, the interpretation of CPT data is largely dependent on site-specific or published correlations, which can present challenges when relying on the CPT as the primary tool for stratigraphic profiling, interpretation of soil behaviour and for defining geotechnical parameters for engineering design. This paper presents recent developments and processes that enabled the delivery of an optimised CPT based geotechnical design basis for the Dogger Bank Wind Farm. The processes and tools that enabled this approach comprised a novel SI strategy, focussed CPT interpretation and CPT tool development. The strategic approach for the novel SI strategy is presented and the individual elements described. Challenges and limitations associated with the interpretation of CPT data are discussed, including size and scale effects, resolution, calibration with laboratory and large-scale field test data and rate effects. Finally, the challenges with using statistical methods to derive design values from CPT records are briefly discussed.

1 INTRODUCTION

The Dogger Bank offshore wind farm comprises three project areas (Dogger Bank A, B and C) within the Dogger Bank Offshore Development Zone, located 125 to 290 km off the east coast of Yorkshire, UK. The development zone covers ca. 8660 km² and water depths range from 18 to 63 m (Dogger Bank Wind Farm, 2022).

Dogger Bank has a complex geology, resulting from the different depositional environments and post-depositional processes that have formed it over the last 120 000 years (Cotterill, et al., 2017a & b). Dogger Bank is generally accepted to be a complex of highly deformed glacial till, created as the ice sheets from Britain and Scandinavia oscillated across the area, bringing eroded soils with them that were often left in ridges (terminal moraines) at the front of the ice. As the ice moved backwards and forwards these soils were "rucked up" forming features known

as push-moraines, which were then overridden and eroded by later glacial advances. Between these ridges shallow lakes developed. The soils are therefore typically non-sedimented and have been deposited and reshaped by a number of different environments ranging from tundra, permafrost, subglacial, pro-glacial - through to temperate - including lacustrine, fluvial and estuarine or lagoonal and to changes as the sea level rose and flooded the Dogger Bank about 7000 years ago. Thus, desiccation due to drying, evapotranspiration and freezing are considered to be important post-depositional processes in the geologic history of the Dogger Bank soils. The resulting variability in the soil conditions are significant for the ground investigations and the ensuing characteristic values of soil properties derived for geotechnical design of the monopile foundations. At Dogger Bank, seafloor CPTs were the primary intrusive ground investigation tool performed at each wind turbine generator (WTG) location. The CPT

data were a key input to the ground model developed for the site, which combined high quality 3D seismic profiling and targeted borehole locations from which site-specific CPT correlations were developed.

2 CHALLENGES AND LIMITATIONS ASSOCIATED WITH INTERPRETATION OF CPT DATA

The soils present at Dogger Bank are, in general, not classic sedimented clays and sands, or conventional glacial lodgement tills or glaciomarine tills. The Dogger Bank soils must therefore not be forced into a classical framework for sedimented soils nor the correlations that have been developed for such soils. It follows that a key challenge with the Dogger Bank site is the natural variability encountered in the geotechnical parameters, especially for the clays of the Dogger Bank Formation. This variability is primarily attributed to the different depositional environments and varying post-depositional processes to which the soils have been subjected, as discussed above. Consequently, the soils vary in composition (particle size distribution and plasticity), stress and strain histories, and in their current state (in situ stresses, density) and fabric. Coupled with this natural variability are possible sample disturbance effects (including effects of dissolved gas coming out of solution when sample is recovered to deck (Lunne et al. 2001), uncertainty with in situ stress conditions, limitations with laboratory testing, and scale effects. A further complication when using CPT data to develop site-specific correlations, is that these data are invariably noncoincident with the other test data used to develop the correlation. Examples of the variability in geotechnical parameters are given below.

For low to medium overconsolidation (OCR) ratio clays, it has been shown that the preconsolidation stress (p_c') assessed from oedometer tests usually correlates well with the undrained shear strength from anisotropically consolidated triaxial compression (CAUC) tests (s_{uC}), as shown in Figure 1. The post-depositional processes to which the Dogger Bank clays have been subjected have imposed stress histories that are very different to simple vertical loading, unloading and reloading. Consequently, very large scatter is evident in the $s_{uC} - p_c'$ dataset shown in Figure 1 for the Dogger Bank clays.

It should be emphasized that the p_c' and OCR values derived from oedometer tests performed on these soils are "apparent" values. Correlations developed from loading-unloading-reloading data, such as those linking p_c' and s_{uC} and those linking OCR and in situ horizontal stress (or the later earth pressure at rest, K_0), therefore do not apply to the Dogger Bank clays. As noted by Yetginer & Tjelta (2021), the inability to reliably estimate p_c', OCR and K_0 increases the uncertainty in laboratory test results for these soils.

Figure 2 presents plots of corrected cone resistance (q_t) versus depth for Upper Dogger Bank clay. The cone resistance data have been filtered to remove sand-like layers based on expected Soil Behaviour Type (SBT), however some spikes in the q_t data are still present. It is seen that q_t increases with depth, but that there is variability in the cone resistance. This variability leads to challenges and uncertainties when developing cone resistance based geotechnical parameter correlations.
Figure 1. Preconsolidation stresses from odeometer tests compared with undrained shear strengths from anisotropically consolidated triaxial compression tests (updated from DeGroot et al., 2019).

