All the excitatory synapses between the excitatory neurons use glutamate as a transmitter and have short time constant ($\tau_{\text{AMPA}}=10$ ms) receptors that open ion channels, and long time constant ($\tau_{\text{NMDA}}=100$ ms) receptors that open voltage-dependent ion channels, both of which inject currents into a neuron and produce depolarization in the direction of the firing threshold. (Details are provided in Section B.6.3, and further background to these networks is provided by Rolls (2016b) and Rolls and Deco (2010).) The inclusion of the long time constant NMDA receptors in the model helps to maintain the persistence of the high firing rate attractor state (Wang, 1999), and also prevents gamma oscillations, which arise only if the NMDA receptor contribution is insufficient (Brunel and Wang, 2003; Rolls, Webb and Deco, 2012; Wang, 2010). [I hypothesize that in evolution the NMDA to AMPA channel conductance ratios have been set to a level that minimizes gamma oscillations consistent with the need to allow AMPA to be sufficiently strong to ensure rapid processing into attractor states (Battaglia and Treves, 1998a; Panzeri et al., 2001).] The inhibitory neurons use GABA as a transmitter which hyperpolarizes the neurons, with the strength of w_{inh} typically 1.0 (Fig. 11.33b).

The evidence λ_1 for decision 1 is applied to pool D1 through 800 synapses onto each neuron, and the evidence λ_2 for decision 2 is applied to pool D2 in the same way (Fig. 11.33b). The same sets of 800 synapses on every neuron in the network also receive external inputs at a rate $\lambda_{\text{ext}}=3$ spikes/s, a typical firing rate for the spontaneous activity of cortical neurons, to reflect background activity from other cortical areas. The distribution of these inputs onto each neuron over time is what would be produced by Poisson spikes trains at 3 spikes/s on each of the 800 externally connected synapses onto each neuron, and this is one of the sources of noise in the network. Another of the sources of noise (randomness) in the network is the almost Poisson distributed spike times of the neurons in the network. As the network becomes larger and approaches an infinite number of neurons, the statistical fluctuations caused by this source of noise in the network become smoothed out and disappear, as described in more detail elsewhere (Rolls, 2016b).

The full model of decision-making is described in Sections B.6–B.8. The parameters for the models were calculated with the mean-field approach described in Sections B.7 – B.8.3, as described by Rolls and Deco (2010). The model of decision-making that we worked with is different from that analyzed by Wang (2002) in that our model is multistable, in that the spontaneous state is stable even when the decision cues are applied, as well as the decision states (see Sections 5.7 and 5.8 of Rolls and Deco (2010)). Thus it is only noise fluctuations in our models that cause the network to jump out of its spontaneous state of firing to move towards a decision. This influences for example the distribution of reaction times. Differences of this integrate-and-fire model of decision-making from the much less biologically plausible drift-diffusion model are set out in Section 5.7 of Rolls and Deco (2010) and by Deco, Rolls, Albantakis and Romo (2013). The book by Rolls and Deco (2010) *The Noisy Brain: Stochastic Dynamics as a Principle of Brain Function* is available for download from <https://www.oxcns.org>.

11.5.2 Analyses of reward-related decision-making mechanisms in the orbitofrontal cortex

In this Section fMRI evidence to investigate decision-making mechanisms in the orbitofrontal cortex is described. These investigations test whether the decision-making is consistent with the mechanisms described in Section 11.5.1.

The analyses relate to the ways in which probabilistic decision-making is influenced by the easiness vs the difficulty of the decision, and how confidence in a decision emerges as a property of the neuronal attractor network decision-making process.

To address these issues, we first simulated integrate-and-fire models of attractor-based choice decision-making, and predicted from them the neuronal firing rates in the decision attractor populations and the fMRI BOLD signals on easy vs difficult trials (Rolls, Grabenhorst and Deco, 2010b) as described next. We then performed the two fMRI investigations of decision-making described in Section 11.3.6 about the reward value and subjective pleasantness of thermal and olfactory stimuli, and showed that areas implicated by other analyses in decision-making (Rolls and Grabenhorst, 2008; Grabenhorst, Rolls and Parris, 2008b; Rolls, Grabenhorst and Parris, 2010d) do show the predicted difference between activations on easy vs difficult trials in the orbitofrontal cortex (Rolls, Grabenhorst and Deco, 2010b).

11.5.2.1 Neuronal responses on difficult vs easy trials, and decision confidence

Figure 11.35a and e show the mean firing rates of the two neuronal populations D1 and D2 for two trial types, easy trials ($\Delta I=160$ Hz) and difficult trials ($\Delta I=0$) (where ΔI is the difference in spikes/s summed across all synapses to each neuron between the two inputs, λ_1 to population D1, and λ_2 to population D2). The results are shown for correct trials, that is, trials on which the D1 population won the competition and fired with a rate of > 10 spikes/s more than the rate of D2 for the last 1000 ms of the simulation runs. Figure 11.35b shows the mean firing rates of the four populations of neurons on a difficult trial, and Fig. 11.35c shows the rastergrams for the same trial, for which the energy landscape is also shown in Fig. 11.33d. Figure 11.35d shows the firing rates on another difficult trial ($\Delta I=0$) to illustrate the variability shown from trial to trial, with on this trial prolonged competition between the D1 and D2 attractors until the D1 attractor finally won after approximately 1100 ms. Figure 11.35f shows firing rate plots for the four neuronal populations on an example of a single easy trial ($\Delta I=160$), Fig. 11.35g shows the synaptic currents in the four neuronal populations on the same trial, and Fig. 11.35h shows rastergrams for the same trial (Rolls, Grabenhorst and Deco, 2010b).

Three important points are made by the results shown in Fig. 11.35. First, the network falls into its decision attractor faster on easy trials than on difficult trials. We would accordingly expect reaction times to be shorter on easy than on difficult trials. We might also expect the BOLD signal related to the activity of the network to be higher on easy than on difficult trials because it starts sooner on easy trials.

Second, the mean firing rate after the network has settled into the correct decision attractor is higher on easy than on difficult trials. We might therefore expect the BOLD signal related to the activity of the network to be higher on easy than on difficult trials because the maintained activity in the attractor is higher on easy trials. This shows that the exact firing rate in the attractor is a result not only of the internal recurrent collateral effect, but also of the external input to the neurons, which in Fig. 11.35a is 32 Hz to each neuron (summed across all synapses) of D1 and D2, but in Fig. 11.35e is increased by a further 80 Hz to D1, and decreased (from the 32 Hz added) by 80 Hz to D2 (i.e. the total external input to the network is the same, but $\Delta I=0$ for Fig. 11.35a, and $\Delta I=160$ for Fig. 11.35b).

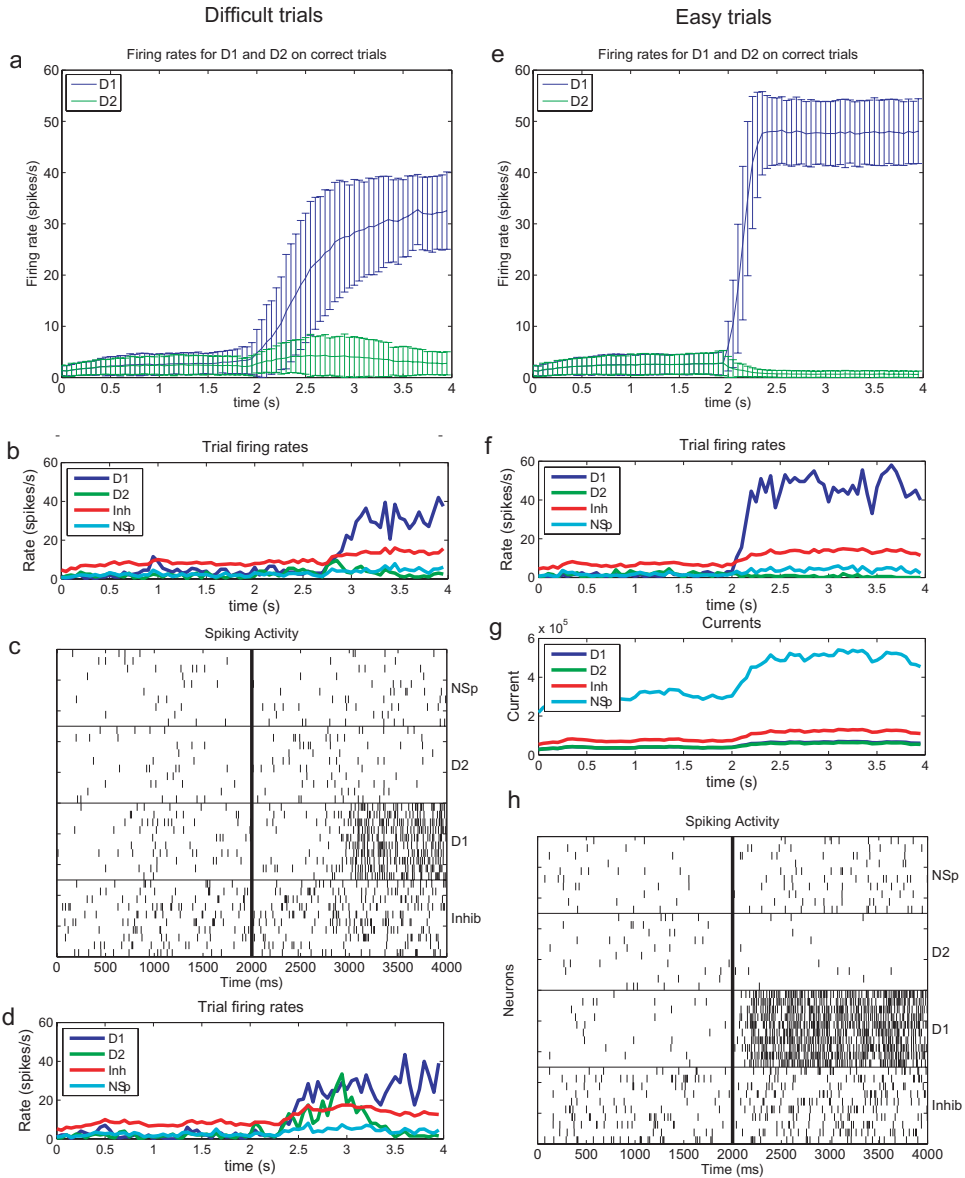

Fig. 11.35 The operation of attractor decision-making networks. (a) and (e) Firing rates (mean \pm sd) for difficult ($\Delta I=0$) and easy ($\Delta I=160$) trials. The period 0–2 s is the spontaneous firing, and the decision cues were turned on at time = 2 s. D1: firing rate of the D1 population of neurons on correct trials on which the D1 population won. D2: firing rate of the D2 population of neurons on the correct trials on which the D1 population won. A correct trial was one in which the mean rate of the D1 attractor averaged > 10 spikes/s for the last 1000 ms of the simulation runs. (b) The mean firing rates of the four populations of neurons on a difficult trial. Inh is the inhibitory population that uses GABA as a transmitter. NSp is the non-specific population of neurons (see Fig. 11.33). (c) Rastergrams for the trial shown in b. 10 neurons from each of the four pools of neurons are shown. (d) The firing rates on another difficult trial ($\Delta I=0$) showing prolonged competition between the D1 and D2 attractors until the D1 attractor finally wins after approximately 1100 ms. (f) Firing rate plots for the 4 neuronal populations on a single easy trial ($\Delta I=160$). (g) The synaptic currents in the four neuronal populations on the trial shown in f. (h) Rastergrams for the easy trial shown in f and g. 10 neurons from each of the four pools of neurons are shown. (Reproduced from Edmund T. Rolls, Fabian Grabenhorst, and Gustavo Deco (2010) Choice, difficulty, and confidence in the brain. *NeuroImage* 33: 694–706. © Elsevier Inc.)

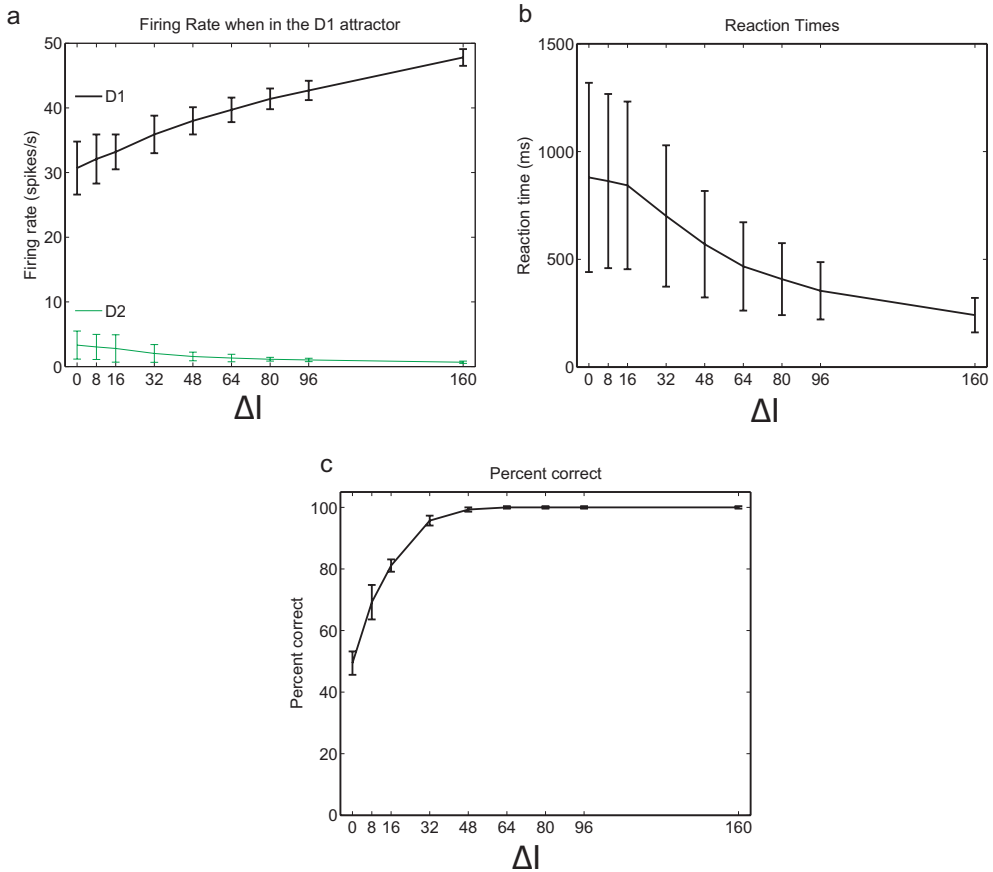

Fig. 11.36 The operation of attractor decision-making networks. (a) Firing rates (mean \pm sd) on correct trials when in the D1 attractor as a function of ΔI . $\Delta I=0$ corresponds to difficult, and $\Delta I=160$ spikes/s corresponds to easy. The firing rates for both the winning population D1 and for the losing population D2 are shown for correct trials by thick lines. All the results are for 1000 simulation trials for each parameter value, and all the results shown are statistically highly significant. (b) Reaction times (mean \pm sd) for the D1 population to win on correct trials as a function of the difference in inputs ΔI to D1 and D2. (c) Per cent correct performance, i.e. the percentage of trials on which the D1 population won, as a function of the difference in inputs ΔI to D1 and D2. The mean was calculated over 1000 trials, and the standard deviation was estimated by the variation in 10 groups each of 100 trials. (Reproduced from Edmund T. Rolls, Fabian Grabenhorst, and Gustavo Deco (2010) Choice, difficulty, and confidence in the brain. *NeuroImage* 33: 694–706. © Elsevier Inc.)

Third, the variability of the firing rate is high, with the standard deviations of the mean firing rate calculated in 50 ms epochs indicated in order to quantify the variability. The large standard deviations on difficult trials for the first second after the decision cues are applied at $t=2$ s reflect the fact that on some trials the network has entered an attractor state after 1000 ms, but on other trials it has not yet reached the attractor, although it does so later. This trial by trial variability is indicated by the firing rates on individual trials and the rastergrams in the lower part of Fig. 11.35. The effects evident in Fig. 11.35 are quantified, and elucidated over a range of values for ΔI , next.

Figure 11.36a shows the firing rates (mean \pm sd) on correct trials when in the D1 attractor as a function of ΔI . $\Delta I=0$ corresponds to the most difficult decision, and $\Delta I=160$ corresponds to easy. The firing rates for both the winning population D1 and for the losing population D2 are shown. The firing rates were measured in the last 1 s of firing, i.e. between $t=3$ and $t=4$ s. It is clear that the mean firing rate of the winning population increases monotonically as ΔI increases, and interestingly, the increase is approximately linear (Pear-

son $r = 0.995$, $p < 10^{-6}$). The higher mean firing rates as ΔI increases are due not only to higher peak firing, but also to the fact that the variability becomes less as ΔI increases ($r = -0.95$, $p < 10^{-4}$), reflecting the fact that the system is more noisy and unstable with low ΔI , whereas the firing rate in the attractor is maintained more stably with smaller statistical fluctuations against the Poisson effects of the random spike timings at high ΔI . (The measure of variation indicated in the figure is the standard deviation, and this is shown here unless otherwise stated to quantify the degree of variation, which is a fundamental aspect of the operation of these neuronal decision-making networks.)

As shown in Fig. 11.36a, the firing rates of the losing population decrease as ΔI increases. The decrease of firing rate of the losing population is due in part to feedback inhibition through the inhibitory neurons by the winning population. Thus the difference of firing rates between the winning and losing populations, as well as the firing rate of the winning population D1, both clearly reflect ΔI , and in a sense the confidence in the decision.

The increase of the firing rate when in the D1 attractor (upper thick line) as ΔI increases thus can be related to the confidence in the decision, and, as will be shown next in Fig. 11.36b, the performance as shown by the percentage of correct choices. The firing rate of the losing attractor (D2, lower thick line) decreases as ΔI increases, due to feedback inhibition from the winning D1 attractor, and thus the difference in the firing rates of the two attractors also reflects well the decision confidence.

I emphasize from these findings (Rolls, Grabenhorst and Deco, 2010b) that the firing rate of the winning attractor reflects ΔI , and thus the confidence in the decision which is closely related to ΔI .

11.5.2.2 Decision times of the neuronal responses

The time for the network to reach the correct D1 attractor, i.e. the reaction or decision time of the network, is shown as a function of ΔI in Fig. 11.36b (mean \pm sd). Interestingly, the reaction time continues to decrease ($r = -0.95$, $p < 10^{-4}$) over a wide range of ΔI , even when as shown in Fig. 11.36c the network is starting to perform at 100% correct. The decreasing reaction time as ΔI increases is attributable to the altered 'effective energy landscape' (Rolls, 2016b): a larger input to D1 tends to produce occasionally higher firing rates, and these statistically are more likely to induce a significant depression in the landscape towards which the network flows sooner than with low ΔI . Correspondingly, the variability (quantified by the standard deviation) of the reaction times is greatest at low ΔI , and decreases as ΔI increases ($r = -0.95$, $p < 10^{-4}$). This variability would not be found with a deterministic system (i.e. the standard deviations would be 0 throughout, and such systems include those investigated with mean-field analyses), and is entirely due to the random statistical fluctuations caused by the random spiking of the neurons in the integrate-and-fire network.

11.5.2.3 Percentage correct

At $\Delta I=0$, there is no influence on the network to fall more into attractor D1 representing decision 1 than attractor D2 representing decision 2, and its decisions are at chance, with approximately 50% of decisions being for D1. As ΔI increases, the proportion of trials on which D1 is reached increases. The relation between ΔI and percentage correct is shown in Fig. 11.36c. Interestingly, the performance becomes 100% correct with $\Delta I=64$, whereas as shown in Figs. 11.36a and b the firing rates while in the D1 attractor (and therefore potentially the BOLD signal), continue to increase as ΔI increases further, and the reaction times continue to decrease as ΔI increases further. It is a clear prediction for neurophysiological and behavioral measures that the firing rates with decisions made by this attractor process continue to increase as ΔI is increased beyond the level for very good performance as indicated by the percentage of correct decisions, and the neuronal and behavioral reaction times

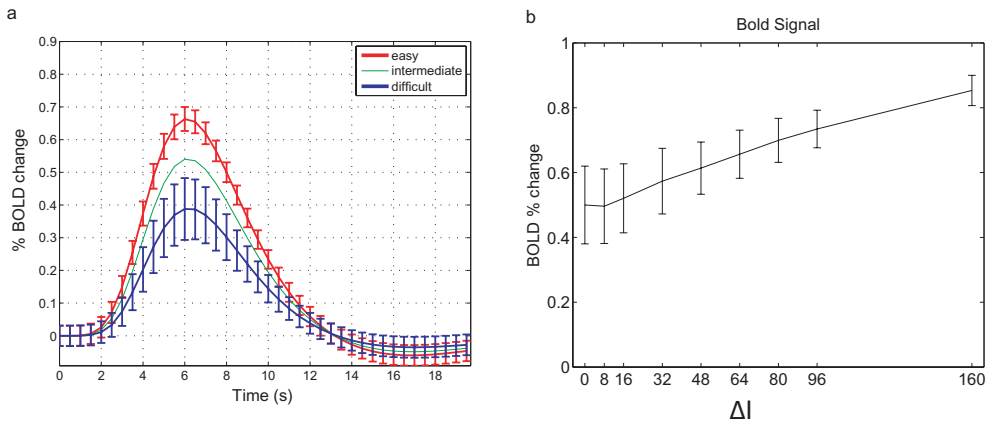

Fig. 11.37 The operation of attractor decision-making networks. (a) The percentage change in the simulated BOLD signal on easy trials ($\Delta I=160$ spikes/s), on intermediate trials ($\Delta I=80$), and on difficult trials ($\Delta I=0$). The mean \pm sd are shown for the easy and difficult trials. The percentage change in the BOLD signal was calculated from the firing rates of the D1 and D2 populations, and analogous effects were found with calculation from the synaptic currents averaged for example across all 4 populations of neurons. (b) The percentage change in the BOLD signal (peak mean \pm sd) averaged across correct and incorrect trials as a function of ΔI . $\Delta I=0$ corresponds to difficult, and $\Delta I=160$ corresponds to easy. The percent change was measured as the change from the level of activity in a period of 1 s immediately before the decision cues were applied at $t=0$ s, and was calculated from the firing rates of the neurons in the D1 and D2 populations. The BOLD per cent change scaling is arbitrary, and is set so that the lowest value for the peak of a BOLD response is 0.5%. (Reproduced from Edmund T. Rolls, Fabian Grabenhorst, and Gustavo Deco (2010) Choice, difficulty, and confidence in the brain. *NeuroImage* 33: 694–706. © Elsevier Inc.)

continue to decrease as ΔI is increased beyond the level for very good performance. Figure 11.36c also shows that the variability in the percentage correct (in this case measured over blocks of 100 trials) is large with $\Delta I=0$, and decreases as ΔI increases. This is consistent with unbiased effects of the noise producing very variable effects in the energy landscape at $\Delta I=0$, but in the external inputs biasing the energy landscape more and more as ΔI increases, so that the flow is much more likely to be towards the D1 attractor.

11.5.2.4 Prediction of the BOLD signals on difficult vs easy decision-making trials

It is now shown how this model makes predictions for the fMRI BOLD signals that would occur in brain areas in which decision-making processing of the type described is taking place. The BOLD signals were predicted from the firing rates of the neurons in the network (or from the synaptic currents flowing in the neurons as described later) by convolving the neuronal activity with the haemodynamic response function.

As shown in Fig. 11.37a, the predicted fMRI response is larger for easy ($\Delta I = 160$ spikes/s) than for difficult trials ($\Delta I=0$), with intermediate trials ($\Delta I=80$) producing an intermediate fMRI response. The difference in the peak response for $\Delta I=0$ and $\Delta I=160$ is highly significant ($p \ll 0.001$). Importantly, the BOLD response is inherently variable from brain regions associated with this type of decision-making process, and this is nothing to do with the noise arising in the measurement of the BOLD response with a scanner. If the system were deterministic, the standard deviations, shown as a measure of the variability in Fig. 11.37a, would be 0. It is the statistical fluctuations caused by the noisy (random) spike timings of the neurons that account for the variability in the BOLD signals in Fig. 11.37a. Interestingly, the variability is larger on the difficult trials ($\Delta I=0$) than on the easy trials ($\Delta I=160$), as shown in Fig. 11.37a, and indeed this also can be taken as an indicator that attractor decision-making processes of the type described here are taking place in a brain region.

Figure 11.37b shows that the percentage change in the BOLD signal (peak mean \pm sd)

averaged across correct and incorrect trials increases monotonically as a function of ΔI . This again can be taken as an indicator (provided that fMRI signal saturation effects are minimized) that attractor decision-making processes of the type described here are taking place in a brain region. The percentage change in Fig. 11.37b was calculated by convolution of the firing rates of the neurons in the D1 and D2 populations with the haemodynamic response function. Interestingly, the percentage change in the BOLD signal is approximately linearly related throughout this range to ΔI ($r = 0.995, p < 10^{-7}$). The effects shown in Figs. 11.37a and b can be related to the earlier onset of a high firing rate attractor state when ΔI is larger (see Figs. 11.35 and 11.36b), and to a higher firing rate when in the attractor state (as shown in Figs. 11.35 and 11.36a). As expected from the decrease in the variability of the neuronal activity as ΔI increases (Fig. 11.36a), the variability (standard deviation) in the predicted BOLD signal also decreases as ΔI increases, as shown in Fig. 11.37b ($r = 0.955, p < 10^{-4}$).

The description of decision-making implemented by this integrate-and-fire model provided in Sections 11.5.1 and 11.5.2 is supplemented by a formal description of the equations in the model in Sections B.6.2 and B.6.3. As noted above, other approaches to decision-making, including the drift-diffusion and race models, are described by Deco, Rolls, Albantakis and Romo (2013). The application of this approach to decision-making for other brain regions is described in Rolls and Deco (2010) and Deco, Rolls, Albantakis and Romo (2013).

11.5.3 A neurophysiological and computational basis for stimulus–reinforcer association learning and reversal in the orbitofrontal cortex

A possible mechanism for the initial learning of stimulus–reward associations is Hebbian (associative) modification of synapses conveying visual input on to taste-responsive neurons, implementing a pattern-association network (Section B.2). In this model the unconditioned stimulus forcing the output neurons to respond is the (taste) primary reinforcer, and the (visual or olfactory) conditioned stimulus becomes associated with this by associatively modifiable synapses (Fig. B.1 on page 816) (Rolls and Treves, 1998; Rolls, 1999a, 2016b).

A first approach to the reversal is as follows, and can be understood by referring to Fig. B.1. Consider a neuron with unconditioned responses to taste in the orbitofrontal cortex. When a particular visual stimulus, say a triangle, was associated with the taste of glucose, the active synaptic connections for this visual (conditioned) stimulus would have shown long-term synaptic potentiation on to the taste neuron, which would respond to the sight of the triangle. During reversal, the same visual stimulus, the triangle, would again activate the same synaptic afferents to the neuron, but that neuron would be inactive when the taste of saline was given. Active presynaptic inputs and a low level of postsynaptic activation is the condition for homosynaptic long-term synaptic depression (LTD, Fig. 1.5 on page 11, see Rolls (2016b)), which would then occur, resulting in a decline of the response of the neuron to the triangle. At the same time, visual presentation of a square would now be associated with the taste of glucose, which would activate the postsynaptic neuron, leading now to long-term potentiation of afferents on to that neuron made active by the sight of the square.

Although reversal might be implemented in the way just described by having long-term synaptic depression for synapses that represented the reward-associated stimulus before the reversal, and long-term potentiation of the new stimulus that after reversal is associated with reward, this would require one-trial LTP and one-trial homosynaptic LTD to account for one-trial stimulus–reward reversal (Thorpe, Rolls and Maddison, 1983; Rolls, Critchley, Mason and Wakeman, 1996b; Rolls, 2000d). Moreover, the mechanism would not account for rever-

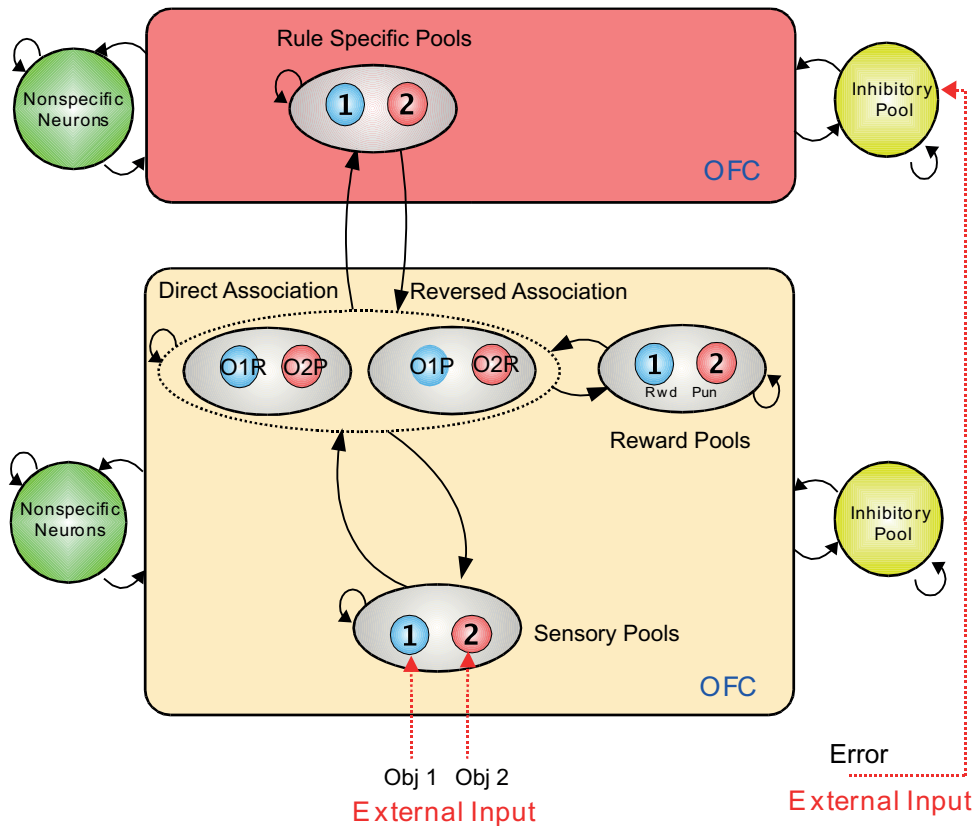

Fig. 11.38 Cortical architecture of the reward reversal computational model. There is a rule module (top) and a sensory – intermediate neuron – reward module (below). Neurons within each module are fully connected, and form attractor states. The sensory – intermediate neuron – reward module consists of three hierarchically organized levels of attractor network, with stronger synaptic connections in the forward than the backprojection direction. The intermediate level of the sensory – intermediate neuron – reward module contains neurons that respond to combinations of an object and its association with reward or punishment, e.g. object 1–reward (O1R, in the direct association set of pools), and object 1–punishment (O1P in the reversed association set of pools). These intermediate level neurons have the properties of ‘conditional reward neurons’ described in Section 11.3.1.2 and illustrated in Fig. 11.7, and provide a function for such conditional reward neurons. The rule module acts as a biasing input to bias the competition between the object–reward combination neurons at the intermediate level of the sensory – intermediate neuron – reward module. The whole model is implemented with integrate-and-fire neurons. (From G. Deco and E. T. Rolls (2005) *Synaptic and spiking dynamics underlying reward reversal in the orbitofrontal cortex*. *Cerebral Cortex* 15: 15–30. © Oxford University Press.)

sal learning set, the process by which during repeated reversal learning, performance gradually improves until reversal can occur in one trial. Even more, the mechanism would not account for the fact that after reversal learning set has been acquired, when the contingency is reversed, the animal makes a response to the current S+ expecting to get reward, but instead obtains the punisher. On the very first subsequent trial on which the pre-reversal S– is shown, the animal will perform a response to it expecting now to get reward, *even though the post-reversal S+ has not since the reversal been associated with reward to produce LTP for the post-reversal S+*. (This is in fact illustrated in Fig. 11.14 on page 496.) To implement this very rapid stimulus–reinforcer association reversal, a different mechanism is therefore needed. The mechanism can not rely on associative processes, but instead on a rule-based (i.e. model-based) process, which requires the current rule to be held in mind, in short-term memory. This, and non-reward neurons that maintain their firing for many seconds as illustrated in Fig. 11.14, may be developments provided for by the evolution of granular orbitofrontal cortex areas in primates (see Section 2.6).

A model for how the very rapid, one-trial, reversal could be implemented has been developed (see Deco and Rolls (2005d) for a full description). The model uses a short-term memory autoassociation attractor network with associatively modifiable synaptic connections to hold the neurons representing the current rule active (see Fig. 11.38). Rule one might correspond to ‘stimulus 1 (e.g. a triangle) is associated with reward, and stimulus 2 (e.g. a square) is associated with punishment’. Rule 2 might correspond to the opposite contingency. A small, very biologically plausible, modification of the standard one-layer autoassociation network is that there is a small amount of adaptation in the recurrent collateral synapses that keep the neurons representing the current rule firing. Now consider the case when the neurons representing rule one are firing. How does the rule module reverse? The proposal is that when the non-reward or error neurons described above (Section 11.3.4) fire, this additional set of firing neurons destabilizes the rule attractor module, by for example producing extra firing of the inhibitory neurons in the orbitofrontal cortex, which in turn inhibit the excitatory neurons in the rule autoassociation network, thus quenching its attractor state. This error input to the rule attractor network is shown in Fig. 11.38. After neuronal firing in the network has stopped and the error signal, which may last for 10 s as illustrated in Fig. 11.14 on page 496, is no longer present, then firing gradually can build up again in the rule attractor network. (This build-up may be assisted by non-specific inputs from other neurons in the area, as illustrated in Deco and Rolls (2005d).) However, with the competitive processes operating within the rule attractor network between the populations of neurons representing rule 1 and those representing rule 2, and the fact that the neurons or synapses that are part of the rule 1 attractor are partly adapted, the neurons that win the competition and become active are those representing rule 2, and the rule attractor has reversed its state. This process is illustrated in Fig. 11.39, and takes one trial. Reversal learning set takes a number of reversals to acquire because the correct attractors for the relevant rules, and their connections to other ‘mapping’ neurons, have to be learned.

To achieve the correct ‘mapping’ from stimuli to their reinforcer association, and thus emotional state, the rule neurons bias the competition in a mapping module, illustrated in Fig. 11.38. The mapping module has sensory input neurons, intermediate ‘conditional reward’ neurons (of the type described in Section 11.3.1.2 and illustrated in Fig. 11.7) which respond to combinations of stimuli and whether they are currently associated with reward (or for other neurons to a punisher), and output neurons which represent the reinforcement association of the stimulus currently being viewed. (In the case described there are four populations or pools of neurons at the intermediate level, two for the direct rewarding context: object 1-rewarding, object 2-punishing, and two for the reversal condition: object 1-punishing, object 2-rewarding.) These intermediate pools or populations of neurons respond to combinations of the sensory stimuli and the expected reward, e.g. to object 1 and an expected reward (glucose obtained after licking), and are the conditional reward neurons described in Section 11.3.1.2 and illustrated in Fig. 11.7 on page 487. The sensory – intermediate – reward module thus consists of three hierarchically organized levels of attractor network, with stronger synaptic connections in the forward direction from input to output than the backprojection direction. The rule module acts as a biasing input to bias the competition between the object–reward combination neurons at the intermediate level of the sensory – intermediate – reward module. This biasing is achieved because rule 1 has associatively strengthened connections to object 1–rewarding and object 2–punishing neurons. (The whole network could be set up by simple associative learning operating to strengthen connections made with low probability between different neurons that are conjunctively active during the task in the network – see Deco and Rolls (2005d).)

Thus when object 1, e.g. the triangle, is being presented and rule one for direct mapping is in the rule module and biasing the intermediate neurons of the sensory – intermediate –

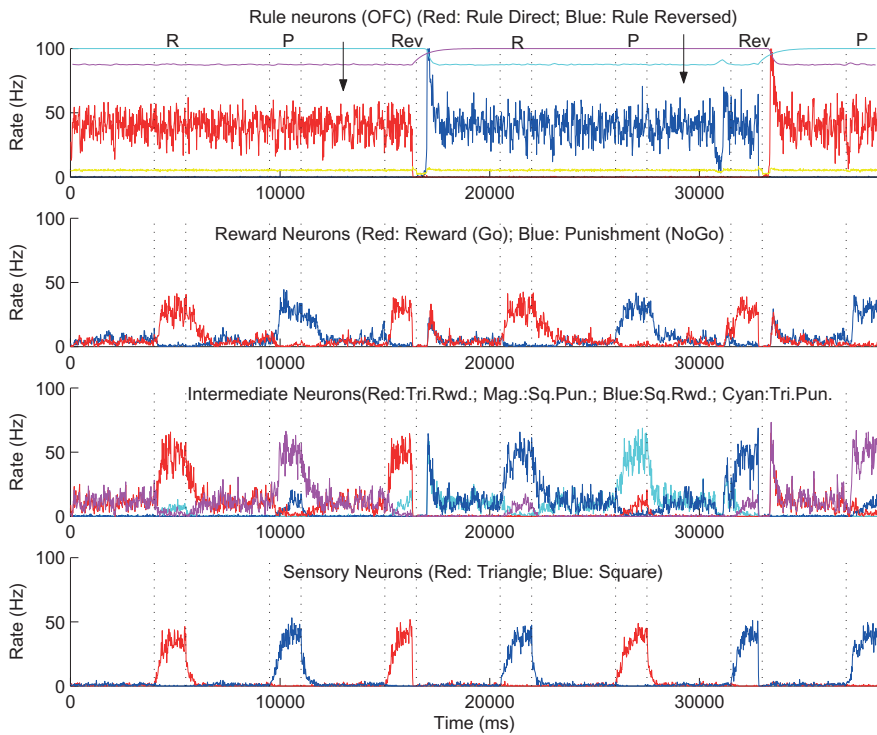

Fig. 11.39 Reward reversal model: Temporal evolution of the averaged population activity for all neural pools (sensory, intermediate (stimulus–reward), and Reward/Punishment) in the stimulus – intermediate – reward module and the rule module, during the execution and the reversal of the Go/NoGo visual discrimination task with a pseudorandom trial sequence after Thorpe, Rolls and Maddison (1983) and Rolls, Critchley, Mason and Wakeman (1996). Bottom row: the sensory neuronal populations, one of which responds to Object 1, a triangle (red), and the other to Object 2, a square (blue). The intermediate conditional stimulus–reward and stimulus–punishment neurons respond to for example Object 1 (Triangle, Tri) when it is associated with reward (Rwd) (e.g. on trial 1, corresponding to O1R in Fig. 11.38), or to Object 2 (Square, Sq) when it is associated with punishment (Pun) (e.g. on trial 2, O2P). The top row shows the firing rate activity in the rule module, with the thin line at the top of this graph showing the mean probability of release P_{rel} of transmitter from the synapses of each population of neurons. The arrows show when the contingencies reversed. R: Reward trial; P: Punishment Trial; Rev: Reversal trial, i.e. the first trial after the reward contingency was reversed when Reward was expected but Punishment was obtained. The intertrial interval was 4 s. The yellow line shows the average activity of the inhibitory neurons. (See text for further details.) (From G. Deco and E. T. Rolls (2005) *Synaptic and spiking dynamics underlying reward reversal in the orbitofrontal cortex*. *Cerebral Cortex* 15: 15–30. © Oxford University Press.)

reward module, then the intermediate neurons that fire are the object 1-reward neurons (O1R in Fig. 11.38), and these in turn through associative connections activate the reward neurons (Rwd in Fig. 11.38) at the third, reward/punishment, level of the hierarchy. If on the other hand object 1, e.g. the triangle, is being presented and rule two for reversed mapping is in the rule module and biasing the intermediate neurons of the sensory – intermediate – reward module, then the intermediate neurons that fire are the object 1–punishment (O1P) neurons, and these in turn through associative connections activate the punishment neurons (Pun) at the third, reward/punishment, level of the hierarchy. This model can thus account for one-trial reversal learning, and provides a computationally interesting account for the presence of the conditional reward and conditional punishment neurons found by Thorpe, Rolls and Maddison (1983) and Rolls, Critchley, Mason and Wakeman (1996b) in the orbitofrontal cortex (Section 11.3.1.2).

It is an important part of the architecture that at the intermediate level of the sensory – intermediate – reward module one set of neurons fire if an object being presented is currently associated with reward, and a different set if the object being presented is currently

associated with punishment. This representation means that these neurons can be used for different functions, such as the elicitation of emotional or autonomic responses, which can occur for example to particular stimuli associated with particular reinforcers (Rolls, 1999a). For example, particular emotions might arise if a particular cognitively processed input such as a particular person is associated with a particular type of reinforcer or reinforcement contingency.

It is also an interesting part of the architecture that associative synaptic modifiability (LTP, and LTD if present) is needed only to set up the functional architecture of the network while the reversal learning set is being acquired. However, once the correct synaptic connections have been set up to implement the architecture illustrated in Fig. 11.38, then no further synaptic modifiability is needed each time reversal occurs, as reversal is achieved just by the error signal quenching the current rule attractor, and the attractor for the other rule then starting up because its synapses are not adapted. This is an interesting prediction of the model. If tested by NMDA receptor blockers, which can block LTP, then it would be important to ensure that non-specific factors produced by the NMDA blockade such as less overall activity in the network, and the stabilizing effects of the long time constants of NMDA receptors, do not contribute to any result obtained. For this reason, use of a procedure for impairing synaptic modifiability other than NMDA receptor blockade would be useful in testing this prediction.

The network just described uses biased competition from a rule module to bias the mapping from sensory stimuli to the representation of a reward vs a punisher. An analogous rule network reversed in the same way by error signals quenching the current rule attractor, can be used to reverse the mapping from stimuli via intermediate stimulus–response neurons to response neurons, and thus to switch the stimulus-to-motor response being mapped in a model of conditional response learning (Deco and Rolls, 2003, 2005d). While reward rule neurons have not been described yet for the orbitofrontal cortex, neurons that may correspond to stimulus–response rule neurons have been found in the dorsolateral prefrontal cortex (Wallis et al., 2001).