Figure 3 shows considerable variation of N_{kt}-factor versus depth (where $N_{kt} = q_{net}/s_{uC}$), despite efforts to filter the data based on sample quality and sampling techniques. Possible explanations for this scatter include:

1) The presence of fissures and planes of weakness in the clay fabric which influence the measured undrained shear strength.
2) Sample disturbance effects which are difficult to quantify in overconsolidated/non-sedimented clays and possibly includes dissolved gas coming out of solution.
3) Uncertainties in the selected q_t value due to non-coincident borehole and CPT data (i.e. the physical inability to measure q_t on the soil sample tested in the laboratory).
4) Limitations in laboratory testing procedures, including the inability to reliably estimate p_c', OCR and K_0, as noted previously.

3 EVOLVEMENT OF A NOVEL SOIL INVESTIGATION STRATEGY

Soil investigation (SI) for the Dogger Bank offshore wind farm has been conducted in three principal phases. These phases were not conceived entirely at the outset but developed organically to address arising challenges and constraints.
Figure 2. Corrected cone resistance versus depth for Upper Dogger Bank clay.

Phase I:
An initial phase with regional geophysical and geotechnical investigations (incorporating boreholes and CPTUs) and including study of geological information. All information was integrated into a regional ground model that was used for wind farm layout and foundation feasibility studies. Routines to provide "synthetic CPT data" from the ground model at untested locations were also developed (Forsberg et al. 2017).

Development of site-specific correlations between CPT data and geotechnical parameters started during this phase. Two of the most important challenges were:

1) Available seafloor CPT equipment did not give sufficiently deep penetrations for the expected monopile embedment's.
2) The "normal" approach of correlating corrected cone resistance (q_t) to undrained shear strength (s_u) resulted in exceptionally large scatter in the derived N_{kt} factors.
Figure 3. Example variation in N_{kt}-factor versus depth for clay from the Dogger Bank Formation.

Phase II
A hypothesis that the scatter in apparent p_c', s_{uC} and N_{kt} data is a function of sampling, testing, and/or scale (fabric) effects was tested by deployment of spudcan penetration tests (see Section 5.1) and detailed soil characterization, including seismic CPTs at a small number of carefully selected "focus" locations. These focus locations provided detailed information on the soils, including the depositional and post-depositional regimes, for the various geological units identified at each location. CPT correlations were then developed using the data gathered at the focus locations. Phase II also included the trialling of enhanced seafloor CPT equipment with the aim to achieve penetrations beyond the expected monopile embedment's, and finalization of the CPT interpretation scheme.

Phase III
In order to optimise project execution, the Phase III SI and final Geotechnical Design Basis (GBD) production were squeezed into a 10-month period.

The final phase of SI comprised at least one enhanced (deep) seafloor CPTU at each WTG location. Seismic CPTs and soil borings were performed at selected locations identified from the updated ground model.

Due to the lack of soil sampling at turbine locations, a complementary 3D Ultra High Resolution Seismic (UHRS) survey was also conducted. This survey and associated detailed geological

interpretation provided a high reliability of regional geological unitisation, which was critical given the lack of sampling at WTG locations.

The key elements to the success of the soil investigation strategy are:

1) Enhanced CPTs extending below monopile embedment depths, enabling reliance on CPTs as the primary WTG location specific dataset, and thereby minimising the final survey campaign period and laboratory testing period;
2) Integration of CPT, borehole and interpreted 3D UHRS geophysical survey data;
3) A geological model developed by the BGS (Cotterill, et al., 2017a & b);
4) Site- and unit-specific CPT-correlations for geotechnical parameters;
5) Spudcan penetration tests to validate the 'operational shear strength' and application of regional unit specific N_{kt}-factors.

4 RECENT DEVELOPMENTS WITH CPT EQUIPMENT

For monopile foundations it is generally necessary to obtain soil parameter data to a depth of 40 – 50 m bsf. Using seafloor CPTs to obtain the required data is approximately 10 times more efficient than using combined down-hole sampling and CPT boreholes. Thus, there is a significant productivity gain in being able to penetrate to 45-50 m bsf with seafloor CPTs. However, from a CPT and monopile design perspective, the very dense sands of the Eem Formation, present at a depth of 30 – 40 m bsf at the Dogger Bank site are important. Seafloor CPT refusal was invariably encountered in the upper few metres of this unit, with q_c values of up to 150 MPa being recorded. This presented a challenge for the project and led to enhancements of the standard CPT equipment, such as using lubrication behind the cone to reduce rod friction. However, even with lubrication, it can be difficult, or even impossible, to penetrate a deep very dense sand layer. A new approach where water is flushed through holes near the cone tip has been developed and successfully used at the Dogger Bank Offshore Wind Farm. The development of these enhanced CPTs for Dogger Bank project has been successful due to close cooperation between the soil investigation contractor and the wind farm developer, as presented in Tjelta et al. (2022).

These enhancements increased the seafloor CPT penetration depth, as indicated in Table 1 and thus permitted efficient use of the CPT data to derive full depth geotechnical design parameter profiles at each WTG location.

Table 1. Summary of seafloor CPT penetration depths for the Dogger Bank project area.

		Final penetration depth (m bsf)		
Year	No. CPTs*	Minimum	Maximum	Average
2010	97	3.8	40.2	22.5
2012	87	8.9	40.1	27.2
CPT equipment enhancements from 2018 onwards				
2018	35	12.4	40.0	27.5
2019	100	14.3	45.6	38.8
2020	120	7.5	50.3	40.1
2021	98	23.5	58.8	44.5

* excluding tests with premature refusal and seismic CPTs

5 IMPROVEMENTS IN CPT INTERPRETATION

5.1 Giant "CPTs"

A novel feature of the Dogger Bank SI strategy was the use of large scale plate loading tests in the form of spudcans from a jack-up unit to assess the mass *operational* undrained shear strengths for the clay units at selected focus locations (Yetginer & Tjelta, 2021). Back-analysis of spudcan penetrations recorded from these jacking trials resulted N_{kt}^{*1} factors for most clay units in the range 18-22 with a best estimate of 20. The corresponding reduced range in undrained shear strengths avoided designing foundations for a potentially unrealistic low strength for capacity, yielding large foundations, and then an equally unrealistic high strength for installation, resulting in high refusal risk.

Corrected CPT cone resistance measurements were interpreted both individually and collectively (over the wider jacking footprint area) to derive design undrained shear strength profiles for input into the back-analysis calculations. Location specific average operational N_{kt}^* factors were fine-tuned to best match the predicted spudcan penetration behaviour with the observed offshore penetration record. Spudcan penetration predictions were made by means of both traditional bearing capacity calculations using NGI's in-house SPLAT software (Zhang et al., 2015) and Large Deformation Finite Element (LDFE) analyses using Abaqus. Example details from a back-analysis are shown in Figure 4.

Results from the spudcan penetration tests help to highlight that scale and fabric effects are an important consideration for the Dogger Bank clays. Comparison of the laboratory CAUC

---

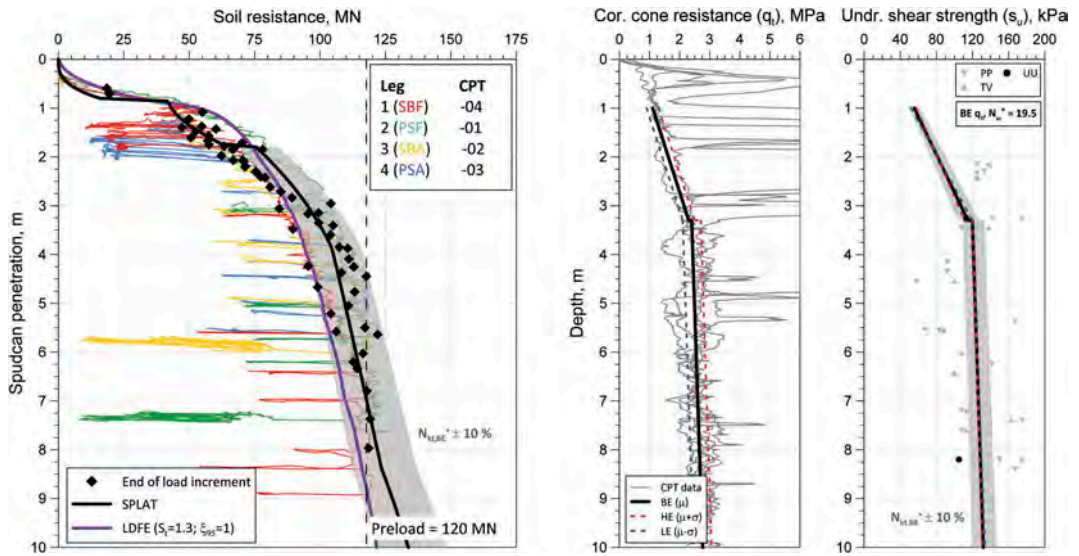
1 Herein N_{kt}^* denotes the factor used to infer the mass operational shear strength, whereas N_{kt} denotes the factor used to estimate the undrained shear strength in triaxial compression, s_{uC}.


Figure 4. Example details from back analysis of recorded spudcan penetrations using SPLAT and large deformation finite element (LDFE) analyses.

strengths and the mass operational undrained shear strengths determined from back-analysis of spudcan penetration records at Dogger Bank, suggests the data shows a positive scale effect, with undrained strength increasing with increasing sample size. The size of the spudcans are comparable to the diameter of a monopile and the scale of the penetration tests is such that the varying responses due to natural variability and to different behaviour patterns in undrained shear (e.g. Hight et al., 2003) are integrated to some extent. The resulting range in N_{kt} values applicable to back-calculated strengths are lower than for the laboratory tests.

Differences in the kinematic restraints between the field and laboratory tests as well as rate-effects are noted to contribute to this observation.

The cost of performing the spudcan penetration tests were comparable to those for an SI vessel, particularly when these tests could be timed with existing operations. Such tests also have the advantage of providing valuable information for future WTG installation operations.

5.2 V_s and G_{max} correlations

Soil unit specific correlations for shear wave velocity (v_s) were developed in terms of net cone resistance (q_{net}) and in situ effective vertical stress (σ_{v0}'):

$$v_s = \beta_0 \cdot q_{net}{}^{\beta_1} \cdot \sigma'_{v0}{}^{\beta 2} \qquad (4.1)$$

where β_0, β_1 and β_2 are best-fit empirical factors. The unit for q_{net} and σ_{v0}' is kPa and that for v_s is m/s. The small strain shear modulus (G_{max}) is evaluated from:

$$G_{max} = \rho \cdot v_s^2 \qquad (4.2)$$

where ρ is the soil density.

The correlations are primarily developed from seafloor and downhole seismic CPTs (SCPTs). Data from borehole suspension logging as well as bender element measurements performed during triaxial, direct simple shear and resonant column laboratory tests were also considered. Figure 5 presents a comparison of measured versus calculated shear wave velocity for Upper and Lower Dogger Bank clay. As with the N_{kt} dataset, there is also variability in the v_s data. This suggests that factors such as the depositional environment and varying post-depositional processes to which the soils have been subjected also influence the shear stiffness of the soil.