This model also provides a computational account for why the orbitofrontal cortex may play a more important role in rapid reversal learning than the amygdala. The account is based on the fact that a feature of cortical architecture is a highly developed set of local (within 1–2 mm) recurrent collateral excitatory associatively modifiable connections between pyramidal cells (Rolls and Deco, 2002; Rolls and Treves, 1998; Rolls, 2021c). These provide the basis for short-term memory attractor networks, and thus the basis for the rule attractor model which is at the heart of the proposal for how rapid reversal learning is implemented (Deco and Rolls, 2005d). In contrast, the amygdala is thought to have a much less well developed set of recurrent collateral excitatory connections, and thus may not be able to implement rapid reversal learning in the way described using competition biased by a rule module. Instead, the amygdala would need to rely on synaptic relearning as described in the first approach above, and this would be likely to be a slower process, and would certainly not lead to correct choice of the new S+ the first time it is presented after a punishment trial when the reversal contingency changes. Of course, in addition it is possible that the rapidity of LTP, and the efficacy of LTD, both of which would also facilitate rapid reversal, may be enhanced in the orbitofrontal cortex compared to the amygdala. Thus, the cortical neuronal reversal mechanism in the orbitofrontal cortex may be effectively a faster implementation in two ways than what is implemented in the amygdala. The cortical (in this case orbitofrontal cortex) mechanism may have evolved particularly to enable rapid updating by received reinforcers in social and other situations in primates. This hypothesis, that the orbitofrontal cortex, as a rapid learning mechanism, effectively provides an additional route for some of the functions performed by the amygdala, and is very important when this stimulus–reinforcer learning must be rapidly

readjusted, has been developed elsewhere (Rolls, 1990c, 1992b, 1996a, 1999a, 2000c, 2005a, 2019e).

Another feature of the rule attractor model of rapid reversal learning (Deco and Rolls, 2005d) is that it does utilize a set of coupled attractor networks in the orbitofrontal cortex. Consistent with this, Hikosaka and Watanabe (2000) have shown that a short-term memory for reward, such as the flavor of a food, is represented by continuing firing in orbitofrontal cortex neurons in a reward delayed match-to-sample short-term memory task. This could be implemented by associatively modified synaptic connections between taste reward neurons in the orbitofrontal cortex.

Although the mechanism has been described so far for visual-to-taste association learning, this is because neurophysiological experiments on this are most direct. It is likely, given the evidence from the effects of lesions, that taste is only one type of primary reinforcer about which such learning occurs in the orbitofrontal cortex, and is likely to be an example of a much more general type of stimulus–reinforcer learning system. Some of the evidence for this is that humans with orbitofrontal cortex damage are impaired at visual discrimination reversal when working for a reward that consists of points (Rolls, Hornak, Wade and McGrath, 1994a) or money (Hornak, Bramham, Rolls, Morris, O’Doherty, Bullock and Polkey, 2003). Moreover, as described above, there is evidence that the representation of the affective aspects of touch are represented in the human orbitofrontal cortex (Rolls, O’Doherty, Kringelbach, Francis, Bowtell and McGlone, 2003d; McCabe, Rolls, Bilderbeck and McGlone, 2008), and learning about what stimuli are associated with this class of primary reinforcer is also likely to be an important aspect of the stimulus–reinforcer association learning performed by the orbitofrontal cortex.

11.5.4 A theory and model of non-reward neural mechanisms in the orbitofrontal cortex

Single neurons in the primate orbitofrontal cortex respond when an expected reward is not obtained, and behavior must change. The human lateral orbitofrontal cortex is activated when non-reward, or loss occurs. The neuronal computation of this negative reward prediction error is fundamental for the emotional changes associated with non-reward, and with changing behavior. A mechanism for this computation has been proposed (Rolls and Deco, 2016), as follows.

A single attractor network has a Reward population (or pool) of neurons that is activated by Expected Reward (Fig. 11.40), and maintain their firing until, after a time, synaptic depression reduces the firing rate in this neuronal population. If a Reward Outcome is not received, the decreasing firing in the Reward neurons releases the inhibition implemented by inhibitory neurons, and this results in a second population of Non-Reward neurons to start and continue firing encouraged by the spiking-related noise in the network. This is illustrated in the integrate-and-fire simulation shown in Fig. 11.41.

If a Reward Outcome is received, this keeps the Reward attractor active, and this through the inhibitory neurons prevents the Non-Reward attractor neurons from being activated. If an Expected Reward has been signalled, and the Reward Attractor neurons are active, their firing can be directly inhibited by a Non-Reward Outcome, and the Non-Reward neurons become activated because the inhibition on them is released (Rolls and Deco, 2016).

The neuronal mechanisms in the orbitofrontal cortex for computing negative reward prediction error are important, for this system may be over-reactive in depression, under-reactive in impulsive behavior, and may influence the dopaminergic ‘reward prediction error’ neurons.

Fig. 11.40 A model for the computation of non-reward in the orbitofrontal cortex. The excitatory neurons are divided into two selective pools S1 (termed the Reward Attractor population of neurons) and S2 (termed the Non-Reward Attractor population of neurons) (with 80 neurons each) with strong intra-pool connection strengths w_+ and one non-selective pool (NS) (with 640 neurons). The value of w_+ for S2 is a little higher than that for S1, so that S2 tends to emerge into a high firing rate if activity is not maintained in S1 after an Expected Reward input has been received. The other connection strengths are 1 or weak w_- . The network contains 1000 neurons, of which 800 are in the excitatory pools and 200 are in the inhibitory pool IH. Every neuron in the network also receives inputs from 800 external neurons, and these neurons increase their firing rates to apply a stimulus to one of the pools S1 or S2. (Modified from Rolls, E. T. and Deco, G. (2016) Non-reward neural mechanisms in the orbitofrontal cortex. *Cortex* 83: 27–38. © Elsevier Ltd.)

11.6 Highlights: what are the special computational roles of the orbitofrontal cortex in reward, emotion, and decision-making?

It is important in terms of our understanding of brain function to consider what is special about the primate including human orbitofrontal cortex for reward, decision-making, and emotion, compared to other brain regions including the amygdala. This invites an answer about what is special about the computations performed by the orbitofrontal cortex compared to other brain regions.

First, the orbitofrontal cortex, as a neocortical area, has highly developed recurrent collateral connections between its pyramidal cells, which together with associative synaptic plasticity, provide the basis for autoassociation or attractor networks (Rolls, 2021c). (The amygdala in contrast has little recurrent collateral connectivity (Millhouse and DeOlmos, 1983).) These attractor networks provide the basis for short-term memory functions, by maintaining neuronal firing in a stable attractor. These attractor networks can hold on-line which stimuli (and this could be other individuals) are currently rewarding, which is important for social interactions and economic decisions. This memory capability is an important component of rule-based one-trial reversal, in which the current rule must be held in short-term memory (Deco and Rolls, 2005d). Short-term memory is also potentially very useful for holding mood online for some time, so that if for example a reward is not received, the non-reward state of frustration can lead to continuing attempts to regain the reward. Similar short-term memory processes might enable one to remember the recent reinforcement history of individuals, and again can be important in decision-making. The short-term memory aspects of these attractor networks are also important for holding the expected value online, until the reward outcome is received, after which non-reward neurons may be activated in the ways just described (Rolls and Deco, 2016), and such computations may also contribute to reward prediction error, de-

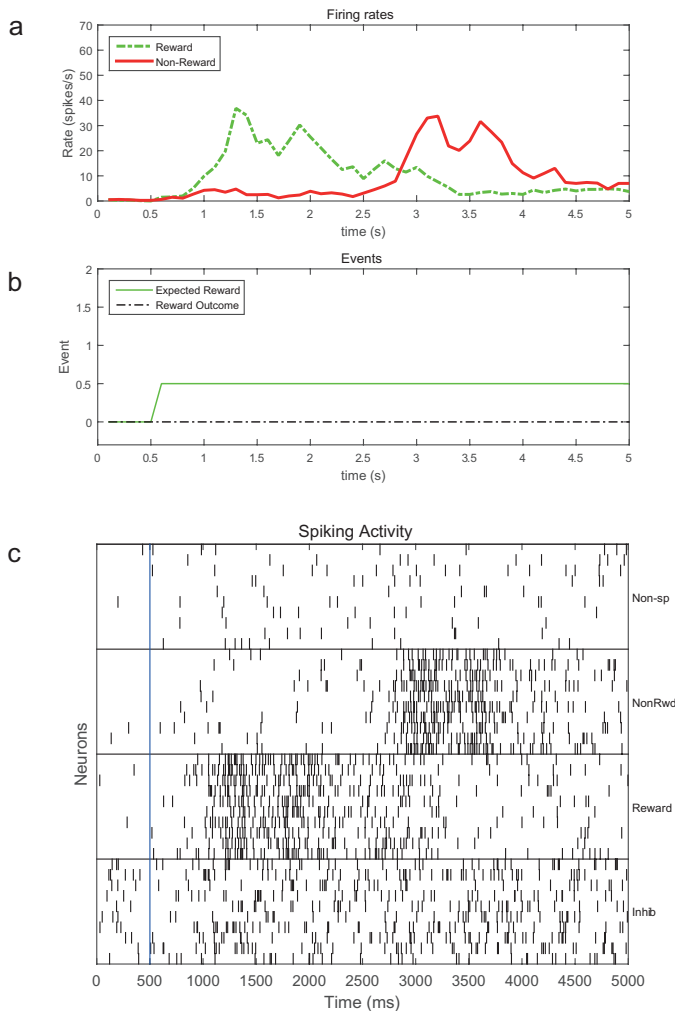

Fig. 11.41 A model for the computation of non-reward in the orbitofrontal cortex. The operation of the network when an Expected Reward is not obtained (extinction). a. The firing rates of the Reward population of neurons and the Non-Reward population of neurons during a 5 s trial. b. After a period of spontaneous activity from 0 until 0.5 s, the Expected Reward input was applied to the reward attractor population of neurons, and maintained at that level for the remainder of the trial. No Reward Outcome input was received. c. Rastergrams showing for each of the four populations of neurons, Non-Specific, Non-Reward, Reward, and Inhibitory, the spiking of ten neurons chosen at random from each population. Each small vertical line represents a spike from a neuron. Each horizontal row shows the spikes of one neuron. The different neurons are from the same trial. (Modified from Rolls, E. T. and Deco, G. (2016) Non-reward neural mechanisms in the orbitofrontal cortex. *Cortex* 83: 27–38. © Elsevier Ltd.)

defined as the reward outcome value minus the expected reward. The short-term memory also provides the biasing system for top-down attention to reward value (Grabenhorst, Rolls and Bilderbeck, 2008a; Rolls, Grabenhorst, Margot, da Silva and Velazco, 2008b; Grabenhorst and Rolls, 2008; Rolls, 2008f; Ge, Feng, Grabenhorst and Rolls, 2012; Luo, Ge, Grabenhorst, Feng and Rolls, 2013) implemented by biased competition (Sections 2.12 and B.8.4), or by biased activation (Grabenhorst and Rolls, 2010; Rolls, 2013a) (Section 4.3.5).

These attractor networks in the orbitofrontal cortex and ventromedial prefrontal cortex also provide the basis for reward-related decision-making, in which inputs to two competing attractor states in an attractor network lead to a bifurcation and to a decision (Deco, Rolls and Romo, 2009; Rolls and Deco, 2010, 2011b; Deco, Rolls, Albantakis and Romo, 2013).

Part of the utility of this approach to decision-making is that once the decision has been taken in the attractor network, the results of the decision are kept active in the decision-making attractor network to provide the goals for the selection of actions by the cingulate cortex to obtain the rewards (Rolls, 2019e,c).

Second, the primate and human orbitofrontal cortex as a neocortical area is beautifully connected anatomically to receive inputs from representations of ‘what’ stimulus is present from every sensory modality at the top of each sensory cortical hierarchy, independently of reward value (as shown in Fig. 11.1), and then to compute multimodal representations that are then represented in terms of their reward value. This is very different from the rodent, in which reward is represented throughout the processing systems (Rolls, 2019e) (Section 19.10).

Third, the primate orbitofrontal cortex specializes in reward value, rather than action. This separation allows the value of many stimuli in the high dimensional space of different rewards (Rolls, 2014a) to be represented, and for competition between them to be useful for computing relative reward value (Grabenhorst and Rolls, 2009). Moreover, mood states can be maintained, independently of any actions being performed. In contrast, as described above, the rodent ‘orbitofrontal cortex’ is also involved in motor responses and actions (Wilson, Takahashi, Schoenbaum and Niv, 2014b), so can be less specialized for representing reward value, and rapidly changing it.

Fourth, the primate orbitofrontal cortex projects reward value representations to the pregenual anterior cingulate cortex, and punishment value representations to the supracallosal anterior cingulate cortex (Hsu et al., 2020; Du et al., 2020; Rolls et al., 2023c), where they can be associated with actions performed recently represented in the supracallosal anterior cingulate cortex (Rolls et al., 2023c), received partly via the posterior cingulate cortex from the parietal cortex, to implement action-outcome learning (Rolls, 2019c). Outputs are then directed from mid-cingulate areas to the premotor cortical areas (Rolls, 2019c; Rolls et al., 2023c). The amygdala does not have similar connectivity.

Fifth, the human lateral orbitofrontal cortex has considerable connectivity with the inferior frontal gyrus areas 45 and 44 which in the left are Broca’s area, and this may be part of the route by which the orbitofrontal cortex, especially laterally, becomes functionally connected with language areas in the posterior temporal and parietal areas (Hsu, Rolls, Huang, Chong, Lo, Feng and Lin, 2020; Du, Rolls, Cheng, Li, Gong, Qiu and Feng, 2020; Rolls, Deco, Huang and Feng, 2023c). This provides a route for top-down influences of language-related processing on emotional and social behavior, and indeed is part of the long-loop interactions between attractor networks that are proposed to contribute to increased rumination in depression (Rolls, 2016e; Rolls et al., 2020a) (Section 18.5). This route also enables emotional states represented in the orbitofrontal cortex to gain access to language systems to provide for declarative reports about felt emotional states (Rolls et al., 2023c,b).

To finish this Chapter, it may be interesting to consider the following hypothesis about the evolutionary basis for why the primate including human orbitofrontal cortex has become the part of the cerebral cortex that specialises in reward (and punishment) value decoding, and in emotion. The hypothesis is that the primary taste cortex in the anterior insula projects to the next stage in its hierarchy, which is the orbitofrontal cortex just immediately in front of it (Baylis, Rolls and Baylis, 1995; Rolls, Deco, Huang and Feng, 2023f,c), and that the next computation that needs to be implemented in the taste system after the insular primary taste cortex is reward processing of food, which is rather important for survival. The hypothesis is that the main place to which the primary taste cortex in the anterior insula could project to for reward processing in a hierarchy is the orbitofrontal cortex, for all the cortex posterior to the anterior insula was occupied by body somatosensory insula (see Chapter 6). The hypothesis further is that for the orbitofrontal cortex to implement food reward well, the orbitofrontal

cortex needed also olfactory inputs, and somatosensory inputs for the texture of food to build food flavor, and also visual object inputs for the sight of food to be associated with its flavor (which is very important in primates in their ecological niches).

But why did other rewards than food also get built into the orbitofrontal cortex? That is a more open question. But once the orbitofrontal cortex has somatosensory reward for the texture of food, this could be extended to other types of texture, such as the soft gentle touch of skin, with mutual grooming a sign of affiliation and cooperation in primates (Dunbar, 2022). And somatosensory inputs as rewards may also be relevant to reproductive behavior. Again, there is a need for relevant visual inputs to become associated with these primary reinforcers, with it being important to visually recognise the partner in whom you are investing, in part with the evolutionary adaptive value of producing offspring and investing in them to increase their chances of reproduction and maintaining the gene line. That type of reward, and related rewards such as monetary value, may all thereby be computed in the primate including human orbitofrontal cortex, with food reward as an evolutionary origin.

12 The cingulate cortex

12.1 Introduction to and overview of the cingulate cortex

12.1.1 Introduction

A key area included by Broca in his limbic lobe (Broca, 1878) is the cingulate cortex, which hooks around the corpus callosum. The term limbic used by Broca referred to structures that are at the border or edge (the literal meaning of limbic) of the hemispheres (when seen in medial view), and led to the development of the concept of a limbic system (Pessoa and Hof, 2015). Other limbic structures include the hippocampus, and the amygdala (which has major connections with the orbitofrontal cortex). These structures appear to have very different connections and functions. The amygdala and orbitofrontal cortex are key structures involved in emotion and reward value with connections from ventral stream processing areas that decode ‘what’ the stimulus is (Rolls, 2014a, 2019e) (Chapter 11). The hippocampus is a key structure in episodic memory with ‘where’ inputs about spatial scenes from the ventromedial visual stream and from the parietal cortex for self-motion update, as well as from the ‘what’ ventral processing stream and the value system in the orbitofrontal cortex (Kesner and Rolls, 2015; Rolls, 2018b, 2023c) (Chapter 9). Because of the different connectivity and functions of these limbic structures (amygdala, orbitofrontal cortex, and hippocampus) in emotion and in memory, it has been proposed that the concept of a single ‘limbic system’ is not realistic, and that we should consider separately the connectivity and functions of different limbic structures in emotion and memory (Rolls, 2015b).

However, that leaves the cingulate cortex in an interesting position straddling the emotional and memory domains. The anterior cingulate cortex receives inputs from the orbitofrontal cortex and amygdala which receive from ventral stream areas. Moreover, there is evidence relating the anterior cingulate cortex to action-outcome learning, in which actions are learned to obtain goals based on the outcomes, the rewards and punishers, received for different actions (Rushworth, Kolling, Sallet and Mars, 2012; Kolling, Wittmann, Behrens, Boorman, Mars and Rushworth, 2016; Rolls, 2019c; Klein-Flugge, Bongioanni and Rushworth, 2022a; Rolls, Deco, Huang and Feng, 2023c). The selection of which action to perform to obtain the best reward outcome may involve deciding whether to continue with the present action, termed in the language of foraging ‘exploit’, or whether to ‘explore’, that is switch to a different action aimed at a different goal and reward outcome (Klein-Flugge et al., 2022a).

Some parts of the posterior cingulate cortex receive from spatial ‘where’ systems including via the ventromedial visual stream to the parahippocampal cortex and from the parietal cortex, and other parts from ‘what’ inferior temporal cortex and related regions, and both connect to the hippocampal memory system.

In this Chapter I provide a framework for understanding the connectivity and functions of the cingulate cortex, and how the cingulate cortex can be involved in at least three important functions, emotion, action-outcome learning, and memory.

Fig. 12.1 Connections of the anterior cingulate cortex shown on views of the primate brain (see text). The anterior cingulate cortex (including the subgenual cingulate cortex area 25) is shaded in red, the posterior cingulate cortex (areas 23 and 31) and retrosplenial cortex (areas 29 and 30) in green, and the corpus callosum (cc) in grey. The arrows show the main direction of connectivity, but there are connections in both directions. Connections reach the pregenual cingulate cortex especially from the medial/mid-orbitofrontal cortex; and reach the supracallosal anterior cingulate cortex especially from the orbitofrontal cortex as well as premotor cortex regions. Connections to the pregenual anterior cingulate cortex from the temporal lobe are from the (auditory) superior temporal gyrus (STG), from the visual and auditory cortex in the superior temporal sulcus; and from the amygdala. Abbreviations: as – arcuate sulcus; cf – calcarine fissure; cgs – cingulate sulcus; cs – central sulcus; ls – lunate sulcus; ios – inferior occipital sulcus; mos – medial orbital sulcus; os – orbital sulcus; ps – principal sulcus; sts – superior temporal sulcus; Sf – Sylvian (or lateral) fissure (which has been opened to reveal the insula); Am – amygdala; INS – insula; TE (21) – inferior temporal visual cortex; STG (22) – superior temporal gyrus auditory association cortex; TF and TH – parahippocampal cortex; TPO – multimodal cortical area in the superior temporal sulcus; 28 – entorhinal cortex; 38, TG – temporal pole cortex; 13, 11 – medial orbitofrontal cortex; 12 – lateral orbitofrontal cortex; 10 – ventromedial prefrontal cortex; 14 – gyrus rectus; 51 – olfactory (prepyriform and periamygdaloid) cortex.

12.1.2 Overview of what is computed in the cingulate cortex

1. In humans, the pregenual and subgenual anterior cingulate cortex receive information directly and via the ventromedial prefrontal cortex (vmPFC) from the medial orbitofrontal cortex where rewards are represented, and from the lateral orbitofrontal cortex where aversive stimuli are represented. These orbitofrontal cortex areas represent information about value, not about actions or responses, as shown by neuronal recordings in macaques.
2. The pregenual anterior cingulate cortex in humans is activated by many rewards.
3. The pregenual anterior cingulate cortex has onward effective connectivity directed to the hippocampal system, both directly, and via the posterior cingulate cortex. This provides a route for emotional states, and the rewards and punishers that elicit them, to become incorporated into hippocampal episodic memory, and potentially to provide the goals for

navigation. It is appropriate that the reward-related pregenual anterior cingulate cortex should have some of its output directed towards a navigational system, which is set up to find goals.

4. The pregenual anterior cingulate cortex also has effective connectivity directed to the septal nuclei which provide the cholinergic innervation of the hippocampus. This modulation may influence episodic memory consolidation.
5. The memory deficits produced by vmPFC / anterior cingulate cortex damage in humans are probably related to interference with the incorporation of value information into episodic memory, and when the value component is recalled, its effects on memory consolidation by enhancing the depth of processing. In addition, damage to the vmPFC / anterior cingulate regions may impair memory consolidation by interference with the modulation of cholinergic function produced by connectivity from the anterior cingulate cortex to the septal region. This evidence indicates that the vmPFC / anterior cingulate cortex does not implement the computations required for episodic memory, which are performed by the hippocampus.
6. The supracallosal anterior cingulate cortex (also known as the dorsal anterior cingulate cortex dACC) is activated by aversive stimuli and non-reward, receives value-related information about outcomes from the orbitofrontal cortex and pregenual anterior cingulate cortex, and is implicated in action-outcome learning. It has connectivity to premotor cortical regions including the mid-cingulate cortex, which is appropriate for producing actions. If aversive stimuli or non-reward are received, this is likely to lead to a change of actions: in the terminology of foraging, changing from 'exploit' to 'explore'. It is involved in actions directed to obtaining goals, in that devaluation of the goal results in an immediate cessation of the action, even before there has been an opportunity for the action to be made and then not followed by the reward.
7. This is different from stimulus-response habits learned by dopamine-dependent reinforcement learning, which are not driven by the goal, and continue for some time even when the reinforcer is devalued.
8. The anterior cingulate cortex is thereby implicated in emotion, because the pregenual anterior cingulate cortex is involved in processing rewards received from the orbitofrontal cortex and connecting them to navigational systems to obtain rewards; and because the supracallosal anterior cingulate cortex is involved in processing aversive stimuli and non-reward received from the orbitofrontal cortex, and changing actions to 'explore' in order to avoid the punishers and non-reward, and to search for new goals with new actions.
9. The subgenual cingulate cortex (area 25) may link rewards and punishers to autonomic output.
10. The posterior cingulate division postero-ventral regions receive information from the visual inferior temporal cortex and auditory and semantic superior temporal sulcus regions, and from vmPFC and pregenual cingulate reward regions. They have connectivity to the hippocampal system thereby contributing to 'what' information for hippocampal episodic memory.
11. The posterior cingulate division antero-dorsal regions (including the RSC region) receive inputs from the parietal cortex, including areas 7a, VIP and LIP laterally, and area 7m medially, and have effective connectivity to the hippocampal systems thereby contributing to 'where' information for the idiothetic update of scene representations used for hippocampal episodic memory.
12. The retrosplenial scene area is located in DVT the dorsal visual transitional region and in ProS the prostriate cortex region, receives inputs from the occipital scene area, and connects to the parahippocampal scene area (or PPA), providing a ventromedial visual

cortical route for ‘where’ information about scenes to reach the hippocampal episodic memory system.

12.1.3 Overview of how the computations are performed by the cingulate cortex

1. For action-outcome learning, the system needs to hold active a representation of the action that has just been performed, so that it can be associated with the outcome when it arrives. It may also be useful to hold online evidence about outcomes received from the previously few trials, as this is likely to be useful in probabilistic tasks, that is under uncertainty. Cortical attractor networks in the anterior cingulate cortex are likely to implement this local short-term memory function.
2. The outcomes are in the high dimensional space of many different types of reward that are represented in the orbitofrontal cortex. This enables rapid learning of which actions to perform for which outcomes, because this requires simple associative learning between the particular actions recently performed, and the particular outcomes that have recently been received, with the outcome information provided by the orbitofrontal cortex.
3. This action-outcome learning implemented in the supracallosal anterior cingulate cortex (dACC) is thus much more efficient than stimulus-response habit formation, in which a one-dimensional reinforcer, the dopamine neuron reward prediction error signal, is used to reinforce whatever representations of stimuli and responses throughout the dopamine-influenced basal ganglia system may recently have been active (see Chapter 16).
4. The orbitofrontal cortex–supracallosal anterior cingulate cortex action-outcome learning system is also much more rapid and efficient than the reinforcement learning stimulus-response habit system implemented by dopamine and the basal ganglia, because if the association between the stimulus and the outcome (a stimulus-stimulus association) changes or is reversed, this can be corrected in one trial by the stimulus-reward reversal learning system in the orbitofrontal cortex described in Chapter 11.
5. Error signals generated in the dACC reflect a mismatch between the expected outcome and the action. This is different from the orbitofrontal cortex, in which the error signals reflect a mismatch between the expected value of a stimulus (e.g. the sight of food) and the outcome (e.g. a taste of food).
6. It is proposed that the error signal in the dACC acts to destabilize and reset an attractor network neuronal population that indicates ‘exploit’ to allow another neuronal population that represents ‘explore’ to become active in the same attractor network, in order to generate ‘explore’ behavior when non-reward or a punisher is received from the orbitofrontal cortex. The computational mechanism is similar to that described for reversal of the rule attractor network in Section 11.5.3.
7. The spatial part of the posterior cingulate cortex, together with the retrosplenial cortex, connects information from the parietal lobe which may be at least partly in egocentric coordinates with the hippocampal system via the parahippocampal gyrus which is largely in allocentric coordinates. The posterior cingulate cortex and retrosplenial scene area may be involved in helping to perform these coordinate transforms, in ways that are described in Section 3.4.

12.2 Anterior cingulate cortex

12.2.1 Anterior cingulate cortex anatomy and connections in primates

The anterior cingulate regions occupy approximately the anterior one third of the cingulate cortex (see Fig. 12.1) and are involved in emotion. They may be distinguished from a mid-cingulate area (i.e. further back than the anterior cingulate regions and occupying approximately the middle third of the cingulate cortex) which has been termed the cingulate motor area (Vogt et al., 1996; Vogt, 2009, 2016, 2019b) and may be involved in action selection (Rushworth et al., 2004, 2011). The anterior cingulate cortex includes parts of area 32 and 24, and comprises the pregenual anterior cingulate cortex, the supracallosal anterior cingulate cortex, and area 25 the subgenual cingulate cortex (Figs. 12.1 and 11.3) (Price, 2006; Ongur, Ferry and Price, 2003; Ongur and Price, 2000; Carmichael and Price, 1996; Vogt, 2009, 2019b). (The midcingulate cortex has been described as having an anterior and a posterior part, with the criteria including cytoarchitecture (Vogt, 2016, 2019b).)

As shown in Figs. 12.1 and 12.2, the anterior cingulate cortex receives strong inputs from the orbitofrontal cortex, and is also characterised by connections with the amygdala (Carmichael and Price, 1995a; Morecraft and Tanji, 2009; Vogt, 2009, 2019b). The anterior cingulate cortex also has connections with some temporal cortical areas involved in memory including the parahippocampal gyrus (which provides via the entorhinal cortex a bridge to the hippocampus); and with the rostral superior temporal gyrus, the auditory superior temporal gyrus, and the dorsal bank of the superior temporal sulcus (Saleem et al., 2008; Vogt, 2009) (see Fig. 12.1). (The cortex in the superior temporal sulcus contains visual neurons that respond to face expression, gesture, and head movement (Hasselmo, Rolls and Baylis, 1989a; Hasselmo, Rolls, Baylis and Nalwa, 1989b).)

In more detail, in macaques a ‘medial prefrontal network’ (mainly anterior cingulate cortex) selectively involves medial areas 14r, 14c, 24, 25, 32, and 10m, rostral orbital areas 10o and 11m, and agranular insular area 1ai in the posterior orbital cortex (Carmichael and Price, 1996). An ‘orbital’ prefrontal network links most of the areas within the orbital cortex, including areas 1am, 1apm, 1al, 12i, 12m, and 12r in the caudal and lateral parts of the orbital cortex, with areas 13i, 13m, and 13b in the central orbital cortex, which have further onward connections to the rostral orbital area 11i (Carmichael and Price, 1996; Ongur and Price, 2000; Price, 2006). Several orbital areas (including 13a, 12o and 11m) have connections with both the medial and orbital networks. Many of these areas are shown in Figs. 12.1 and 11.2. It is interesting that this macaque medial prefrontal network (anterior cingulate cortex) has connections with the posterior cingulate / retrosplenial cortex, and parahippocampal cortex (Saleem et al., 2008), and has access to the hippocampus in this way; whereas the orbitofrontal cortex has projections to the perirhinal cortex (Saleem et al., 2008), and thus has access to the hippocampus via a more ventral route (Fig. 12.2).

The outputs of the anterior cingulate cortex reach further back in the cingulate cortex towards the mid-cingulate cortex, which includes the cingulate motor area (Vogt et al., 1996; Morecraft and Tanji, 2009; Vogt, 2009, 2016). The anterior cingulate cortex also projects forwards to medial prefrontal cortex area 10 (Price, 2006; Ongur and Price, 2000), and to temporal lobe areas including the parahippocampal gyrus, perirhinal cortex, and entorhinal cortex (Vogt, 2009).

Another route for output is via the projections to the striatum / basal ganglia system.

The anterior cingulate cortex, including the subgenual cingulate cortex area 25, also has outputs that can influence autonomic/visceral function via the hypothalamus, midbrain periaqueductal gray, and insula, as does the orbitofrontal cortex (Rempel-Clower and Barbas, 1998; Price, 2006; Ongur and Price, 2000; Critchley and Harrison, 2013).

The connectivity of the human anterior cingulate cortex (Rolls et al., 2023c) is described

in Section 12.2.5, and that has further implications for what is computed in the human anterior cingulate cortex.

12.2.2 Anterior cingulate cortex: A framework

The pregenual anterior cingulate cortex regions can be conceptualized as receiving information from the orbitofrontal cortex about expected rewards and outcomes, and linking to hippocampal systems for navigation towards goals (rewards) and for storage in memory; and linking to the supracallosal anterior cingulate cortex for action-outcome learning; and also linking to the striatum / basal ganglia (see Fig. 12.3 for humans).

The supracallosal anterior cingulate cortex (dACC) can be conceptualized as receiving information from the orbitofrontal cortex about expected punishers and outcomes including non-reward outcomes, and linking these to actions recently performed to implement action-outcome learning. The supracallosal anterior cingulate cortex has much connectivity with premotor and somatosensory systems (Rolls et al., 2023c) (Fig. 12.3), and with the mid-cingulate motor cortex (Vogt, 2016, 2009), to associate recent actions with the outcomes received, in order to optimize the action selected at any given time. If the action involves no change of behavior, this is described as ‘exploit’. If behavior changes, perhaps in response to not receiving an expected reward (referred to as ‘non-reward’), then behavior changes to ‘explore’ possible different actions. The mid-cingulate cortex receives inputs about actions from premotor and somatosensory cortical regions and from the parietal cortex directly and via the spatial parts of the posterior cingulate cortex (Rolls et al., 2023i). The learning of action-outcome associations in the supracallosal anterior cingulate cortex enables the correct actions to be selected in future. The connections that provide for this are shown in Figs. 12.1, 12.2, and for humans 12.3.

Bringing together information about specific rewards with information about actions, and the costs associated with actions, is important for associating actions with the value of their outcomes and for selecting the correct action that will lead to a desired reward (Walton et al., 2003; Rushworth et al., 2007b; Rolls, 2009a; Rushworth et al., 2011; Grabenhorst and Rolls, 2011; Rolls, 2014a; Kolling et al., 2016). Indeed, consistent with its strong connections to motor areas (Morecraft and Tanji, 2009), lesions of the anterior cingulate cortex impair reward-guided action selection (Kennerley et al., 2006; Rudebeck et al., 2008), neuroimaging studies have shown that the anterior cingulate cortex is active when outcome information guides choices (Walton et al., 2004), and single neurons in the anterior cingulate cortex encode information about both actions and outcomes including reward prediction errors for actions (Matsumoto et al., 2007; Luk and Wallis, 2009; Kolling et al., 2016; Klein-Flügge et al., 2022a). For example, Luk and Wallis (2009) found that in a task where information about three potential outcomes (three types of juice) had to be associated on a trial-by-trial basis with two different responses (two lever movements), many neurons in the anterior cingulate cortex encoded information about both specific outcomes and specific actions. Action-outcome learning in a pure form to illustrate the concept might involve making an action in the dark (i.e. with no visible stimuli, though perhaps preceded by a ‘start’ tone to indicate when to start the action), and obtaining a reward outcome or not, and gradually learning the correct action to obtain a reward.

This supracallosal anterior cingulate connectivity with major outputs to premotor cortical areas (green) is compared in Fig. 12.2 with that of the hippocampus, which receives information from the ventral ‘what’ processing stream (blue) and the dorsal ‘where’ or ‘action’ processing stream (red), but then projects back to the neocortical areas from which it receives inputs. The hippocampus receives its inputs via the parahippocampal gyrus (areas TF and TH), and the perirhinal cortex (areas 35 and 36), both of which in turn project to

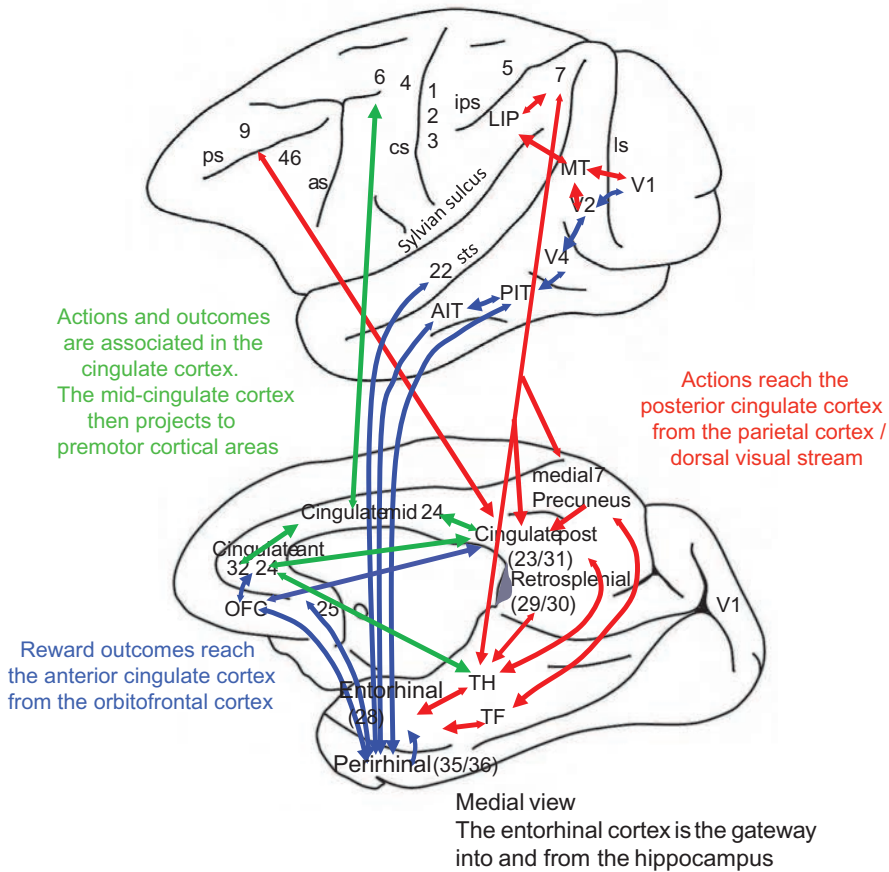

Fig. 12.2 Connections of the anterior, mid- and posterior cingulate cortex with a framework for understanding the functions of the cingulate cortex in action-outcome learning. A medial view of the macaque brain is shown below, and a lateral view is above. The green arrows show the convergence of reward or outcome information from the anterior cingulate cortex (ACC) (red) and of information about actions from the posterior cingulate cortex (red) to the mid-cingulate motor area, which then projects to premotor areas including the premotor cortex area 6 and the supplementary motor area (green). This provides connectivity for action-outcome learning. The ACC receives reward outcome information from the orbitofrontal cortex (OFC) derived from the ventral processing streams (blue). The posterior cingulate cortex receives information about actions from the parietal cortex dorsal processing streams (red). The mid-cingulate cortex projects to premotor areas (green). Abbreviations: as - arcuate sulcus; cs - central sulcus; ips - intraparietal sulcus; ios - inferior occipital sulcus; ls - lunate sulcus; sts - superior temporal sulcus; and see text.

the entorhinal cortex (area 28), send inputs to the hippocampus and receive backprojections from the hippocampus. The forward inputs towards the entorhinal cortex and hippocampus are shown with large arrowheads, and the weaker return backprojections with small arrowheads. The hippocampus receives via the perirhinal cortex areas 35 and 36 which project to the lateral entorhinal cortex area 28 from the ends of the hierarchically organised ventral visual system pathways (V1, V2, V4, PIT, AIT) that represent ‘what’ object is present (including also faces, and even scenes), from the anterior inferior temporal visual cortex (AIT, BA21, TE) where objects and faces are represented which receives from the posterior inferior temporal cortex (PIT, BA20, TEO); from the reward system in the orbitofrontal cortex (OFC) and amygdala, and from an area to which the OFC projects, the anterior cingulate cortex BA32 and subgenual cingulate cortex (BA25); from the high order auditory cortex (BA22); and from olfactory, taste, and somatosensory ‘what’ areas (not shown). The hippocampus also re-

ceives via the parahippocampal cortex areas TF and TH inputs (shown in red) from the dorsal visual ‘where’ or ‘action’ pathways, which reach parietal cortex area 7 via the dorsal visual stream hierarchy, including V1, V2, MT, MST, LIP, and VIP, and from areas to which they are connected, including the dorsolateral prefrontal cortex BA46 and the posterior cingulate (Cingulate post) and retrosplenial cortex. The hippocampus provides a system for all the high-order cortical regions including the reward-related orbitofrontal cortex and pregenual anterior cingulate cortex to converge into a single network in the hippocampal CA3 region, and then for backprojections to reach back to the neocortex (Rolls, 2018b) (see Chapter 9).

12.2.3 Anterior cingulate cortex and action-outcome representations

Some single neuron studies indicating encoding of actions and outcomes have often involved rather dorsal recordings above the pregenual cingulate cortex in the dorsal anterior cingulate cortex (dACC in the dorsal bank of the cingulate sulcus), termed here the supracallosal anterior cingulate cortex (Matsumoto et al., 2007; Luk and Wallis, 2009; Kolling et al., 2016; Klein-Flugge et al., 2022a). In this dACC region, action–outcome associations appear to be represented, in that in tasks in which there were different relations between actions and rewards, it was found that even before a response was made, while the monkey was looking at a visual cue, the activity of anterior cingulate cortex neurons depended on the expectation of reward or non-reward (25%), the intention to move or not (25%), or a combination of movement intention and reward expectation (11%) (Matsumoto et al., 2003). Luk and Wallis (2013) described recordings in the same dorsal anterior cingulate cortex area that reflected the outcomes when monkeys made a choice of a left or right lever response to obtain a reward outcome, and also described a weak dissociation for more stimulus–outcome neurons in the orbitofrontal cortex, that is when monkeys had to choose the reward outcome based on which visual stimulus was shown. In the same dorsal anterior cingulate area neurons were more likely to take into account the costs of the actions required to obtain rewards, as well as the probability of obtaining the reward, than were neurons in the orbitofrontal cortex (Kennerley and Wallis, 2009; Kennerley et al., 2011; Kolling et al., 2016). In the dorsal anterior cingulate cortex, neurons may reflect evidence about the several most recent rewards, and use this to help guide choices (Kolling et al., 2016; Klein-Flugge et al., 2022a).

More ventrally in the pregenual anterior cingulate cortex, neurons are more likely to reflect reward outcome rather than primarily actions, and the outcome representation trailed that in the orbitofrontal cortex (Cai and Padoa-Schioppa, 2012). These findings are consistent with the hypothesis developed here and elsewhere (Rolls, 2019c,b) that the orbitofrontal cortex represents the value of stimuli, and in its more anterior / ventromedial prefrontal area 10 takes decisions about relative reward value (Rolls, Grabenhorst and Deco, 2010b,c; Rolls and Grabenhorst, 2008). That value information is transmitted from the orbitofrontal cortex (in part via the pregenual anterior cingulate cortex, see Fig. 12.3) to the supracallosal anterior cingulate cortex, where there are action-related neurons, and where action–outcome learning takes place. Consistently, in humans the supracallosal anterior cingulate cortex (also referred to as dorsal anterior cingulate cortex dACC) is activated during action–outcome learning (Morris, Dezfouli, Griffiths, Le Pelley and Balleine, 2022; Klein-Flugge, Bongioanni and Rushworth, 2022a).