Shear wave velocities determined at the end of consolidation in triaxial tests using bender elements typically give v_s values which are lower than those determined in situ (Figure 6). Such observations are not uncommon and highlight the importance of in situ shear wave velocity measurements for structures, such as monopiles, which are sensitive to the small strain stiffness response of the soil.
Figure 5. Measured versus calculated shear wave velocity for Upper and Lower Dogger Bank clay.
Figure 6. Example G_{max} data from investigations at a focus location.

6 FINAL CPT DATA INTERPRETATION SCHEME

A key advantage with CPT testing is the speed with which the data can be acquired, processed and interpreted to provide geotechnical engineering parameters. This is advantageous for the development of offshore wind farm projects which may have 100 or more WTGs. For the Dogger Bank WTG locations, continuous seafloor CPT data permitted semi-automatic processing and analysis of data and thus:

1) Rapid development of geotechnical design profiles (preliminary profiles available in a matter of minutes);
2) Early phase monopile driveability predictions for identifying the potential risk of refusal during installation.

The geotechnical design profiles can also be used in automated routines for monopile design, such as those presented by Klinkvort et al. (2020).

Design parameter profiles for each WTG monopile foundation were developed from the site-specific CPT data acquired at each location coupled with the ground model developed for the Dogger Bank site. Figure 7 presents an example design parameter profile, showing q_t together with interpreted parameter profiles for undrained shear strength (s_u), relative density (D_r), peak drained effective stress friction angle (ϕ'), small strain shear modulus (G_{max}) and soil behaviour type (SBT).

Figure 8 presents example soil resistance to driving (SRD) and blow count predictions derived automatically from the site-specific CPT data. These predictions proved very valuable and indicated that monopile installation should be nonproblematic (earlier estimations made using composite CPT profiles gave strong indications for driving refusal).

7 INTEGRATION OF 3D UHRS SURVEY DATA

At each WTG location, refined interpretation of the 3D UHRS seismic data was performed to validate the variations in the CPT data accounted for in the characteristic design profiles. These detailed interpretations focused primarily on the continuity of soil layers within a 40 × 40 m box surrounding each CPT position, as shown in Figure 9. Such interpretations provide confidence that the CPT-derived stratigraphic profiles are representative for the much larger scale application of monopile foundation design.

8 STATISTICAL INTERPRETATION OF CPT DATA

The continuous nature of seafloor CPT data lends itself towards the development of design parameter profiles using statistical methods. However, this approach has some challenges, as discussed below.

Linear regression can be used to derive a best estimate (i.e. central estimation) trend for q_t data over a specified depth interval. For such data, which can be considered to have a single independent variable, the confidence on the mean value, $\overline{q_t}$, together with the predictive interval (e.g. 5 and 95% percentiles) can be estimated from DNV (2012).

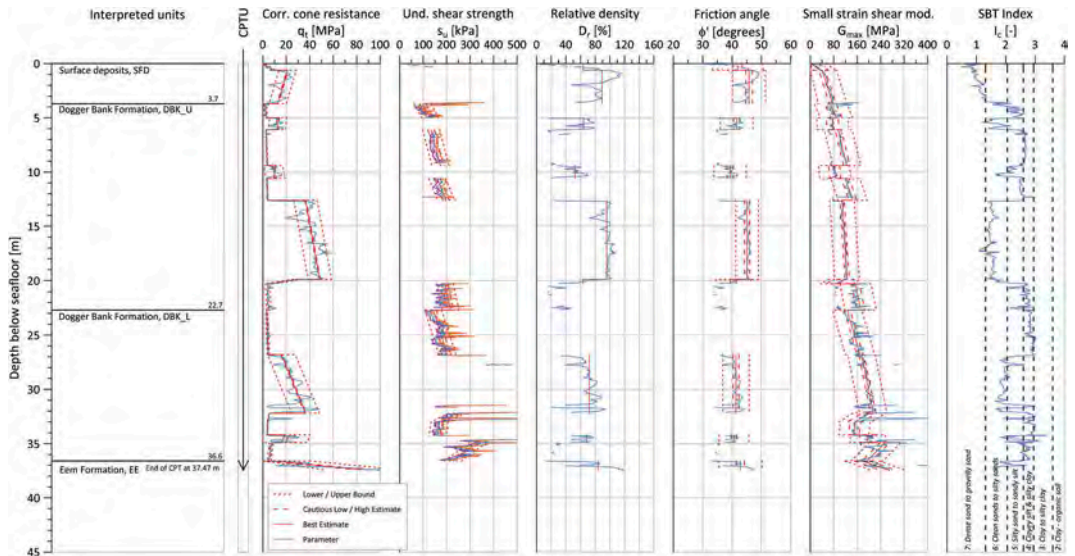
It is important to emphasise that the formulations in DNV (2012) only apply where there is a single independent variable. Where multiple variables are present, such as when geotechnical parameters are derived from CPT-based correlations (e.g. s_u or G_{max}), an


Figure 7. Example design parameter profile for a WTG location.
Figure 8. Example SRD and blow count predictions.

alternative methodology needs to be adopted which also considers the uncertainty in the correlation itself. One such method is the first-order second-moment (FOSM) method, which determines the stochastic moments of a function with random input variables using a first-order Taylor series (Haldar & Mahadevan, 2000). However, this approach is also not without its challenges and limitations, which include:

1) Assessment of the statistical uncertainty associated with each coefficient and exponent in the correlation formula. Such information may not be readily available.
2) Assessment of the equivalent number of independent data points for CPT data.