Foraging studies also implicate the dorsal anterior cingulate cortex in representing value, and in taking into account costs (Klein-Flugge, Bongioanni and Rushworth, 2022a). For example, some neurons responded at higher rates when the monkeys were about to move to another foraging patch, and the threshold amount of this firing before the monkey switched to a new patch depended on the cost of switching (in this case the delay before foraging in the new patch could resume) (Hayden et al., 2011). Consistent with this, the costs of actions can

influence reward value representations in the macaque orbitofrontal cortex, even though the actions themselves are not represented in the orbitofrontal cortex (Cai and Padoa-Schioppa, 2019).

In a neuroimaging study that provides evidence that the anterior cingulate cortex is active when outcome information guides choices made by the individual (Walton et al., 2004), the activations were relatively far back in the supracallosal anterior cingulate cortex ($y=22$, dACC) towards the mid-cingulate cortex. This is consistent with the hypothesis that the reward value information in the pregenual cingulate cortex and the negative value representations in the supracallosal anterior cingulate cortex are being interfaced to action and projected posteriorly to the mid-cingulate motor cortex.

12.2.4 Anterior cingulate cortex lesion effects

Consistent with the points made above and in Chapter 11, lesion studies in monkeys (Rudebeck et al., 2008) and humans (Camille, Tsuchida and Fellows, 2011), have demonstrated a dissociation in the role of the anterior cingulate cortex in action–outcome associations to guide behavior; and of the orbitofrontal cortex in stimulus–outcome associations to update expected value (Rushworth et al., 2012). Lesions of the anterior cingulate cortex in rats impair the ability to take into account the costs of actions, and this is supported by a neuroimaging study in humans (Croxson, Walton, O’Reilly, Behrens and Rushworth, 2009).

An investigation more closely related to the understanding of emotion showed that patients with selective surgical lesions of the antero-ventral part of the anterior cingulate cortex (ACC) and/or medial BA9 were in some cases impaired on voice and face expression identification, had some change in social behavior, such as inappropriateness, and had significant changes in their subjective emotional state (Hornak, Bramham, Rolls, Morris, O’Doherty, Bullock and Polkey, 2003).

There is also neuroimaging evidence that complements the effects of lesions (Hornak et al., 2003) in suggesting a role for certain medial regions in the subjective experience of emotion. In neuroimaging studies with normal human subjects bilateral activations in medial BA9 were found as subjects viewed emotion-laden stimuli, and in both medial BA9 as well as in ventral ACC during self-generated emotional experience (i.e. in the absence of a stimulus) as subjects recalled emotions of sadness or happiness (Lane et al., 1997a,b, 1998; Phillips et al., 2003). On the basis of a review of imaging studies which consistently emphasize the importance of anterior and ventral regions of the anterior cingulate cortex for emotion, Bush et al. (2000) argue that the anterior cingulate cortex can be divided into a ventral ‘affective’ division (which includes the subcallosal region and the pregenual anterior cingulate cortex), and a dorsal ‘cognitive’ division (presumably the supracallosal anterior cingulate cortex or dACC), a view strengthened by the demonstration of reciprocally inhibitory interactions between these two regions.

12.2.5 Anterior cingulate cortex and ventromedial prefrontal cortex connectivity and functions in humans

The concepts described above about ‘what’ computations are performed in different parts of the anterior cingulate cortex can be developed further and elucidated by considering the connectivity of the anterior cingulate cortex and ventromedial prefrontal cortex (vmPFC) in humans (Rolls et al., 2023c) and its implications in Sections 12.2.5 – 12.2.11. To illustrate the points made next, reference to Fig. 12.3 (repeated from earlier) may be helpful.

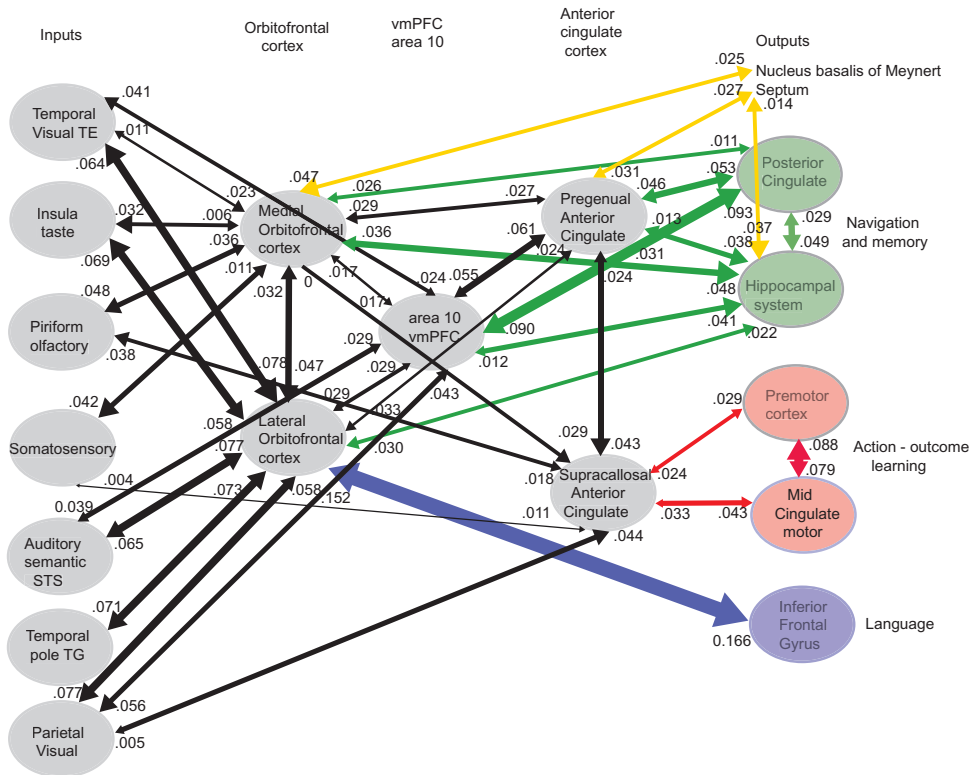

Fig. 12.3 Synthesis of the effective connectivity of the orbitofrontal cortex, vmPFC, and anterior cingulate cortex shown in the middle, with inputs on the left and outputs on the right. The regions included for each of the 5 central ellipses are as defined in the paper cited below. The width of the arrows is proportional to the effective connectivity in the highest direction, and the size of the arrows reflects the strength of the effective connectivity in each direction. The effective connectivities shown are for the strongest link where more than one link between regions applies for a group of brain regions. Effective connectivities with hippocampal memory system regions are shown in green; with premotor / mid-cingulate regions in red; with inferior prefrontal language regions in blue; and in yellow to the basal forebrain nuclei of Meynert which contains cholinergic neurons that project to the neocortex and to the septal nuclei which contain cholinergic neurons that project to the hippocampus. The Somatosensory regions include 5 and parietal PF and PPop, which also connect to the pregenual anterior cingulate but are not shown for clarity; the Parietal regions include visual parietal regions 7, PGI and PFm. The connectivity with dorsolateral prefrontal cortex is not included here for clarity. Connectivity is shown for the five groups in the centre of the Figure, and does not include for example connectivity between somatosensory and premotor cortical regions. (From Rolls, E.T., Deco, G., Huang, C-C. and Feng, J. (2023) The human orbitofrontal cortex, vmPFC, and anterior cingulate cortex effective connectome: emotion, memory, and action. *Cerebral Cortex* 33: 350-356. doi: 10.1093/cercor/bhac270. Copyright © Oxford University Press.)

12.2.5.1 Ventromedial prefrontal cortex connectivity

The connectivity of the human ventromedial prefrontal cortex (vmPFC) regions (10v, 10r, 10d, and 9m in the HCP-MMP atlas) is summarised in Fig. 12.3 and illustrated in Figs. 11.24, 11.25, and 11.27 (Rolls et al., 2023c). These vmPFC regions have effective connectivity with the medial (OFC and pOFC) and lateral (47m, 47s, 47l) orbitofrontal cortex. The vmPFC also has strong effective connectivity with the pregenual anterior cingulate cortex (including especially pregenual areas a24, d32, and p32 to which the effective connectivity is directed). The diffusion tractography indicates direct connections of these area 10 regions with orbitofrontal cortex and with anterior cingulate cortex regions. The vmPFC also has effective connectivity with the hippocampal system and posterior cingulate cortex (including 31pd, 31pv, 7m, d23ab, and v23ab) which are implicated in memory (Rolls et al., 2023i). The vmPFC thus appears to be related in humans to the memory / spatial system and hippocampus as described below for pregenual anterior cingulate cortex. The vmPFC also has some effective connec-

tivity with the auditory association STS cortical areas which are also implicated in semantic processing, and with visual inferior temporal cortex TE, and temporal pole TG (Rolls et al., 2022b; Bonner and Price, 2013; Rolls, 2021b; Rolls et al., 2023e).

Fig. 12.3 summarizes evidence that these vmPFC area 10 regions can be seen as connecting the medial and lateral orbitofrontal cortex with especially the pregenual anterior cingulate cortex and hippocampal memory system.

The connectivity of these vmPFC regions is different from pregenual anterior cingulate regions in that there is connectivity with the superior temporal sulcus (STS), temporal pole (TG), and superior frontal language (SFL) regions implicated in language (Rolls et al., 2022b). These vmPFC regions are also distinguished by little connectivity with the inferior and dorsolateral prefrontal cortex areas that have activity related to short-term memory and executive function (Passingham, 2021) (Chapter 13).

12.2.5.2 Pregenual anterior cingulate cortex connectivity

The pregenual anterior cingulate cortex includes regions s32, a24, p24, p32, d32 in the HCP-MMP atlas (Rolls et al., 2023c) (Figs. 11.24, 11.25, and 11.27). As background, the pregenual anterior cingulate cortex is activated in humans by many rewarding stimuli (Grabenhorst and Rolls, 2011; Rolls, 2019c, 2021b). The effective connectivity to these regions (which are interconnected) includes connectivity from medial orbitofrontal cortex regions (pOFC, OFC and 13l) with much less from lateral orbitofrontal cortex regions 47 (Fig. 12.3). There is also effective connectivity from the anterior agranular insular complex (AAIC) which is probably taste/olfactory/visceral-related; the hippocampal system (Hippocampus and presubiculum); with parts of the posterior cingulate cortex (31pv, 31pd, 7m, d23ab, v23ab) related to memory (Rolls et al., 2023i); with some ventromedial prefrontal regions (10r, 10v, 10d); with prefrontal cortex 8Av, 8Ad, 9a and 9p; and (for d32) with the frontal pole.

Effective connectivities from the pregenual cingulate cortex to the hippocampal system and the memory-related parts of the posterior cingulate are prominent (Fig. 12.3) (Rolls et al., 2023i). Several of the pregenual anterior cingulate cortex regions have bidirectional connectivity with the septum (Rolls et al., 2023c) (Fig. 12.3) which includes cholinergic neurons that project to the hippocampus (Zaborszky et al., 2018, 2008; Rolls et al., 2023i).

12.2.5.3 Subgenual anterior cingulate cortex area 25

Area 25 has relatively similar effective connectivity to the pregenual anterior cingulate cortex regions, except that 25 does not have effective connectivity with the inferior frontal gyrus and dorsolateral prefrontal cortex regions (Rolls et al., 2023i). The connectivity of region 25 is also similar to that of the medially adjacent pOFC. Region 25 also has some connectivity directed to the hippocampus, and interestingly bidirectional connectivity with the septum (Rolls et al., 2023i) which includes cholinergic neurons that project to the hippocampus (Rolls et al., 2023i; Zaborszky et al., 2018, 2008).

12.2.5.4 Supracallosal anterior cingulate cortex

The supracallosal anterior cingulate cortex includes regions a32pr, a24pr, 33pr, p32pr, and p24pr in the HCP-MMP atlas (Rolls et al., 2023c) (Figs. 11.24, 11.25, and 11.27). Part of the context is that this region is activated by aversive stimuli and non-reward in humans (Grabenhorst and Rolls, 2011; Rolls, 2019c, 2021b; Rolls et al., 2020e).

These supracallosal anterior cingulate cortex regions have very similar effective connectivity to each other (Rolls et al., 2023c). There is effective connectivity to supracallosal anterior cingulate cortex regions from somatosensory cortex 5L, 5mv and PFop (Rolls et al., 2023f,d); from superior parietal 7AL and 7Am; from posterior cingulate 23d which is part of the antero-dorsal visuo-motor part (Rolls et al., 2023i); and from the medial orbitofrontal cor-

tex regions 111, 131, OFC and pOFC. There is effective connectivity to midcingulate cortex premotor regions 24dd and 24dv; premotor area 6 and the frontal eye fields FEF; frontal opercular FOP and related opercular somatosensory areas; somatosensory insular regions (e.g. MI, PI, AVI, PoI); and to the Peri-Sylvian Language area (PSL). The supracallosal anterior cingulate cortex thus has outputs to cortical areas involved in limb and body movements. The diffusion tractography provides evidence for direct connections with some of the posterior cingulate cortex regions (Rolls et al., 2023c).

This set of connectivities suggests (Rolls et al., 2023c) that the dACC is the key part in humans of the anterior cingulate cortex that is related to learning associations between actions and the rewards or punishers associated with the actions (Rushworth et al., 2012; Noonan et al., 2011), as developed further in Section 12.2.7. As a prelude to that, strong evidence about how reward, punishers, and non-reward are represented in the anterior cingulate cortex is described.

12.2.6 Pregenual anterior cingulate representations of reward value, and supracallosal anterior cingulate representations of punishers and non-reward

Functional magnetic resonance neuroimaging (fMRI) studies show that there are rather separate representations of positively affective, pleasant, stimuli in the pregenual anterior cingulate cortex (yellow in Fig. 11.18); and of negative, unpleasant, stimuli just posterior to this above the corpus callosum in the supracallosal anterior cingulate cortex (white in Fig. 11.18) (Rolls, 2009a; Grabenhorst and Rolls, 2011).

The regions involved can be illustrated by the pregenual cingulate activations produced by the pleasant taste of glucose (Fig. 4.6 top right image), and the supracallosal anterior cingulate cortex region activated by the much less pleasant taste of inosine monophosphate (Fig. 4.6 second image down on the right) (De Araujo, Kringelbach, Rolls and Hobden, 2003b). In this investigation, small amounts of the taste solutions were delivered into the mouth, and the participants just rated the intensity of the tastes, so there is no particular change of action necessary that depended on the particular taste that was delivered.

The area activated by pain is typically 10–30 mm behind and above the most anterior (i.e. pregenual) part of the anterior cingulate cortex (see e.g. Rolls, O’Doherty, Kringelbach, Francis, Bowtell and McGlone (2003d), Fig. 11.18, Vogt and Sikes (2000) and Vogt et al. (1996)). Pleasant touch was found to activate the most anterior part of the anterior cingulate cortex, just in front of the genu (or knee) of the corpus callosum (i.e. pregenual anterior cingulate cortex) (Rolls, O’Doherty, Kringelbach, Francis, Bowtell and McGlone, 2003d; McCabe, Rolls, Bilderbeck and McGlone, 2008) (Fig. 11.18). Pleasant temperature applied to the hand also produces a linear activation related to the degree of subjective pleasantness in the pregenual cingulate cortex (Grabenhorst, Rolls and Parris, 2008b). Oral somatosensory stimuli such as viscosity and the pleasantness of fat texture also activate this pregenual part of the anterior cingulate cortex (De Araujo and Rolls, 2004; Grabenhorst, Rolls, Parris and D’Souza, 2010b). Not only does pleasant taste activate the pregenual anterior cingulate cortex (De Araujo and Rolls, 2004; De Araujo, Kringelbach, Rolls and Hobden, 2003b), but in addition attention to pleasantness (Grabenhorst and Rolls, 2008) and cognitive modulation of pleasantness (Grabenhorst, Rolls and Bilderbeck, 2008a) also enhance activations. The same is found for pleasant odors in the pregenual anterior cingulate cortex (Rolls, Kringelbach and De Araujo, 2003c) (Fig. 5.5), and effects are found here too for cognitive inputs that influence the pleasantness of odors (De Araujo et al., 2005), and also top-down inputs that produce selective attention to odor pleasantness (Rolls, Grabenhorst, Margot, da Silva and Velazco, 2008b). Unpleasant odors activate the supracallosal anterior cingulate cortex (Rolls,

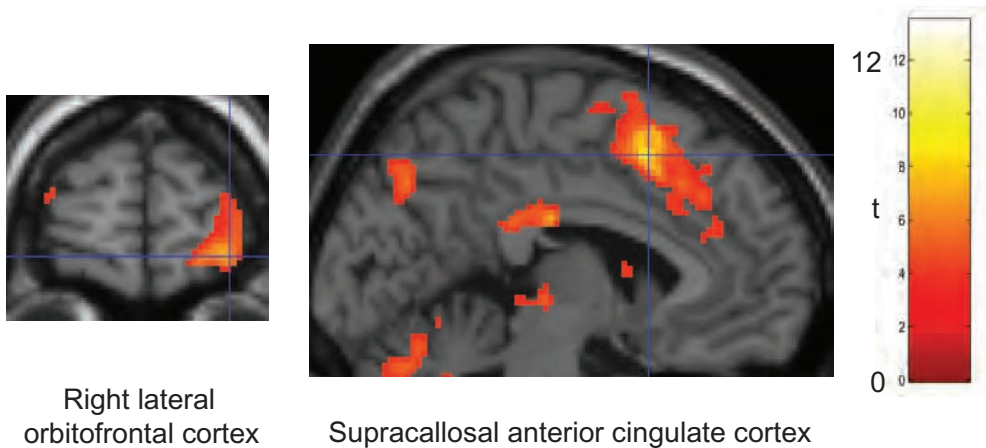

Fig. 12.4 Brain regions activated on reward reversal trials in a deterministic Go/NoGo visual discrimination task for points reward. The supracallosal anterior cingulate cortex and the right lateral orbitofrontal cortex and adjoining part of the inferior frontal gyrus were activated on the reversal trials when an expected large reward was not obtained, and the human participants changed their behavior to select the other visual stimulus in this one-trial rule-based reversal. (After Rolls, Vatansever, Li, Cheng and Feng. (2020) Rapid rule-based reward reversal and the lateral orbitofrontal cortex. *Cerebral Cortex Communications* 1: tgaa087. Copyright © Oxford University Press.)

Kringelbach and De Araujo, 2003c) (Fig. 5.5). Activations in the pregenual cingulate cortex are also produced by the taste of water when it is rewarding because of thirst (De Araujo, Kringelbach, Rolls and McGlone, 2003c), by the flavor of food (Kringelbach, O’Doherty, Rolls and Andrews, 2003), and by monetary reward (O’Doherty, Kringelbach, Rolls, Hornak and Andrews, 2001a). Moreover, the pregenual anterior cingulate cortex is activated by both the outcome value and the expected value of monetary reward (Rolls, McCabe and Redoute, 2008e). The locations of some of these activations are shown in Fig. 11.18.

In these studies, the anterior cingulate activations were linearly related to the subjective pleasantness or unpleasantness of the stimuli, providing evidence that the pregenual anterior cingulate cortex provides a representation of value on a continuous scale (Fig. 11.18). Moreover, evidence was found that there is a common scale of value in the pregenual anterior cingulate cortex, with the affective pleasantness of taste stimuli and of thermal stimuli applied to the hand producing identically scaled BOLD activations (Grabenhorst, D’Souza, Parris, Rolls and Passingham, 2010a). The implication is that the pregenual anterior cingulate cortex contains a value representation used in decision-making, but that the decision itself may be made elsewhere. Decisions about actions that reflect the outcomes represented in the pregenual anterior cingulate cortex may be made in the supracallosal (i.e. dorsal) anterior cingulate cortex which is further posterior towards the mid-cingulate cortex. Decisions about the value of stimuli may be made in the medial prefrontal cortex area 10 (or ventromedial prefrontal cortex, vmPFC) (Rolls et al., 2010b,c), which receives inputs from the orbitofrontal cortex and also from the anterior cingulate cortex. Consistent with this, in macaques single neurons in the ventromedial prefrontal cortex rapidly come to signal the value of the chosen offer, suggesting that the circuit serves to produce a choice (Strait et al., 2014), and consistent with the attractor model of decision-making (Rolls and Deco, 2010; Rolls, 2016b) (Sections 11.5.1 and 11.5.2).

Value representations in the pregenual anterior cingulate cortex are confirmed by recording studies in monkeys (Rolls, 2008c, 2009a; Kolling et al., 2016). For example, Gabbott, Verhagen, Kadohisa and Rolls found neurons (see Rolls (2008c)) in the pregenual anterior

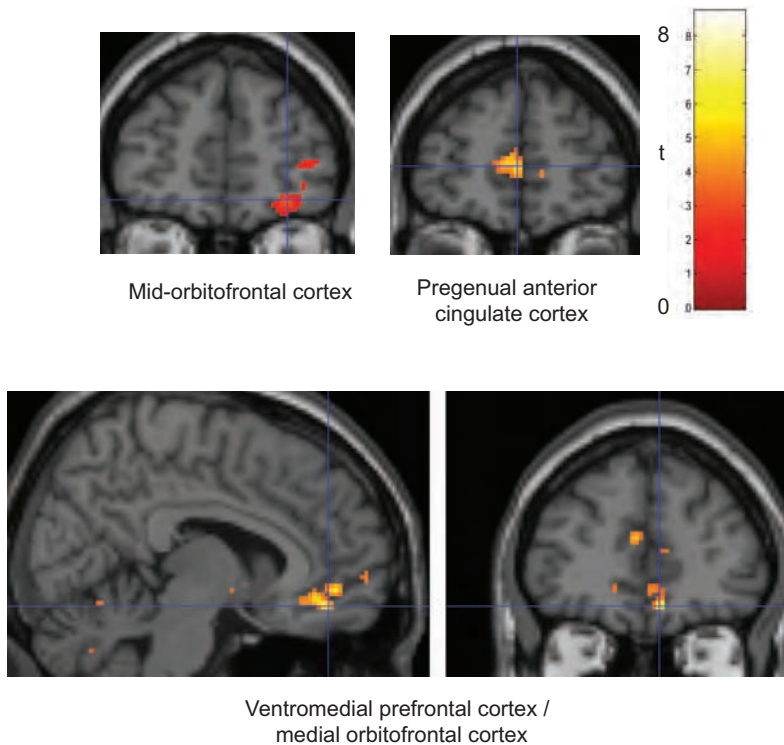

Fig. 12.5 Brain regions activated by reward, winning 25 points, in a deterministic Go/NoGo visual discrimination task for points reward. Activations to the reward outcome were found in the medial/mid-orbitofrontal cortex, ventromedial prefrontal cortex, and pregenual anterior cingulate cortex. (After Rolls, Vatansever, Li, Cheng and Feng. (2020) Rapid rule-based reward reversal and the lateral orbitofrontal cortex. *Cerebral Cortex Communications* 1: tgaa087. Copyright © Oxford University Press.)

cingulate cortex that respond to taste and it was demonstrated that the representation is of reward value, for devaluation by feeding to satiety selectively decreased neuronal responses to the food with which the animal was satiated. The supracallosal part of the anterior cingulate cortex is proposed to use these value representations in action-outcome learning, as considered in Section 12.2.5.4 (Rolls et al., 2023c; Rolls, 2022b). The functions of the pregenual anterior cingulate cortex are considered further below.

Evidence that the supracallosal anterior cingulate cortex is activated by non-reward is shown in Fig. 11.16 for reward reversal in a probabilistic task using face expressions as the stimuli (Kringelbach and Rolls, 2003).

In a one-trial deterministic visual reversal task for points, the supracallosal anterior cingulate cortex, and the right lateral orbitofrontal cortex and adjoining part of the inferior frontal gyrus, were activated on the reversal trials, as shown in Fig. 12.4 (Rolls, Vatansever, Li, Cheng and Feng, 2020e). This shows that the supracallosal anterior cingulate cortex is activated when an expected reward was not received, that is, to non-reward. This type of non-reward computation is likely to be important in action-outcome learning, and in changing behavior in foraging tasks, from ‘exploit’, to ‘explore’.

Obtaining a reward outcome (+25 points) on reward (Go) trials produced (as expected) reward-related activations in the medial/mid orbitofrontal cortex, pregenual anterior cingulate cortex, and ventromedial prefrontal cortex (Fig. 12.5). On NoGo trials, on which there was a small loss of 5 points, activations were found in the lateral orbitofrontal cortex, with a small loss-related activation in the supracallosal anterior cingulate cortex (Rolls et al., 2020e). The one-trial rule-based Go/NoGo visual discrimination reversal task used in this investigation

(Rolls et al., 2020e) was the same as that used in macaques in which non-reward neurons were discovered (Thorpe, Rolls and Maddison, 1983) (and in further single-neuron investigations in the orbitofrontal cortex (Rolls, Critchley, Mason and Wakeman, 1996b), inferior temporal visual cortex (Rolls, Judge and Sanghera, 1977), amygdala (Sanghera, Rolls and Roper-Hall, 1979; Wilson and Rolls, 2005), basal forebrain (Wilson and Rolls, 1990b,a), and ventral striatum (Williams, Rolls, Leonard and Stern, 1993; Rolls, 1994c). (Points instead of fruit juice reward were provided for the human participants.)

12.2.7 The human supracallosal anterior cingulate cortex, dACC, and action-outcome learning

The connectivities of the human supracallosal anterior cingulate cortex (dACC) (Section 12.2.5.4), and the other evidence described above (including in Sections 12.2.2 and 12.2.3), provide evidence (Rolls et al., 2023c) that the dACC is the key part in humans of the anterior cingulate cortex that is related to learning associations between actions and the rewards or punishers associated with the actions (Rushworth et al., 2012; Noonan et al., 2011; Klein-Flugge et al., 2022a). For this, the orbitofrontal cortex inputs provide it is proposed the reward/punishment representation, and the connectivity of the dACC with somatosensory and premotor regions the required evidence about actions just performed, and the required outputs to especially limb and body systems. The findings that the supracallosal anterior cingulate cortex is activated primarily by punishers and non-reward (Grabenhorst and Rolls, 2011; Rolls, 2019c, 2021b; Rolls et al., 2020e) (Section 12.2.6) may relate to the limb and body movements that utilise premotor cortical output regions often made to avoid aversive stimuli. However, reward information is also likely to reach the supracallosal anterior cingulate cortex, in part via the pregenual anterior cingulate cortex (Fig. 12.3) (Rolls et al., 2023c).

If aversive stimuli or non-reward are received, this is likely to lead to a change of actions: in the terminology of foraging, changing from ‘exploit’ to ‘explore’ (Klein-Flugge et al., 2022a). Error signals generated in the dACC reflect a mismatch between the expected reward outcome for the action and the actual outcome (Klein-Flugge et al., 2022a). The computational mechanism proposed for ‘how’ this system operates is that the error signal in the dACC activates a neuronal population that represents ‘explore’ to become active in a single attractor network with ‘explore’ vs ‘exploit’ neuronal populations in competition with each other. The computational mechanism is similar to that described for reversal of the rule attractor network in Section 11.5.3. In ‘explore’ mode, actions can be made to test whether the outcomes are better than previously, and if so the ‘exploit’ attractor neuronal population is activated by the higher reward rate than previously, and the behavior becomes stable in ‘exploit’ mode.

In summary, the proposed computational mechanism is that non-reward or punishment resets the ‘exploit’ neuronal population to fall out of its attractor in the exploit/explore rule attractor network, thereby releasing the ‘explore’ population from inhibition by the inhibitory neurons. This could be achieved by non-reward or punishment directly activating the ‘explore’ attractor to produce exploratory behavior. Then while exploring, rewards that are better than previously activate the ‘exploit’ attractor neuronal population, which quench the ‘explore’ neuronal population through the inhibitory neurons in the exploit/explore rule attractor single network. The actual location of this exploit/explore rule attractor single network could be in the dACC, but another interesting possibility is that it is in the frontal pole, from where it can control the whole of the dorsolateral prefrontal cortex, as described in Section 13.5 (Rolls et al., 2023a).

12.2.8 Reward value outputs from the orbitofrontal and pregenual anterior cortex, and vmPFC, to the hippocampal memory system

It is indicated in green in Fig. 9.19, and in Fig. 12.3 (Rolls et al., 2023c), that the human medial and lateral orbitofrontal cortex have effective connectivity directed to the hippocampal system (hippocampus, entorhinal cortex, perirhinal cortex) both directly, and via the vmPFC, via the pregenual anterior cingulate cortex, and via the memory-related (posterior) parts of the posterior cingulate cortex (Rolls et al., 2023i). These are the routes by which value / emotion-related information can reach the human hippocampal memory system from the orbitofrontal cortex. The information does reach the hippocampus and is incorporated into memory in that some primate hippocampal spatial view cells (Georges-François et al., 1999; Rolls et al., 1997a; Rolls and Wirth, 2018; Rolls, 2021f,b; Rolls et al., 1998b; Robertson et al., 1998; Rolls et al., 2005c; Wirth et al., 2017; Rolls, 2023c) respond to the reward value of a location viewed in space in a reward-spatial location memory task (Rolls and Xiang, 2005, 2006).

A considerable part of the output of the human medial and lateral orbitofrontal cortex value / emotion system is thus directed towards the hippocampal system for memory (Fig. 12.3) (Rolls et al., 2023c; Rolls, 2022b). It is proposed that this connectivity provides a key input about reward / punishment value for the hippocampal episodic memory system, adding to the ‘what’, ‘where’, and ‘when’ information that are also key components of episodic memory. Damage to the vmPFC / anterior cingulate cortex system is likely to contribute to episodic memory impairments produced by damage to these OFC/ vmPFC / anterior cingulate cortex regions by impairing a key component of episodic memory, the reward / punishment / emotional value component. Such damage would impair the value information reaching the hippocampal system for storage, and also for later retrieval. Indeed, if one of the possible inputs such as the reward input used for hippocampal memory retrieval by completion in the CA3 attractor network was missing, that would be expected to impair memory retrieval (Treves and Rolls, 1994; Rolls, 2018b; Treves and Rolls, 1991; Rolls, 2021b). That is one mechanism that is proposed (Rolls, 2022b) to contribute to the episodic memory impairments produced by damage in humans to the anterior cingulate cortex and vmPFC (Ciaramelli et al., 2019; McCormick et al., 2018) (Section 9.2.8.5).

12.2.9 The pregenual anterior cingulate cortex has connectivity with the septal cholinergic system that is involved in memory consolidation

The human pregenual anterior cingulate cortex (with subgenual 25 and vmPFC 10r) in humans has effective connectivity directed to the septal nuclei (yellow in Fig. 12.3 (Rolls et al., 2023c)), which contains cholinergic neurons that project to the hippocampus in humans (Mesulam, 1990; Zaborszky et al., 2018, 2008). These pregenual anterior cingulate regions are likely to be important influences on septal neurons, for the only other cortical regions found with substantial effective connectivity to the human septal region (Rolls et al., 2023c) are the hippocampus, subiculum, and v23ab which is part of the posterior cingulate cortex also implicated in episodic memory (Rolls et al., 2023i). In accordance with this, it is proposed (Rolls, 2022b) that the damage in humans to the orbitofrontal and anterior cingulate cortex regions that impairs episodic memory (Ciaramelli et al., 2019; McCormick et al., 2018) arises in part because of the reduced release of acetylcholine to reward / punishing / salient stimuli, which may impair long-term synaptic potentiation and thus memory storage in both the hippocampus and neocortex (Zaborszky et al., 2018; Newman et al., 2012; Hasselmo and

Sarter, 2011; Giacomo and Hasselmo, 2007; Hasselmo and Giacomo, 2006; Rolls, 2021b) (Section 9.2.8.5).

There are thus three memory-related influences of the orbitofrontal and pregenual anterior cingulate cortex uncovered by the effective connectivity in humans (Fig. 12.3): (1) reward as a component of hippocampal episodic memory; and cholinergic influences both on (2) the neocortex and (3) on the hippocampus driven by the orbitofrontal and pregenual anterior cingulate cortex (Rolls et al., 2023c; Rolls, 2022b) (Section 9.2.8.5). Together, these three processes are it is proposed likely to make major contributions to the memory deficits reported to follow ventromedial prefrontal cortex damage in humans (McCormick and Maguire, 2021; McCormick et al., 2020; Ciaramelli et al., 2019; McCormick et al., 2018; Bonnici and Maguire, 2018; Ciaramelli and Treves, 2019). Although it has been suggested that scene processing types of computation are affected by ventromedial prefrontal cortex damage (De Luca, McCormick, Ciaramelli and Maguire, 2019), this might be expected given that the hippocampus with its spatial view neurons (Georges-François et al., 1999; Robertson et al., 1998; Rolls et al., 1997a; Rolls and Xiang, 2006; Rolls et al., 2005c; Rolls and Xiang, 2005; Rolls and Wirth, 2018; Wirth et al., 2017; Tsitsiklis et al., 2020; Rolls, 2023c) is involved in scene processing (Rolls, 2021f); and given that the cholinergic influence on the hippocampus is likely to be very important in hippocampal functioning including memory storage (because acetylcholine facilitates synaptic long-term potentiation and reduces at the same time the relative efficacy of the CA3 recurrent collateral synapses to help emphasise new rather than existing memories) (Zaborszky et al., 2018; Newman et al., 2012; Hasselmo and Sarter, 2011; Giacomo and Hasselmo, 2007; Hasselmo and Giacomo, 2006; Rolls, 2021b).

These new discoveries provide a new approach to understanding how memory is consolidated in the human brain (Rolls, 2022b) (Section 9.2.8.5).

12.2.10 Reward value outputs from the orbitofrontal and pregenual anterior cortex, and vmPFC, to the hippocampal system to provide the goals for navigation

The hippocampus is also implicated in navigation (O'Keefe and Nadel, 1978; Burgess and O'Keefe, 1996; Ekstrom et al., 2014; Miller et al., 2013; Tsitsiklis et al., 2020; McNaughton et al., 2006; Bellmund et al., 2018; Ekstrom and Isham, 2017; Clark et al., 2019; Nau et al., 2018a; Rolls and Wirth, 2018; Rolls, 2021f). It is proposed that the reward value input from the orbitofrontal / vmPFC / pregenual anterior cortex to the hippocampal and memory-related posterior cingulate cortex (green in Fig. 9.19 (Rolls et al., 2023c)) provides important connectivity also required for navigation, and indeed it is a key feature of navigation that it is generally towards goals, usually rewards (Rolls et al., 2023c; Rolls, 2023c). Supporting this, neurons in the primate hippocampus encode the locations in viewed scenes at which rewards are located (Rolls and Xiang, 2005), including the goals for navigation (Wirth et al., 2017; Rolls and Wirth, 2018). The information transmitted from the orbitofrontal cortex is about which particular of many possible rewards represented in the orbitofrontal cortex (Rolls, 2014a, 2016g, 2019e,f) is the current goal for navigation, so is a high-dimensional vector on neuronal firing.

The navigation in humans and other primates is proposed to frequently involve navigation from viewed landmark to viewed landmark using spatial view cells (Rolls, 2021f). This is in contrast to what is frequently proposed to be used in rodents, which is path integration from place to place performed by the hippocampus (McNaughton, Barnes, Gerrard, Gothard, Jung, Knierim, Kudrimoti, Qin, Skaggs, Suster and Weaver, 1996; Burgess and O'Keefe, 1996; Hartley, Lever, Burgess and O'Keefe, 2014; Edvardsen, Bicanski and Burgess, 2020). Humans might wish to try some navigation themselves with the eyes closed to help to confirm

the greatly utility of landmarks in views of spatial scenes in navigation in humans, which are encoded by hippocampal and parahippocampal spatial view cells (Rolls, 2023c).

12.2.11 Subgenual cingulate cortex

The subgenual part (area 25) of the anterior cingulate cortex is, via its outputs to the hypothalamus and brainstem autonomic regions, involved in at least the autonomic component of emotion (Koski and Paus, 2000; Barbas and Pandya, 1989; Ongur and Price, 2000; Gabbott et al., 2003; Vogt, 2009; Alexander et al., 2019). The anterior cingulate cortex is also activated in relation to autonomic events, and Nagai, Critchley, Featherstone, Trimble and Dolan (2004) have shown that there is a correlation with skin conductance, a measure of autonomic activity related to sympathetic activation, in the anterior cingulate cortex and related areas. The dorsal anterior and mid-cingulate cortical areas may be especially related to blood pressure, pupil size, heart rate, and electrodermal activity, whereas the subgenual cingulate cortex, with ventromedial prefrontal cortex, appears antisympathetic (and parasympathetic) (Critchley and Harrison, 2013). The subgenual cingulate cortex is connected with the ventromedial prefrontal cortical areas (Johansen-Berg et al., 2008; Hsu et al., 2020).

Evidence implicating the subgenual and more generally the subcallosal cingulate cortex in depression (Hamani et al., 2011; Laxton et al., 2013; Price and Drevets, 2012; Drevets et al., 2008; Holtzheimer et al., 2017) is described in Section 18.5.4.4. Interestingly, neurons in the human subcallosal cingulate cortex responded to emotion categories present in visual stimuli, with more neurons responding to negatively valenced than positively valenced emotion categories (Laxton, Neimat, Davis, Womelsdorf, Hutchison, Dostrovsky, Hamani, Mayberg and Lozano, 2013).

12.3 Posterior cingulate cortex

12.3.1 Introduction and overview

The human posterior cingulate cortex (PCC) includes Brodmann areas 23 and 31, is also present in macaques, and is absent in rodents (Vogt, 2009). The retrosplenial cortex (RSC) Brodmann area 29/30 in humans is a small region wrapped round the splenium of the corpus callosum (Vogt, 2019a, 2009; Vogt et al., 1995) (see Figs. 12.6 and 12.7). The HCP-MMP (Section 1.12) ‘Posterior Cingulate Division’ (PCD) includes also some medial parietal cortex regions such as 7m, and some transitional regions with earlier cortical visual regions (DVT and ProS where the retrosplenial scene area is located (Sulpizio et al., 2020; Rolls, 2023c), Section 9.2.8.1).

The research described in this section (Rolls, Wirth, Deco, Huang and Feng, 2023i) shows that the postero-ventral parts of the PCD (31pd, 31pv, 7m, d23ab and v23ab) have effective connectivity with the temporal pole, inferior temporal visual cortex, cortex in the superior temporal sulcus implicated in auditory and semantic processing, with the reward-related vmPFC and pregenual anterior cingulate cortex, with the inferior parietal cortex, and with the hippocampal system (Fig. 12.6). This connectivity implicates it in hippocampal episodic memory, providing routes for ‘what’, reward and semantic schema-related information to access the hippocampus.

The antero-dorsal parts of the PCD (especially 31a and 23d, the precuneus visual region PCV, and also RSC) have connectivity with early visual cortical areas including those that represent spatial scenes, with the superior parietal cortex, with the pregenual anterior cingulate cortex, and with the hippocampal system (Fig. 12.7). This connectivity implicates it in

the ‘where’ component for hippocampal episodic memory and for spatial navigation (Rolls, Wirth, Deco, Huang and Feng, 2023i).

The transitional regions Dorsal-Transitional-Visual (DVT) and ProStriate where the retrosplenial scene area is located (Sulpizio et al., 2020) (see Fig. 9.18) have connectivity from early visual cortical areas to the parahippocampal scene area, providing a ventromedial route for spatial scene information to reach the hippocampus (Rolls et al., 2023i,e).

These groups of human posterior cingulate division regions are based on the connectivities and functions of the different regions, as described by Rolls, Wirth, Deco, Huang and Feng (2023i).

These connectivities of the posterior cingulate division regions provide important routes for ‘what’, reward, and ‘where’ scene-related information for human hippocampal episodic memory and navigation (Rolls et al., 2023i).

A hypothesis less based on this connectivity evidence has suggested that the dorsal Posterior Cingulate Cortex is involved in executive function, that the ventral Posterior Cingulate Cortex is involved in memory, and that the retrosplenial cortex is involved in spatial processing (Foster et al., 2023).

12.3.2 Postero-ventral posterior cingulate and medial parietal regions 31pd, 31pv, d23ab, v23ab and 7m, and their relation to episodic memory

This group of posterior cingulate division (PCD) regions has connectivity illustrated in Fig. 12.6 (Rolls, Wirth, Deco, Huang and Feng, 2023i):

with ventral stream high-order visual (TE) and auditory (STS) association cortical areas that represent what object or person is present as shown by discoveries in macaques (Perrett, Rolls and Caan, 1982; Booth and Rolls, 1998; Rolls, 2021d,b; Arcaro and Livingstone, 2021; Freiwald, 2020; Lehky and Tanaka, 2016; Rolls, Deco, Huang and Feng, 2023e) with complementary evidence in humans (Kanwisher et al., 1997; Finzi et al., 2021; Collins and Olson, 2014);

with the pregenual anterior cingulate cortex (9m, a24, d32, p32 and 10d) and vmPFC (10r and 10v) where reward value and emotion are represented (Grabenhorst and Rolls, 2011; Rolls et al., 2023c; Rolls, 2019c, 2022b) (Section 12.2.6);

with some inferior parietal cortex regions (PGi and PGs, which are in the angular gyrus BA 39 and are implicated in memory and semantic processing (Davis et al., 2018; Papagno, 2018; Rolls et al., 2023d), Section 10.5);

with temporal pole (TG) regions implicated in semantic memory (Bonner and Price, 2013; Rolls et al., 2022b);

with frontal pole regions (10pp, p10p) (Rolls et al., 2023a);

and with the hippocampal system which is involved in episodic memory (Squire and Wixted, 2011; Dere et al., 2008; Moscovitch et al., 2016; Ekstrom and Ranganath, 2018; Rolls, 2018b, 2021b).

The connections to this set of brain regions (Rolls, Wirth, Deco, Huang and Feng, 2023i) suggest that this ventral and posterior part of the PCD is involved in hippocampal episodic memory, providing routes for the relevant ‘what’, reward and semantic schema-related information to gain access to the hippocampus during storage; and to be on the route back to these cortical areas during hippocampal episodic memory retrieval (Rolls, 2022b, 2021b). The regions in this group are thus especially related to ventral stream ‘what’ processing (Ungerleider and Haxby, 1994; Rolls, 2021d), and allow many widely separated brain regions at the top of processing streams to provide ‘what’, ‘when’ and reward inputs to the hippocampal system. Consistent with involvement of these PCD regions in linking reward and emotion

the lateral orbitofrontal cortex non-reward / punishment system (Cheng, Rolls, Qiu, Yang, Ruan, Wei, Zhao, Meng, Xie and Feng, 2018c).

The relation of this group of PCD regions to memory is strengthened by the evidence (Rolls, Wirth, Deco, Huang and Feng, 2023i) that these regions associated with hippocampal function receive effective connectivity from the mammillary bodies which are part of a hippocampal circuit involved in episodic memory (Bubb et al., 2017), and the septum (which projects to the hippocampal system) and adjoining basal nucleus of Meynert both of which contain cholinergic neurons that are implicated in memory (Hasselmo and Giocomo, 2006; Rolls and Deco, 2015b; Rolls, 2022b).

12.3.3 Antero-dorsal Posterior Cingulate Division regions 23d, 31a, PCV; and RSC, POS2, and POS1; and their relation to navigation and executive function

POS1 and POS2 are visual areas in the parieto-occipital sulcus close to the primary visual cortex V1 (Fig. 12.7), have extensive connections and functional connectivity with early visual cortical areas, and provide inputs to the other brain regions in this group, 23d, 31a, PCV, and RSC (Rolls, Wirth, Deco, Huang and Feng, 2023i). Further, POS1 and POS2 also have effective connectivity to the medial parahippocampal gyrus PHA1-3 regions (corresponding to macaque TH) where scenes are represented (Sulpizio et al., 2020; Natu et al., 2021; Kamps et al., 2016; Epstein and Kanwisher, 1998; Epstein and Baker, 2019; Epstein and Julian, 2013; Epstein, 2008, 2005; Rolls, 2023c), and with the hippocampal system. POS1 and POS2 may thus be involved in scene representations reaching the hippocampal system, and are likely to contribute to the activation of hippocampal spatial view cells, and thereby be involved in providing information important in episodic memory and navigation (Rolls and Wirth, 2018; Rolls, 2023c). POS1 and POS2 are also likely to be involved in memory and navigation by providing inputs to other members of this group of regions as follows.

Anterior to POS1 and POS2 and receiving visual inputs from these regions are the precuneus visual area (PCV) and 31a and 23d which are dorsal and extend anteriorly in the Posterior Cingulate Division (Fig. 12.7) and have connectivity (Fig. 12.7, Rolls, Wirth, Deco, Huang and Feng (2023i)) directed to the hippocampal system (hippocampus, entorhinal cortex, and subiculum), to the parahippocampal PHA1-3 regions with visual scene representations (Sulpizio et al., 2020; Natu et al., 2021; Kamps et al., 2016; Epstein and Kanwisher, 1998; Rolls et al., 2023e), and to the mid-cingulate cortex. They receive effective connectivity not only from POS1 and POS2, but also from the temporo-parietal junction (a multimodal region implicated in social behavior and language (Patel et al., 2019; Coslett and Schwartz, 2018; DiNicola et al., 2020; Buckner and DiNicola, 2019; Quesque and Brass, 2019; Rolls et al., 2022b)); the superior parietal cortex (7Pm and 7Am) (Rolls et al., 2023d); frontal pole regions p10p and a10p implicated in planning and sequencing (Shallice and Cipolotti, 2018; Shallice and Burgess, 1996; Gilbert and Burgess, 2008), ‘exploit’ vs ‘explore’ (Rolls et al., 2023a) (Section 13.5), and prospective as well as retrospective memory (Underwood et al., 2015); the pregenual anterior cingulate including d32, p24, and p32 implicated in reward (Grabenhorst and Rolls, 2011; Rolls et al., 2023c; Rolls, 2022b); and dorsolateral prefrontal cortex 8Ad, 9a, 9p involved in short-term memory and thereby top-down attention (Germann and Petrides, 2020b; Deco and Rolls, 2005a; Rolls et al., 2023f) (Chapter 13). This part of the Posterior Cingulate Division is special in its strong connectivity from p10p which is part of the frontal pole cortex (Rolls et al., 2023a) (Section 13.5); the reward-related pregenual anterior cingulate d32, p24, p32 and medial orbitofrontal cortex (regions 11l, 13l and OFC) (Rolls et al., 2023c); and the midcingulate premotor cortex.

This connectivity including the connectivity to the parahippocampal scene or place area

Dorsal anterior Posterior Cingulate Division with RSC, POS1 and POS2

Fig. 12.7 Effective connectivity of the anterior and dorsal parts of the posterior cingulate cortex and related regions shown on medial (below) and lateral (above) views of the human brain, with the sulci expanded to show regions inside the sulci. The brain regions include POS1 and POS2 (early visual cortical areas), which provide inputs to the other members of the group (surrounded by a black boundary), PCV, 31a, 23d, and the retrosplenial cortex (RSC). The width of the lines reflects the effective connectivity in the strongest direction, and the size of the arrow heads reflects the effective connectivity in each direction. Visuo-spatial inputs are also received from medial parietal cortex areas 7Pm and 7Am. These regions also have connectivity with the pregenual anterior cingulate cortex p24 and d32, with region OFC, with parietal PGs, with frontal pole p10p, and with dorsolateral prefrontal cortex 9p. Outputs of these regions are directed to the hippocampal system, including the hippocampus, presubiculum and parahippocampal TH (PHA1-3); and to the midcingulate motor cortex 23c. The abbreviations are listed in Section 1.12. (From Rolls, E.T., Wirth, S., Deco, G., Huang, C.-C. and Feng, J. (2023) The human posterior cingulate, retrosplenial and medial parietal cortex effective connectome, and implications for memory and navigation. *Human Brain Mapping* 44: 629-655. doi: 10.1002/HBM.26089.)

in PHA1-3 implicates this group of PCD regions in spatial and executive function, which is supported by other evidence (Foster et al., 2013, 2012; Buckner and DiNicola, 2019; Fox et al., 2018; Dastjerdi et al., 2011). Spatial roles for this part of the PCC are emphasised too by the connectivity with superior parietal areas 7Am and 7Pm, parts of dorsal stream processing that are implicated in visuo-motor spatial functions (Snyder et al., 1998; Orban et al., 2021b; Rolls et al., 2023e,d) and coordinate transforms from egocentric eye-based frames to allocentric world-based frames suitable for idiothetic update of hippocampal spatial representations (Rolls, 2021f, 2020b; Snyder et al., 1998; Rolls, 2023c). Consistent with this, a cingulate sulcus visual area has been described that responds selectively to visual and vestibular cues to self-motion (Smith et al., 2018), and this may be in or near 23d (Rolls et al., 2023i). Consistent with the above evidence that this group of PCD regions is involved in navigation, area 31 which receives from POS1 and POS2 is implicated by neuroimaging in representing heading direction (Baumann and Mattingley, 2021). Consistent with the concept that navigation and executive function are performed to achieve goals, this part of the posterior cingulate and medial parietal cortex (31a, 23d and PCV) receives from the reward-related medial orbitofrontal cortex and pregenual anterior cingulate cortex (Rolls et al., 2023i; Grabenhorst and Rolls, 2011; Rolls et al., 2023c; Rolls, 2022b; Rolls et al., 2020e; Rolls, 2023c).

The retrosplenial cortex region RSC has similar connectivity to the PCV, 31a and 23d, but also has connections with early visual cortical areas (Rolls et al., 2023i). Consistent with visuo-spatial roles for these regions, the RSC, which also receives from POS2, is implicated by neuroimaging studies in representing permanent features of an environment such as landmark identity and location (Rolls et al., 2023i; Auger et al., 2012; Baumann and Mattingley, 2021; Persichetti and Dilks, 2019). However care is needed here, for the retrosplenial scene area is located in humans not in RSC, but just posterior to it in DVT and ProS (Sulpizio et al., 2020; Rolls, 2023c). The input from the reward-related pregenual anterior cingulate cortex and medial orbitofrontal cortex (p24, p32, 111) to region RSC is of interest, for it provides a pathway for navigation to be performed to reach rewards or goals (Rolls et al., 2023c; Rolls, 2022b).

An important type of navigation involves update of location based on self-motion, and one area in which vestibular and optic flow information is represented is macaque area 7a (Avila et al., 2019; Cullen, 2019; Bremmer et al., 2000; Wurtz and Duffy, 1992). As shown by Rolls, Wirth, Deco, Huang and Feng (2023i), there is connectivity of area 7 regions with the regions in this PCD group, which in turn connect to the parahippocampal gyrus (PHA1-3, TH in macaques) / hippocampal system (Fig. 12.7). It is proposed that these PCD regions provide one route for optic flow and vestibular signals to reach the hippocampus in which whole body motion neurons are found (O'Mara, Rolls, Berthoz and Kesner, 1994). Some of these whole body motion neurons respond to linear and others to rotational motion, and some of them respond to vestibular inputs, others to visual inputs for motion, and some to both (O'Mara et al., 1994). These neurons are probably involved in navigation especially when the view details are obscured, that is, idiothetic (self-motion updated) navigation (O'Mara et al., 1994; Rolls, 2020b, 2021f). (The rodent equivalent is probably 'speed cells' (Kropff et al., 2015; Spalla et al., 2022).) Consistent with this proposal, in macaques there are neurons in a dorsal posterior cingulate region (and to a smaller extent in the RSC) that respond to vestibular inputs (Liu et al., 2021). Additional egomotion areas in the human brain as shown by neuroimaging include intraparietal sulcus area 1 (IPS1) and V3A in the occipital region; and V6 (Sulpizio et al., 2020); and all of these regions connect to DVT and ProS, which in turn connect to the PCD regions in the present antero-dorsal group, which in turn connect to parietal 7 (7Pm and 7Am) (Rolls, Wirth, Deco, Huang and Feng, 2023i). These connectivities help to show how self-motion information can reach hippocampal whole body motion cells

(O'Mara et al., 1994) for use in idiothetic navigational updating (Rolls, 2020b, 2021f; Rolls et al., 2023e; Rolls, 2023c).

It is therefore proposed that the regions in this antero-dorsal PCD group by virtue of the connectivity described here support spatial functions including navigation, and executive function, consistent with human neuroimaging and brain lesion evidence (Foster et al., 2013, 2012; Buckner and DiNicola, 2019; Fox et al., 2018; Dastjerdi et al., 2011; Ekstrom et al., 2017; Teghil et al., 2021).

12.3.4 Dorsal Visual Transitional area and ProStriate region: the retrosplenial scene area

The ProStriate region (ProS) is adjacent to V1, and the Dorsal Transitional Visual Area (DVT) is an area posterior to most of the Posterior Cingulate Division, found just lateral to POS2 (Fig. 12.7). Importantly, the retrosplenial cortex scene area is located in the dorsal visual transitional region (DVT) and prostriate region (ProS) with some extension into parieto-occipital sulcus region 1 (POS1) (Sulpizio et al., 2020; Rolls et al., 2023i) (Fig. 9.18). The ProS and DVT regions have connectivity with early cortical visual regions, with areas representing visual scenes (PHA1-3 and VMV regions (Rolls et al., 2023i; Sulpizio et al., 2020)), with the parietal cortex, with hippocampal system regions (hippocampus and presubiculum), and with the premotor mid-cingulate cortex and associated somatosensory area 5 (Rolls et al., 2023i). Unlike the postero-ventral DVD regions (Section 12.3.2), ProS and DVT do not have connectivity as a hub-like region useful for episodic memory, in that they have no connectivity with the inferior temporal visual cortex (TE) or superior temporal auditory association cortex, with the dorsolateral prefrontal cortex, or with the postero-ventral PCD regions (Section 12.3.2). Unlike the antero-dorsal regions, the DVT and ProS regions have connectivity with somatosensory cortex (5), and have no connectivity with the frontal cortex (Rolls et al., 2023i). The DVT and ProS regions thus appear to be involved in relatively low-level visual processing, with connectivity with the superior parietal cortex area 7 which suggests that these regions are involved in visuo-motor control appropriate for motor actions in visual space (Andersen, 1995b; Huang and Sereno, 2018; Urgen and Orban, 2021; Orban et al., 2021b; Rolls et al., 2023e,d), and perhaps in the necessary spatial coordinate transforms (Salinas and Sejnowski, 2001; Rolls, 2020b). Indeed, spatial coordinate transforms are also necessary for idiothetic update of spatial representations useful for hippocampal function including navigation when the spatial view is obscured (Snyder et al., 1998; Rolls, 2020b, 2021f; Dean and Platt, 2006; Vedder et al., 2017; Rolls, 2023c).

The DVT receives input from V6 and V6A (Rolls, Wirth, Deco, Huang and Feng, 2023i). Area V6A in the macaque is a visual-somatosensory area which occupies the posterior part of the dorsal precuneate cortex (Gamberini et al., 2021, 2020; Rolls et al., 2023e). It represents the upper limbs and is involved in the control of goal-directed arm movements (Fattori et al., 2017). Macaque V6A hosts the so called 'real-position cells', that is visual cells that encode spatial position in head-based (craniotopic) coordinates not in retinotopic coordinates (Galletti et al., 1993). Area V6A is strongly connected with prestriate visual areas, with superior parietal areas, and with the premotor frontal cortex representing arm movement (Gamberini et al., 2021; Rolls et al., 2023e). Macaque V6A is divided into two subareas that together are involved in the visual and somatosensory aspects of 'reach-to-grasp': V6Av which is more visual and V6Ad which is more somatosensory (Gamberini et al., 2018). The human homolog of V6Av has been identified in the posterior, dorsal-most part of precuneate cortex (Pitzalis et al., 2013), in a territory probably included in the DVT region of the HCP-MMP1 atlas (Glasser et al., 2016a) and which (like macaque V6Av) is activated by optic flow (Pitzalis et al., 2013). Another part of the macaque dorsal precuneate region includes the medial portion

of area PEc (Gamberini et al., 2020). Area PEc is a visual-somatosensory area which represents both upper and lower limbs and is probably involved in locomotion and in the analysis of related optic flow (Gamberini et al., 2020; Raffi et al., 2011). Area PEc is strongly connected with part of posterior cingulate cortex 31, area 7m and retrosplenial cortex (Bakola et al., 2010). The human homolog of PEc has been identified in the dorsal-most part of the precuneate cortex (Pitzalis et al., 2019).

DVT and ProS (in addition to POS1, POS2 and the RSC in the anterodorsal group) may provide a route for scene information to be represented in the VMV regions (Sulpizio et al., 2020) and thus to reach the parahippocampal cortex PHA1-3 (TH) and hippocampal system, and thereby to provide a key input to drive spatial view cells (Rolls and Wirth, 2018; Georges-François et al., 1999; Rolls et al., 1998b; Robertson et al., 1998; Rolls et al., 1997a; Tsitsiklis et al., 2020; Wirth et al., 2017; Rolls, 2023c). These spatial view cells provide a component of primate (including human) episodic memory by enabling objects, people, or rewards to be associated with their location in visual scenes (Rolls and Xiang, 2006; Rolls et al., 2005c; Rolls and Xiang, 2005), and are likely to be useful in navigation from viewed landmark to viewed landmark too (Rolls, 2021f). This is part of a ventromedial visual cortical stream that is proposed to encode scene information to provide ‘where’ inputs to the hippocampal spatial and memory system (Rolls et al., 2023e). In this context, the dorsal visual transitional region (DVT) and prostriate region (ProS) are key parts of the retrosplenial scene area (Sulpizio et al., 2020), which connect earlier visual cortex ventral stream regions to the parahippocampal scene area (or PPA) in the VMV and PHA1-3 regions (Rolls et al., 2023e; Rolls, 2023c) (Fig. 9.18).

DVT and ProS may also provide a route for vestibular and optic flow information useful in navigation to reach hippocampal whole body motion neurons, for they receive inputs from VIP and V6A in which optic flow is represented (Duhamel et al., 1997; Sherrill et al., 2015; Delle Monache et al., 2021).

12.4 Mid-cingulate cortex, the cingulate motor area, and action–outcome learning

The anterior cingulate area may be distinguished from a mid-cingulate area (i.e. further back than the perigenual cingulate region and occupying approximately the middle third of the cingulate cortex), which has been termed the cingulate motor area (Vogt et al., 1996, 2003; Vogt, 2009, 2016, 2019b). The mid-cingulate area may be divided into an anterior or rostral cingulate motor area (24c' and 24a') concerned with skeletomotor control which may be required in avoidance and fear tasks, and a posterior or caudal cingulate motor area (24d and p24') which may be more involved in skeletomotor orientation (Vogt et al., 2003; Vogt, 2016). (As has been noted above, what has been termed the anterior mid-cingulate cortex (Vogt, 2016) may overlap with or be similar to what is described as the supracallosal part of the anterior cingulate cortex in this Chapter.)

This midcingulate cortex is activated by pain but, because this area is also activated in response selection tasks such as divided attention and Stroop tasks (which involve cues that cause conflict such as the word red written in green when the task is to make a response to the green color), it was suggested that activation of this mid-cingulate area by painful stimuli is related to the response selection processes initiated by painful stimuli (Vogt et al., 1996; Derbyshire et al., 1998). Both the anterior cingulate and the mid-cingulate areas may be activated in functional neuroimaging studies not only by physical pain, but also by social pain, for example being excluded from a social group (Eisenberger and Lieberman, 2004).

In human imaging studies it has been found that the anterior/mid-cingulate cortex is activated when there is a change in response set or when there is conflict between possible responses, but it is not activated when only stimulus selection is at issue (van Veen et al., 2001; Rushworth et al., 2002).

Some anterior/mid-cingulate neurons respond when errors are made (Niki and Watanabe, 1979; Kolling et al., 2016; Procyk et al., 2016), or when rewards are reduced (Shima and Tanji, 1998) (and activations are found in corresponding imaging studies (Bush et al., 2002; Procyk et al., 2016)). In humans, an event-related potential (ERP), called the error related negativity (ERN), may originate in the area 24c' (Ullsperger and von Cramon, 2001), and many studies provide evidence that errors made in many tasks activate the anterior/mid-cingulate cortex, whereas tasks with response conflict activate the superior frontal gyrus (Rushworth et al., 2004; Kolling et al., 2016; Procyk et al., 2016).

Correspondingly, in rodents a part of the medial prefrontal / anterior cingulate cortex termed the prelimbic cortex is involved in learning relations between behavioral responses and reinforcers, that is between actions and outcomes (Balleine and Dickinson, 1998; Cardinal et al., 2002; Killcross and Coutureau, 2003). Balleine and Dickinson (1998) showed that the sensitivity of instrumental behavior to whether a particular action was followed by a reward was impaired by prelimbic cortex lesions. When making decisions about actions, it is important to take into account the costs as well as the benefits. There is some evidence implicating the rodent anterior cingulate cortex (prelimbic cortex) in this, in that rats with prelimbic cortex lesions were impaired in a task that required decisions about an action with a large reward but a high barrier to climb, vs an action with a lower reward but no barrier (Walton et al., 2002, 2003; Klein-Flugge et al., 2022a).

The concept has been advanced (Rolls, 2019c) that the midcingulate cortex may be part of a cingulate system that enables reward outcome information from the orbitofrontal cortex to be associated with action information from the posterior cingulate cortex, with the output directed to premotor cortical areas, as described in this Chapter.

12.5 How the computations are performed by the cingulate cortex

12.5.1 The anterior cingulate cortex and emotion

The anterior cingulate cortex receives information from its topologically nearby neocortical area, the orbitofrontal cortex (most of which is neocortical in primates, and which receives from ventral stream 'what' areas), and also the amygdala (also a recipient of ventral stream projections), and projects this information to a number of areas, including autonomic areas in the brainstem as well as in the insula, to the midcingulate cortex, and to the striatum. Because reward value is important in producing emotions, the anterior cingulate cortex becomes involved in emotion (Rolls, 2014a, 2019e), and damage to it in humans can impair emotions (Hornak, Bramham, Rolls, Morris, O'Doherty, Bullock and Polkey, 2003). This provides for an emotion-related function of the cingulate cortex.

The reciprocal connections between the reward-related medial orbitofrontal cortex and the pregenual and subgenual anterior cingulate cortex (Du et al., 2020; Hsu et al., 2020; Rolls et al., 2023c), and the local topology for reward representations in these areas (Grabenhorst and Rolls, 2011), may help in the formation of attractor networks for positive emotions, because within each of these cortical areas connections are likely to be made onto reward neurons, without dilution caused by intermingling of punishment neurons. The attractor potentiality is likely to be facilitated by associative synaptic modifiability of the forward and

Fig. 12.8 Effective connectivity to the orbitofrontal cortex (OFC) and anterior cingulate cortex (ACC) from all 180 cortical regions in the left hemisphere of the human brain. The area 10 group consists of 10v, 10r, 10d and 9m, and are included here because they are close to and have somewhat similar connectivity to the pregenual ACC group, and are part of what is sometimes termed the ventromedial prefrontal cortex. The effective connectivity is read from column to row. All effective connectivities greater than 0 are shown, and effective connectivities of 0 are shown as a blank. The connectivities from the first set of cortical regions are shown above, and from the second set below. All effective connectivity maps are scaled to show 0.15 as the maximum, as this is the highest effective connectivity found between this set of brain regions. The effective connectivity algorithm for the whole brain is set to have a maximum of 0.2, and this was for connectivity between V1 and V2. The abbreviations are listed in Section 1.12, and the brain regions are illustrated in Fig. 11.24. (From Rolls,E.T., Deco,G., Huang,C-C. and Feng,J. (2023) The human orbitofrontal cortex, vmPFC, and anterior cingulate cortex effective connectome: emotion, memory, and action. *Cerebral Cortex* 33: 350-356. doi: 10.1093/cercor/bhac270. Copyright © Oxford University Press.)

backconnections, which also help to build an attractor network. This may help mood related attractors to be stable and enduring, which is likely to be evolutionarily adaptive.

The anterior cingulate cortex may also provide an important route for value representations in the orbitofrontal cortex to produce goal-related actions, as described above. For example, sensation-seeking behavior in humans can be predicted from the strength of the functional connectivity between the medial orbitofrontal cortex and the anterior cingulate cortex (Wan, Rolls, Cheng and Feng, 2020), and so can risk-taking behavior (Rolls et al., 2022c). Our hypothesis is that because some rewards have high value to particular individuals, the orbitofrontal representation of this may strongly drive the action system in the anterior cingulate cortex to perform actions to obtain these rewards. Part of the interest here is that risk-taking may be being driven by strong effects from the reward system, rather than problems with responding to non-reward or failing to inhibit behavior because of less functionality of the lateral orbitofrontal cortex / inferior frontal gyrus, which may be a different type of impulsivity (Aron et al., 2014; Deng et al., 2017).

12.5.2 Action-outcome learning in the supracallosal anterior cingulate cortex (dACC)

An important function of the supracallosal anterior cingulate cortex (or dACC) is to associate actions with outcomes, as indicated by the connections shown in green in Fig. 12.2 and in red in Fig. 12.3. My hypotheses are as follows. As shown by effective connectivity analyses in humans, the supracallosal anterior cingulate cortex receives information about recent actions from the premotor cortical area 6 and midcingulate cortex; somatosensory cortical regions including area 5, frontal opercular (FOP) regions and the insula; from parietal area 7 and

inferior parietal region PF; and from the posterior cingulate cortex (23d and 31a) (Rolls et al., 2023c) (see Fig. 12.8). The supracallosal anterior cingulate cortex also receives effective connectivity from reward-related regions that provide evidence about reward outcome, the medial orbitofrontal cortex (pOFC, OFC, 131 and 111) and pregenual anterior cingulate cortex (d32, p24) (Rolls et al., 2023c). The same analyses show that the supracallosal anterior cingulate cortex has connectivity with the dorsolateral prefrontal cortex regions 46 and 9-46d (Rolls et al., 2023c), and these prefrontal regions implicated in short-term memory may help to maintain a memory trace of recent actions and outcomes, so that an average can be made that is useful in probabilistic tasks and situations. Computationally, this enables the high dimensional space of many possible actions, and any relevant spatial information from the parietal cortex or some object information from the inferior temporal visual cortex (regions PIT and TE2p in Fig. 12.8) to be associated with the high dimensional space of many possible reward/punishment/non-reward outcomes received from the orbitofrontal cortex and anterior cingulate cortex, to enable the outcomes of each possible action to become associated. The type of action-outcome learning involved could be as simple as pattern association between the action input and the reward outcome output, with previous actions and their associated outcomes taken into account using the neocortical short-term memory capability.

The computational issue then arises about how to choose the action that leads to best outcome currently available. Part of the selection involved it is proposed takes place at the level of the reward value as implemented in the orbitofrontal cortex, using mechanisms such as sensory-specific satiety, long-term sensory specific satiety, homeostatic reward modulation by internal state, etc (Chapter 11). But an important part of the mechanism for the action to select to obtain the best reward currently available may be using an ‘exploit’ vs ‘explore’ mechanism. As described above, the proposed computational mechanism is that non-reward or punishment resets an ‘exploit’ neuronal population to fall out of its attractor in an exploit/explore rule attractor network, thereby releasing the ‘explore’ population from inhibition by the inhibitory neurons. This could be achieved by non-reward or punishment directly activating the ‘explore’ attractor to produce exploratory behavior. Then while exploring, rewards that are better than previously received activate the ‘exploit’ attractor neuronal population, which quenches the ‘explore’ neuronal population through the inhibitory neurons in the exploit/explore rule single attractor network. The computational mechanism is similar to that described for reversal of the rule attractor network in Section 11.5.3. The actual location of this exploit/explore rule attractor single network could be in the dACC, but another interesting possibility is that it is in the frontal pole, from where it can control the whole of the dorsolateral prefrontal cortex, as described in Section 13.5 (Rolls et al., 2023a).

A useful computational property of the exploit/explore network would be some adaptation over time in its synapses. That would enable the system if in ‘exploit’ mode to gradually reduce its tendency to exploit, so that eventually the ‘explore’ attractor population of neurons would jump up out of the noise (see Section 11.5.1 and Rolls and Deco (2002)), and exploration would occur behaviorally to investigate whether different rewards were available. Correspondingly, adaptation in the ‘explore’ population of neurons would ensure that if exploration had been proceeding for a long time, the ‘exploit’ neuronal population in the exploit/explore single attractor network should jump up out of the noise, so that behaviorally the individual would settle on the exploitation of whatever resource was currently available.

The outcomes are in the high dimensional space of many different types of reward that are represented in the orbitofrontal cortex. This enables rapid learning of which actions to perform for which outcomes, because this requires simple associative learning between the particular action that has just been performed, and the particular outcome that has just been received and is signalled by the orbitofrontal cortex. It also seem likely that the cingulate

cortex has a repertoire of previously learned actions, which can rapidly be associated with new different outcomes by rapid associative learning between actions and outcomes.

This cingulate action-outcome learning is thus much more efficient than stimulus-response habit formation, in which a one-dimensional reinforcer, the dopamine neuron reward prediction error signal, is used to reinforce whatever representations of stimuli and responses throughout the dopamine-influenced system in for example the basal ganglia may recently have been active (see Section 19.5 and Chapter 16).

The orbitofrontal cortex–cingulate cortex action-outcome learning system is also much more rapid and efficient than the reinforcement learning stimulus-response habit system implemented by dopamine and the basal ganglia, because if the association between the stimulus and the outcome (a stimulus-stimulus association) changes or is reversed, this can be corrected in one trial by the stimulus-reward reversal learning system in the orbitofrontal cortex described in Chapter 11.

Error signals generated reflect a mismatch between the expected outcome and the action. This is different from the orbitofrontal cortex, in which the error signals reflect a mismatch between the expected value of a stimulus (e.g. the sight of food) and the outcome (e.g. a taste of food).

12.5.3 Connectivity of the posterior cingulate cortex with the hippocampal memory system

Another important function of the cingulate cortex is related to the hippocampal memory system (Rolls, 2018b), as shown in Figs. 12.2 and Fig. 12.3. The connectivity shown in these Figures indicate two routes for reward-related information to reach the hippocampal memory system. The first, more direct, route is from the orbitofrontal cortex, vmPFC, anterior cingulate cortex and amygdala to the perirhinal cortex with information derived from the ventral visual and auditory ‘what’ processing streams (blue in Fig. 12.2). A second route for reward-related information is via the orbitofrontal cortex / vmPFC / pregenual anterior cingulate cortex to the posterior cingulate cortex and thereby to the hippocampal system (Fig. 12.3). These concepts are further elaborated elsewhere (Rolls, 2019c,b; Rolls et al., 2023i; Rolls, 2022b).

The posterior cingulate cortex appears to have three main groups of region. A posterior ventral group provides a path for ‘what’ information to reach the hippocampal memory system (Section 12.3.2). An anterodorsal group provides a path of ‘where’ information to reach the hippocampal memory system (Section 12.3.3). The retrosplenial scene area in DVT and PRoS provides a route for ventral visual stream information to reach the parahippocampal scene area (Section 12.3.4). The coordinates in the parahippocampal scene area and hippocampus are at least for many neurons in allocentric coordinates (Chapter 9 including Section 9.6). Humans often describe scenes in a perhaps partly egocentric view-based framework, as the view of a scene from where they are located, though in practice exactly where they are located on one side of the scene often makes little difference (see Section 9.6). Hippocampal spatial view cells could also be involved in this type of episodic / autobiographical memory. However, of course the information at earlier stages of the visual system is in egocentric coordinates, so transforms from retinal through to allocentric coordinates are needed. Possible mechanisms for these spatial coordinate transforms are described in Section 3.4. The retrosplenial cortical regions, and perhaps the antero-dorsal posterior cingulate division regions, connect information from the parietal lobe which may be at least partly in egocentric coordinates with the hippocampal system via the parahippocampal gyrus. The posterior cingulate and retrosplenial cortex may be involved in helping to perform these coordinate transforms, in the ways that are described in Section 3.4.

12.6 Synthesis and conclusions

The conceptualization provided here of the cingulate cortex, a key brain region with proisocortical structure, shows how its connections are related to both the ventral and the dorsal cortical processing streams; how its functions are important in emotion, episodic memory, and action-outcome learning; and how its functions are related to those of other limbic structures including the hippocampus, and to the functions of different neocortical areas. Some of the key points that are made (Rolls, 2019c; Rolls et al., 2023c,i) are as follows, and relate to what is shown in Figs. 12.2, 12.3, 12.6, 12.7, and 9.18.

1. The cingulate cortex has several different functions, which can be related to the connections of its different parts. As an area of proisocortex (a type of neocortex) it forms a connectional bridge between neocortical areas and areas such as the hippocampus (which is archicortex, a type of allocortex) (Pandya et al., 2015; Rolls, 2019c). The connections of the cingulate cortex can in this way be related to its evolutionary history as a proisocortical structure, and the topological position of its different parts.

2. In this framework, the posterior cingulate cortex in its anterodorsal part (including 23d, 31a, and retrosplenial regions, Fig. 12.7) receives information from the nearby neocortical areas such as the parietal cortex about spatial representations, and projects this onwards via the PHA1-3 medial parahippocampal cortex to the hippocampus, where it provides a spatial component related to idiothetic update for object-space episodic memories. This provides for a ‘where’ memory-related contribution of the cingulate cortex.

3. The posterior cingulate in its posteroventral part (most of regions 31 and 23, Fig. 12.6) has connectivity with ‘what’ regions including the inferior temporal visual cortex and cortex in the superior temporal sulcus involved in auditory and semantic representations, and with reward / value / emotion-related regions including the vmPFC and pregenual anterior cingulate cortex. The onward connectivity to the hippocampal system (Fig. 12.6, (Rolls et al., 2023i)) provides for a ‘what’ and reward memory-related function of the cingulate cortex.

4. The retrosplenial regions DVT and PROs are where the retrosplenial scene area is located, and may be involved in coordinate transforms from egocentric to allocentric representations.

5. The pregenual anterior cingulate cortex receives from the orbitofrontal cortex and the vmPFC, and has connectivity directly with the hippocampal system and via the posteroventral part of the posterior cingulate cortex to provide reward / value / emotion-related information to the hippocampus (Fig. 12.3). The hippocampus can use this as a key component of episodic memory, and to set the goals for navigation.

6. The pregenual anterior cingulate cortex has connectivity to the septal nuclei which contain cholinergic neurons that project to the hippocampus. This enables the pregenual anterior cingulate cortex to influence memory consolidation. This complements the functions of the medial orbitofrontal cortex region pOFC which has effective connectivity to the basal forebrain nuclei of Meynert which contain cholinergic neurons that project to the neocortex, and also thereby can influence memory consolidation.

7. The effects of damage to the human anterior cingulate cortex and vmPFC and orbitofrontal cortex which produce memory impairments therefore probably do so largely by disconnecting reward value inputs from the hippocampal system and by impairing the roles of the cholinergic

gic systems in memory consolidation (Rolls, 2022b) (Section 9.2.8.5), rather than by implementing the computational functions required for episodic memory, which are performed by the hippocampus (Chapter 9).

8. The supracallosal anterior cingulate cortex has strong connectivity with somatosensory, premotor, and midcingulate motor areas, and also receives reward outcome information from the orbitofrontal cortex and pregenual anterior cingulate cortex (Fig. 12.3). This provides a foundation for its involvement in goal-related action-outcome learning which is a key output system for the orbitofrontal cortex to implement actions in relation to emotion-provoking stimuli, i.e. rewards and punishers.

The further conclusions described next add detail to the framework just described.

9. The orbitofrontal cortex, which represents value and not actions, projects reward value information from the medial orbitofrontal cortex, and punishment and non-reward information from the lateral orbitofrontal cortex, to the anterior cingulate cortex. The pregenual anterior cingulate cortex is activated by rewards, and the supracallosal anterior cingulate cortex by punishers and non-reward (Grabenhorst and Rolls, 2011; Rolls, 2019e).

10. A source of information about actions reaches the posterior cingulate cortex from the parietal cortex (Vogt, 2009). The parietal cortex represents actions in terms of body and eye movements in space (lateral parietal cortex), and of the self in a spatial context (medial parietal cortex including the precuneus) (Rolls and Wirth, 2018; Rolls, 2020b) (Chapter 10).

11. After storage of information in the hippocampus, the information needs to be retrieved from the hippocampus, and utilizes backprojections originating in hippocampal CA1 back to neocortex, through the whole series of backprojections involving the lateral entorhinal cortex, and perirhinal cortex to the ventral stream areas, and orbitofrontal cortex, for the ventral route shown in blue in Fig. 12.2; and involving the medial entorhinal cortex, parahippocampal gyrus, posterior cingulate cortex, to the parietal cortex areas, for the dorsal route shown in red in Fig. 12.2.

This backprojection system enables the object information from an episodic memory to be recalled to the ventral stream areas, the reward information to the orbitofrontal cortex, and the spatial information to the parietal cortex (Kesner and Rolls, 2015; Rolls, 2016b, 2018b).

12. These functions related to different connectivity of the different parts of the cingulate cortex provide further evidence that we should no longer think of a single limbic system, but instead of multiple limbic systems (Rolls, 2015b).

One limbic system may involve the amygdala, orbitofrontal cortex, and anterior cingulate cortex for emotion.

A second limbic system may involve the hippocampus, perirhinal and parahippocampal cortex, and posterior cingulate cortex for episodic memory, including object-spatial associations, and object or spatial associations with temporal order. Reward information can also enter this hippocampal episodic memory system from the orbitofrontal cortex and anterior cingulate cortex so that reward value information can be included in an episodic memory (Kesner and Rolls, 2015; Rolls, 2016b, 2018b; Rolls and Wirth, 2018; Rolls, 2022b, 2023c).

A third limbic system may involve associations with the cingulate cortex for action-outcome learning, with the action information entering via the posterior cingulate cortex, the reward value outcome information via the anterior cingulate cortex, and the resulting association directed from the midcingulate cortex to premotor cortical areas.

The cingulate cortex is of interest within this context, as a limbic structure that is involved in all three of these functions, and this is related to the different connectivity of the different parts of this proisocortical structure.

13. It is useful to note that spatial scene representations are built along a pathway from early visual areas to the occipital scene area, then to the retrosplenial scene area in DVT and ProS, and then to the parahippocampal scene area in VMV1-3 and PHA1-3, and then to the hippocampus (Fig. 9.18, (Rolls et al., 2023e)).

14. The overall computational role of the posterior cingulate and related regions in the HCP-MMP posterior cingulate division can be conceptualised as now proposed. The cortical regions can be thought of as transitional in structure and evolutionary history between the hippocampal type of archicortex, and the neocortex or isocortex (Pandya, Seltzer, Petrides and Cipolloni, 2015). Parts of the posterior cingulate division are likely to have arisen in evolution after the hippocampal archicortex, and before the neocortex become highly developed. The posterior cingulate cortex can be thought of as interfacing neocortical regions involved in 'what', 'where' and reward representations to the hippocampal memory and navigation system. In another example, the pregenual anterior cingulate cortex connects the orbitofrontal cortex with the hippocampus to enable reward value information to enter the hippocampal memory system. The supracallosal anterior cingulate cortex can be thought of as interfacing neocortical somatosensory and premotor cortex regions with reward systems including the orbitofrontal cortex. Thus a conceptual framework for understanding the cingulate cortex is in terms of its transitional role in structure and evolutionary history for connectivity between later neocortex and earlier structures involved in memory such as the hippocampus and with reward systems.

13 The prefrontal cortex

13.1 Introduction and overview

The prefrontal cortex is the part of the frontal lobe anterior to motor area 4 and premotor area 6, and is approximately the cortex in and anterior to the arcuate sulcus, as shown in Fig. 13.1. It comprises architectonic areas 46 in and close to the principal sulcus; 45 and 44 inferiorly (the inferior frontal gyrus in humans); 8A, which includes the frontal eye field posterior to the principal sulcus and anterior to the arcuate sulcus; area 8B superiorly (which continues onto the medial wall); and areas 9 and 10 anteriorly. The prefrontal cortex also includes the orbitofrontal cortex, and that is considered in Chapter 11. Fig. 13.2 compares the prefrontal areas in macaques and humans. The prefrontal cortex also includes the anterior cingulate cortex, and that is considered in Chapter 12.

Fig. 13.1 provides a foundation for understanding the computational architecture of the prefrontal cortex. The occipital cortex is dominated by visual sensory input. The temporal lobe is dominated by hierarchical levels of analysis of ventral stream visual and auditory inputs. The parietal lobe is dominated by spatial dorsal visual stream and somatosensory processing (and their combination). All of these processing systems must devote their resources to sensory processing, and must remain continuously dedicated to this, otherwise we would be blind or deaf to what was happening in the world, which would be in evolutionary terms at great risk. The motor and premotor cortex (areas 4 and 6) must remain continuously devoted to and ready for action. That leaves the prefrontal cortex in a position to perform ‘off-line’ processing, including holding items in a short-term memory when the items are no longer present in the input processing streams. This off-line capacity develops into a capability of manipulating and rearranging items in short-term memory, and this is called working memory, which is also implemented in the prefrontal cortex. This ability in humans develops into systems that can plan ahead, and then can control behavior according to such plans, which is referred to as ‘executive function’ (Rosati, 2017; Fiske and Holmboe, 2019; Shallice and Cipolotti, 2018).

This concept, that computationally the posterior cortical regions including the temporal and parietal cortex must be devoted to incoming sensory inputs from the world, and that the prefrontal cortex therefore can specialise in short-term memory for previous states using inputs from posterior cortical regions, provides a key computational basis for understanding the prefrontal cortex. This concept was missed in some earlier descriptions of the functions of the prefrontal cortex as being involved in ‘voluntary action’ (Passingham and Wise, 2012; Passingham, 2021), which is difficult to define and measure (Rolls et al., 2023f). A more precise approach to the functions of the prefrontal cortex is to take a computational approach that the prefrontal cortex is involved when actions are generated from short-term or working memory. This type of computation provides an approach to planning ahead, for which keeping several steps of a plan active in working memory is needed (Rolls et al., 2023f). This foundation for understanding the functions of the prefrontal cortex emphasises that it is involved when actions are internally generated (from short term and working memory), rather than being in response to an incoming stimulus from the world processed by posterior cortical, temporal and parietal, regions (Rolls et al., 2023f). Working memory refers here to the ability to ma-

Fig. 13.1 Lateral view of the macaque brain showing some connections to the prefrontal cortex. The ventral visual stream projects to the temporal lobe visual cortical areas which in turn project to ventral parts of the prefrontal cortex. The dorsal visual stream projects to parietal cortex areas which in turn project to dorsal parts of the prefrontal cortex. There are backprojections from the prefrontal cortex. V1, primary visual area; V2, V4, extrastriate visual areas; IT, inferior temporal visual cortex; LIP, lateral intraparietal cortex visual area; PP, posterior parietal cortex; PFCv, ventrolateral prefrontal cortex; PFCd, dorsolateral prefrontal cortex; VIP, ventral intraparietal cortex visual area; as, arcuate sulcus; cal, calcarine sulcus; io, inferior occipital sulcus; ip, intraparietal sulcus; lun, lunate sulcus; ps, principal sulcus. (Modified from Gustavo Deco and Edmund T. Rolls (2005) Attention, short-term memory, and action selection: A unifying theory. *Progress in Neurobiology* 76: 236–256. © Elsevier Ltd.)

nipulate items held in short-term memory, and provides a basis for planning (Baddeley, 2007, 2012; Baddeley et al., 2019; Baddeley, 2021).

In order to operate in this way, the prefrontal cortex needs material to work on in its short-term or working memory. As indicated in Fig. 13.1, the prefrontal cortex receives visual, auditory and somatosensory information from the temporal and parietal lobes. The prefrontal cortex also receives taste and olfactory and reward value information from the orbitofrontal cortex. To then control behavior based on what is in its short-term or working memory, the prefrontal cortex then needs routes to motor output, and it is well placed for this, as it is placed close to, and sends projections to, premotor cortical areas including area 6. For the computations performed by the prefrontal cortex to be useful, it must be able to influence behavioral output, via for example its connections to premotor cortical areas.