Coupled with this are how the design parameter profiles should be defined. Treatment of these topics is beyond the scope of this paper, but it is emphasized
Figure 9. Example showing correlation between interpreted geophysical profile and CPT data (image courtesy of Geosurveys /MMT).

that these are important topics which the industry should address.

9   CONCLUDING REMARKS

The Dogger Bank project has demonstrated that the CPT can be used as the primary intrusive site investigation tool for offshore wind farm projects despite

complex geology and challenging ground conditions comprising stiff clays and very dense sands. A novel soil investigation strategy evolved for the project which addressed these challenges as they arose and had the following key elements:

1) Enhanced CPTs extending below monopile embedment depths. This enabled CPTs to be the primary intrusive SI dataset for each monopile location which had significant project timeline benefits. In order to attain target CPT penetration depths, innovative technical developments comprising rod lubrication and/or water injection at the cone tip were developed. The developments were the result of close collaboration between the SI contractor and the project developer.
2) Development of a reliable ground model which integrated CPT and borehole information with interpreted 3D UHRS geophysical survey data and the regional geological model for the site.
3) Development of site- and unit-specific CPT correlations for geotechnical parameters. Laboratory testing necessary for the development of these correlations was programmed early in the project timeline, where possible.
4) Innovative use of spudcan penetration tests to validate the operational undrained shear strength of the clays and enable application of regional unit specific N_{kt}-factors. Such tests highlight the value of large scale in situ testing of soils.

The CPT tool developments outlined in this paper, together with the novel site investigation strategy developed for the Dogger Bank wind farm, indicate the CPT will continue to have a central role in future offshore wind projects. However, it is contended that CPT tool development now probably lies in front of CPT interpretation, especially when it comes to the determination of design parameter profiles inferred from CPT data and associated coupling with statistical analysis.

Procedures to evaluate seismic settlement in dry sand based on CPT data – an update

Fred Yi

Mid Pacific Engineering Inc., California, USA

ABSTRACT: The seismic settlement of dry sands becomes one of the major geological hazards in areas where loose sandy deposits exist, and groundwater is relatively deep as human activities and urban development moving towards these areas. Research related to the evaluation of seismic settlement of dry sand seems paused for a period since pioneer work of Silver and Seed (1971) in the early 1970's. Later research related to the topic was found by Tokimatsu and Seed (1987) and Pradel (1998). Both papers were based on the use of Standard Penetration Test (SPT). Yi (2010) was the first attempting to evaluate the seismic settlement of dry sand using Cone Penetration Test (CPT) data. In this paper, the procedures to evaluate seismic settlement in dry sand based on CPT data was summarized and the relationship between volumetric strain and cyclic shear strain was updated for CPT data by considering various effects such as fine contents and overburden pressure based on the most recent research findings.

1 INTRODUCTION

Cone Penetration Tests (CPT) have become one of the most used and accepted in situ testing methods for soil investigation in recent year due to its advantages such as the continuation of sampling, the repeatability, and economical efficiency. Various papers were published by researchers for the interpretation and application of CPT data since Robertson and Campanella, as the pioneer, published two major papers in 1983 on the interpretation of CPT data. Most of the later publications were contributed to the interpretations or the application in liquefaction potential evaluations (Robertson, 2009; Robertson & Wride, 1998; Mayne, 2007). In the inland areas where groundwater is relatively deep and soil deposits consist of aeolian accumulations, one of the important applications of CPT is the evaluation of seismic dry sand settlement. Yi (2010a) was the first attempting this application by correlating laboratory test results of volumetric strain of dry sand (Silver & Seed, 1971) and CPT tip resistance. About the same time, Robertson and Shao (2010) also addresses this topic by converting CPT data into equivalent Standard Penetration Test (SPT) blowcounts and applying calculation method developed for SPT data (Pradel, 1998). Since then, the evaluations of seismic dry sand settlement were widely performed in California. In recent years, it is discovered that the cyclic volumetric strain of dry sand is significantly affected by the amount of fines (Yee et al., 2014; Stewart 2014). In this paper, the procedures to evaluate

seismic settlement in dry sand based on CPT data was summarized and the relationship between volumetric strain and cyclic shear strain was updated for CPT data by considering various effects such as fine contents and overburden pressure based on the most recent research findings. The approaches were compared with the results predicted by currently used methods.

2 SEISMIC SETTLEMENT OF DRY SAND

In the simplified method, the evaluation of the seismic settlement of dry sand generally follows the following procedures:

1. Calculate shear stress, τ_{av}.
2. Calculate cyclic shear strain, γ.
3. Calculate volumetric strain, ε_v.
4. Correct for various factors.
5. Calculate accumulated settlement, S_v.

The details of each step were discussed in the following sections.

2.1 *Evaluation of cyclic shear stress*

Seed & Idriss (1971) proposed an equation to calculate of the average equivalent uniform cyclic shear stress caused by an earthquake as

$$\tau_{av} = 0.65 \cdot (a_{\max}/g) \cdot \sigma_{v0} \cdot r_d \qquad (1)$$

where α_{max} is the peak horizontal acceleration at ground surface generated by the earthquake, g is the acceleration of gravity, σ_{v0} is the total vertical overburden stresses, and r_d is a stress reduction coefficient. Seed & Idriss (1971) assumed τ_{av} being 65% of the peak cyclic stress. The choice of 0.65 is somewhat arbitrary but has been in use ever since (Idriss & Boulanger, 2008).

Various equations have been proposed to calculate r_d (Seed & Idriss 1971; Lao & Whitman 1986, Seed et al. 2003). The author recommends the equation proposed by Idriss (1999).

$$r_d = \exp[\alpha(z) + \beta(z) \cdot M] \qquad (2)$$

$$\alpha(z) = -1.012 - 1.126 \sin(z/11.73 + 5.133) \quad (2a)$$

$$\beta(z) = 0.106 + 0.118 \sin(z/11.28 + 5.142) \quad (2b)$$

where z is the depth below ground surface in meters.

2.2 Evaluation of cyclic shear strain

Utilizing the nonlinear relationship between the shear modulus ratio (G/G_0) and shear strain, the cyclic shear strain induced in the soil can be determined by the following equation.

$$\gamma = \frac{\tau_{av}}{G_0 \cdot (G/G_0)} \qquad (3)$$

where G_0 is the maximum shear modulus of the soil. Robertson (2009) proposed a relationship between G_0 and corrected cone resistance, q_t.

$$G_0 = \alpha_G(q_t - \sigma_{v0}) \qquad (4)$$

where α_G is the shear modulus factor. For an average unit weight of 18 kN/m³, Robertson obtained

$$\alpha_G = 0.0188\left[10^{(0.55I_c + 1.68)}\right] \qquad (5)$$

where I_c is Soil Behavior Type index.

Due to the nonlinear relationship, the calculation of γ in Eq. 3 usually requires iterations. Using the relationships between the shear modulus and the shear strain obtained experimentally by Iwasaki et al. (1978), Pradel (1998) formulated an equation which avoids the iterative process.

$$\gamma = \left[\frac{1 + a \cdot \exp(b \cdot \tau_{av}/G_0)}{1 + a}\right] \cdot \frac{\tau_{av}}{G_0} \times 100\,(\%) \quad (6a)$$

where

$$a = 0.0389(p/p_a) + 0.124 \text{ and } b = 6400(p/p_a)^{-0.6} \qquad (6b)$$

where p is the average stress, p_a is the atmospheric pressure. For at-rest condition,

$$p = \left(\frac{1 + 2K_0}{3}\right)\sigma_{v0} \qquad (6c)$$

K_0 is the coefficient of lateral earth pressure at rest. Mayne and Kulhawy (1982) found that K_0 depends on the internal frictional angle (φ) of soil and the overconsolidation ratio (OCR) as shown in following equation.

$$K_0 = (1 - \sin\varphi)OCR^{\sin\varphi} \qquad (7)$$

2.3 Evaluation of volumetric strain

Under cyclic loading, loose dry sands tend to compress, resulting a settlement at ground surface, termed as seismic dry sand settlement or seismic compression. For clean sand, laboratory tests of past research indicate that the compositional factors principally affecting the seismic compression potential of clean sands is relative density (D_R) and the magnitude of the cyclic shear strain (γ). Volumetric strain generally decreases with increasing relatively density and increases with increasing cyclic shear strain.

2.3.1 Relative density

Relative density (D_R) is one of the important parameters affecting the settlement of dry sand under seismic loading. Several correlations between relative density and CPT resistance were proposed in past years (Tatsuoka et al., 1990; Jamiolkowski et al, 2001; Idriss & Boulanger, 2004). Those correlations are generally fallen in a band as shown in Figure 1. Yi (2010) recommended an average correlation as expressed in Eq. 8.

$$D_R = 77.29\log(q_{c1N}) - 94.36\ (\%),\ (25 \le q_{c1N} \le 250) \qquad (8)$$

2.3.2 Volumetric strain of clean sand

The relationship between volumetric strain and shear strain of dry sand, termed as volumetric strain material model (VSMM) by UCLA research group, was built based on laboratory tests. The pioneer work
Figure 1. Relations between relative density and equivalent normalized clean sand resistance (after Yi, 2010).

Figure 2. Relationship between volumetric strain and shear strain for dry clean sands (after Silver & Seed 1971).

was performed by Silver & Seed (1971). They conducted a series of one-directional cyclic shear tests on dry sand with relative densities of 45, 60, and 80%, and obtained relationships between volumetric and shear strains as shown in Figure 2. These relationships were widely used in the seismic dry sand settlement analysis for SPT data (Tokimatsu & Seed, 1987; Pradel, 1998). Yi (2010) applied the relationships in Figure 2 to CPT tip resistance as shown in Eq. 9.

$$\varepsilon_{vc,M=7.5} = 10^n \gamma, \;\; n = 18.4/(q_{c1Ncs})^{0.61} - 1 \quad (9)$$

where q_{c1Ncs} is normalized tip resistance of clean sand.

The test results shown in Figure 2 are based solely on a single clean quartz material (Crystal Silica No. 20). Additional data have been compiled since then on other materials. Unfortunately, the database is inadequate to systematically investigate the effects of compositional and environmental factors on seismic compression susceptibility. The research group in UCLA (Steward & Whang, 2003; Steward et al. 2004; Duku et al., 2008) expanded the database by performing cyclic simple shear tests on various different clean sands. The representative results for D_R=60% are shown in Figure 4.