But the prefrontal cortex can do more than this. Because it can hold items in short-term memory, and because it has top-down backprojections to the temporal and parietal areas from which it receives inputs, it can implement top-down attentional control, again by the pathways shown in Fig. 13.1. This enables the prefrontal cortex to gently bias incoming sensory inputs using top-down biased competition (see Section 2.12) and top-down biased activation (see Section 4.3.5) to give preference to whatever sensory and other inputs and processing may be relevant to the goal that may be being implemented by what is held in the prefrontal cortex short-term memory / planning system.

Thus the prefrontal cortex can influence behavioral output both by its connections to nearby premotor cortex areas, and also by top-down biasing of inputs in the temporal and parietal sensory processing streams.

Different parts of the prefrontal cortex are organised to implement these functions by connections to different parts of the temporal and parietal cortex. For example, the dorsal

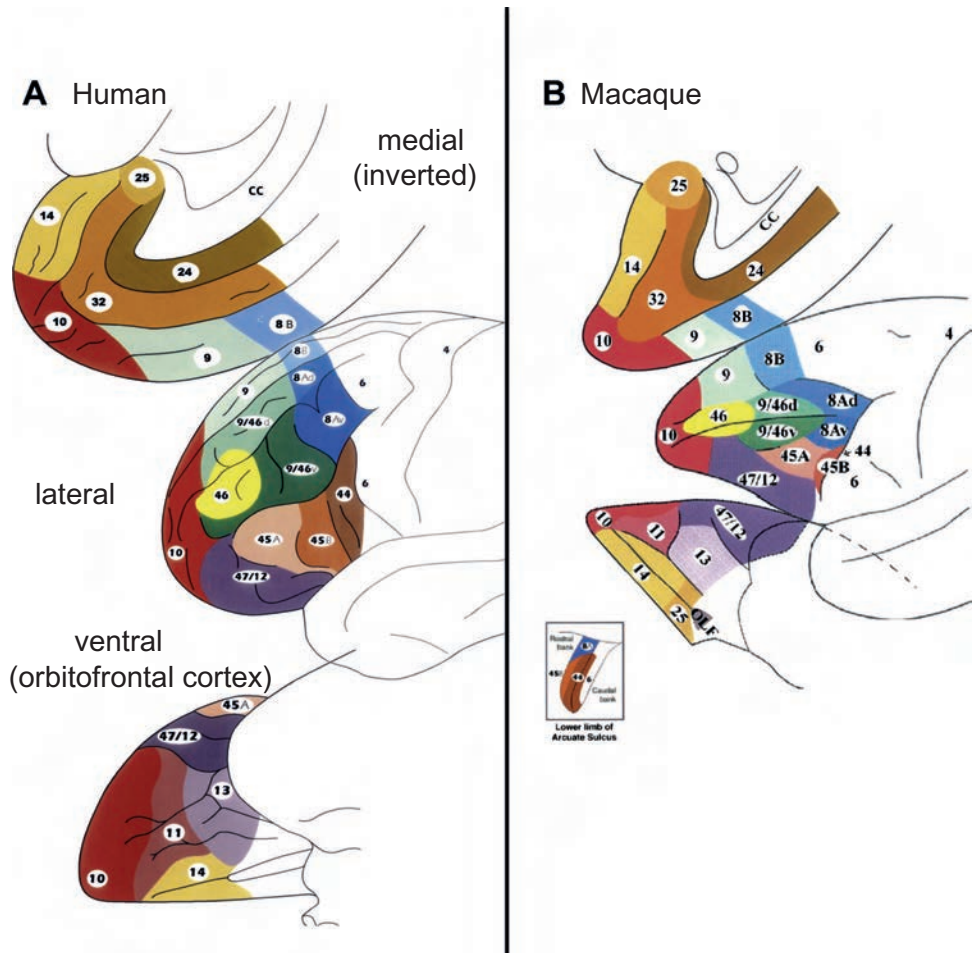

Fig. 13.2 Cytoarchitectonic maps of the lateral, medial, and orbital surfaces of the frontal lobe of the human (A) and the macaque monkey (B) brains as parcellated by Petrides and Pandya (1994). In B, the inset diagram displays the region within the lower limb of the arcuate sulcus to show the cytoarchitectonic areas lying within its banks. (Modified from Michael Petrides, Francesco Tomaiuolo, Edward H. Yeterian, and Deepak N. Pandya (2012) The prefrontal cortex: Comparative architectonic organization in the human and the macaque monkey brains. *Cortex* 48: 46–57. © Elsevier Srl.)

parts of area 46 in the dorsal bank of the principal sulcus are involved especially in spatial ('where') short-term memory, because they tend to receive projections from the dorsal parts of the sensory processing systems, the parietal cortex (as indicated in Fig. 13.1). Conversely, the ventral parts of area 46 in the ventral bank of the principal sulcus are involved especially in object ('what') spatial short-term memory, because they tend to receive projections from the ventral parts of the sensory processing systems, the temporal cortex. In addition, the frontal eye field in area 8A is involved in spatial working memory for eye position, with connections to the parts of the parietal lobe involved in eye position control such as LIP and VIP.

The computational ability to hold items in a short-term memory, and even better to rearrange them in a working memory and to plan ahead, has clear evolutionary adaptive value, by enabling behavior to extend beyond the current sensory input. This computational capability was driven by the development of the cortex, which by implementing associatively modifiable synaptic connections between nearby pyramidal cells, enables autoassociation or attractor networks to be implemented, which are the building blocks of short-term memory

(see Section B.3) (Rolls, 2016b). However, having attractor networks in the sensory processing areas in the temporal and parietal cortex is not sufficient to overcome the issue that the next sensory input must drive these areas into the next state. The great evolutionary advantage of the prefrontal cortex is that it provides computationally separate attractor networks from what is happening in the sensory processing cortical areas. The prefrontal networks are sufficiently connected to sensory areas that the prefrontal networks can receive information, and can go into an attractor state that represents the inputs from posterior brain regions. But once in that attractor state, the prefrontal autoassociation networks must be sufficiently stable that they can remain in their short-term memory attractor state, and be independent of the changing sensory processing in the sensory processing streams. This requires the correct degree of coupling between the prefrontal and the posterior networks: if too weak, the prefrontal networks will never be activated by the sensory input; and if too strong, then the sensory input will dominate the prefrontal attractor networks, which will not be independent. This is an important computational issue for understanding the functions of the prefrontal cortex, and we have therefore investigated this considerably, and have identified the quantitative regimes within which the correct operation occurs, as described in Sections B.9 and 13.6.2.2 (Renart, Parga and Rolls, 1999b,a). Further, if the stability of this prefrontal processing is too great, then this may lead to malfunction in behavior, and indeed a number of mental disorders including obsessive-compulsive disorder, depression and attention deficit hyperactivity disorder (ADHD) are likely to reflect overstability or at least altered stability of some prefrontal and related processing modules, and some other disorders such as some aspects of schizophrenia and over-impulsivity may reflect too little stability (see Chapter 18).

The mechanisms that implement the short-term memory in the prefrontal cortex are auto-association or attractor networks, as described in this Chapter, with the operation of this type of network described in Section B.3.

This computational approach to understanding the functions of the prefrontal cortex can be contrasted with the more neuropsychological approach based considerably on the effects of lesions to different parts of the prefrontal cortex (Passingham and Wise, 2012; Passingham, 2021). The approach there was to list the many tasks in monkeys that are impaired by lesions of the prefrontal cortex, and to infer a function from those. Many of the tasks were described as involving “flexibility”. This led to the proposal that “The granular prefrontal cortex generates goals that are appropriate to the current context and current needs, and it can do so based on a single event.” In terms of the evolutionary advantage, it was proposed that “the granular prefrontal cortex evolved in primates as an adaptation to reducing the number of unproductive, risky, or costly foraging choices that phylogenetically older learning mechanisms produce. ... The new mechanism that primates evolved brings single events – conjunctions of contexts, goals, actions, and outcomes – to bear on the choice of foraging goals” (Passingham and Wise, 2012).

That is an interesting contrast to the more computational description provided above of the functions of the prefrontal cortex and its adaptive value. The computational account recognises a unifying function of the prefrontal cortex, as an offline buffer store that can hold items in a short-term and working memory; and of course must be able to influence actions based on what is in the memory or plan, which must in that sense provide goals for actions. Of course the fractionation of the prefrontal cortex based on the connectivity of its different parts, the effects of lesions to its different parts, and the neuronal activity and neuroimaging activations in its different parts, together with computational neuroscience approaches are key to understanding exactly how the system operates, and it is to what has been learned with these approaches that we now turn.

Some of the background evidence on the neuroscience of the prefrontal cortex is available elsewhere (Fuster, 2015; Passingham and Wise, 2012; Passingham, 2021). Here the focus is

on what computations are performed by the prefrontal cortex (Sections 13.2–13.4), and how they are performed (Section 13.6).

13.2 Divisions of the lateral prefrontal cortex

Some parts of the prefrontal cortex are described elsewhere in this book. The orbitofrontal cortex is considered in Chapter 11. The anterior cingulate cortex is considered in Chapter 12. The left inferior frontal gyrus, which includes Broca's area and is involved in language production, is described in Chapter 14 and Section 8.3.

Here we consider other parts of the prefrontal cortex, which are those mainly on the lateral surface as shown in Figs. 13.1 and 13.2. The computations in which these areas are involved include short-term memory (Sections 13.2.1–13.2.3), and top-down attentional control (Section 13.4). The connectional and computational organisation of the human prefrontal cortex is described in Section 13.3. How these computations for short-term memory and for attention are performed are described in Section 13.6.

13.2.1 The dorsolateral prefrontal cortex

This is area 46, the cortex in and close to the principal sulcus. The dorsal part has strong connectivity with parietal cortex areas, as shown in Fig. 13.1. It is involved in spatial short-term memory, for example remembering where in space a response should be made. A prototypical task is a delayed spatial response task (Goldman-Rakic, 1996; Fuster, 2015). In such a task performed by a monkey, a light beside one of two response keys illuminates briefly, there is then a delay of several seconds, and then the monkey must touch the appropriate key in order to obtain a food reward. The monkey must not initiate the response until the end of the delay period, and must hold a central key continuously in the delay period. Lesions of the prefrontal cortex in the region of the principal sulcus impair the performance of this task if there is a delay, but not if there is no delay. Some neurons in this region fire in the delay period, while the response is being remembered (Fuster, 1973, 1989; Goldman-Rakic, 1996; Fuster, 2015). Different neurons fire for the two different responses.

In pioneering research, Patricia Goldman-Rakic and colleagues had shown that lesions of the cortex in the principal sulcus impaired such spatial tasks, but only if there was a delay involved, showing that this is a system needed for short-term memory (Goldman et al., 1971; Goldman-Rakic, 1996).

The ventral part of the lateral prefrontal cortex has strong connectivity with temporal cortical areas including the inferior temporal cortex, as shown in Fig. 13.1. It is involved in object short-term memory, for example in a delayed match to sample task. For example, neuronal firing is found in the delay period in an object short-term memory task (delayed match to sample) in the inferior frontal convexity cortex, in a region connected to the ventral temporal cortex (Fuster, 1989; Wilson, Scalaidhe and Goldman-Rakic, 1993).

Some neurons in the principal sulcus region area 46 may be involved in both spatial and object short-term memory tasks (Rao, Rainer and Miller, 1997). Heterogeneous populations of neurons, some with more spatial input, others with more object input, and top-down attentional modulation of the different subpopulations depending on the task, start to provide an explanation for these findings (Kadohisa et al., 2023).

Given that inputs from the parietal cortex, involved in spatial computation, project more to the dorsolateral prefrontal cortex, for example to the cortex in the principal sulcus, and that inputs from the temporal lobe visual cortex, involved in computations about objects, project ventrolaterally to the prefrontal cortex (see Figs. 2.1, 3.1, and 2.3), it could be that

the dorsolateral prefrontal cortex is especially involved in spatial short-term memory, and the inferior convexity prefrontal cortex more in object short-term memory (Goldman-Rakic, 1996, 1987; Fuster et al., 1982). This organization-by-stimulus-domain hypothesis (Miller, 2000) holds that spatial ('where') working memory is supported by the dorsolateral PFC in the neighborhood of the principal sulcus (Brodmann's area (BA) 46/9 in the middle frontal gyrus (MFG)); and object ('what') working memory is supported by the ventrolateral PFC on the lateral/inferior convexity (BA 45 in the inferior frontal gyrus (IFG)). Consistent with this, lesions of the cortex in the principal sulcus impair delayed spatial response memory, and lesions of the inferior convexity can impair delayed (object) matching to sample short-term memory (Goldman-Rakic, 1996) (especially when there are intervening stimuli between the sample and the matching object, as described above). Further, Wilson, Scaldidhe and Goldman-Rakic (1993) found that neurons dorsolaterally in the prefrontal cortex were more likely to be related to spatial working memory, and in the inferior convexity to object working memory. Some fMRI studies in humans support this topographical organization (Leung et al., 2002), and some do not (Postle and D'Esposito, 2000, 1999). Rao, Rainer and Miller (1997) found in a task that had a spatial short-term memory component and an object short-term memory component that some prefrontal cortex neurons are involved in both, and thus questioned whether there is segregation of spatial and object short-term memory in the prefrontal cortex. Some segregation does seem likely, in that for example the neurons with activity related to delayed oculomotor saccades are in the frontal eye field (Funahashi, Bruce and Goldman-Rakic, 1989) (see Fig. 13.3), and this area has not been implicated in object working memory. Further, neurons in the dorsolateral prefrontal cortex are more likely to be involved in spatial processing in a delay task, and neurons in the inferior prefrontal convexity (ventrolateral prefrontal cortex) and more likely to be involved in object and spatial coding (Kadohisa et al., 2023).

Part of the conceptual resolution of the discussion about segregation of functions in the lateral prefrontal cortex is that sometimes combinations of objects and places must be held in short-term memory. For example, in one such task, a *conditional object–response (associative) task* with a delay, a monkey was shown one of two stimulus objects (O1 or O2), and after a delay had to make either a rightward or leftward oculomotor saccade response depending on which stimulus was shown. In another such task, a *delayed spatial response task*, the same stimuli were used, but the rule required was different, namely to respond after the delay towards the left or right location where the stimulus object had been shown (Asaad, Rainer and Miller, 2000). The tasks could be run on some trial blocks with the mappings reversed. Thus the monkey had to remember in any trial block the particular object–place mapping that was required in the delay period. In this task, neurons were found that responded to combinations of the object and the spatial position (Asaad et al., 2000). This bringing together of the spatial and object components of the task is important in how the short-term memory task was solved, as described in the computational model of these functions in Section 13.6.3. Mixed object and spatial coding in a more complex foraging task with a short-term memory component was also found (Kadohisa et al., 2023). However, this makes the conceptual point that at least some mixing of the spatial and object representations in the lateral prefrontal cortex is needed in order for some short-term memory tasks to be solved, and thus total segregation of 'what' and 'where' processing in the lateral prefrontal cortex should not be expected.

The maintenance of a short-term memory by the continuing firing of neurons in a delay period is a fundamental aspect of the operation of the prefrontal cortex, but there has been discussion of whether the neuronal firing is maintained sufficiently well in the short-term memory period (Miller et al., 2018). Part of the resolution to this is that we have shown that if even a few neurons in the population maintain some firing in the delay period, then at the end of the delay period the firing of the whole population can be reinstated from those few neur-

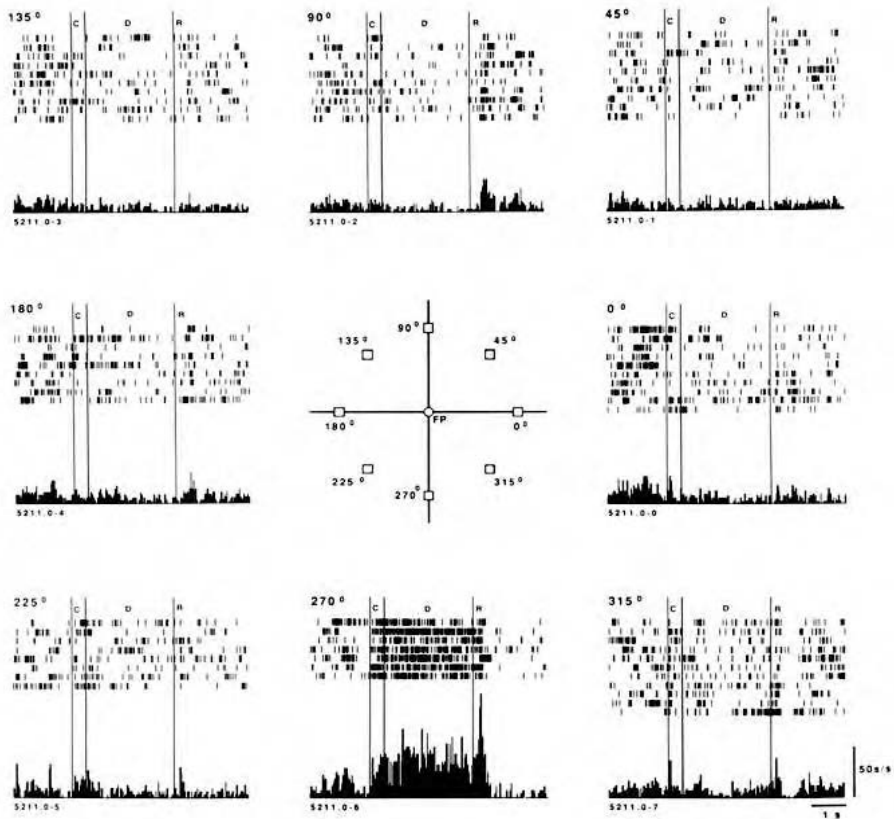

Fig. 13.3 The activity of a single neuron in the dorsolateral prefrontal cortical area involved in remembered saccades. Each row is a single trial, with each spike shown by a vertical line. A cue is shown in the cue (C) period, there is then a delay (D) period without the cue in which the cue position must be remembered, then there is a response (R) period. The monkey fixates the central fixation point (FP) during the cue and delay periods, and saccades to the position where the cue was shown, in one of the eight positions indicated, in the response period. The neuron increased its activity primarily for saccades to position 270° . The increase of activity was in the cue, delay, and response period while the response was made. The time calibration is 1 s. (Reproduced from Funahashi, S., Bruce, C. and Goldman-Rakic, P. (1989) Mnemonic coding of visual space in monkey dorsolateral prefrontal cortex. *Journal of Neurophysiology* 61: 331–349. © American Physiological Society.)

ons that are still active by a non-specific retrieval cue such as a cue that the delay period has ended (Martinez-Garcia, Rolls, Deco and Romo, 2011; Deco, Rolls and Romo, 2010). Another possible computational mechanism is short-term synaptic plasticity (Martinez-Garcia, Rolls, Deco and Romo, 2011).

The dorsolateral prefrontal cortex is also involved in temporal order / sequence memory, which is evident in the recall of items from short-term memory in the original order, and in neuronal firing (Naya, Chen, Yang and Suzuki, 2017; Tiganj, Cromer, Roy, Miller and Howard, 2018). The recall of the last few items in short-term memory is in the correct order, and this is a property of the ‘recency’ effect in short-term memory (Baddeley, 2012, 2021).

13.2.2 The caudal prefrontal cortex

The caudal prefrontal cortex is area 8A shown in Fig. 13.1. It is known as the frontal eye field, and is involved in eye movement related tasks that require a short-term memory, such as a delayed saccade task. This area is strongly connected with parietal areas involved in eye movement control, including VIP and LIP.

An example of a neuron responding in this dorsal and posterior part of the prefrontal cortex involved in remembering the position in visual space to which an eye movement (a saccade) should be made is illustrated in Fig. 13.3 (Funahashi, Bruce and Goldman-Rakic, 1989; Goldman-Rakic, 1996). In this case, the monkey was asked to remember which of eight lights appeared, and, after the delay, to move his eyes to the light that was briefly illuminated. The short-term memory function is topographically organized, in that lesions in small parts of the system impair remembered eye movements only to that eye position. Moreover, neurons in the appropriate part of the topographic map respond to eye movements in one but not in other directions (see Fig. 13.3). As shown below, such a memory system could be easily implemented in such a topographically organized system by having local cortical connections between nearby pyramidal cells which implement an attractor network (Fig. 13.9). Then triggering activity in one part of the topographically organized system would lead to sustained activity in that part of the map, thus implementing a short-term or working memory for delayed eye movements to that position in space.

13.2.3 The ventrolateral prefrontal cortex

The ventrolateral prefrontal cortex includes area 45, which on the left with 44 is Broca's area in the human inferior frontal gyrus. It has strong connections with the superior (auditory) and inferior (visual) temporal cortex. One of its functions in macaques may be to map visual and auditory inputs to motor responses, for damage to this region impairs conditional visual-spatial response learning, that is, when a visual stimulus must be mapped to a particular spatial response (Passingham, 2021). In macaques, the ventrolateral prefrontal cortex contains neurons that respond to auditory stimuli and that process both face and vocal stimuli, supporting the hypothesis that this may be an essential brain region for both auditory and audiovisual working memory (Plakke and Romanski, 2016).

In humans, this may be a key region in mapping semantic representations in the anterior temporal lobe to motor responses that include the generation of speech, as considered in more detail in Section 14.5. There is strong connectivity in humans between areas 45 and 44 and the temporal pole as well as other anterior parts of the temporal lobe (Rolls, Deco, Huang and Feng, 2022b; Hsu, Rolls, Huang, Chong, Lo, Feng and Lin, 2020).

On the inferior prefrontal convexity there is a part that in humans is termed the inferior frontal gyrus pars orbitalis, and which has similarities both with the lateral orbitofrontal cortex (area 12), and with the inferior frontal gyrus (see Section 13.3.1 and Chapters 14, 11 and 18), including in its connectivity (Rolls, Deco, Huang and Feng, 2022b; Du, Rolls, Cheng, Li, Gong, Qiu and Feng, 2020; Hsu, Rolls, Huang, Chong, Lo, Feng and Lin, 2020).

13.3 The connectivity and computational organisation of the human prefrontal cortex

The organisation of the human prefrontal cortex using the Human Connectome Project - Multimodal cortical Parcellation (HCP-MMP, Section 1.12), and measuring effective connectivity, complemented by functional connectivity and diffusion tractography (Section 1.13) with data from the Human Connectome Project, is described next (Rolls et al., 2023f).

Fig. 13.4 Inferior prefrontal cortex effective connectivity. The connectivity of IFSa is shown as an example of the connectivity of IFJa, IFJp, IFSa and IFSp. The width of the arrows reflects the effective connectivity with the size of the arrowheads reflecting the connectivity in each direction. The effective connectivity with the inferior temporal visual cortex (TE1p, TE2p and PHT); and with the medial orbitofrontal cortex 13l and 11l, and the lateral orbitofrontal cortex p47r and a47r are notable. IFSa has moderate effective connectivity with the other IF regions. (From Rolls, E.T., Deco, G., Huang, C.-C. and Feng, J. (2023) Prefrontal and somatosensory-motor cortex effective connectivity in humans. *Cerebral Cortex* doi: 10.1093/cercor/bhac391. Copyright © Oxford University Press.)

13.3.1 Inferior frontal gyrus

The inferior frontal gyrus regions include 44, 45, 47l, a47r, IFJa, IFJp, IFSa, IFSp and p47r (Fig. 13.4).

The three inferior frontal gyrus regions 44, 45 and 47l are considered first, and are considered further in Chapter 14 and elsewhere (Rolls et al., 2022b) (Fig. 14.3). Areas 44 and 45 are brain regions normally considered as Broca's area (Sprung-Much et al., 2022; Weiller et al., 2021; Petrides, 2014; Sprung-Much et al., 2022; Weiller et al., 2021; Rauschecker, 2018a; Milton et al., 2021; Friederici et al., 2017), but 47l at least in the left hemisphere has very similar connectivity to them. These regions receive from two semantic systems (Rolls et al., 2023f, 2022b). One semantic system is in the ventral part of the superior temporal sulcus (STSva and STSvp) connected with the inferior temporal visual cortical TE regions and parietal PGI and PGs involved in visual representations of objects (Rolls et al., 2022b).

A second semantic system is in the STSda and STSdp, STGa, auditory A5, TPOJ1, the STV and the PeriSylvian Language area (PSL) and has effective connectivity with auditory areas (A1, A4, A5, Pbelt); with relatively early visual areas involved in motion e.g. MT and MST, and faces/words (FFC); with somatosensory regions (frontal opercular FOP, insula and parietal PF); with other TPOJ regions; and with the inferior frontal gyrus regions (IFJa and IFSp) (Rolls et al., 2022b, 2023f,h). In macaques, area 45 has connectivity with the cortex in the superior temporal sulcus (Petrides and Pandya, 2002). Of relevance to the findings described here, the somatosensory ‘ventral what stream’ regions (frontal opercular FOP, insula and parietal PF) are incorporated into the second semantic system (Rolls et al., 2022b, 2023f), and the somatosensory ‘dorsal action’ stream is less incorporated into language-related semantic processing.

Of especial interest is that Broca’s area 44 and 45 at least in the left hemisphere involves much surrounding cortex as shown by the connectivity, including 47l which is part of the lateral orbitofrontal cortex, and whole swathes of the inferior frontal gyrus, including IFJa, IFSp and IFSa which are strongly interconnected (Rolls et al., 2023f). Area 44 is implicated in syntax (Friederici, Chomsky, Berwick, Moro and Bolhuis, 2017), but the close interconnections of 44, 45 47l, IFJa, IFSp and IFSa are consistent with the hypothesis that inferior frontal gyrus sequentially linked attractor networks could provide an implementation of the sequential syntactic operations involved in speech production, but would need many such linked attractor systems to deal with the different sequential processing needed for the active vs the passive tense, and for different languages (Rolls and Deco, 2015a) (Section 14.5).

The connectivity of inferior frontal regions IFJa, IFJp, IFSa, IFSp is considered next, with Fig. 13.4 providing a schematic overview of the effective connectivity of IFSa, chosen as typical of this set of interconnected regions (Rolls et al., 2023f). A feature of the connectivity of the IFJ and IFS regions is that they receive from inferior temporal visual cortical regions (e.g. TE1p, TE2a, TE2p and PHT) involved in object representations (Rolls, 2021d,b; Rolls et al., 2023e). This makes it likely that in humans these IFJ and IFS regions specialize in the short-term memory of visual object-based ‘what’ representations. The connectivity of some of these regions with language-related regions 44, 45, 47l, TPOJ1, STV, 55b and some STS regions also provides a route for this visual object and face related information to gain access to these language-related regions (Rolls et al., 2022b). There are also some inputs from intraparietal visual motion/grasp-related regions (Rolls et al., 2023d) such as AIP, LIPd, MIP and IP0-2, so that some aspects of the motion of objects, also represented in the superior temporal sulcus (STS) regions (Rolls et al., 2023e) are utilised in the inferior frontal regions. Interestingly, there are also inputs from the orbitofrontal cortex (e.g. 11l and 13l) (Rolls et al., 2023f) involved in reward / punishment value representations and thereby in emotion (Rolls, 2019e,f; Rolls et al., 2023c). The IFS and IFJ regions may therefore be involved in maintaining information about visual objects, visual motion, and emotional value and mood in short-term memory by maintaining firing in attractor networks in these inferior frontal gyrus regions (Fuster, 2015; Constantinidis et al., 2018; Martinez-Garcia et al., 2011; Rolls, 2021b). These IFS and IFJ regions also provide a route for these types of input to access language systems, and may also provide additional attractor networks that can be involved with Broca’s area regions in syntax (Rolls and Deco, 2015a; Rolls et al., 2022b) (Section 14.5). Conversely, these IFS and IFJ regions may provide a route for language-related rational thought systems to have a top-down influence on the emotion-related processing system in the orbitofrontal cortex.

a47r and p47r are anterolateral parts of the orbitofrontal cortex considered by (Rolls et al., 2023c) (Chapter 11). They have connectivity with other orbitofrontal cortex regions (13l, 11l, OFC, 47m), inferior temporal cortex (TE1p, TE2a, TE1m and PHT), medial prefrontal 8BM,

Fig. 13.5 Dorsolateral prefrontal cortex effective connectivity. The connectivity of region 46 is shown as an example of the connectivity of regions 46, 9-46d, a9-46v and p9-46v. The width of the arrows reflects the effective connectivity with the size of the arrowheads reflecting the connectivity in each direction. The effective connectivity with the superior parietal cortex 7Am and 7PL, the strong connectivity with inferior parietal PF and with the medial orbitofrontal cortex 11l are notable. 46 has moderate effective connectivity with the other DLPFC regions 9-46d, a9-46v and p9-46v. (From Rolls, E.T., Deco, G., Huang, C.-C. and Feng, J. (2023) Prefrontal and somatosensory-motor cortex effective connectivity in humans. *Cerebral Cortex* doi: 10.1093/cercor/bhac391. Copyright © Oxford University Press.)

and inferior parietal visual region PFm, and are involved in value/emotion-related processing (Rolls et al., 2023c; Rolls, 2019e,f; Rolls et al., 2020a, 2023b).

13.3.2 Dorsolateral prefrontal cortex division

The effective connectivity of the regions in the dorsolateral prefrontal cortex division (46, 8Ad, 8Av, 8BL, 8C, 9-46d, 9a, 9p, a9-46v, i6-8, p9-46v and s6-8) is illustrated in Fig. 13.5 (Rolls et al., 2023f).

A first group of regions comprises dorsolateral prefrontal cortex (DLPFC) regions 46, 9-46d, a9-46v and p9-46v, with the connectivity of region 46 a key example illustrated schematically in Fig. 13.5. These regions have connectivity with superior parietal cortex regions in area 7 and intraparietal regions involved in actions in space (‘where’), and with inferior parietal PF and PFm and the insula which can be considered as in the somatosensory ‘what’

hierarchy (Rolls et al., 2023f,d) (Chapter 6). Interestingly, these regions also receive inputs from the orbitofrontal cortex (11l, 13l, Fig. 13.5). These DLPFC regions are thus classic dorsolateral prefrontal cortex regions, and are probably involved in limb/body-related spatial working memory functions probably in egocentric space (rather than eye movement-related) (Passingham, 2021). There is connectivity directed towards premotor 6ma, 6a and 6r and the midcingulate motor region 23c, and to the supracallosal anterior cingulate a24pr, p24pr, a32pr, p32pr, and 33pr. The latter connectivity could be useful it is proposed for action-outcome learning implemented in the supracallosal anterior cingulate cortex (Rolls et al., 2023c), by providing a memory-related input about recent actions until a reward or punishment outcome is received (Chapter 12).

A second group of regions that is more dorsal (superior) in the prefrontal cortex comprises 8Ad, 8Av, 8BL, 9p, i6-8 and s6-8, with the connectivity of region 8Ad as an example illustrated schematically in Fig. 13.6 (Rolls et al., 2023f). The effective connectivity of this 'dorsal prefrontal' group with the inferior parietal visual regions PFm, PGs and PGI is notable. There is also connectivity with the entorhinal cortex (EC) and parahippocampal gyrus regions PHA1-2, and with the memory-related parts of the posterior cingulate division (31pd, 31pv, v23ab), and 7m (Rolls et al., 2023i). This group also has some connectivity with visual inferior temporal TE1m, TE1p and TE2a; and with STSvp; and with the frontal pole a10p and p10p. 8BL, 9a and 9p have connectivity with temporal pole TGd and TGv. 8Ad also has some connectivity with reward-related regions the ventromedial prefrontal cortex 10d and 10r, and the pregenual anterior cingulate cortex d32 and p32 (Rolls et al., 2023c). 8Ad has moderate effective connectivity with other dorsal prefrontal regions 8Av, 9p, i6-8 and s6-8. There is connectivity directed towards language regions: the superior frontal language area SFL, 44, 45, 47l and 55b; and to the premotor eye field PEF. These dorsal frontal regions in front of the eye fields may be involved in visual and auditory attention (Germann and Petrides, 2020a,b; Passingham, 2021), and their connectivity with inferior parietal visual/multimodal cortical regions may be part of the implementation of top-down attention (Deco and Rolls, 2005b,a; Rolls, 2021b).

The computational functions of these dorsolateral and dorsal prefrontal cortex regions are likely to be to maintain information in short-term/working memory by maintaining firing in attractor networks (Fuster, 2015; Constantinidis et al., 2018; Martinez-Garcia et al., 2011; Rolls, 2021b; Goldman-Rakic, 1996; Funahashi et al., 1989). The dorsolateral prefrontal cortex could thereby implement some aspects of executive function (Funahashi, 2017), with those aspects perhaps being described better not as 'voluntary action' (Passingham and Wise, 2012; Passingham, 2021) which is difficult to define and measure, but I suggest instead as 'internally generated from for example memory'. But other key aspects of the dorsolateral and dorsal prefrontal cortex include top-down attention implemented by providing the biasing source held in short-term memory, which can also bias action selection (Deco and Rolls, 2005a, 2004, 2003; Rolls, 2021b). Another key property of prefrontal cortex attractor networks may be not only holding information in a short-term memory, but also transferring information using linked attractor networks from for example a short-term memory attractor network for sensory stimuli to another attractor network in which actions are represented (Deco, Ledberg, Almeida and Fuster, 2005), thereby implementing stimulus-delay-response tasks.

In macaques the connections and neuronal recordings suggest the following subregions of the dorsolateral prefrontal cortex (Petrides and Pandya, 1999; Passingham, 2021; Goulas et al., 2017; Pandya et al., 2015; Petrides, 2014; Yeterian et al., 2012; Petrides et al., 2012; Kelly et al., 2010). The posterior part near the arcuate sulcus contains a frontal eye field FEF. A dorsal part, FEFd is closely associated with the immediately anterior 8Ad which has connectivity with dorsal stream intraparietal regions, and a ventral part FEFv is closely

Dorsal Prefrontal 8Ad connectivity: lateral view

Dorsal Prefrontal 8Ad connectivity: medial view

Fig. 13.6 Dorsal prefrontal cortex effective connectivity. The effective connectivity of region 8Ad is shown as an example of the connectivity of regions 8Ad, 8Av, 9p, i6-8 and s6-8. The width of the arrows reflects the effective connectivity with the size of the arrowheads reflecting the connectivity in each direction. The effective connectivity with the inferior parietal PGs and PGi, and with 7Pm are notable. There is also connectivity with the entorhinal cortex (EC) and parahippocampal gyrus regions PHA1-2, and with the memory-related parts of the posterior cingulate division (31pd, 31pv, v23ab), and 7m. 8Ad also has some connectivity with TE1m and TE1p. 8Ad also has some connectivity with reward-related regions the ventromedial prefrontal cortex 10d and 10r, and the pregenual anterior cingulate cortex d32, p32 (Rolls et al., 2023c). 8Ad has moderate effective connectivity with the other dorsal prefrontal regions 8Av, 9p, i6-8 and s6-8. (From Rolls, E.T., Deco, G., Huang, C.-C. and Feng, J. (2023) Prefrontal and somatosensory-motor cortex effective connectivity in humans. *Cerebral Cortex* doi: 10.1093/cercor/bhac391. Copyright © Oxford University Press.)

associated with the immediately anterior 8Av which has connectivity with ventral stream inferior temporal visual cortex regions (Petrides and Pandya, 1999; Passingham, 2021). The FEF and the adjacent area 46 cortex in the posterior part of the principal sulcus is especially

implicated in eye movements to visual stimuli remembered over a short delay (Funahashi et al., 1989, 1993; Goldman-Rakic, 1996), consistent with short-term memory functions of the dorsolateral prefrontal regions. The more mid and anterior parts of area 46 in the macaque principal sulcus are involved more in remembered limb movements (Passingham, 2021). In humans, area 46 is far anterior (Sallet et al., 2013), and probably includes some of 46 and a9-46v in the HCP-MMP atlas (Glasser et al., 2016a; Huang et al., 2022).

13.4 The lateral prefrontal cortex and top-down attention

The lateral prefrontal cortex is a region implicated in top-down attentional control (Corbetta and Shulman, 2002; Bressler et al., 2008; Pessoa, 2009; Rolls, 2008d, 2016b, 2014a; Fiebelkorn and Kastner, 2020).

In an example of this, we have found that with taste and flavor stimuli (Grabenhorst and Rolls, 2008), and olfactory stimuli (Rolls, Grabenhorst, Margot, da Silva and Velazco, 2008b), selective attention to pleasantness modulates representations in the orbitofrontal cortex, whereas selective attention to intensity modulates activations in areas such as the insular primary taste cortex (Fig. 13.7).

In a study using psychophysiological interaction (PPI) analysis (Friston, Buechel, Fink, Morris, Rolls and Dolan, 1997), we found that two sites where selective attention to pleasantness increased the activation to taste, the orbitofrontal cortex and a region to which it is connected, the pregenual anterior cingulate cortex, both had functional connectivity with a quite anterior (mean $Y \approx 50$) part of the lateral prefrontal cortex (Grabenhorst and Rolls, 2008), illustrated in Grabenhorst and Rolls (2010) (Fig. 13.8). These parts of the orbitofrontal cortex and pregenual anterior cingulate cortex are a functionally appropriate target site for a top-down attentional modulation, in that their activations are correlated with the subjectively rated pleasantness of the taste (Grabenhorst and Rolls, 2008). Moreover, the lateral prefrontal cortex has been shown to represent current task sets and attentional demands for different types of tasks (Passingham and Wise, 2012; Passingham, 2021).

The implication of these findings is therefore that a part of the lateral prefrontal cortex, not a site normally implicated in affective value and emotion, may be able to modulate emotion-related / affect-related processing in the brain by a top-down attentional influence. This may be one way in which higher cognitive functions, such as a reasoning-based strategy and route to action, or verbal instruction to direct processing towards or away from emotion-related brain processing, or conscious volition, can influence the degree to which the affect-related parts of the brain process incoming (or potentially remembered) stimuli that can produce emotional responses. This is thus a part of the way in which cognition can influence, and control, emotion (Rolls, 2014a, 2018a, 2023b).

We also found that two sites where selective attention to intensity increased the activation to the taste delivery into the mouth, the anterior and mid insula, both had functional connectivity with a less anterior (mean $Y \approx 37$) part of the lateral prefrontal cortex (Grabenhorst and Rolls, 2010) (Fig. 13.8). These parts of the insula are a functionally appropriate site for a top-down attentional modulation, in that their activations are correlated with the subjectively rated intensity of the taste (Grabenhorst and Rolls, 2008; Grabenhorst et al., 2008a). The anterior insular site may be the primary taste cortex (Pritchard, Hamilton, Morse and Norgren, 1986; Yaxley, Rolls and Sienkiewicz, 1990; De Araujo, Kringelbach, Rolls and Hobden, 2003b; De Araujo and Rolls, 2004; Rolls, 2008c, 2016c), and the mid-insular site a region activated by other oral including somatosensory and fat texture inputs from the oral cavity (De Araujo, Kringelbach, Rolls and McGlone, 2003c; De Araujo and Rolls, 2004) and perhaps by taste

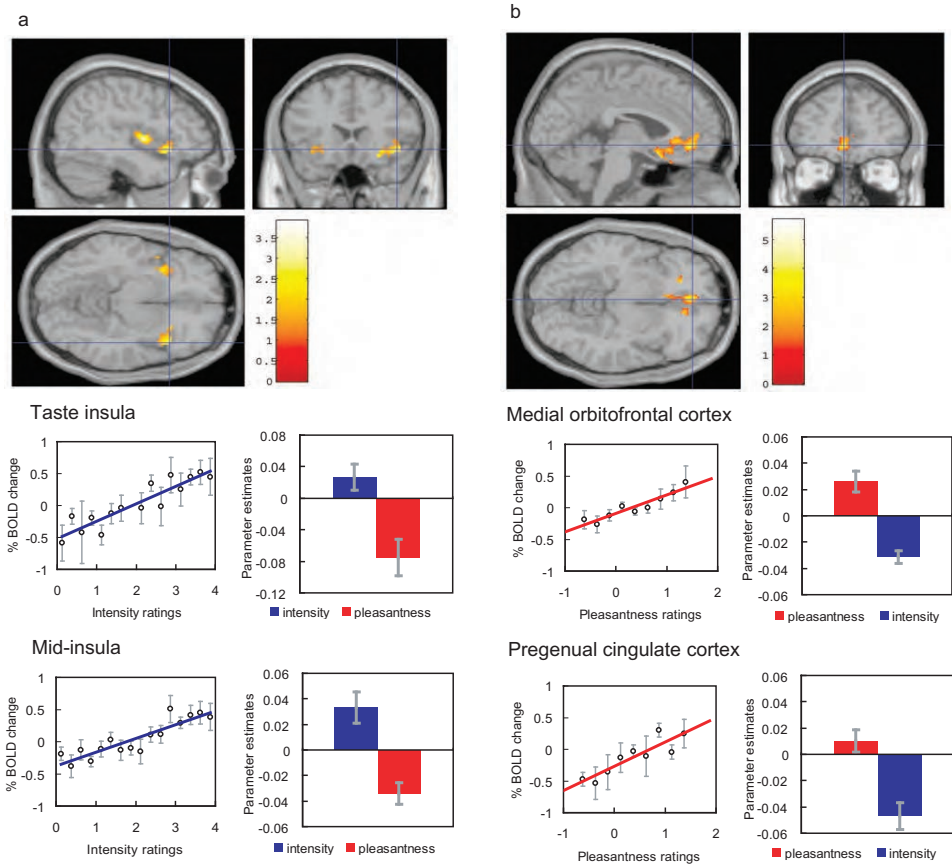

Fig. 13.7 Effect of paying attention to the pleasantness vs the intensity of a taste stimulus. a. Top: A significant difference related to the taste period was found in the taste insula at [42 18 -14] (indicated by the cursor) and in the mid insula at [40 -2 4]. Middle: Taste Insula. Right: The parameter estimates (mean \pm sem) for the activation at the specified coordinate for the conditions of paying attention to pleasantness or to intensity. The parameter estimates were significantly different for the taste insula $p=0.001$. Left: The correlation between the intensity ratings and the activation (% BOLD change) at the specified coordinate ($r=0.91$, $p<0.001$). Bottom: Mid Insula. Right: The parameter estimates for the activation at the specified coordinate for the conditions of paying attention to pleasantness or to intensity. The parameter estimates were significantly different for the mid insula $p=0.001$. Left: The correlation between the intensity ratings and the activation at the specified coordinate ($r=0.89$, $p<<0.001$). The taste stimulus, monosodium glutamate, was identical on all trials. b. Top: A significant difference related to the taste period was found in the medial orbitofrontal cortex at [-6 14 -20] (towards the back of the area of activation shown) and in the pregenual cingulate cortex at [-4 46 -8] (at the cursor). Middle: Medial orbitofrontal cortex. Right: The parameter estimates for the activation at the specified coordinate for the conditions of paying attention to pleasantness or to intensity. The parameter estimates were significantly different for the orbitofrontal cortex $p<10^{-4}$. Left: The correlation between the pleasantness ratings and the activation at the specified coordinate ($r=0.94$, $p<0.001$). Bottom: Pregenual cingulate cortex. Conventions as above. Right: The parameter estimates were significantly different for the pregenual cingulate cortex $p<10^{-5}$. Left: The correlation between the pleasantness ratings and the activation at the specified coordinate ($r=0.89$, $p=0.001$). The taste stimulus, 0.1 M monosodium glutamate, was identical on all trials. (Reproduced from Fabian Grabenhorst and Edmund T. Rolls (2008) Selective attention to affective value alters how the brain processes taste stimuli. *European Journal of Neuroscience* 27: 723–729.)

per se (Small, 2010; Rolls, 2016c), in that the activations there were correlated with the trial-by-trial subjective ratings of the taste intensity made during the scanning (Grabenhorst and Rolls, 2008). In the analyses described here, such somatosensory inputs could contribute to the attention-dependent correlations found between the mid insula and other areas.

The statistics used in the calculation of PPI effects (Friston, Buechel, Fink, Morris, Rolls and Dolan, 1997) do not reveal the directionality of the connectivity, for they are based on correlations. However, the directionality in this case is likely to be from the prefrontal cor-

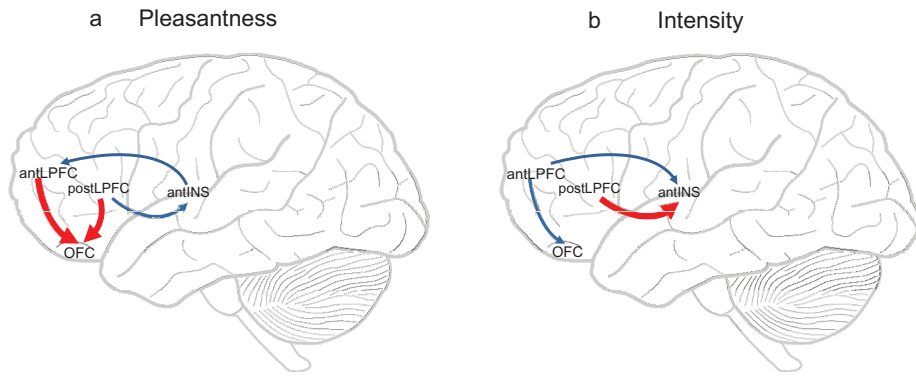

Fig. 13.8 Componential Granger causality analysis of top-down effects on taste processing from different lateral prefrontal cortex areas during attention to either the pleasantness (a) or to the intensity (b) of a taste. Significant causal influences from t tests with a Bonferroni correction are marked by blue arrows (i.e. cross-componential Granger causality is greater than 0). Red arrows indicate where significant top-down effects exist in addition to significant causal influences (i.e. a significant cross-componential Granger causality that is different in the two directions). The areas are anterior (mean $Y \approx 50$) and posterior (mean $Y \approx 37$) lateral prefrontal cortex (antLPFC, postLPFC); orbitofrontal cortex secondary cortical taste area (OFC); and anterior insular primary cortical taste area (antINS). (Reprinted from Tian Ge, Jianfeng Feng, Fabian Grabenhorst, and Edmund T. Rolls (2012) Componential Granger causality, and its application to identifying the source and mechanisms of the top-down biased activation that controls attention to affective vs sensory processing. *NeuroImage* 59: 1846–58. © Elsevier Inc.)

tex to the orbitofrontal and pregenual cingulate cortices, for the following reasons. First, the prefrontal cortex has a powerfully developed recurrent collateral system (Elston et al., 2006), which provides the basis for the short-term memory that is needed to hold the subject of attention active, providing the source of the bias for top-down biased competition. Second, prefrontal cortex lesions impair attention (Beck and Kastner, 2009; Rossi et al., 2009; Passingham, 2021). Third, activations in areas of the lateral prefrontal cortex are related to task set, attentional instructions, and remembering rules that guide task performance (Beck and Kastner, 2009; Rossi et al., 2009; Passingham and Wise, 2012; Passingham, 2021). Fourth, direct anatomical connections have been shown in macaques between the lateral prefrontal cortex and the orbitofrontal and pregenual anterior cingulate cortices (Price, 2006).

Given that PPI analysis is based on correlations, it is helpful to go beyond this. Understanding how one brain area may influence another, for example by providing it with inputs, or by top-down modulation, is fundamental to understanding how the brain functions. Hence, inferring causal influences from time series data has been attracting intense interest. Granger causality has become popular due to its easy implementation and many successful applications to econometrics, neuroscience, etc., and in particular, the study of brain function (Bressler and Seth, 2011; Ding et al., 2006). The application of Granger causality analysis to BOLD fMRI signals which are inherently slow has been discussed elsewhere (Stephan and Roebroek, 2012). The use of this approach is described next, though effective connectivity measured with the Hopf algorithm is providing a very useful alternative (Rolls et al., 2022a, 2023c,i,d, 2022b, 2023e,h,f,a).

Granger causality is based on precedence and predictability. Originally proposed by Wiener (1956) and further formalized by Granger (1969), it states that given two times series x and y , if the inclusion of the past history of y helps to predict the future states of x in some plausible statistical sense, then y is a cause of x in the Granger sense. In spite of the wide acceptance of this definition, classical Granger causality is not tailored to measure the effects of interactions between time series x and y on the causal influences, and cannot measure systematically the effects of the past history of x on x (Ge, Feng, Grabenhorst and Rolls, 2012). In this situation, a componential form of Granger causality analysis has been intro-

duced that has advantages over classical Granger analysis (Ge, Feng, Grabenhorst and Rolls, 2012). Componential Granger causality measures the effect of y on x , but allows interaction effects between y and x to be measured (Ge, Feng, Grabenhorst and Rolls, 2012). In addition, the terms in componential Granger causality sum to 1, allowing causal effects to be directly compared between systems.

We showed using componential Granger causality analysis applied to the above fMRI investigations that there is a top-down attentional effect from the anterior dorsolateral prefrontal cortex to the orbitofrontal cortex when attention is paid to the pleasantness of a taste, and that this effect depends on the activity in the orbitofrontal cortex as shown by the interaction term (Ge, Feng, Grabenhorst and Rolls, 2012). Correspondingly there is a top-down attentional effect from the posterior dorsolateral prefrontal cortex to the insular primary taste cortex when attention is paid to the intensity of a taste, and this effect depends on the activity of the insular primary taste cortex as shown by the interaction term. The prefrontal cortex sites are those identified by the PPI analysis (Grabenhorst and Rolls, 2010) and the effects are shown schematically in Fig. 13.8. Componential Granger causality thus not only can reveal the directionality of effects between areas (and these can be bidirectional), but also allows the mechanisms to be understood in terms of whether the causal influence of one system on another depends on the state of the system being causally influenced. Componential Granger causality measures the full effects of second order statistics by including variance and covariance effects between each time series, thus allowing interaction effects to be measured, and also provides a systematic framework within which to measure the effects of cross, self, and noise contributions to causality (Ge, Feng, Grabenhorst and Rolls, 2012).

These findings reveal some of the mechanisms involved in a biased activation theory of selective attention, which is summarized in Section 4.3.5. The top-down biased competition approach is summarized in Section 2.12.

13.5 The frontal pole cortex

The connectivity and functions of the human frontal polar cortex, Area 10, are being explored. Shallice and colleagues found that patients with frontal pole damage had problems optimising a plan to visit many shops in an efficient order, and more generally had disorganized behavior (Shallice and Cipolotti, 2018; Shallice and Burgess, 1991). These patients also have deficits in tasks that require abstract reasoning, problem-solving, or multitasking (Hogeveen, Medalla, Ainsworth, Galeazzi, Hanlon, Mansouri and Costa, 2022a). In humans, the frontal pole is activated by tasks that require cognitive branching, value-based decision-making, and metacognition (Hogeveen et al., 2022a). These are tasks that require appropriate action to two or more competing goals (Mansouri et al., 2017b; Hogeveen et al., 2022b,a; Mansouri et al., 2017a; Averbeck, 2015). The frontal pole in humans is activated by counterfactual choice tasks with the frontal pole sensitive to the value of unchosen or alternative options during decision-making (Hogeveen et al., 2022a). Consistent with this, in a foraging task, the frontal pole cortex is implicated in whether to exploit what is currently available, or to explore other options in case greater rewards might be available (Hogeveen et al., 2022b). However, relatively little is known of the connectivity of the frontal pole cortex. In macaques, connections from superior temporal cortex auditory regions, from dorsolateral prefrontal cortex (Areas 9 and 46), and orbitofrontal cortex have been described (Barbas, 2015; Yeterian et al., 2012; Petrides et al., 2012; Markov et al., 2014a; Medalla and Barbas, 2010, 2014; Hogeveen et al., 2022a).

Give this background, the connectivity of the human frontal pole cortex, regions 10d, 10pp, a10p, and p10p in the HCP-MMP atlas, with also the two regions 10r and 10v that

extend more posteriorly, has been investigated (Rolls et al., 2023a). Unlike dorsolateral prefrontal cortex regions implicated in working memory with which the frontal pole regions were compared, the frontal pole does not have connectivity to premotor and related regions via which behavior can be controlled. However, the frontal pole regions have surprisingly stronger connectivity directed to than from the dorsolateral prefrontal cortex regions, and inferior temporal, inferior parietal, posterior cingulate, and orbitofrontal cortex (Rolls et al., 2023a).

With this evidence and the known effects of damage to and the activations of the frontal pole cortex, it is proposed that the frontal pole contains autoassociation networks with attractor dynamics that are normally stable in a short-term memory state, and maintain stability in dorsolateral prefrontal networks, temporal and parietal networks when stable exploitation of goals and strategies is useful. However, if an input is received from regions such as the orbitofrontal or anterior cingulate cortex that non-reward or punishment is being received, this input destabilises the frontal pole networks to enable exploration of competing alternative goals and strategies. The frontal pole thus in the context of this connectivity is proposed to provide a control over brain resources to influence whether to exploit or explore (Rolls et al., 2023a).

13.6 How the computations are performed in the prefrontal cortex

13.6.1 Cortical short-term memory systems and attractor networks

There are a number of different prefrontal cortex short-term memory systems, each implemented in a different cortical area. The particular systems considered here each implement short-term memory by subpopulations of neurons that show maintained activity in a delay period, while a stimulus or event is being remembered. These memories may operate as auto-associative attractor networks, the operation of which is described in Section B.3. The actual autoassociation could be implemented by associatively modifiable synapses between connected pyramidal cells within an area, or by the forward and backward connections between adjacent cortical areas in a hierarchy.

An example of how this could be implemented to account for the delayed saccade type of neuronal firing illustrated in Fig. 13.3 is shown in Fig. 13.9. The short-term memory function is topographically organized, in that lesions in small parts of the system impair remembered eye movements only to that eye position. Moreover, neurons in the appropriate part of the topographic map respond to eye movements in one but not in other directions (see Fig. 13.3). Such a memory system could be easily implemented in such a topographically organized system by having local cortical connections between nearby pyramidal cells which implement an attractor network (Fig. 13.9). Then triggering activity in one part of the topographically organized system would lead to sustained activity in that part of the map, thus implementing a short-term or working memory for eye movements to that position in space.

Another short-term memory system is implemented in the inferior temporal visual cortex, especially more ventrally towards the perirhinal cortex (see Section 9.2.7). This memory is for whether a particular visual stimulus (such as a face) has been seen recently. This is implemented in two ways. One way is that some neurons respond more to a novel than to a familiar visual stimulus in such tasks, or in other cases respond to the familiar, selected, stimulus (Baylis and Rolls, 1987; Miller and Desimone, 1994) (see Section 9.2.7). The other way is that some neurons, especially more ventrally, continue to fire in the delay period of a delayed match to sample task (Fahy et al., 1993; Miyashita, 1993), and fire for several

Local autoassociation networks in the prefrontal cortex
for delayed spatial responses, eg. saccades

Fig. 13.9 A possible cortical model of a topographically organized set of attractor networks in the prefrontal cortex that could be used to remember the position to which saccades should be made. Excitatory local recurrent collateral Hebb-modifiable connections would enable a set of separate attractors to operate. The input that would trigger one of the attractors into continuing activity in a memory delay period would come from the parietal cortex, and topology of the inputs would result in separate attractors for remembering different positions in space. (For example inputs for the Upper Left of space would trigger an attractor that would remember the upper left of space.) Neurons in different parts of this cortical area would have activity related to remembering one part of space; and damage to a part of this cortical area concerned with one part of space would result in impairments in remembering targets to which to saccade for only one part of space.

hundred milliseconds after a 16 ms visual stimulus has been presented (Rolls and Tovee, 1994) (see Fig. C.19). These neurons can be considered to reflect the implementation of an attractor network between the pyramidal cells in this region (Amit, 1995; Rolls, 2016b). A cortical syndrome that may reflect loss of such a short-term visual memory system is simultanagnosia, in which more than one visual stimulus cannot be remembered for more than a few seconds (Warrington and Weiskrantz, 1973; Kolb and Whishaw, 2021).

Continuing firing of neurons in short-term memory tasks in the delay period is also found in other cortical areas. It is found in the parietal cortex when monkeys are remembering a target to which a saccade should be made (Andersen, 1995a); and in the motor cortex when a monkey is remembering a direction in which to reach with the arm (Georgopoulos, 1995).

Another short-term memory system is human auditory–verbal short-term memory, which appears to be implemented in the left hemisphere at the junction of the temporal, parietal, and occipital lobes. Patients with damage to this system are described clinically as showing conduction aphasia, in that they cannot repeat a heard string of words (cannot conduct the input to the output) (Warrington and Weiskrantz, 1973; Kolb and Whishaw, 2021).

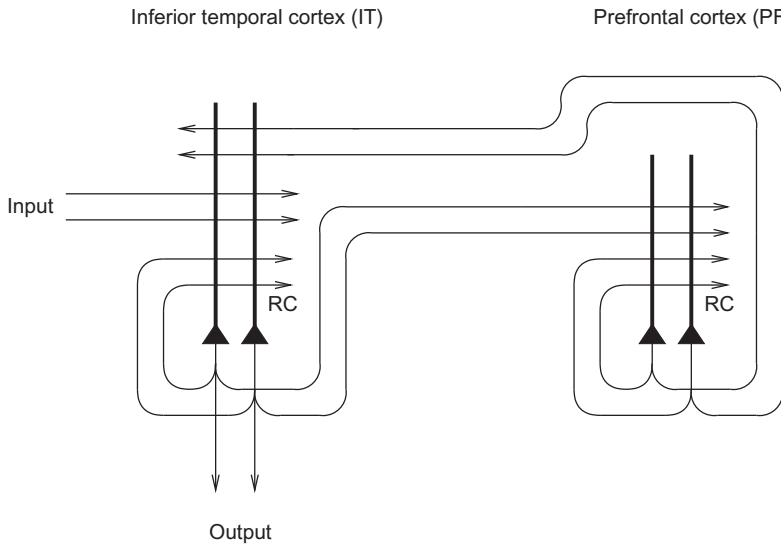

Fig. 13.10 Role of the prefrontal cortex in short-term memory. A short-term memory autoassociation network in the prefrontal cortex could hold active a working memory representation by maintaining its firing in an attractor state. The prefrontal module would be loaded with the to-be-remembered stimulus by the posterior module (in the temporal or parietal cortex) in which the incoming stimuli are represented. Backprojections from the prefrontal short-term memory module to the posterior module would enable the working memory to be unloaded, to for example influence on-going perception (see text). RC, recurrent collateral connections.

13.6.2 Prefrontal cortex short-term memory networks, and their relation to temporal and parietal perceptual networks

13.6.2.1 A prefrontal short-term memory network supporting a temporal lobe perceptual system

As described in Section 13.6.1, a common way that the brain uses to implement a short-term memory is to maintain the firing of neurons during a short memory period after the end of a stimulus (see Rolls (2016b) and Fuster (2015)). In the inferior temporal cortex this firing may be maintained for a few hundred milliseconds even when the monkey is not performing a memory task (Rolls and Tovee, 1994; Rolls, Tovee, Purcell, Stewart and Azzopardi, 1994b; Rolls, Tovee and Panzeri, 1999b; Desimone, 1996) (see Fig. C.19). In more ventral temporal cortical areas such as the entorhinal cortex the firing may be maintained for longer periods in delayed match to sample tasks (Suzuki, Miller and Desimone, 1997), and in the prefrontal cortex for even tens of seconds (Fuster, 1997, 2015).

For the short-term memory to be maintained during periods in which new stimuli are to be perceived, there must be separate networks for the perceptual and short-term memory functions, and indeed two coupled networks, one in the inferior temporal visual cortex for perceptual functions, and another in the prefrontal cortex for maintaining the short-term memory during intervening stimuli, provide a precise model of the interaction of perceptual and short-term memory systems (Renart, Parga and Rolls, 2000; Renart, Moreno, Rocha, Parga and Rolls, 2001) (see Fig. 13.10). In particular, this model shows how a prefrontal cortex attractor (autoassociation) network could be triggered by a sample visual stimulus represented in the inferior temporal visual cortex in a delayed match to sample task, and could keep this attractor active during a memory interval in which intervening stimuli are shown. Then when the sample stimulus reappears in the task as a match stimulus, the inferior temporal cortex module shows a large response to the match stimulus, because it is activated both by the

visual incoming match stimulus, and by the consistent backprojected memory of the sample stimulus still being represented in the prefrontal cortex memory module (see Fig. 13.10).

This computational model makes it clear that in order for ongoing perception to occur unhindered implemented by posterior cortex (parietal and temporal lobe) networks, there must be a separate set of modules that is capable of maintaining a representation over intervening stimuli. This is the fundamental understanding offered for the evolution and functions of the dorsolateral prefrontal cortex, and it is this ability to provide multiple separate short-term attractor memories that provides I suggest the basis for its functions in planning.

Renart, Parga and Rolls (2000) and Renart, Moreno, Rocha, Parga and Rolls (2001) performed analyses and simulations which showed that for working memory to be implemented in this way, the connections between the perceptual and the short-term memory modules (see Fig. 13.10) must be relatively weak. As a starting point, they used the neurophysiological data showing that in delayed match to sample tasks with intervening stimuli, the neuronal activity in the inferior temporal visual cortex (IT) is driven by each new incoming visual stimulus (Miller, Li and Desimone, 1993; Miller and Desimone, 1994), whereas in the prefrontal cortex, neurons start to fire when the sample stimulus is shown, and continue the firing that represents the sample stimulus even when the potential match stimuli are being shown (Miller, Erickson and Desimone, 1996).

The architecture studied by Renart, Parga and Rolls (2000) is as shown in Fig. 13.10, with both the intramodular (recurrent collateral) and the intermodular (forward IT to PF, and backward PF to IT) connections trained on the set of patterns with an associative synaptic modification rule. A crucial parameter is the strength of the intermodular connections, g , which indicates the relative strength of the intermodular to the intramodular connections. (This parameter measures effectively the relative strengths of the currents injected into the neurons by the inter-modular relative to the intra-modular connections, and the importance of setting this parameter to relatively weak values for useful interactions between coupled attractor networks was highlighted by Renart, Parga and Rolls (1999b) and Renart, Parga and Rolls (1999a), as shown in Sections B.9 and 13.6.2.2.) The patterns themselves were sets of random numbers, and the simulation utilized a dynamical approach with neurons with continuous (hyperbolic tangent) activation functions (see Section 13.6.2.2) (Shiino and Fukai, 1990; Kuhn, 1990; Kuhn, Bos and van Hemmen, 1991; Amit and Tsodyks, 1991). The external current injected into IT by the incoming visual stimuli was sufficiently strong to trigger the IT module into a state representing the incoming stimulus. When the sample was shown, the initially silent PF module was triggered into activity by the weak ($g > 0.002$) intermodular connections. The PF module remained firing to the sample stimulus even when IT was responding to potential match stimuli later in the trial, provided that g was less than 0.024, because then the intramodular recurrent connections could dominate the firing (see Fig. 13.11). If g was higher than this, then the PF module was pushed out of the attractor state produced by the sample stimulus. The IT module responded to each incoming potentially matching stimulus provided that g was not greater than approximately 0.024. Moreover, this value of g was sufficiently large that a larger response of the IT module was found when the stimulus matched the sample stimulus (the match enhancement effect found neurophysiologically, and a mechanism by which the matching stimulus can be identified). This simple model thus shows that the operation of the prefrontal cortex in short-term memory tasks such as delayed match to sample with intervening stimuli, and its relation to posterior perceptual networks, can be understood by the interaction of two weakly coupled attractor networks, as shown in Figs. 13.10 and 13.11.

The same network can also be used to illustrate the interaction between the prefrontal cortex short-term memory system and the posterior (IT or PP) perceptual regions in visual search tasks, as illustrated in Fig. 13.12.

Fig. 13.11 Role of the prefrontal cortex in short-term memory. Interaction between the prefrontal cortex (PF) and the inferior temporal cortex (IT) in a delayed match to sample task with intervening stimuli with the architecture illustrated in Fig. 13.10. Above: activity in the IT attractor module. Below: activity in the PF attractor module. The thick lines show the firing rates of the set of neurons with activity selective for the sample stimulus (which is also shown as the match stimulus, and is labelled **A**), and the thin lines the activity of the neurons with activity selective for the non-match stimulus, which is shown as an intervening stimulus between the sample and match stimulus and is labelled **B**. A trial is illustrated in which **A** is the sample (and match) stimulus. The prefrontal cortex module is pushed into an attractor state for the sample stimulus by the IT activity induced by the sample stimulus. Because of the weak coupling to the PF module from the IT module, the PF module remains in this sample-related attractor state during the delay periods, and even while the IT module is responding to the non-match stimulus. The PF module remains in its sample-related state even during the non-match stimulus because once a module is in an attractor state, it is relatively stable. When the sample stimulus reappears as the match stimulus, the PF module shows higher sample stimulus-related firing, because the incoming input from IT is now adding to the activity in the PF attractor network. This in turn also produces a match enhancement effect in the IT neurons with sample stimulus-related selectivity, because the backprojected activity from the PF module matches the incoming activity to the IT module. (From Renart, A., Moreno, R., de la Rocha, J., Parga, N. and Rolls, E. T. (2001) A model of the IT-PF network in object working memory which includes balanced persistent activity and tuned inhibition. *Neurocomputing* 38–40: 1525–1531. © Elsevier B.V.)

13.6.2.2 Computational details of the prefrontal–inferior temporal model of short-term memory

The model network of Renart, Parga and Rolls (2000) and Renart, Moreno, Rocha, Parga and Rolls (2001) consists of a large number of (excitatory) neurons arranged in two modules with the architecture shown in Fig. 13.10. Following Kuhn (1990) and Amit and Tsodyks (1991), each neuron is assumed to be a dynamical element which transforms an incoming afferent current into an output spike rate according to a given transduction function. A given afferent current I_{ai} to neuron i ($i = 1, \dots, N$) in module a ($a = \text{IT}, \text{PF}$) decays with a characteristic time constant τ but increases proportionally to the spike rates of the rest of the neurons in the network (from both inside and outside its module) connected to it, the contribution of each presynaptic neuron, e.g. neuron j from module b , and in proportion to the synaptic efficacy J_{ij}^{ab} between the two²⁰. This can be expressed through the following equation

²⁰On this occasion we revert to the theoretical physicists' usual notation for synaptic weights or couplings, J_{ij} instead of w_{ij} .

Fig. 13.12 Role of the prefrontal cortex in short-term memory. Interaction between the prefrontal cortex (PF) and the inferior temporal cortex (IT) in a visual search task with the architecture illustrated in Fig. 13.10. Above: activity in the IT attractor module. Below: activity in the PF attractor module. The thick lines show the firing rates of the set of neurons with activity selective for search stimulus **A**, and the thin lines the activity of the neurons with activity selective for stimulus **B**. During the cue period either **A** or **B** is shown, to indicate to the monkey which stimulus to select when an array containing both **A** and **B** is shown after a delay period. The trial shown is for the case when **A** is the cue stimulus. When stimulus **A** is shown as a cue, then via the IT module, the PF module is pushed into an attractor state **A**, and the PF module remembers this state during the delay period. When the array **A + B** is shown later, there is more activity in the PF module for the neurons selective for **A**, because they have inputs both from the continuing attractor state held in the PF module and from the forward activity from the IT module which now contains both **A** and **B**. This PF firing to **A** in turn also produces greater firing of the population of IT neurons selective for **A** than in the IT neurons selective for **B**, because the IT neurons selective for **A** are receiving both **A**-related visual inputs, and **A**-related backprojected inputs from the PF module. (From Renart, A., Moreno, R., de la Rocha, J., Parga, N. and Rolls, E. T. (2001) A model of the IT-PF network in object working memory which includes balanced persistent activity and tuned inhibition. *Neurocomputing* 38–40: 1525–1531. © Elsevier B.V.)

$$\frac{dI_{ai}(t)}{dt} = -\frac{I_{ai}(t)}{\tau} + \sum_{b,j} J_{ij}^{(a,b)} v_{bj} + h_{ai}^{(\text{ext})} . \quad (13.1)$$

An external current $h_{ai}^{(\text{ext})}$ from outside the network, representing the stimuli, can also be imposed on every neuron. Selective stimuli are modelled as proportional to the stored patterns, i.e. $h_{ai}^{(\text{ext})} = h_a \eta_{ai}^\mu$, where h_a is the intensity of the external current to module a .

The transduction function of the neurons transforming currents into rates was chosen as a threshold hyperbolic tangent of gain G and threshold θ . Thus, when the current is very large the firing rates saturate to an arbitrary value of 1.

The synaptic efficacies between the neurons of each module and between the neurons in different modules are respectively

$$J_{ij}^{(a,a)} = \frac{J_0}{f(1-f)N_t} \sum_{\mu=1}^P (\eta_{ai}^\mu - f) (\eta_{aj}^\mu - f) \quad i \neq j ; a = \text{IT, PF} \quad (13.2)$$

$$J_{ij}^{(a,b)} = \frac{g}{f(1-f)N_t} \sum_{\mu=1}^P (\eta_{ai}^\mu - f) (\eta_{bj}^\mu - f) \quad \forall i, j ; a \neq b . \quad (13.3)$$

The intra-modular connections are such that a number P of sparse independent configurations of neural activity are dynamically stable, constituting the possible sustained activity states in each module. This is expressed by saying that each module has learned P binary patterns $\{\eta_{ai}^\mu = 0, 1, \mu = 1, \dots, P\}$, each of them signalling which neurons are active in each of the sustained activity configurations. Each variable η_{ai}^μ is allowed to take the values 1 and 0 with probabilities f and $(1 - f)$ respectively, independently across neurons and across patterns. The inter-modular connections reflect the temporal associations between the sustained activity states of each module. In this way, every stored pattern μ in the IT module has an associated pattern in the PF module which is labelled by the same index. The normalization constant $N_t = N(J_0 + g)$ was chosen so that the sum of the magnitudes of the inter- and the intra-modular connections remains constant and equal to 1 while their relative values are varied. When this constraint is imposed the strength of the connections can be expressed in terms of a single independent parameter g measuring the relative intensity of the inter- vs the intra-modular connections (J_0 can be set equal to 1 everywhere).

Both modules implicitly include an inhibitory population of neurons receiving and sending signals to the excitatory neurons through uniform synapses. In this case the inhibitory population can be treated as a single inhibitory neuron with an activity dependent only on the mean activity of the excitatory population. We chose the transduction function of the inhibitory neuron to be linear with slope γ .

Since the number of neurons in a typical network one may be interested in is very large, e.g. $\sim 10^5 - 10^6$, the analytical treatment of the set of coupled differential equations (13.1) becomes untractable. On the other hand, when the number of neurons is large, a reliable description of the asymptotic solutions of these equations can be found using the techniques of statistical mechanics (Kuhn, 1990). In this framework, instead of characterizing the states of the system by the state of every neuron, this characterization is performed in terms of *macroscopic* quantities called *order parameters* which measure and quantify some global properties of the network as a whole. The relevant order parameters appearing in the description of the system are the overlap of the state of each module with each of the stored patterns m_a^μ and the average activity of each module x_a , defined respectively as:

$$m_a^\mu = \frac{1}{\chi N} \ll \sum_i (\eta_{ai}^\mu - f) \nu_{ai} \gg_\eta ; \quad x_a = \frac{1}{N} \ll \sum_i \nu_{ai} \gg_\eta , \quad (13.4)$$

where the symbol $\ll \dots \gg_\eta$ stands for an average over the stored patterns.

Using the free energy per neuron of the system at zero temperature \mathcal{F} (which is not written explicitly to reduce the technicalities to a minimum), Renart, Parga and Rolls (2000) and Renart, Moreno, Rocha, Parga and Rolls (2001) modelled the experiments by giving the order parameters the following dynamics:

$$\tau \frac{\partial m_a^\mu}{\partial t} = - \frac{\partial \mathcal{F}}{\partial m_a^\mu} ; \quad \tau \frac{\partial x_a}{\partial t} = - \frac{\partial \mathcal{F}}{\partial x_a} . \quad (13.5)$$

These dynamics ensure that the stationary solutions, corresponding to the values of the order parameters at the attractors, correspond also to minima of the free energy, and that, as the system evolves, the free energy is always minimized through its gradient. The time constant of the macroscopical dynamics was chosen to be equal to the time constant of the individual neurons, which reflects the assumption that neurons operate in parallel. Equations (13.5) were solved by a simple discretizing procedure (first order Runge–Kutta method). An appropriate value for the time interval corresponding to one computer iteration was found to be $\tau/10$ and the time constant was the value $\tau = 10$ ms.

Since not all neurons in the network receive the same inputs, not all of them behave in the same way, i.e. have the same firing rates. In fact, the neurons in each of the modules can

be split into different subpopulations according to their state of activity in each of the stored patterns. The mean firing rate of the neurons in each subpopulation depends on the particular state realized by the network (characterized by the values of the order parameters). Associated with each pattern there are two large subpopulations denoted as foreground (all active neurons) and background (all inactive neurons) for that pattern. The overlap with a given pattern can be expressed as the difference between the mean firing rate of the neurons in its foreground and its background. The average was calculated over all other subpopulations to which each neuron in the foreground (background) belonged, where the probability of a given subpopulation is equal to the fraction of neurons in the module belonging to it (determined by the probability distribution of the stored patterns as given above). This partition of the neurons into subpopulations is appealing since, in neurophysiological experiments, cells are usually classified in terms of their response properties to a set of fixed stimuli, i.e. whether each stimulus is effective or ineffective in driving their response.

The modelling of the different experiments proceeded according to the macroscopic dynamics (13.5), where each stimulus was implemented as an extra current into free energy for a desired period of time.

Using this model, results of the type described in Section 13.6.2 were found (Renart, Parga and Rolls, 2000; Renart, Moreno, Rocha, Parga and Rolls, 2001). The paper by Renart, Moreno, Rocha, Parga and Rolls (2001) extended the earlier findings of Renart, Parga and Rolls (2000) to integrate-and-fire neurons, and it is results from the integrate-and-fire simulations that are shown in Figs. 13.11 and 13.12.

13.6.3 Mapping from one representation to another in short-term memory

Short-term memory attractor dynamics helps us to understand the underlying mechanisms that implement mappings from one representation to another, for example from sensory to motor, and where short-term memory is required. For example, Deco and Rolls (2003) investigated the 3-level integrate-and-fire hierarchical model of the prefrontal cortex, with sensory neurons, intermediate neurons, and premotor neurons illustrated in Fig. 13.13, in a model of the neuronal activity recorded in the prefrontal cortex during such tasks (Asaad, Rainer and Miller, 2000). The hierarchical structure of the populations (or pools) of neurons is to ensure that the mapping is from the sensory pools to the intermediate pools and then to the premotor pools, and is achieved by setting the synaptic weights to be stronger in the forward than in the reverse direction between the thus hierarchically organized 3 levels of attractor networks. In this particular investigation, a top-down rule bias could be applied to the intermediate level neurons, so that the mapping could be selected to be for example according to an object-response or a spatial-response mapping rule. The attractor dynamics of each population of neurons enables the task to be performed when there are delays between the stimuli and the responses.

This concept of a set of attractor networks that are hierarchically organized in this way is formally somewhat similar to the interacting attractors used to solve short-term memory with intervening stimuli described in Section 13.6.2, and the interacting attractors used to describe attentional processing (Rolls and Deco, 2002; Rolls, 2016b).

Another application of this concept that shows the temporal organization that can be involved is in delayed response tasks in which there may be separate attractors for the sensory stimuli and for the responses. The sensory attractors may be started by sensory cues, may hold the cue for a time, but there may then be a gradual transition to premotor neuron attractors, so that some pools gradually become quiescent, and others start up, during a delay period (Deco et al., 2005) (see Fig. 13.14). For this, the forward coupling between the sensory and

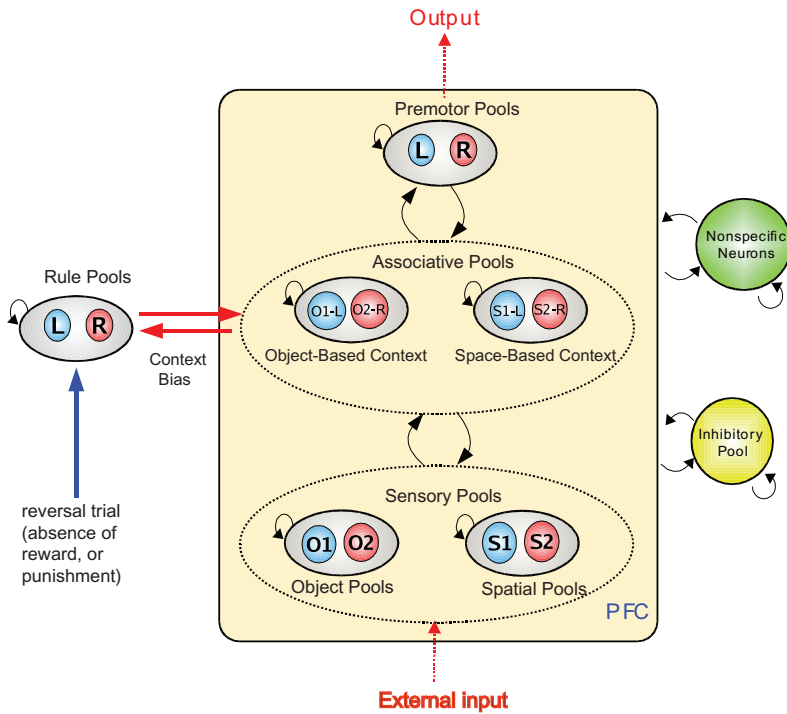

Fig. 13.13 Network architecture of the prefrontal cortex unified model of attention, working memory, and decision-making. There are sensory neuronal populations or pools for object type (O1 or O2) and spatial position (S1 or S2). These connect hierarchically (with stronger forward than backward connections) to the intermediate or 'associative' pools in which neurons may respond to combinations of the inputs received from the sensory pools for some types of mapping such as reversal, as described by Deco and Rolls (2003). For the simulation of the neurophysiological data of Asaad, Rainer and Miller (2000) these intermediate pools respond to O1-L, O2-R, S1-L, or S2-R. These intermediate pools receive an attentional bias from the Rule Pools, which in the case of this particular simulation biases either the object-based context pools or the spatial-based context pools. The Rule Pools are reset by an error to bias the opposite set of associative pools, so that the rule attentional context switches from favouring mapping through the object-based context pools to through the spatial-based context pools, or vice versa. The intermediate pools are connected hierarchically to the premotor pools, which in this case code for a Left or Right response. Each of the pools is an attractor network in which there are stronger associatively modified synaptic weights between the neurons that represent the same state (e.g. object type for a sensory pool, or response for a premotor pool) than between neurons in the other pools or populations. However, all the neurons in the network are associatively connected by at least weak synaptic weights. The attractor properties, the competition implemented by the inhibitory interneurons, and the biasing inputs result in the same network implementing both short-term memory and biased competition, and the stronger feed forward than feedback connections between the sensory, intermediate, and premotor pools results in the hierarchical property by which sensory inputs can be mapped to motor outputs in a way that depends on the biasing contextual or rule input. (After Deco, G. and Rolls, E. T. (2003) Attention and working memory: a dynamical model of neuronal activity in the prefrontal cortex. *European Journal of Neuroscience* 18: 2374–2390.)

motor attractors must be weak (Rolls, 2016b). This whole process will be stochastic, with the transition times, especially of individual neurons in each of the attractors, being probabilistic from trial to trial because the process is being influenced by noise. The activity of the different populations of neurons shown in Fig. 13.14 matches those recorded in the prefrontal cortex (Fuster, Bodner and Kroger, 2000).

13.6.4 The mechanisms of top-down attention

The top-down biased competition approach is summarized in Section 2.12. Some of the mechanisms involved in a biased activation theory of selective attention are summarized in Section 4.3.5. Similar mechanisms are likely to apply to the top-down effects that cognition has on earlier processing. The process and mechanisms of top-down attention are considered

Fig. 13.14 Paired-associate / temporal order memory using stronger forward than reverse connections between attractors. In this spiking network model, input attractor network neuronal pools tone high (TH) and tone low (TL) have stronger forward than reverse synaptic connections to output attractor network neuronal pools color red (CR) and color green (CG) respectively. (In addition, there are associative attractor populations of neurons AH and AL that receive stronger forward inputs from TH and TL respectively, and have stronger forward than reverse weights to CR and CG respectively. These associative pools help to keep a short-term memory state initiated by one of the stimuli active throughout a trial.) The mean firing rate of some of these pools is shown in the figure on a trial on which the TH stimulus was shown at time 0–2 s, there was then a delay from 2–12 s, and then red and green stimuli were shown from time 12–14 s, with red being the correct paired associate. On average across trials there is a gradual transition from the stimulus input pool of neurons (in this case TH) to the associated output pool of neurons (in this case CR), which is frequently found in the dorsolateral prefrontal cortex during paired associate tasks. On individual trials the dynamics are noisy, with different time courses averaged across neurons for the transition from the input to the output neuronal population, and in addition somewhat different time courses for different neurons within a pool within a trial. (After Deco, G., Ledberg, A., Almeida, R. and Fuster, J. (2005) Neural dynamics of crossmodal and crosstemporal associations. *Experimental Brain Research* 166: 325–336.)

much further elsewhere (Desimone and Duncan, 1995; Deco and Rolls, 2003, 2004; Fletcher et al., 1998; Deco and Rolls, 2005a; Rolls, 2008f,d, 2013a; Luo et al., 2013; Rolls, 2014a, 2016b).

13.6.5 Computational necessity for a separate, prefrontal cortex, short-term memory system

This approach emphasizes that in order to provide a useful brain lesion test of prefrontal cortex short-term memory functions, the task set should require a short-term memory for stimuli over an interval in which other stimuli are being processed, because otherwise the posterior cortex perceptual modules could implement the short-term memory function by their own recurrent collateral connections. This approach also emphasizes that there are many at least partially independent modules for short-term memory functions in the prefrontal cortex (e.g. several modules for delayed saccades; one or more for delayed spatial (body) responses in the dorsolateral prefrontal cortex; one or more for remembering visual stimuli in the more ventral prefrontal cortex; and at least one in the left prefrontal cortex used for remembering

the words produced in a verbal fluency task – see Section 13.6.1; and Section 10.3 of Rolls and Treves (1998)).

This computational approach thus provides a clear understanding of why a separate (prefrontal) mechanism is needed for working memory functions, as elaborated in Section 13.6.2. It may also be commented that if a prefrontal cortex module is to control behavior in a working memory task, then it must be capable of assuming some type of executive control. There may be no need to have a single central executive additional to the control that must be capable of being exerted by every short-term memory module. This is in contrast to what has traditionally been assumed for the prefrontal cortex (Shallice and Burgess, 1996).

13.6.6 Synaptic modification is needed to set up but not to reuse short-term memory systems

To set up a new short-term memory attractor, synaptic modification is needed to form the new stable attractor. Once the attractor is set up, it may be used repeatedly when triggered by an appropriate cue to hold the short-term memory state active by continued neuronal firing even without any further synaptic modification (see Section B.3 and Kesner and Rolls (2001)). Thus manipulations that impair the long term potentiation of synapses (LTP) may impair the formation of new short-term memory states, but not the use of previously learned short-term memory states. Kesner and Rolls (2001) analyzed many studies of the effects of blockade of LTP in the hippocampus on spatial working memory tasks, and found evidence consistent with this prediction. Interestingly, it was found that if there was a large change in the delay interval over which the spatial information had to be remembered, then the task became susceptible, during the transition to the new delay interval, to the effects of blockade of LTP. The implication is that some new learning is required when the rat must learn the strategy of retaining information for longer periods when the retention interval is changed.