Based on the new test results, a new empirical relationship between volumetric strain associated with 15 cycles of loading, $(\varepsilon_v)_{N=15}$, and the uniform cyclic shear strain amplitude, γ_c, was developed by UCLA group (Duku et al., 2008).

$$(\varepsilon_v)_{N=15} = a(\gamma_c - \gamma_{tv})^b (\%) \quad (10)$$

Figure 3. Relationship between volumetric strain, shear strain and normalized CPT tip resistance for dry clean sands (after Yi, 2010).
Figure 4. Volumetric strain versus shear strain of 16 clean sands (after Steward & Whang, 2003).

$$K_{FC} = (a)_{FC}/(a)_{FC=0} \qquad (12)$$

Yee et al. (2014) discovered that this correction factor is generally independent of D_R. The regression of test data shows

$$
\begin{aligned}
K_{FC} &= 1 & (FC = 0 - 10\%) \\
K_{FC} &= e^{[-0.042(FC-10)]} & (FC = 10\% - FC_L) \\
K_{FC} &= 0.35 & (FC \geq FC_L)
\end{aligned}
\qquad (13)
$$

where FC_L is limiting fines content (~35%).

2.5 Other effecting factors

According to Yee et al. (2014), other major factors affect the seismic compression are number of strain cycles (N), overburden pressure (σ_v) and degree of saturation (S). The effects of these factors can be expressed as below:

Effect of Number of Strain Cycles:

$$C_N = \varepsilon_{v,N}/\varepsilon_{v,N=15} = 1 + R \cdot ln(N/15) \qquad (14)$$

where $R = -0.026\ln(\gamma_c - \gamma_{tv}) + 0.26$ based on regression.

Effect of Overburden Pressure:

$$K_{\sigma,\varepsilon} = (a)_\sigma/(a)_{\sigma=1atm} = (\sigma_v/p_a)^{-0.29} \qquad (15)$$

where p_a = atmospheric pressure.

Effect of Saturation:

$$K_S = (a)_S/(a)_{S=0} \qquad (16)$$

$$
\begin{aligned}
K_S &= 1 - 0.017S & (S < 30\%) \\
K_S &= 0.5 & (30\% \leq S < 50\%) \\
K_S &= 0.05S - 2 & (50\% \leq S < 60\%) \\
K_S &= 1 & (S \geq 60\%)
\end{aligned}
\qquad (17)
$$

2.6 Volumetric strain for any soil conditions

By introducing above discussed factors, the volumetric strain after 15 cycles of loading for any low plasticity sandy and silty soils and at any stress and saturation conditions can be expresses as

$$\varepsilon_{v,N=15} = K_{FC} \cdot K_{\sigma,} \cdot K_S \cdot \left(\varepsilon_{v,N=15}\right)_{cs} \qquad (18)$$

where γ_{tv} is volumetric threshold strain, and a and b are material specific constants. A typical range of γ_{tv} for sands is 0.01–0.03%. For average conditions,

$$a = 5.38 \cdot \exp(-0.023 \cdot D_R) \qquad (10a)$$

$$b = 1.2 \qquad (10b)$$

By introducing Eq. 8 into Eq. 10, we obtained

$$(\varepsilon_v)_{N=15} = 47.133(q_{c1N})^{-0.772}(\gamma_c - 0.02)^{1.2} \qquad (11)$$

that applies to average conditions of clean sand.

2.4 Effects of low plasticity fines

The VSMM developed based on laboratory test results of clean sands limits its application in real engineering practice due to the existence of fines in the subsurface soil materials in most of the project sites. The surface settlement may be over-estimated resulting in over design.

Yee et al. (2014) performed a series of cyclic simple shear tests using natural soils with low plasticity fines contents (*FC*) between 14 and 35% and natural soils based artificial mixtures with FC values of between 10 and 100%. The effects of fines on seismic compression are expressed by the ratio of the parameter *a* of Eq. 10 for an arbitrary fines contents to clean sand value (*FC=0*).

where $(\varepsilon_{v,N=15})_{cs}$ is the volumetric strain of clean sand after 15 cycles of loading calculated using Eq. 10 or 11.

2.7 Volumetric strain at any loading cycle (N)

Eq. 18 is only applicable when there are 15 equivalent uniform strain cycles ($N=15$), typically corresponding to an earthquake magnitude of 7.5. For any loading cycles or earthquake magnitude, the effect of number of strain cycles (Eq. 14) should be incorporated.

$$\varepsilon_{v,N} = C_N \cdot \varepsilon_{v,N=15} = \left[1 + R \, \ln\left(\frac{N}{15}\right)\right] \cdot \varepsilon_{v,N=15}$$

(19)

2.8 Equivalent number of uniform strain cycles

Liu et al. (2001) developed empirical regression equations to evaluate the equivalent number (N) of uniform stress cycles of earthquake shaking as a function of magnitude (M), site-source distance (r), site condition ($S=0$ for rock, $S=1$ for soil), and near-fault rupture directivity effects, using a strong motion data set for tectonically active regions.

$$\ln(N) = \ln\left[\frac{\left(\frac{exp(b_1+b_2(M-5.8))}{10^{1.5M+16.05}}\right)^{-1/3}}{4.9 \cdot 10^6 \beta} + Sc_1 + rc_2\right]$$

(20)

where r is in km. Stewart et al. (2002) found that the weighting factor set, $b_1 = 1.53$, $b_2 = 1.51$, $c_1 = 0.75$, $c_2 = 0.095$, $\beta = 3.2$, is appropriate for evaluation of equivalent number of uniform strain cycles (N). Figure 5 shows the variation of N with

source distance for earthquake magnitude from 5.25 to 7.5.