13.6.7 Sequence memory

The hippocampus has a mechanism for implementing temporal sequence memory using time cells (Section 9.3.4). The dorsolateral prefrontal cortex is also involved in temporal order / sequence memory, which is evident from impairment in the recall of the order of items from short-term memory after prefrontal cortex damage, and in neuronal firing (Naya, Chen, Yang and Suzuki, 2017; Tiganj, Cromer, Roy, Miller and Howard, 2018). Neurons in the prefrontal cortex can respond to combinations of temporal order and object, and can maintain their activity in a delay period (Naya, Chen, Yang and Suzuki, 2017). The hippocampal time cells described in Section 9.3.4 may contribute to the temporal order encoding of the prefrontal cortex, by providing temporal order information.

13.6.8 Working memory, and planning

Baddeley (2007; 2012; 2019) has argued that a key type of human memory is working memory, the ability to manipulate items in short-term memory. An example of such a task might be to repeat a set of numbers backwards. This is probably implemented in the prefrontal cortex, but the computational mechanisms involved in rearranging the order of items in working memory are not known. This ability is likely to be a component of planning, which is also implemented in the prefrontal cortex. For example, people with damage to the anterior part of area 10 are impaired in a planning task, in which they have to plan the optimal route to a number of shops, but again the mechanisms are not yet known (Shallice and Burgess, 1991; Shallice and Cipolotti, 2018; Gilbert and Burgess, 2008; Spiers and Gilbert, 2015).

14 Language and syntax in the brain

14.1 Introduction and overview

14.1.1 Introduction

When considering the computational processes underlying language, it is helpful to analyze the rules being followed (Chomsky, 1965; Pinker, 1995; Jackendoff, 2002). From this, it is tempting to see what one can infer about how the computations are implemented, using for example logical operations within a rule-based system, and switches turned on during development. [The wider issue of whether there is a universal grammar with innate rules raised by these approaches has many critics (e.g. Evans (2014)).]

In this Chapter, instead the approach is to take what has been learned from a great deal of the neuropsychology of language based on the types of language deficit occurring after damage to different regions of the brain (Kemmerer, 2015), and now supplemented by neuro-imaging studies of language (Kemmerer, 2015), neurolinguistics (Brennan, 2022), and language modelling investigations (Reichle, 2021), to build an understanding of what computations may be being performed by different brain regions. This is complemented by a computational neuroscience approach in which we take some of the key principles of the operation of the cerebral cortex (Rolls, 2016b), and how information is encoded in the brain (Appendix C), and then set up hypotheses that are then tested in computational models about how some of these computational mechanisms might be useful and used in the implementation of language in the brain (e.g. Rolls and Deco (2015a)).

However, language is perhaps the last major frontier where we do not yet have a good set of computational ideas for how the computations are implemented in the brain, so what is described here is intended to provide a foundation of ideas for future research, rather than proposals for how the brain approaches this computational problem. This is a contrast with many other brain systems, as described in this book.

Some of the brain regions involved in different aspects of language and speech are shown in Figs. 14.1 and 14.2.

14.1.2 Overview

1. Semantic representations are in the anterior temporal lobe as described in Section 8.3, with the possible computational mechanisms involved considered in Sections 8.5 and 14.4. It is suggested that the parietal lobe provides inputs to the semantic system when information about the body and actions needs to be part of the semantic representation (Section 14.2.6).
2. Effective connectivity identifies a semantic system that includes cortex in the inferior bank of the superior temporal sulcus (STS) that extends from the temporal pole, includes the inferior temporal visual cortex, extends up into parietal region PGi, and is involved in the visual representation of objects and people. Another semantic system includes cortex in the superior bank of the STS and some auditory regions, and extends from the frontal pole to the temporo-parieto-occipital junction. This system is involved in semantic representations of auditory and especially moving visual stimuli including heads and faces. Both semantic systems connect to Broca's area regions 44 and 45 and the nearby inferior frontal

Fig. 14.1 Brain structures implicated in language are shown on a lateral view of the left hemisphere of the human brain. Broca's area, a traditional term, refers to the Inferior Frontal Gyrus pars triangularis area 45, and the Inferior Frontal Gyrus pars opercularis area 44. It is implicated in syntactic manipulations of semantic information for speech production. The Anterior Temporal Lobe is involved in semantic representations, as described in Section 8.3. Wernicke's area, a traditional term, refers to the posterior part of the superior temporal gyrus area, part of area 22, and a part of the supramarginal gyrus area 40. It is involved in phonological processing but not in language comprehension. The angular gyrus, area 39 in the parietal cortex, may be involved in providing and combining attributes for semantic representations. The Auditory cortex is also shown. cs—central sulcus; ITG—Inferior temporal Gyrus; MTG—Middle Temporal Gyrus; STG—Superior Temporal Gyrus.

gyrus regions which are proposed to use linked attractor networks to implement the serial nature of language (Rolls et al., 2022b) (Section 14.3).

3. The dual-stream model (Section 14.2.2) holds that a ventral stream, which involves the temporal lobe, is involved in processing speech signals for comprehension. A dorsal stream, which involves structures at the left parietal-temporal junction and the left inferior frontal gyrus ('Broca's area'), is involved in translating acoustic-based representations of speech signals into articulatory representations essential for speech production.
4. A fundamental computational issue is how the cortex implements binding of elements such as words or features with the correct relationship between the elements. The problem in the context of language might arise if we have neuronal populations each firing to represent a subject, a verb, and an object of a sentence. If all we had were three populations of neurons firing, how would we know which was the subject, which the verb, and which the object? How would we know that the subject was related to the verb, and that the verb operated on the object? How these relations are encoded is part of the problem of syntactic binding (Sections 14.2.5 and 14.5).
5. One possible solution that is described in this Chapter is that a place code is used to solve syntax, which would simply bring syntax into the same framework as is used

for representations in most other cortical areas (Section 14.5). Place codes are defined in Section 1.7.

6. The hypothesis is that a place code is used, with for example one cortical module or region or set of neurons used to represent subjects, another cortical module used to represent verbs, and another cortical module used to represent objects.
7. An interesting implication is that within the brain, the problem of syntax is then solved, but that the problem then becomes of how the syntactic role of each word is transmitted from one individual to another. One such principle is word order used in some languages such as English. Another principle is the use of inflections, usually suffixes, that indicate the function of a noun, used in other languages such as Latin and Greek. In Latin for example the cases for *amica*, a friend, are nominative (*amica*, used for the subject), vocative (*amica*), accusative (*amicam*, used for the object), genitive (*amicae*), dative (*amicae*), and ablative (*amica*).
8. A key idea in this Chapter is that syntactical operations involving word order might be implemented by a temporal trajectory through a state space of linked attractor networks each specializing in different syntactic roles, for example subject, verb, and object, with each attractor network being activated by the appropriate semantic representation from the temporal lobe (Section 14.5 and Rolls and Deco (2015a)).
9. An important property of this system is that the actual trajectory through the system, the order of for example the subject, verb, and object, would be learned for each language by experience with that language, using mechanisms such as stronger forward than backward connections between coupled cortical attractor networks, and spike-timing dependent plasticity. This is thus not an innate system. In the situation where word order is important in syntax, the subject and object are essentially defined by where they occur in the temporal trajectory through the state space (e.g. subject > verb > object in English).
10. Simulations of a set of linked cortical attractor networks with stronger forward than backward interconnections between the networks show how a temporal trajectory could be made through a state space of grammatical entities to generate appropriate sequences of word orders. It is also shown how a recipient could decode such a word order sequence, and assign the words to activate the correct cortical modules (Section 14.5) (Rolls and Deco, 2015a).

14.2 What is computed in different brain systems to implement language

14.2.1 The Wernicke-Lichtheim-Geschwind hypothesis

The classical Wernicke-Lichtheim-Geschwind model of the neural architecture of language held that language comprehension involves Wernicke's area, and language production involves Broca's area. Conduction aphasia, the inability to repeat a spoken phrase, was described as a disconnection between these two (Geschwind, 1970; Coslett and Schwartz, 2018). It has now become clear that comprehension and production are not as clearly separated as once thought (Hagoort and Indefrey, 2014; Binder, 2015). Further, the region known as Wernicke's area, in the posterior superior temporal gyrus and part of the supramarginal gyrus area 40, is involved in phonological processing, but not in language comprehension (Binder, 2015). Damage to 'Wernicke's area' results in conduction aphasia and in phonemic paraphasias, providing evidence that this region is involved in phonemic retrieval (Binder, 2015).

14.2.2 The dual-stream hypothesis of speech comprehension

The dual-stream model (Fig. 14.2) (Hickok, 2022) holds that a ventral stream, which involves structures bilaterally in the superior and middle portions of the temporal lobe, is involved in processing speech signals for comprehension. The evidence that this is bilateral is that it is bilateral not unilateral lesions of the superior temporal cortex that have a major effect on auditory language comprehension, evident as word deafness (Hickok and Poeppel, 2015).

A dorsal stream, which involves structures at the left parietal-temporal junction and in the left inferior frontal gyrus, is involved in translating acoustic-based representations of speech signals into articulatory representations essential for speech production (Hickok and Poeppel, 2007, 2015; Bornkessel-Schlesewsky et al., 2015; Kemmerer, 2015; Hickok, 2022). Monitoring self-produced speech and motor control are associated with the posterior Superior Temporal Gyrus, part of the auditory dorsal stream (DeWitt and Rauschecker, 2013). The functional role of the dorsal stream in the model is to subserve speech production by computing a mapping between phonological representations of speech in the STG/STS and motor-based speech codes in the frontal lobe. This mapping is mediated by a cortical auditory-motor transformation zone in the posterior Sylvian region at the temporal–parietal boundary (termed Spt) (Hickok, 2022).

For the ventral stream (Hickok and Poeppel, 2007, 2015; Bornkessel-Schlesewsky et al., 2015; Kemmerer, 2015; Hickok, 2022), one area involved in speech comprehension is the posterior part of the middle temporal gyrus, and this is also implicated in lexical-semantic access (Hickok and Poeppel, 2015). This is of course not far from the primary auditory cortex (Fig. 14.1). Anterior temporal lobe regions are implicated in sentence-level processing (syntactic and/or semantic integration processes), and more generally in semantic processing (Hickok and Poeppel, 2015; Patterson et al., 2007). Indeed, the anterior Superior Temporal Gyrus (STG), part of the auditory ventral stream, is involved in the recognition of species-specific vocalizations in non-human primates and word-form recognition in humans (DeWitt and Rauschecker, 2013). Auditory object formation is a form of categorization, in which spectrotemporal properties are grouped into perceptual and, at higher hierarchical levels, conceptual units. Thus, it provides the computational basis for a mapping from spectrotemporal patterns to concepts (DeWitt and Rauschecker, 2013). Consistent with this hierarchical model, damage to the anterior parts of the temporal lobes, as in semantic variant primary progressive aphasia, provides evidence for the anterior part of the temporal lobe as being a main centre for semantic representations (DeWitt and Rauschecker, 2013). It may be that the attributes or properties of objects are represented in the anterior part of the temporal lobe which operates as a hub area with associative connections to modality-specific cortical areas that encode for example the visual properties of objects (visual inferior temporal lobe areas), their auditory properties (superior temporal auditory areas), their reward value (orbitofrontal cortex), and/or actions that can be performed on or by the objects (parietal cortex), etc.

It is suggested that sequence-based processing in which the order of the items is important in the syntax, as in English, is supported by the dorsal stream; and that case-based processing (for example nominative vs accusative), which are order insensitive (as in German), is supported by the ventral cortical stream (DeWitt and Rauschecker, 2013).

14.2.3 Reading requires different brain systems to hearing speech

It has been proposed that a mechanism very much like the hierarchical feature combination VisNet model of object recognition described in Chapter 2 (Wallis and Rolls, 1997; Rolls, 2012d, 2021d) is used for building visually-evoked representations of individual letters, and then low-order combinations of letters, and then whole words, in the occipito-temporal cortex (Dehaene et al., 2005). The mechanism was described as a Local Combination Detector

Fig. 14.2 Dual streams supporting language processing in the human brain. A left (postero-)dorsal (red) stream is involved in translating acoustic-based representations of speech signals into articulatory representations essential for speech production. An (antero-)ventral (green) stream is involved in processing speech signals for comprehension. Cross-stream integration in the inferior frontal gyrus is depicted by the transition from red to green. Black broken arrows denote feedback connections. Inferior Frontal Gyrus pars triangularis area 45, and the Inferior Frontal Gyrus pars opercularis area 44 are Broca's area. It is implicated in syntactic manipulations of semantic information for speech production. The posterior part of the superior temporal gyrus area 22, and a part of the supramarginal gyrus area 40 is traditionally referred to as Wernicke's area. It is involved in phonological processing but not in language comprehension. Abbreviations: AC, auditory cortex; CS, central sulcus; IFC, inferior frontal cortex; IPL, inferior parietal lobule; PMC, premotor cortex; STS, superior temporal sulcus. Numbers denote Brodmann areas (Section 1.11). (From Ina Bornkessel-Schlesewsky, Matthias Schlewsky, Steven L. Small, and Josef P. Rauschecker (2014) *Neurobiological roots of language in primate audition: common computational properties*. *Trends in Cognitive Sciences* 19: 142–150. © Elsevier Ltd.)

Model of visual word recognition (Dehaene et al., 2005; Kemmerer, 2015; Hannagan et al., 2021). Indeed, in the macaque inferior temporal visual cortex, neurons are found to respond to combinations of letters that have been visually presented previously (Rajalingham et al., 2020), heightening the likelihood that the mechanisms utilised in VisNet (Rolls, 2021d) are used for letter combination recognition. fMRI evidence in humans suggested that this letter combination mechanism was implemented in the ventral visual system up to a region in the left occipito-temporal sulcus at $y=-48$ (Vinckier et al., 2007) leading to the Visual Word Form Area for orthographic representations, in the left mid-fusiform cortex (Dehaene and Cohen, 2011; Hannagan et al., 2021). Activations in the Visual Word Form Area are visual and prelexical, yet invariant for the location and the upper vs lower case of the stimulus words, but not for mirror reflection of letters (as required for reading to distinguish between for example b and d). Lesions affecting the Visual Word Form Area cause pure alexia, a selective deficit in word recognition (Dehaene and Cohen, 2011).

For processing beyond the Visual Word Form Area, a dual-route model of reading is

described next, one involving phoneme-to-grapheme conversion, and the other a whole-word route (Coltheart et al., 1993; Pritchard et al., 2018).

The indirect, or sublexical, or grapho-phonological, route goes via grapheme-to-phoneme conversion to a phonological word representation and from there to word meaning. According to this hypothesis, the relay stations of the indirect route are located in the left superior and middle temporal gyrus, the supramarginal gyrus and the inferior frontal gyrus pars opercularis (area 44), while the regions involved in processing meaning are located in the left basal temporal area, posterior middle temporal gyrus, and inferior frontal gyrus pars triangularis (area 45) (Jobard et al., 2003).

The direct, or lexical, or lexico-semantic, route is based on whole-word recognition, maps the written word form directly onto the meaning, and goes directly from the visual word form area to the regions involved in processing meaning including the medial temporal gyrus (Jobard et al., 2003; Liuzzi et al., 2019).

14.2.4 Semantic representations

Semantics refers to the meanings that language expresses (Jackendoff, 2002; Kemmerer, 2015). We have already seen in Sections 8.3 and 14.2.2 that the anterior part of the temporal lobe is involved in semantic representations. Further, I suggest in Section 14.2.6 that the angular gyrus area 39 provides semantic attributes derived from processing in the dorsal processing stream about for example actions performed by or on objects, whereas the ventral stream anterior temporal lobe system provides semantic attributes related to the visual, auditory, tactile, and olfactory descriptors of objects. Approaches to brain systems involved in semantics are considered further here. At a more general level, a ‘Hub and Spoke Model’ postulates that there is a semantic hub in the anterior temporal lobe, with associative links to modality-specific cortical areas involved in processing different attributes of objects such as their visual appearance, odor, sound, etc (Kemmerer, 2015).

Comprehending speech involves the rapid and optimally efficient mapping from sound to meaning. A cohort model for lexical representations produced by spoken words proposes that the onset of a spoken word initiates a continuous process of activation of the lexical and semantic properties of the word candidates matching the speech input, and competition between them, which continues until the point at which the word is differentiated from all other cohort candidates (the uniqueness point, UP) (Marslen-Wilson and Welsh, 1978). At this point, the word is recognized uniquely and only the target word’s semantics are active. Using magnetoencephalography (MEG), early transient effects approximately 400 ms before the UP of lexical competition were found in the left supramarginal gyrus, left superior temporal gyrus, left middle temporal gyrus (MTG) which is associated with processing the semantic properties of words, and left inferior frontal gyrus (IFG). Evidence was found of semantic competition in the MTG, left angular gyrus, and IFG. After the UP, target-specific semantic effects were found in the middle temporal gyrus (Kocagoncu, Clarke, Devereux and Tyler, 2017).

The use of semantic models in neuroimaging has confirmed that the anterior part of the temporal lobe is involved in semantics, but has pointed in addition to a more medial part of the temporal lobe, the perirhinal cortex (Bruffaerts et al., 2019; Liuzzi et al., 2019). The perirhinal cortex is increasingly engaged for objects that are more semantically confusable, suggesting that object-specific semantic information is represented in the perirhinal cortex (Clarke and Tyler, 2015, 2014).

Object representations, such as those found in the inferior temporal visual cortex, enable an object or face to be identified, as described in Chapter 2. Semantic representations involve in addition information about the attributes of an object, for example for a bicycle that it has

two wheels, handlebars, a saddle, and usually but not always a chain, and just sometimes a second saddle. The suggestion therefore is that the individual object, person, etc needs to be associated with a set of attributes to provide a semantic representation. Those attributes can be learned, at least to some extent, by associative learning. The hypothesis is that this is implemented in the anterior temporal lobe. A well-known connectionist model, *interactive activation*, that captures this, has been described (McClelland, 1981; McClelland, Rumelhart and Hinton, 1986), and has been made available for tutorial use (McClelland and Rumelhart, 1989). This approach has been continued, with an example described in Section 14.4 (Devereux, Clarke and Tyler, 2018).

Further evidence for semantic representations is that some single neurons in the human medial temporal lobe cortex respond not only to the sight of an individual person, such as Jennifer Aniston, but also to her associates, such as people in the same movie, and the places associated with Jennifer Aniston (Quian Quiroga, 2012, 2013; Ison et al., 2015; De Falco et al., 2016; Bausch et al., 2021). These have been termed ‘concept cells’. Although it has been argued that concept cells, in responding to for example the sight of a person, or to places associated with that person, may be specially present in humans (Quian Quiroga, 2012, 2013; Ison et al., 2015; De Falco et al., 2016; Quian Quiroga, 2023), it has been pointed out (Rolls, 2023c,d) that single neurons in the macaque medial temporal lobe might on these bases be described as ‘concept cells’, in that they respond to the sight of an object, or to the place associated with that object (Rolls, Xiang and Franco, 2005c; Rolls and Xiang, 2006; Rolls, 2023d).

14.2.5 Syntactic processing

A good introduction to the many rules of syntactic processing, and the many exceptions to them, is provided by Kemmerer (2015). The proposal made in this Chapter is that one way that syntax may be implemented in the brain is by a temporal trajectory through a state space of attractor networks (Section 14.5). This provides a system that can operate according to what appear to be a series of learned rules, and at the same time can deal with exceptions, which again are learned.

A long history of neuropsychological research places language function within a primarily left-lateralized frontotemporal system (Kemmerer, 2015). However, neuroimaging results appear to extend this language network to include a number of regions (Kemmerer, 2015) traditionally thought of as ‘domain-general’. These include dorsal frontal, parietal, and medial temporal lobe regions known to underpin cognitive functions such as attention and memory. However, it has been argued that these domain-general systems are not required for language processing and are instead an artefact of the tasks typically used to study language. Recent work shows that when syntactic processing – arguably the only domain-specific language function – is measured in a task-free, naturalistic manner, only the left-lateralized frontotemporal syntax system and auditory network are activated. When syntax is measured within the context of a task, several other domain-general networks come online and are functionally connected to the frontotemporal system. Thus syntax appears to be implemented in a domain-specific frontotemporal syntax system (Campbell and Tyler, 2018).

An example of such syntactic processing measured within the context of natural listening is when there is temporary syntactic ambiguity such as: ‘bullying teenagers’ in the sentence ‘The newspaper reported that bullying teenagers are a problem for the local school’). The region involved in this syntactic processing was primarily the left inferior frontal gyrus, with a smaller area in the left superior part of the temporal lobe (Campbell and Tyler, 2018).

There are hypotheses about how syntax is implemented in the brain by a number of different linked processes that perform operations such as mapping participant roles (e.g. actor

or undergoer) to grammatical relations, like subject and object, and then implementing word ordering or case marking (as e.g. subject vs object) (Kemmerer, 2015). However, these have generally not reached the stage of neurobiologically plausible models.

14.2.6 The parietal cortex: supramarginal and angular gyri

Parts of the parietal cortex (especially the angular and supramarginal gyri) were at one time thought to be a major part of the language system (Binder, 2015). The role, at least for the supramarginal gyrus, is now thought to be more limited: phonological processing can activate the parietal cortex, particularly when sound-based representations are transformed into representations that can drive the action system (Coslett and Schwartz, 2018). In addition, the parietal cortex may contribute to auditory-verbal short term memory, with damage there impairing auditory rehearsal. This parietal system is incorporated into the dual-stream hypothesis, and is included in Fig. 14.2. In contrast, the inferior frontal gyrus is implicated more in articulatory rehearsal (Coslett and Schwartz, 2018).

Thus the supramarginal gyrus area 40 appears to support retrieval of phonological forms (mental representations of phoneme sequences), which are used for speech output and short-term memory tasks. Focal damage to this region produces phonemic paraphasia without impairing word comprehension, i.e., conduction aphasia. Phonologic processing does also activate cortex in the superior temporal sulcus (Hickok and Poeppel, 2015).

The angular gyrus area 39, as a multimodal region in the parietal cortex, has been implicated in semantic processing (Seghier, 2013), perhaps, it has been suggested, in combining the different attributes required for semantic representations (Price et al., 2015). I propose that one way in which the angular gyrus is involved in semantic processing is that it provides semantic attributes derived from processing in the dorsal processing stream about for example actions performed by or on objects. I propose that in contrast, the ventral stream anterior temporal lobe system provides semantic attributes related to the visual, auditory, tactile, olfactory and even taste descriptors of objects. It is an interesting issue about whether the parietal information reaches the temporal lobe semantic representations and the combination of the action and object information occurs in the temporal lobe; or whether the parietal action and temporal lobe object information have separate projections to the inferior frontal gyrus.

14.3 Cortical regions for language and their connectivity in humans

The connectivity between brain regions involved in language is a topic of importance for understanding human brain function and in order to minimize language impairments during neurosurgery (Milton et al., 2021; Ding et al., 2016; Hickok and Poeppel, 2015, 2007; Hickok, 2022; Bornkessel-Schlesewsky et al., 2015; DeWitt and Rauschecker, 2013; Rauschecker, 2012; Chang et al., 2015; Bouchard et al., 2013; Battistella et al., 2020). Part of the background is research on the auditory cortex in non-human primates (Kaas and Hackett, 2000; Rauschecker, 1998a; Rauschecker et al., 1995), and the connectivity of auditory cortical regions in humans (Rolls et al., 2023h) (Chapter 7). In research utilising the Human Connectome Project multimodal parcellation (HCP-MMP) atlas (Glasser et al., 2016a), 157 task-based fMRI studies were analyzed to identify brain regions in the HCP-MMP atlas related to semantics based on categorization of visual words and objects, and auditory words and stories, and the following regions were identified as part of the semantic network: 44,

45, 55b, IFJa, 8C, p32pr, SFL, SCEF, 8BM, STSdp, STSvp, TE1p, PHT and PBelt, and were shown to be interconnected with tractography (Milton et al., 2021).

In research on the connectivity of cortical regions involved in language, community analysis was performed on the 360x360 effective connectivity data for both hemispheres, and a community of 26 cortical regions was identified (Rolls et al., 2022b) that included most of those or very similar regions noted above (Milton et al., 2021) related to language. We then performed analyses on the connections, functional connectivity, and effective connectivity of these 26 left hemisphere cortical regions with the 360 cortical regions in the HCP-MMP atlas (Rolls et al., 2022b). Having identified 26 cortical regions related to language in the left hemisphere, a further community analysis (Rubinov and Sporns, 2010) was performed on the effective connectivities of the 26 language-related ROIs from all 180 cortical areas in the left hemisphere, to investigate whether any grouping could be made. It was found that three communities were formed, as follows: Group 1: STSva STSvp TE1a TGd PGI 10v 9m 10pp 47s 8Av 8BL 9a 9p. Group 2: TGv 44 45 47l SFL 55b. Group 3: A5 STGa STSda STSdp PSL STV TPOJ1. The connectivity of these three groups of language-related cortical regions (Rolls et al., 2022b) is described next.

14.3.1 A semantic system that includes the inferior bank of the superior temporal sulcus including object representations

The regions in Group 1 (STSva STSvp TE1a TGd PGI 10v 9m 10pp 47s 8Av 8BL 9a 9p), are considered next. The connectivities of regions in the ventral bank of the superior temporal sulcus, STSva and STSvp, are illustrated in Fig. 2.24, and of another region in this group, PGI, in Fig. 8.3 (Section 8.4.1). The regions involving cortical inferior regions of the superior temporal sulcus (STS) have effective connectivity with the adjacent inferior temporal visual cortex TE1a and temporal pole TG. The connected parietal PGI region has effective connectivity with inferior temporal visual cortex (TE) regions, with parietal PFM which also has connectivity with visual regions, with posterior cingulate cortex and parahippocampal TF memory-related regions, with the frontal pole, with the medial orbitofrontal cortex and related ventromedial prefrontal cortex reward-related regions, with the dorsolateral prefrontal cortex, and with 44 and 45 ('Broca's area') for output regions. PGI also receives inputs from PGs which includes visuo-motor as well as visual object system connectivity (Rolls et al., 2023d). This inferior STS semantic network is likely to be more involved in invariant object and face identity representations for static visual stimuli of the type represented in the inferior temporal visual cortex, whereas the superior (/ dorsal) STS regions are more likely to be involved in responses to face expression and visual motion including that which can be combined with auditory stimuli such as the sight and sound of a vocalization (Baylis et al., 1987; Hasselmo et al., 1989b,a; Rolls, 2021b).

As described in Section 8.4.1, the connectivity of these Group 1 semantic regions with inferior temporal visual cortex TE regions provides for transform-invariant visual representations of objects and faces as shown by discoveries in macaques (Rolls, 2021d,b; Perrett, Rolls and Caan, 1982; Booth and Rolls, 1998; Arcaro and Livingstone, 2021; Freiwald, 2020; Lehky and Tanaka, 2016) with complementary evidence from human neuroimaging (Kanwisher et al., 1997; Finzi et al., 2021; Collins and Olson, 2014) to be incorporated into semantic representations provided by this network of semantic cortical regions.

The connectivity with inferior parietal cortex PGI and to a smaller extent PGs regions may allow information about the visual motion of objects, such as a head turning away, or the eyes closing, or the lips moving, to convey a social signal such as a greeting (lip-smack) or threat, or when vocalizing, to reach STS areas (Rolls et al., 2023d).

Effective connectivity of the Group 1 regions with the frontal pole (10pp, 9m, 9a, 9p)

regions implicated in planning and sequencing (Shallice and Cipolotti, 2018; Shallice and Burgess, 1996; Gilbert and Burgess, 2008) and prospective as well as retrospective memory (Underwood et al., 2015) is likely to provide information about the temporal order / sequence of events, which is important in interpreting causal interactions in the world (Rolls, 2021e).

Similarly, the connectivity via the parahippocampal TF region Fig. 8.3 with the hippocampal system implicated in episodic memory (Dere et al., 2008; Ekstrom and Ranganath, 2018; Rolls, 2018b, 2021b; Moscovitch et al., 2016) is likely to be important in building semantic information about the semantic meaning of events by enabling the memory of particular past events to be taken into account. The connectivity of the Group 1 regions with the posteroventral parts of the posterior cingulate cortex which are implicated in episodic memory (Vann et al., 2009; Leech and Smallwood, 2019; Leech and Sharp, 2014; Rolls et al., 2023i) by providing a route to the hippocampal system may in a similar way be important in enabling the Group 1 regions, especially those in the temporal lobe but also in the inferior parietal cortex (Davis et al., 2018; Papagno, 2018), to build semantic representations by taking particular previous episodes into account. Consistent with this, increasing activation of the angular gyrus and decreasing activation of the hippocampus occurs when episodic memories become incorporated into schemas (van der Linden et al., 2017).

The connectivity of the Group 1 regions with the orbitofrontal cortex (regions OFC and pOFC), pregenual anterior cingulate cortex (d32) and some ventromedial prefrontal cortex regions where reward value and emotion are represented (Grabenhorst and Rolls, 2011; Rolls et al., 2023c; Rolls, 2019c,e; Rolls et al., 2020a; Rolls, 2014a; Padoa-Schioppa and Conen, 2017; Cai and Padoa-Schioppa, 2012; Reber et al., 2017; Rolls, 2021h) provides another fundamental type of input, reward / emotion related, for building semantic representations about people and objects.

This ventral STS Group 1 semantic system also receives information from the top of the somatosensory hierarchy, parietal cortex region PF (Rolls et al., 2023d,f, 2022b) (Section 10.2). PF has effective connectivity directed towards language-related regions - the PeriSylvian language area (PSL), TPOJ2, STSvp (Rolls et al., 2022b) (and to prefrontal cortex areas involved in short-term memory related functions IFsa and 46 (Rolls et al., 2023d)). The diffusion tractography (Rolls et al., 2023d) further emphasizes connections of region PF with language-related areas 44, 45 and PSL (Rolls et al., 2023d). PF may on this connectivity evidence (Fig. 10.1) be the top of a somatosensory hierarchy which adds visual to somatosensory inputs to form semantic representations of felt objects, which can then gain access to language systems, as well as having outputs to superior parietal and intraparietal areas involved in performing actions such as reach and grasping for felt or seen objects. PF may thus build a multimodal, semantic, representation of felt objects. The PeriSylvian Language region (PSL) is very interesting, because it receives somatosensory inputs from the adjacent PF (Fig. 8.4), and has connections to STS semantic areas, so PSL may be a route for tactile inputs to become part of object representations (Rolls et al., 2022b).

The extensive connectivity of the Group 1 regions with the lateral prefrontal cortex which is implicated in working memory and planning (Goldman-Rakic, 1996; Baddeley, 2021) is likely to enable semantic representations to be held online to facilitate planning, reasoning, and rearrangement of the order of components if a task fails (Rolls, 2020a).

Regions in the more inferior part of the STS and linked with inferior temporal cortex visual regions in Group 1 are implicated in 'semantic representations involved in speech, reading, and visual and supra-modal mental objects that are linked to word forms' (Hertrich et al., 2020). The temporo-parietal junction and angular gyrus regions in Group 1 are implicated in 'pragmatic processing, context integration, words with multiple meanings, perspective taking, and social cognition' (Hertrich et al., 2020), consistent with some of the points made above about the regions in the Group 1 network.

Overall, this evidence shows that there is a network of brain regions that includes regions in the ventral bank of the superior temporal sulcus that combines evidence from its strongly interconnected brain regions to build multimodal representations of objects, including visual and somatosensory information. The human connectivity described here shows that this is a remarkable system extending from the temporal pole TG regions through the inferior temporal visual cortex and the ventral bank of the superior temporal sulcus through to PGI as illustrated in Fig. 8.3, and which also has connectivity with some dorsal prefrontal cortex regions 9a, 9b and 9m (Fig. 8.3). This semantic system also has connectivity with the hippocampal memory system, in part through the posterior cingulate cortex postero-ventral ‘what’ memory-related regions (Fig. 8.3, (Rolls et al., 2023i)), and this connectivity is likely to be important in how episodic memory is used to help build semantic representations, as described in Section 9.2.8.5 (Rolls, 2022b).

14.3.2 A semantic system that includes the superior bank of the superior temporal sulcus including visual motion, auditory, somatosensory and social information

The regions in Group 3 (A5 STGa STSda STSdp PSL STV TPOJ1), are considered next, with their connectivities illustrated in Figs. 2.25 and 8.4, with introductions in Sections 2.5.3 and 8.4.2.

In the superior (or dorsal) bank of the cortex in the Superior Temporal Sulcus (STS), regions STSda and STSdp were identified by a community analysis as part of a superior temporal lobe semantic system involved in language (Rolls et al., 2022b). Visual inputs to regions STSda and STSdp in this superior STS semantic system come from PGI (Fig. 2.25), and provide a route for moving visual stimuli / objects analyzed in the parietal cortex to reach STS regions (Rolls et al., 2023d). Visual inputs also reach STSdp from the Superior Temporal Visual (STV) region which receives from both MT and FFC (Fig. 2.25), and which could contribute to the neuronal activity in the cortex in the STS which has been shown to respond to moving heads, faces and objects in macaques (Hasselmo et al., 1989b,a), as described in Section 2.5.3. STSda and STSdp also have connectivity from STSva and STSvp which have strong connectivity with the Ventrolateral Visual Stream (Figs. 2.23 and 2.25). STSda and STSdp also receive auditory effective connectivity from A5 (Fig. 2.25). STSdp has connectivity directed towards Broca’s area 44 and 45, and related areas (471), and to the PeriSylvian Language region PSL and to the Superior Frontal Language region SFL (Rolls et al., 2022b).

It was proposed that this dorsal bank of the STS region is a third visual system that combines inputs from dorsal and ventral visual streams (Hasselmo et al., 1989b,a; Baylis et al., 1987), and this has recently received support (Pitcher and Ungerleider, 2021). Moreover, the same STS regions also contain neurons that respond to auditory stimuli including in some cases vocalization (Baylis, Rolls and Leonard, 1987). It is likely that neurons in these STS regions respond to combinations of auditory and synchronized visual stimuli such as vocalization and moving lips and are important in speech analysis by the viewer/hearer not only in noisy environments, but also to confirm who is speaking, and to learn associations between the sight of a person’s face and the sound of their voice, which is part of what is required for the semantic representation of a person. Neurons of these types, including responsiveness to face expression, underlie the importance of this region in interpreting the social meaning of visual and auditory stimuli, which is a key part of semantic representations implemented in these STS regions, and that contribute to theory of mind, that is, of another individual’s intentions and even thoughts. Consistent with this, individual STS cortex neurons have now

been reported in macaques to respond to both visual face stimuli and to auditory stimuli (Khandhadia, Murphy, Romanski, Bizley and Leopold, 2021).

Region TPOJ1 has robust effective connectivity with auditory association cortex, including A5, A4 and to some extent LBelt, PBelt and TA2 (Fig. 8.4). The visual input to TPOJ1 is not from inferior temporal visual cortex (TE regions), but instead with some earlier visual cortical regions involved in motion processing (MST, MT, especially to STV and TPOJ1) and in face processing (the fusiform face cortex FFC and posterior inferior temporal cortex PIT). This is proposed to contribute to the responsiveness of neurons in this region, and in the dorsal bank of the STS, to moving heads and face movements important in social behavior as described in Section 8.4 (Rolls et al., 2023e, 2022b).

Another type of influence on these Group 3 regions comes from somatosensory cortical areas, as is especially evident in the functional connectivity (Rolls et al., 2022b). The functional connectivity of Group 3 regions is not only with 1-3b and 5, but also with frontal opercular and insular cortex, and there is some evidence for this too in the effective connectivity, including with parietal PF which can be considered as the top of the somatosensory hierarchy (Rolls et al., 2023d). This may contribute to semantic representations of body image and the sense of self (Rolls et al., 2023d).

This ‘superior STS cortex semantic system’ thus enables multimodal representations including visual, auditory, and probably also somatosensory via PGI and earlier somatosensory cortex regions, to gain access to the language system (Rolls et al., 2022b). There is also a link via TF to the hippocampal memory system (Fig. 2.25), which is likely to be important in how episodic memory is used to help build semantic representations, as described in Section 9.2.8.5 (Rolls, 2022b).

Although the description of a region around the temporo-parieto-occipital junction as Wernicke’s area involved in language comprehension is now much less clear than previously thought (Section 14.2.1), what is clear based on the evidence described here (Rolls et al., 2022b) is that regions in this general area of the brain in what are parts of the dorsal and ventral STS semantic streams are very strongly implicated now as having key roles in semantic representations, and with communicating with Broca’s area as described in Section 14.3.4.

An anterior part of the superior temporal lobe (in Group 3) is identified as an auditory word form area (Hertrich et al., 2020; DeWitt and Rauschecker, 2013; Binder, 2017, 2015). A more posterior part of the superior temporal lobe in the superior temporal gyrus is involved in auditory-phonological processing (Hertrich et al., 2020), consistent with the auditory connectivity described here. Just inferior to that in posterior parts of the superior temporal gyrus, superior temporal sulcus, and middle temporal gyrus is a region implicated in ‘syntax and semantics’ (Hertrich et al., 2020). This is probably close to the temporo-parieto-occipital junction region (part of Group 3) the connectivity of which is shown in Fig. 8.4.

14.3.3 Multimodal semantic representations

So far, the emphasis has been on visual and auditory semantic representations, partly because ‘what’ visual and auditory processing, which is primarily about the external world, is performed in the temporal lobes. However, some neurons in the cortex in the macaque superior temporal sulcus do respond to somatosensory stimuli (Baylis, Rolls and Leonard, 1987). Even the parietal PGI system is at least dominated by visual system connectivity (Rolls et al., 2023d), and what seems to be missing so far in the PGI part of this system, is information about the somatosensory properties of objects, and how the objects can be manipulated, perhaps as tools, under somatosensory as well as visual control. Now of course any information from the somatosensory system is quite different in kind from what is represented in

the temporal lobes, for the somatosensory system involves touch to the body or the position of the body, which is not a property that needs to be taken into account by the temporal lobe analysis of objects ‘out there’ in the world. The way in which somatosensory information is incorporated into semantic systems appears to be implemented using the Group 3 regions that have effective connectivity with somatosensory regions (frontal opercular FOP, insula and parietal PF). Consistent with this, the Group 3 regions such as STV receive inputs from posterior cingulate cortex region PCV (precuneus visual region) (Rolls et al., 2023i), and this may provide for visual inputs relating to visually-guided reaching to grasp for objects, to be incorporated into semantic representations of objects.

A key region for multimodal convergence is the set of temporo-parieto-occipital junction regions TPOJ1-3, which are highly connected with each other, and which between them have effective connectivities with all the major systems just described involved in language, including visual, auditory, STS, PF, and PGI (Rolls et al., 2023d). The implication is that in terms of connectivity the TPOJ2 and TPOJ3 regions both of which have connectivity with the Group 3 regions (Rolls et al., 2023d) contribute to bringing together semantic representations involving all of these types of representation in the brain. Further, the Group 3 region PSL, the Peri-Sylvian Language region, receives effective connectivity from PF which can be considered as the top of the somatosensory hierarchy (Rolls et al., 2023d). Another input to the TPOJ regions comes from the cortex just lateral to the fusiform face area, which is the visual word-form area (VWFA) (Yeatman and White, 2021; Dehaene et al., 2005; Dehaene and Cohen, 2011; Caffarra et al., 2021). Disruption of the connectivity of the VWFA is likely to account for problems such as alexia and dyslexia in which the visual analysis required for reading cannot reach the semantic TPOJ regions (Pritchard et al., 2018; Liuzzi et al., 2019). Indeed, the FFC has effective connectivity to TPOJ1 and TPOJ2 and to the superior temporal visual area (STV) which in turn connects strongly with the nearby TPOJ regions. Further, PHT, lateral to the FFC, projects to TPOJ2.

The reward value is also an important semantic property of people, objects, places, etc, and this also can be incorporated into semantic representations by inputs to these semantic systems, especially Group 1, from the orbitofrontal cortex, ventromedial prefrontal cortex, and anterior cingulate cortex (Rolls et al., 2022b).

The temporal pole TG regions of the cortex are also likely to form multimodal ‘semantic’ representations, but primarily based on visual and auditory properties of objects, which is what are represented in the temporal lobes.

The ways in which inputs reach these semantic brain regions in the temporal lobes and temporo-parieto-occipital junction regions from different specialized areas, and the subtypes of sensory modality in which each part of the semantic system appears to specialize as described here in terms of connectivity, not only provides a connectomic basis for the semantic maps that can be visualized using natural speech as inputs (Huth et al., 2016), but also provides a connectional basis for understanding the many dissociations between syndromes found in neuropsychology, including phonological vs visual-based impairments of language processing. Indeed, the connectivity described here is consistent with evidence that the inferior parietal cortex is involved in language-based semantic processing and phonological operations (Coslett and Schwartz, 2018). In this context, it has been suggested that the parietal cortex is involved in the transcoding of sound-based representations into a format that can drive action systems (Coslett and Schwartz, 2018). Although there is much debate about how different language functions may map to different brain regions, one recent study tested patients with strokes in different brain regions, and found some evidence that damage to the posterior middle temporal gyrus is associated with syntactic comprehension deficits; that damage to the posterior inferior frontal gyrus is associated with expressive agrammatism; and that damage to the inferior angular gyrus is associated with semantic category word fluency

deficits (Matchin et al., 2022), consistent with a theoretical proposal (Matchin and Hickok, 2020; Hickok, 2022).

In another approach to brain regions involved in different aspects of language, the long-lasting effects of brain damage on different aspects of language have been described using voxel-based lesion-symptom mapping (VLSM) as follows (Dronkers et al., 2017; Baldo et al., 2018; Turken and Dronkers, 2011). Damage to the middle temporal gyrus (and its underlying white matter) results in difficulty in comprehending sentences, the symptoms of which are those of Wernicke's aphasia. Damage more anteriorly, to the superior temporal gyrus, produces morphosyntactic problems. Damage to the lateral part of BA 47 (the lateral part of the orbitofrontal cortex / inferior prefrontal convexity cortex where it adjoins 'Broca's area' region BA 45) produces complex morphosyntactic problems, for example with sentences such as 'The girl who the man chased'. (This region is likely to include 471 in the HCP-MMP1 parcellation which has connectivity with 45 and 44 and other language regions (Rolls et al., 2022b). This region is likely to be involved in setting up the grammatically appropriate positions of items in sentences.) A region in the posterior superior temporal sulcus BA39 extending up into parietal cortex is described as being involved in auditory memory, and not specifically in language.