2.9 The potential maximum volumetric strain

In computer programming, one should carefully define the conditions of for each equation to avoid calculating unrealistic mathematic number, e.g., Eq. 6 may calculate very high shear strain if G/G_0 is smaller than 0.1 and consequently Eq. 11 may calculate relatively high mathematic volumetric strain value. In order to evaluate realistic value, an upper bound of the potential maximum volumetric strain, ε_{vmax}, is necessary. This issue was discussed by Tsukamoto et al. (2004) and Yi (2010b). Theoretically, the maximum volumetric strain of sandy material is controlled by void ratio "breath" $e\text{-}e_{min}$. Based on laboratory test results of various soils from clean sand to silty sand, Tsukamoto et al. (2004) created a generalized chart correlating the value of $\varepsilon_{vmax}/\varepsilon_{vr}$ and the void ratio range, $e_{max}\text{-}e_{min}$, with a serious of D_R constant curves as shown in Figure 6. From this diagram, it is possible to estimate the value of $\varepsilon_{vmax}/\varepsilon_{vr}$ for a soil with a given relative density D_R and grain composition represented by the void ratio range $e_{max}\text{-}e_{min}$. However, for most of the cases, the grain composition, i.e., e_{max} and e_{min}, is unknown resulting a difficulty in direct application of Figure 6. The author analyzed the e_{max} and e_{min} of 25 different soils. Using the mediums of e_{max} and e_{min}, the potential maximum volumetric strain could be expressed as following equation.

$$\varepsilon_{vmax} = 0.274(100 - D_R)(in\%)$$

(21)

Without further measured data of soil grain composition, the author suggests using Eq. 21 as the upper bond of the calculated volumetric strain.

2.10 Calculation of total settlement

Eq. 10 was developed based on cyclic simple shear tests. According to Pyke et al. (1975), "the settlement caused by combined horizontal motions are about equal to the sum of the settlement caused by the components acting alone." As such, the volumetric strain for any magnitude should be calculated using the following equation to account for the effects of multidirectional shaking and earthquake magnitude.

$$\varepsilon_v = 2 \cdot \varepsilon_{v,N} (<\varepsilon_{vmax}) \qquad (22)$$

The seismic settlement of dry sand can be evaluated by equating the vertical strain to the volumetric strain and then integrating the vertical strains over the depth interval of concern using following equation:

$$S_{v,1D} = \int_0^{z_{max}} \varepsilon_v \cdot dz \qquad (23)$$

2.11 Summary of procedures

The updated procedures for evaluating seismic settlement of dry sand are summarized in Figure 7 in the form of a flow chart. The flow chart clearly shows the step-by-step process involved in using the proposed integrated method based on the CPT data for evaluating seismic dry sand settlement and indicates the recommended equations for each step of the process.

3 APPLICATION OF THE UPDATED PROCESURES

An example of the seismic dry sand settlement using the updated procedures based on CPT data is shown in Figure 8 for a site located in southern California. Based on soil behavior type, soil profile generally consists of clean sand to sandy silt layers with few thin clay to silty clay and clayey sand to very stiff sand layers. The majority of calculated fines contents ranges from less than 5% to near 50%.

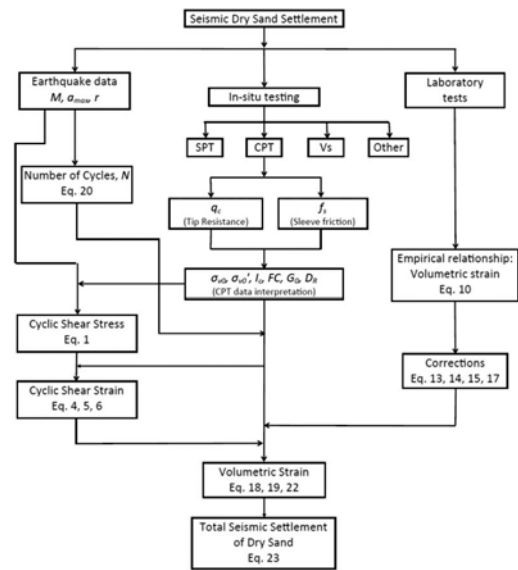
Seismic settlement was calculated using methods proposed by Tokimatsu & Seed (1987), Pradel's (1998), Yi (2010) and the updated method of this paper. The comparison of calculated shear strain, volumetric strain and accumulated settlement is shown in Figure 8. The shear strain based on proposed and Yi (2010) methods are about identical. The volumetric strain of proposed method was corrected for fines contents and overburden pressure. The correction for saturation was omitted due to the lack of data. Overall, the calculated accumulated settlement based on UCLA correction is approximate 28 to 54% of the previous methods. This agrees with the case histories reported by Lew & Tran (2012). Lew & Tran (2012) reported a case history of a site consisted mainly sandy silt profile. The observed settlement was reported approximately 20% of that predicted by currently used methods.


Figure 7. Flow chart illustrating the application of procedure.

4 CONCLUSIONS

This paper updated the procedures for evaluating seismic settlement in dry sand based on CPT data. Efforts were made for the update of the correlation between volumetric strain and shear strain and various corrections such as fines content and overburden pressure utilizing the laboratory test results obtained by UCLA research group. The procedure has been presents in the order of the calculation sequence through a set of equations. The performance of the proposed method was verified by comparing the results obtained using existing methods for field investigation data. The outcome indicates that the proposed method could provide better prediction of seismic dry sand settlement especially for silty soils.