14.3.4 Broca's area and related regions (TGv 44 45 471 SFL 55b)

The Group 2 language-related regions are indicated in bold italic font and are outlined in black in Fig. 14.3, and are: TGv 44 45 471 SFL 55b (Rolls et al., 2022b). Effective connectivity of region 45 is chosen as an example of the effective connectivity of a Group 2 region (Fig. 14.3). There is connectivity with the superior STS auditory-visual semantic stream (e.g. STSdp and STGa), with the inferior STS visual semantic stream (e.g. STSvp and TG), with the Peri Sylvian Language area and TPOJ1, with nearby inferior frontal gyrus regions 44, IFSp, 471 and 47s. Probable output regions for 45 include premotor 55b and the (supplementary area) Superior Frontal Language region (SFL). There is some effective connectivity too with the frontal pole, dorsolateral prefrontal 9a and 8BL.

The Group 2 regions and network are likely to be involved in speech processing (Rolls et al., 2022b). One region in Group 2 is 55b, which is situated in the premotor cortex sandwiched between the frontal eye fields FEF and PEF. 55b is likely to be an output region for 44 and 45, and it was proposed that it is involved in vocalization (Rolls et al., 2022b) given the importance of vocal cord control in speech production (Ekert et al., 2021b). Consistent with this proposal, it has now been found that 55b (a 'dorsal precentral speech area') codes voice pitch during vocalisation, and may be involved in the prosody of speech (Hickok et al., 2023). Similarly, the Superior Frontal Language area (SFL) also part of Group 2 may be a supplementary premotor cortical area involved in speech production. The involvement of 471 and 47s in the inferior frontal gyrus regions linked by effective connectivity with language systems is found here in the context of left hemisphere functions. These orbital parts of the language system may be involved in retrieving articulatory plans from semantic stimuli (i.e. semantic-to-articulatory recoding) (Ekert et al., 2021b). The left inferior frontal sulcus (IFS) regions found here to have connectivity with the Group 2 regions may be involved in similar functions (Ekert et al., 2021b). In the right hemisphere the corresponding 471 and 47s regions may be able to function more as lateral orbitofrontal areas involved in non-reward, punishment, and emotion, and consistent with this, functional connectivities and activations related to emotion computations are more prominent in the right hemisphere (Cheng et al., 2016a; Rolls et al., 2020a,b,e).

The connectivity of Broca's region (Rolls et al., 2022b) extends previous concepts about

Fig. 14.3 Effective connectivity of region 45 chosen as an example of the effective connectivity of a Group 2 language-related region. The Group 2 regions are indicated in bold italic font and are outlined in black, and are: TGv 44 45 47l SFL 55b. There is connectivity with the superior STS auditory-visual stream (e.g. STSdp and STGa), with the inferior STS visual stream (e.g. STSvp and TG), with the Peri Sylvian Language area and TPOJ1, with nearby inferior frontal gyrus regions 44, IFSp, 47l and 47s. Probable output regions for 45 include premotor 55b and the (supplementary area) Superior Frontal Language region (SFL). There is some effective connectivity too with the frontal pole, dorsolateral prefrontal 9a and 8BL. The widths of the lines and the size of the arrowheads indicate the magnitude and direction of the effective connectivity. The abbreviations are listed in Section 1.12. (From Rolls,E.T., Deco,G., Huang,C.-C. and Feng,J. (2022) The human language effective connectome. *Neuroimage* 258: 119352.)

Broca's area (Clos et al., 2013; Amunts and Zilles, 2012), by showing that there is a whole group of interconnected areas in the frontal lobe of the left hemisphere that are implicated in language, not only regions 44 and 45 in the HCP-MMP atlas (which may not correspond exactly to BA44 and BA45), but also IFSp and IFJa, and 47l and 47s. Similarly, the concept of a Wernicke's area involved in speech comprehension at the temporo-parietal junction is no longer accepted (DeWitt and Rauschecker, 2013; Binder, 2017), but the concept here is that there is a semantic system that extends from the temporal pole to PGi (and PF for body including somatosensory representations (Rolls et al., 2023d)) in the parietal lobe, which in the temporal lobe has an inferior more visual and object-related part (Group 1), and a more superior auditory/visual motion/somatosensory related part (Group 3). Region 45 has more effective connectivity with (especially anterior) STS regions than does region 44 (Rolls et al., 2023h). Parts of the supramarginal part of the parietal lobe (which include PF regions) are implicated in auditory short-term memory and articulatory sequencing (Oberhuber et al., 2016). Parts of the angular gyrus of the parietal lobe (which include PG regions) are implicated in semantic processing involved for example in comprehension when reading (Seghier et al., 2010). It should be noted that the inferior STS (Group 1) and superior STS (Group 3) temporal lobe semantic systems identified here by their connectivity do not correspond to the ventral and dorsal auditory pathways in which a ventral pathway is involved in 'what' and a dorsal pathway in 'where' or action processing (DeWitt and Rauschecker, 2013; Rauschecker, 2018b; Rauschecker and Scott, 2009; Tian et al., 2001; Archakov et al., 2020; Rolls et al., 2023h).

It is noted that Broca's area, BA44 and BA45, is no longer thought to be essential for speech production in terms of articulation as shown by the analysis of effects of damage to it (Gajardo-Vidal et al., 2021), but is implicated in some aspects of language, such as the timing of speech items (Long et al., 2016), and syntax as described next (Friederici et al., 2017; Flinker et al., 2015; Matchin and Hickok, 2020; Hickok, 2022).

The Group 2 network described here involving outputs from other language regions to areas 44, 45 and a closely connected inferior frontal gyrus region including IFJa and IFSp, and extending into left orbitofrontal 47s and 47l is suggested here to be involved in syntax (Rolls et al., 2022b), with the syntactic processing (Rolls and Deco, 2015a) being driven by semantic inputs from the Group 1 inferior STS temporal lobe visual object 'what' semantic network and the Group 3 superior STS temporal lobe visual motion / auditory / somatosensory semantic network. Consistent with this, there is evidence from neuroimaging and related neuropsychological studies that implicates area 44 in syntax processing, manipulating and detecting structures above the word level (Hertrich et al., 2020; Friederici et al., 2017). In more detail, area 44 is seen as the key region for syntactic processing by implementing the 'merge' operation that is key for understanding syntax (Friederici, Chomsky, Berwick, Moro and Bolhuis, 2017). Merge is an operation that takes exactly two (syntactic) elements – call them x and y – and puts them together to form the unordered set $\{x,y\}$ (Friederici et al., 2017). The elements x and y can be word-like building blocks that are drawn from the lexicon or previously constructed phrases that are assembled into an unbounded array of hierarchically structured internal representations (phrases and, ultimately, sentences) (Friederici, Chomsky, Berwick, Moro and Bolhuis, 2017). Merge is a recursive operation, but as analyzed by Treves and Rolls (1994), in the brain recurrent processing could be implemented by an equivalent series of linked networks. Area 45 is described as a lexical-semantic core area linking phonological codes to lexical meanings (Hertrich et al., 2020; Friederici et al., 2017).

From a study using direct cortical recordings during vocal repetition of written and spoken words, it was found that Broca's area mediates a cascade of activation from sensory representations of words in temporal cortex to their corresponding articulatory gestures in motor cortex, but is quiescent during articulation (Flinker, Korzeniewska, Shestyuk, Franaszczuk,

Dronkers, Knight and Crone, 2015). It was proposed that Broca's area does not participate in the production of individual words, but coordinates the transformation of information processing across large-scale cortical networks involved in spoken word production, prior to articulation. It has also been proposed that Broca's area is involved in lexical selection / sequencing (Hickok et al., 2023).

It has been remarked (Rolls et al., 2022b) that if neuroimaging studies could be mapped into a single atlas such as the HCP-MMP atlas using the tools that are available (Dickie et al., 2019; Glasser et al., 2016a; Huang et al., 2022), this would help in the development of our understanding of language systems, especially now that the connectivity between these language-related regions is becoming better understood, as described here.

14.4 Hypotheses about how semantic representations are computed

Object representations, such as those found in the inferior temporal visual cortex, enable an object or face to be identified, as described in Chapter 2. Semantic representations involve in addition information about all the attributes of an object, for example for a bicycle that it has two wheels, handlebars, a saddle, and usually but not always a chain, and just sometimes a second saddle, as described in Sections 8.3 and 14.2.4. Those attributes are part of what ventral stream processing helps to define. Further, I suggested in Section 14.2.6 that the angular gyrus area 39 provides semantic attributes derived from processing in the dorsal processing streams about for example actions performed by or on objects, that are also important in building semantic representations. For example, a property of a hammer is that it is to hit the head of a nail; and of the head of a nail that it is that part of the nail that is to be hit. An implication is that damage to the left parietal cortex would impair especially action-related attributes of objects; that damage to the left anterior temporal lobe cortex would impair especially use of the physical properties of objects such as their shape, color, odor, sound, tactile qualities etc as semantic descriptors; and that both types of descriptor would need to be connected to the left inferior frontal gyrus for syntactic processing to produce speech. Consistent with this hypothesis, in humans parietal areas such as the angular gyrus, as well as the anterior temporal lobe, have direct connections with the inferior frontal gyrus language-related areas as shown with diffusion tractography imaging (Hsu, Rolls, Huang, Chong, Lo, Feng and Lin, 2020), with the interactions evident with functional connectivity (Du, Rolls, Cheng, Li, Gong, Qiu and Feng, 2020).

The suggestion therefore is that to form a semantic representation, the individual object, person, etc needs to be associated with a set of attributes. The attributes of objects etc can be learned, at least to a considerable extent, by associative learning. The hypothesis is that this is implemented in the anterior temporal lobe, and may include information from the angular gyrus. A well-known connectionist model, interactive activation, that captures the operation of a semantic system with attributes associated with each individual, has been described (McClelland, 1981; McClelland et al., 1986), and was made available for tutorial use (McClelland and Rumelhart, 1989).

A model that illustrates such a system for semantic representations (Devereux, Clarke and Tyler, 2018) is now considered. The first part of the model involved an artificial deep convolutional neural network to categorise visual inputs. This was followed by an attractor network model of semantics, in which each visual object was associated with a set of attributes or 'semantic features'. There were 2,469 semantic attributes, such as 'has wheels', 'has skin/peel', 'is sweet', selected as appropriate to represent the 629 objects. The synaptic weights between

the object nodes and the semantic attribute nodes were trained using continuous recurrent back-propagation through time, in such a way that correct semantic features were produced when each object was presented. This type of learning is not biologically plausible, so this was an artificial model. The activity in the semantic part of the model was described as similar to fMRI activations that had been found in the perirhinal cortex (Devereux et al., 2018).

These interactive activation approaches to semantic representations do make the useful point that once an object has been recognised by for example the visual system, its semantic attributes then need to be learned.

14.5 A neurodynamical hypothesis about how syntax is computed

14.5.1 Binding by synchrony?

A fundamental computational issue is how the brain implements binding of elements such as features with the correct relationship between the elements. The problem in the context of language might arise if we have neuronal populations each firing to represent a subject, a verb, and an object of a sentence. If all we had were three populations of neurons firing, how would we know which was the subject, which the verb, and which the object? How would we know that the subject was related to the verb, and that the verb operated on the object? How these relations are encoded is part of the problem of binding.

Von der Malsburg (1990) considered this computational problem, and suggested a dynamical link architecture in which neuronal populations might be bound together temporarily by increased synaptic strength which brought them into temporary synchrony. This led to a great deal of research into whether arbitrary relinking of features in different combinations is implemented in visual cortical areas using synchrony (Singer, Gray, Engel, Konig, Artola and Brocher, 1990; Engel, Konig, Kreiter, Schillen and Singer, 1992; Singer and Gray, 1995; Singer, 1999; Abeles, 1991; Fries, 2009), and this has been modelled (Hummel and Biederman, 1992). However, although this approach could specify that two elements are bound, it does not specify the relation (Rolls, 2016b). For example, in vision, we might know that a triangle and a square are part of the same object because of synchrony between the neurons, but we would not know the spatial relation, for example whether the circle was inside the triangle, or above, below it, etc. Similarly for language, we might know that a subject and an object were part of the same sentence, but we would not know which was the subject and which the object, that the subject operated (via a verb) on the object, etc, that is, the syntactic relations would not be encoded just by synchrony. Indeed, neurophysiological recordings show that although synchrony can occur in a dynamical system such as the brain, synchrony *per se* between neurons in high order visual cortical areas conveys little information about which objects are being represented, with 95% of the information present in the number of spikes being emitted by each of the neurons in the population, i.e. a firing rate code (Rolls, 2016b; Rolls and Treves, 2011) (Appendix C).

Instead, in high order visual cortical areas, the spatial relations between features to form objects are implemented by feature combinations neurons (Chapter 2), and this feature/place coding scheme is computationally feasible (Elliffe, Rolls and Stringer, 2002) (Section 2.8.5). The spatial relations between objects are encoded by neurons that have spatially biased receptive fields relative to the fovea (Aggelopoulos and Rolls, 2005; Rolls, 2016b, 2012d). Further, temporal synchrony measured by coherence does not appear to be well suited for information transmission, for in quantitative neuronal network simulations, it is found that information

is transmitted between neuronal populations at much lower values of synaptic strength than those needed to achieve coherence (Rolls, Webb and Deco, 2012) (Section 2.8.5.1).

In this situation, I now make alternative proposals for how syntactic relations are encoded in the cortex, as described next (see Rolls and Deco (2015a)). Approaches used in neurolinguistics to syntax are described elsewhere (Kemmerer, 2015, 2019).

14.5.2 Syntax using a place code

The overview of encoding in the cortex in Appendix C (Rolls, 2016b; Rolls and Treves, 2011) leads to a hypothesis about how syntax, or the relations between the parts of a sentence, is encoded for language. My hypothesis is that a place code is used, with for example one cortical module or region used to represent subjects, another cortical module used to represent verbs, and another cortical module used to represent objects (see Rolls and Deco (2015a)).

The size of any such neocortical module need not be large. An attractor network in the cortex need occupy no more than a local cortical area perhaps 2–3 mm in diameter within which there are anatomically dense recurrent collateral associatively modifiable connections between the neurons (Rolls, 2016b). This cortical computational attractor network module would thus be about the size of a cortical column. It is an attractor network module in the sense that neurons more than a few mm away would not be sufficiently strongly activated to form part of the same attractor network (Rolls, 2016b). An attractor network of this type with sparse distributed representations can store and encode approximately as many items as there are synaptic connections onto each cortical neuron from the nearby neurons (Treves and Rolls, 1991; Rolls and Treves, 1998; Rolls, 2016b). The implication for language is that of order 10,000 nouns could be stored in a single cortical attractor network with 10,000 recurrent collateral connections on to each neuron. This capacity is only realized if there is only a low probability of more than one recurrent collateral connection between any pair of the neurons in a module, and this has been proposed as one of the underlying reasons for why cortical connectivity is diluted, with a probability in the order of 0.1 for connections between any pair of nearby neurons in the neocortex, and 0.02 for CA3 neurons in the rodent hippocampus (Rolls, 2012b).

The hypothesis is further that some local cortical modules encode the nouns that are the subjects of sentences, and that these are different from the cortical modules that encode the objects of sentences. A prediction is thus that there will be single neurons in a human cortical language area that respond to a noun when it is the subject but not the object of a sentence, and vice versa. Consistent with the hypothesis, evidence was found in an fMRI study that the agent (or actor, the subject of an active sentence) is localised separately from the patient (or object of an active sentence) in the left mid-superior temporal cortex (Frankland and Greene, 2015).

Clearly the full details of the system would be more complicated, but the general hypothesis is that adjectives and adjectival phrases that are related to the subject of a sentence will have strong connections to the subject module or modules; that adverbs and adverbial phrases that are related to the verbs of sentence will have strong connections to the verb module or modules; and that adjectives and adjectival phrases that are related to the object of a sentence will have strong connections to the object module or modules.

14.5.3 Temporal trajectories through a state space of attractors

To represent syntactical structure *within* the brain, what has been proposed already might be along lines that are consistent with the principles of cortical computation (Rolls, 2016b). The high representational capacity would be provided for by the high capacity of a local cortical

attractor network, and syntactic binding within a brain would be implemented by using a place code in which the syntactic role would be defined by which neurons are firing – for example, subjects in one cortical module or modules, and objects in another cortical module or modules.

However, a problem arises if we wish to communicate this representation to another person, for the neural implementation described so far could not be transferred to another person without transferring which neurons in the language areas were currently active, and having a well trained person as the decoder!

To transfer or communicate what is encoded in the representations to another person, and the relations or syntax, it is proposed that a number of mechanisms might be used. One might be a temporal order encoding, for example the subject–verb–object encoding that is usual in English, and which has the advantage of following the temporal order that usually underlies causality in the world. Another mechanism might be the use of inflections (usually suffixes) to words to indicate their place in the syntax, such as cases for nouns (e.g. nominative for the subject or agent, and accusative for the object or patient, dative, and genitive), and person for verbs (e.g. first, second, and third person singular and plural, to specify I, you, he/she/it, we, you, they) used to help disambiguate which noun or nouns operate on the verb. Another mechanism is the use of qualifying prepositions to indicate syntactic role of a temporally related word, with examples being ‘with’, ‘to’, and ‘from’. This mechanism is used in combination with temporal order in English.

In this Section, I focus on temporal order as an encoder of syntactical relations, and next set out hypotheses on how this could be implemented in the cerebral cortex based on the above computational neuroscience background (Rolls and Deco, 2015a).

14.5.4 Hypotheses about the implementation of language in the cerebral cortex

In what follows, the Deep Network models semantic representations in the anterior temporal lobe; and the Word network models syntactic operations in the inferior frontal gyrus.

1. Subjects, verbs, and objects are encoded using sparse distributed representations (Rolls, 2016b; Rolls and Treves, 2011) in localised cortical attractor networks. One cortical module with a diameter of 2–3 mm and 10,000 recurrent collateral connections per neuron could encode in the order of 10,000 items (e.g. subjects or verbs or objects) (Rolls, 2016b; Treves and Rolls, 1991) (Appendix B). One cortical module would thus be sufficient to encode all the objects, all the verbs, or all the objects (depending on the module) in most people’s working vocabulary, which is of the order to several thousand nouns, or verbs.

This follows from the analysis that the capacity of an attractor network with sparse encoding a (where for binary networks a is the proportion of neurons active for any one memory pattern) is as follows, and from the fact that there are in the order of 10,000 recurrent collateral connections on each neuron (Rolls, 2016b). The capacity is measured by the number of patterns p that can be stored and correctly retrieved from the attractor network

$$p \approx \frac{C}{a \ln(\frac{1}{a})} k \quad (14.1)$$

where C is the number of synapses on the dendrites of each neuron devoted to the recurrent collaterals from other neurons in the network, and k is a factor that depends weakly on the detailed structure of the rate distribution, on the connectivity pattern, etc., but is roughly in the order of 0.2–0.3 (Treves and Rolls, 1991; Rolls, 2016b, 2012b) (Appendix B).

The use of attractor networks for language-based functions is itself important. Cortical computation operates at the neuronal level by computing the similarity or dot product or correlation between an input vector of neuronal firing rates and the synaptic weights that connect the inputs to the neurons (Rolls, 2016b, 2012e) (Appendix B). The output of the neuron is a firing rate, usually between 0 and 100 spikes/s. Cortical computation at the neuronal level is thus largely analogue. This is inherently not well suited to language, in which precise, frequently apparently logical, rules are followed on symbolic representations. This gap may be bridged by attractor or autoassociation networks in the brain, which can enter discrete attractor high firing rate states that can provide for error correction in the analogue computation, and to the robustness to noise, that are often associated with the processing of discrete symbols (Treves, 2005; Rolls, 2016b, 2012e). These discrete attractor states are network properties, not the properties of single neurons, and this capability is at the heart of much cortical computation including long-term memory, short-term memory, and decision-making (Rolls, 2016b, 2014a), as elucidated in this book.

2. Place coding with sparse distributed representations is used in these attractors. The result is that the module that is active specifies the syntactic role of what is represented in it. One cortical module would be for subjects, another for verbs, another for objects, etc.

3. The presence of these weakly coupled attractors would enable linguistic operations of a certain type to be performed within the brain, but the information with the syntax could not be communicated in this form to other people. In this statement, ‘weakly coupled’ is clearly and quantitatively defined by attractors that have weak interconnections so that they can have different basins of attraction, yet can influence each other (Rolls, 2016b) (Section B.9). The computations involved in these interactions might instantiate a ‘language of thought’ that would be below the level of written or spoken speech, and would involve for example constraint satisfaction within coupled attractors, and the types of brain-style computation described by Rolls (2012e) (see Section 19.3 on brain computation vs computation in a digital computer). The cortical computational processes could be usefully influenced and made creative by the stochastic dynamics of neuronal networks in the brain that are due to the ‘noisy’ Poisson-like firing of neurons (Rolls, 2016b; Rolls and Deco, 2010). When someone has a hunch that they have solved a problem, this may be the computational system involved in the processing. This might be termed a ‘deep’ structure or layer of linguistic processing.

4. To enable these computations that involve syntactical relations to be communicated to another person or written down to be elaborated into an extended argument, the process considered is one involving weakly forward-coupled attractor networks. One such system would be to have weak forward coupling between subject–verb–object attractor networks. The exact trajectories followed (from subject to verb to object) could be set up during early language learning, by forming during such learning stronger forward than reverse connections between the attractors, by for example spike-timing dependent plasticity (Markram et al., 1997; Bi and Poo, 1998; Feldman, 2012) and experience with the order of items that is provided during language learning. Which trajectory was followed would be biased by which subject, which verb, and which object representation was currently active in the deep layer. These temporal trajectories through the word attractors would enable the syntactical relations to be encoded in the temporal order of the words.

With this relatively weak coupling between attractors implemented with integrate-and-fire neurons and low firing rates, the transition from one active attractor to the next can be relatively slow, taking 100–400 or more ms (Deco and Rolls, 2005c). This property of the system adapts it well to the production of speech, in which words are produced sequentially

with a spacing in the order of 300–500 ms, a rate that is influenced by the mechanics and therefore dynamics of the speech production muscles and apparatus.

A simulation testing this system and making the details of the operation of the system and their biological plausibility clear is described in the Methods and Results sections of Rolls and Deco (2015a).

5. The system for enabling the syntax to be communicated to other people or written down would have some computational advantages apart from purely the communication. In particular, once the syntax can be formally expressed in written statements, it becomes easier to perform logical operations on the statements, which become propositional, and can be tested. These logical operations, and reasoning, may not be the style of computation utilized in general by computational processes within the brain (see Rolls (2012e) Section 2.15), but may become algorithms that can be followed to achieve quantitatively precise and accurate results, as in long division, or by learning logic. Thus the importance of communication using syntax may allow other environmental tools to be applied to enable reasoning and logic that is not the natural style of neural computation (see Section 19.3).

6. To enable the system to produce words in the correct temporal order, and also to remember with a lower level of neuronal firing what has just been said for monitoring in case it needs correcting, a mechanism such as spike frequency adaptation may be used, as described next.

A property of cortical neurons is that they tend to adapt with repeated input (Abbott et al., 1997; Fuhrmann et al., 2002a). The mechanism is understood as follows. The afterpolarization (AHP) that follows the generation of a spike in a neuron is primarily mediated by two calcium-activated potassium currents, I_{AHP} and the sI_{AHP} (Sah and Faber, 2002), which are activated by calcium influx during action potentials. The I_{AHP} current is mediated by small conductance calcium-activated potassium (SK) channels, and its time course primarily follows cytosolic calcium, rising rapidly after action potentials and decaying with a time constant of 50 to several hundred milliseconds (Sah and Faber, 2002). In contrast, the kinetics of the sI_{AHP} are slower, exhibiting a distinct rising phase and decaying with a time constant of 1–2 s (Sah, 1996). A variety of neuromodulators, including acetylcholine (ACh) acting via a muscarinic receptor, noradrenaline, and glutamate acting via G-protein-coupled receptors, suppress the sI_{AHP} and thus reduce spike-frequency adaptation (Nicoll, 1988).

When recordings are made from single neurons operating in physiological conditions in the awake behaving monkey, peristimulus time histograms of inferior temporal cortex neurons to visual stimuli show only limited adaptation. There is typically an onset of the neuronal response at 80–100 ms after the stimulus, followed within 50 ms by the highest firing rate. There is after that some reduction in the firing rate, but the firing rate is still typically more than half-maximal 500 ms later (see example in Tovee, Rolls, Treves and Bellis (1993); Fig. 2.16). Thus under normal physiological conditions, firing rate adaptation can occur.

This adaptation can be studied by including a time-varying intrinsic (potassium-like) conductance in the cell membrane (Brown, Gähwiler, Griffith and Halliwell, 1990a; Treves, 1993; Rolls, 2016b). This can be done by specifying that this conductance, which if open tends to shunt the membrane and thus to prevent firing, opens by a fixed amount with the potential excursion associated with each spike, and then relaxes exponentially to its closed state. In this manner sustained firing driven by a constant input current occurs at lower rates after the first few spikes, in a way similar, if the relevant parameters are set appropriately, to the behavior observed in vitro of many pyramidal cells (for example, Lanthorn, Storm and Andersen (1984), Mason and Larkman (1990)). The details of the implementation used are described by Rolls and Deco (2015a).

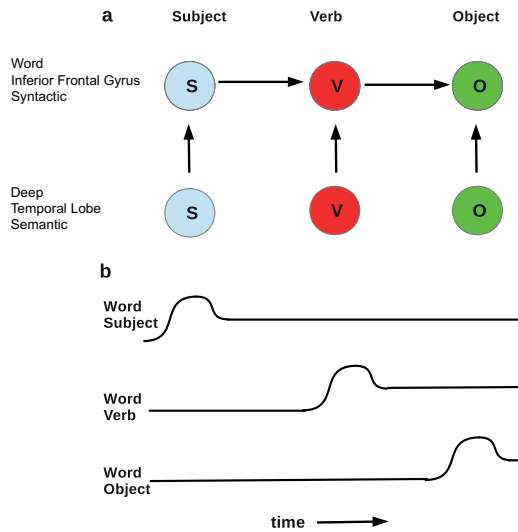

Fig. 14.4 Schematic diagram of a model of syntactic processing. a. Each circle indicates a local cortical attractor network capable of storing 10,000 items. The Deep layer local cortical attractor networks use place coding to encode the syntactic role of the semantic representation in the Deep layer. That is, the syntactic role of each attractor network for semantic representations uses a place code to define its syntactic role. The possible syntactic roles are Subject (S), Verb (V), and Object (O). The deep layer nodes model semantic representations in the anterior temporal lobe. In this implementation there are separate Subject (S), Verb (V), and Object (O) syntactic networks in the inferior frontal gyrus, labelled 'Word'. Syntax within the brain is implemented by place encoding. For communication, the deep representation must be converted into a sequence of words. To implement this, the Deep attractor networks provide a weak selective bias to the Word attractor networks, which have weak non-selective forward coupling S to V to O. b. The operation in time of the system. The Deep networks fire continuously, and the syntax is implemented using place encoding. The Deep networks apply a weak selective bias to the Word networks, which is insufficient to make a word attractor fire, but is sufficiently strong to bias it later into the correct one of its 10,000 possible attractor states, each corresponding to a word. Sentence production is started by a small extra input to the Subject Word network. This with the selective bias from the Deep subject network make the Word subject network fall into an attractor, the peak firing of which is sufficient to elicit production of the subject word. Adaptation in the subject network makes its firing rate decrease, but still remain in a moderate firing rate attractor state to provide a short-term memory for the words uttered in a sentence, in case they need to be corrected or repeated. The high and moderate firing rate in the Subject Word network provides non-selective forward bias to the whole of the Object Word network, which falls into a particular attractor produced by the selective bias from the Deep Verb network, and the verb is uttered. Similar processes then lead to the correct object being uttered next. The sentence can be seen as a trajectory through a high dimensional state space of words in which the particular words in the sentence are due to the selective bias from the Deep networks, and the temporal order is determined by the weak forward non-selective connections between the networks, i.e. connections from subject-to-verb, and verb-to-object networks. The simulations show dynamical network principles by which this type of sentence encoding and also decoding could be implemented. The overall concept is that syntax within the brain can be solved by the place coding used in most other representations in the brain; and that the problems with syntax arise when this place-coded information must be transmitted to another individual, when one solution is to encode the role in syntax of a word by its temporal order in a sentence. (After Rolls, E. T. and Deco, G. (2015) Networks for memory, perception, and decision-making, and beyond to how the syntax for language might be implemented in the brain. *Brain Research* 1621: 316–334. © Elsevier B.V.)

14.5.5 Tests of the hypotheses – a model

14.5.5.1 An integrate-and-fire network with three attractor network modules connected by stronger forward than backward connections

The computational neuroscience aspects of the hypotheses described above were investigated with an integrate-and-fire network with three attractor network modules connected by stronger forward than backward connections, the operation of which is illustrated conceptually in Figs. 14.4 and 14.5, and the architecture of which is illustrated in Fig. 14.6. Each module is an integrate-and-fire attractor network with n possible attractor states. For the simulations described (Rolls and Deco, 2015a) there were $n=10$ orthogonal attractor states in

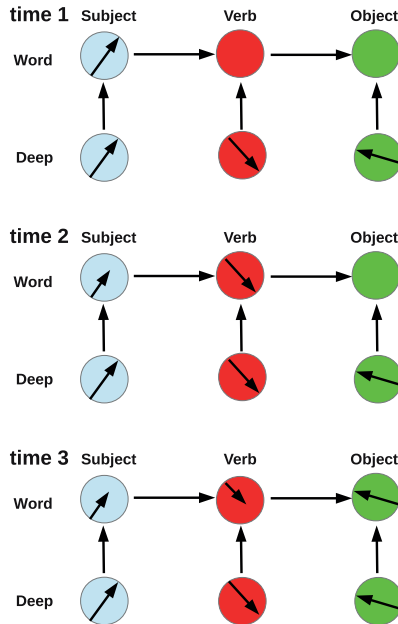

Fig. 14.5 A model of syntactic processing. The operation of the model, illustrated at three different time steps. Time 1 is during the production of the subject word, time 2 during the verb word, and time 3 during the object word. Each circle represents an attractor network that can fall into one of 10,000 possible states indicated by the direction of the arrow vector, each state corresponding to a word (for the Word-level networks) or a semantic concept (for the Deep-level networks). The length of the arrow vector indicates the firing rate of the selected attractor. The Deep attractor networks fire continuously, with the syntactic role indicated by the particular network using place coding. The Deep networks, which represent semantics or meaning, provide a weak selective bias continuously to the Word attractor networks. The sequential operation of the Subject then Verb then Object Word networks is produced by the weak non-selective forward connections between the networks. After its initial high firing rate, a Word attractor network remains active at a lower firing rate as a result of adaptation, to provide a short-term memory for the words uttered in a sentence, in case they need to be corrected or repeated. (After Rolls, E. T. and Deco, G. (2015) Networks for memory, perception, and decision-making, and beyond to how the syntax for language might be implemented in the brain. *Brain Research* 1621: 316–334. © Elsevier B.V.)

each module, each implemented by a population of neurons with strong excitatory connections between the neurons with value $w_+ = 2.1$ for the NMDA and AMPA synapses. There were $N = 8000$ neurons in each module, of which 0.8 (i.e. 6400) were excitatory, and 1600 were inhibitory. The first module could represent one of 10 subjects (S), the second module one of 10 verbs (V), and the third module one of 10 objects (O). In the cerebral cortex, each module might be expected to be able to encode up to 10,000 items using sparse distributed representations, and assuming of order 10,000 excitatory recurrent collateral connection onto each neuron (Treves and Rolls, 1991, 1994; Rolls, 2016b). The parameters in each module were set so that the spontaneous firing state with no input applied was stable, and so that only one of its n possible attractor states was active at any time when inputs were applied (Rolls, 2016b; Rolls and Deco, 2010; Deco, Rolls, Albantakis and Romo, 2013).

In the model, there are forward connections from all excitatory neurons in one module to all excitatory neurons in the next module, with uniform strength w_{ff} . The role of these forward connections is to produce some non-specific input to the next module of the network when the previous module enters an attractor state with one of its neuronal pools. The role of this forward input is to encourage the next module in the series to start firing with some small delay after the previous module, to enable a temporal trajectory through a state space of an active attractor pool in one module to an active attractor pool in the next module. In the cerebral cortex, there are typically both stronger forward than backward connections between modules in different cortical areas, and connections in both directions between modules in

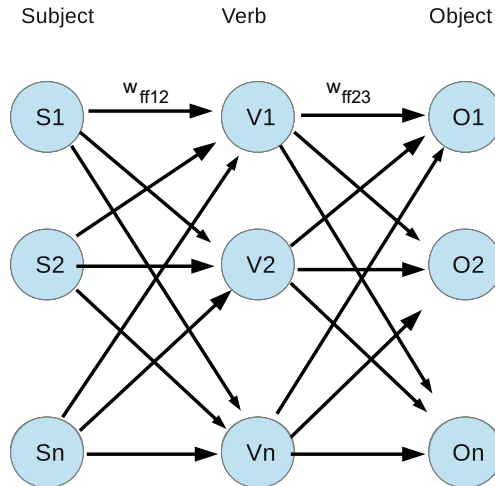

Fig. 14.6 The attractor network model of syntactic processing. There are three Word-level modules, Subject (S), Verb (V), and Object (O). Each module is a fully connected attractor network with $n=10$ pools of excitatory neurons. The ten excitatory pools each have 640 excitatory neurons, and each module has 1600 inhibitory neurons using GABA as the transmitter. Each excitatory pool has recurrent connections with strength $w_{+}=2.1$ to other neurons in the same pool implemented with AMPA and NMDA receptors. There are forward connections with strength w_{ff12} from all excitatory neurons in module 1 (S) to all excitatory neurons in module 2 (V). There are forward connections with strength w_{ff23} from all excitatory neurons in module 2 (V) to all excitatory neurons in module 3 (O). An external bias from a deep, semantic, temporal lobe, pool can be applied to any one or more of the Word-level attractor pools in each of the modules. In operation for production, a stronger bias is applied to one pool in module 1 to start the process, and then an attractor emerges sequentially in time in each of the following modules. The particular Word-level pool that emerges in each of the later modules depends on which pool in that module is receiving a weak bias from the Deep, semantic, temporal lobe, structure that selects the semantic items to be included in a sentence. The syntax of the sentence, encoded in the order of the items, is determined by the connectivity and dynamics of the Word-level network shown in this figure. The same network can be used for decoding (see text). (After Rolls, E. T. and Deco, G. (2015) Networks for memory, perception, and decision-making, and beyond to how the syntax for language might be implemented in the brain. *Brain Research* 1621: 316–334. © Elsevier B.V.)

the same cortical area (Rolls, 2016b). In the latter case, the hypothesis is that the stronger connections in one direction than the reverse between nearby modules might be set up by spike-timing dependent plasticity (Markram et al., 1997; Bi and Poo, 1998; Feldman, 2012) based on the temporal order in which the relevant modules were normally activated during a stage when a language was being learned. For the simulations, only weak forward connections were implemented for simplicity.

During operation, one attractor pool in each module receives a continuous bias throughout a trial from a Deep network (see Figs. 14.4 and 14.5). The Deep Network models semantic representations in the anterior temporal lobe. The Word network models syntactic operations in the inferior frontal gyrus. For example the Subject Word module might receive bias from a Deep attractor pool representing ‘James’, the Verb Word module might receive bias from an attractor pool representing ‘chased’, and the Object Word module might receive bias from an attractor pool representing ‘John’. These biases would represent the deep structure of the sentence, what it is intended to say, but not the generation of the sentence, which is the function of the network shown in Fig. 14.6. The biases in all the modules apart from the first are insufficient to push any attractor pool in a Word module into an attractor state. In the first (or head) Word module, the bias is sufficiently strong to make the attractor pool being biased enter a high firing rate attractor state. The concept is that because of the forward connections to all neurons in the second (Verb Word) module, the attractor pool in the second module receiving a steady bias from the Deep, Verb, pool (in our example, the ‘chased’ pool) then has sufficient input for it to gradually enter an attractor. The same process is then repeated for the biased attractor in Word module 3 which is being biased by the Deep, semantic, temporal

lobe, Object pool, which then enters a high firing rate state. Due to the slow stochastic dynamics of the network, there are delays between the firing in each of the Word modules. It is this that provides the sequentiality to the process that generates the words in the sentence in the correct order.

In addition, a concept of the cortical dynamics of this system is that each module should maintain a level of continuing firing in its winning attractor for the remainder of the sentence, and even for a few seconds afterwards. The purpose of this is to enable correction of the process (by for example a higher order thought or monitoring process, see Rolls (2014a) and Rolls (2020a)) if the process needs to be corrected. The maintenance of the attractors in a continuing state of firing enables monitoring of exactly which attractors did occur in the trajectory through the state space, in case there was a slip of the tongue. (Indeed, ‘slips of the tongue’ or speech production errors are accounted for in this framework by the somewhat noisy trajectory through the state space that is likely to occur because of the close to Poisson spiking times of the neurons for a given mean rate, which introduces noise into the system (Rolls, 2016b; Rolls and Deco, 2010; Rolls, 2014a)). The main parameters of each module that enable this to be achieved are w_+ , and the external bias entering each attractor pool.

However, although it is desired to have a short-term memory trace of previous activity during and for a short time after a sentence, it is also important that each word is uttered at its correct time in the sentence, for this carries the syntactic relations in this system. To achieve the production of the word at the correct time, the firing of each attractor has a mechanism to produce high firing initially for perhaps 200–300 ms, and then lower firing later to maintain an active memory trace of previous neuronal activity. The mechanism used to achieve this initial high firing when a neuronal pool enters a high firing rate state, was spike frequency adaptation, and which has been implemented and utilized previously (Liu and Wang, 2001; Deco and Rolls, 2005c; Rolls and Deco, 2015a).

14.5.5.2 The operation of a single attractor network module

The aim is to investigate the operation of the system in a biophysically realistic attractor framework, so that the properties of receptors, synaptic currents and the statistical effects related to the probabilistic spiking of the neurons can be part of the model. We use a minimal architecture, a single attractor or autoassociation network (Hopfield, 1982; Amit, 1989; Hertz et al., 1991; Rolls and Treves, 1998; Rolls and Deco, 2002; Rolls, 2016b) for each module. A recurrent (attractor) integrate-and-fire network model which includes synaptic channels for AMPA, NMDA and GABA_A receptors (Brunel and Wang, 2001; Rolls and Deco, 2010) was used.

Each Word attractor network contains 6400 excitatory, and 1600 inhibitory neurons, which is consistent with the observed proportions of pyramidal cells and interneurons in the cerebral cortex (Abeles, 1991; Braitenberg and Schüz, 1991). The connection strengths are adjusted using mean-field analysis (Brunel and Wang, 2001; Deco and Rolls, 2006; Rolls and Deco, 2010), so that the excitatory and inhibitory neurons exhibit a spontaneous activity of 3 Hz and 9 Hz, respectively (Wilson et al., 1994b; Koch and Fuster, 1989). The recurrent excitation mediated by the AMPA and NMDA receptors is dominated by the NMDA current to avoid instabilities during delay periods (Wang, 2002).

The architecture of the Word-level cortical attractor network module illustrated in Fig. 14.7 has 10 selective pools each with 640 neurons. The connection weights between the neurons within each pool or population are called the intra-pool connection strengths w_+ , which were set to 2.1 for the simulations described. All other weights including w_{inh} were set to 1.

All the excitatory neurons in each Word-level attractor pool S1, S2 ... SN receive an external bias input $\lambda_1, \lambda_2 \dots \lambda_N$. This external input consists of Poisson external input spikes via AMPA receptors which are envisioned to originate from 800 external neurons. One com-

Fig. 14.7 A model of syntactic processing. The architecture of one Word-level module containing one fully connected attractor network. The excitatory neurons are divided into $N=10$ selective pools or neuronal populations $S1-SN$ of which three are shown, $S1$, $S2$ and SN . The synaptic connections have strengths that are consistent with associative learning. In particular, there are strong intra-pool connection strengths w_+ . The excitatory neurons receive inputs from the inhibitory neurons with synaptic connection strength $w_{inh}=1$. The other connection strengths are 1. The integrate-and-fire spiking module contained 8000 neurons, with 640 in each of the 10 non-overlapping excitatory pools, and 1600 in the inhibitory pool IH. Each neuron in the network receives external Poisson inputs λ from 800 external neurons at a typical rate of 3 Hz/synapse to simulate the effect of inputs coming from Deep, semantic, pools. The biasing inputs remain constant during the operation of the whole network to produce an ordered Word-level output sequence. The Word-level module illustrated is similar for the Subject, Verb, and Object Word-level modules. (After Rolls, E. T. and Deco, G. (2015) Networks for memory, perception, and decision-making, and beyond to how the syntax for language might be implemented in the brain. *Brain Research* 1621: 316–334. © Elsevier B.V.)

ponent of this bias which is present by default arrives at an average spontaneous firing rate of 3 Hz from each external neuron onto each of the 800 synapses for external inputs, consistent with the spontaneous activity observed in the cerebral cortex (Wilson et al., 1994b; Rolls and Treves, 1998; Rolls, 2016b). The second component is a selective bias from a deep structure system which provides a bias present throughout a trial to one of the attractor pools in each module, corresponding to the subject, verb, or object (depending on the module) to be used in the sentence being generated. This bias makes it more likely that the attractor pool will become active if there are other inputs, but is not sufficiently strong (except in the first module) to initiate a high firing rate attractor state. (This selective bias might be set up by associative synaptic modification between the Deep and the Word modules.) In addition, all excitatory neurons in a module receive inputs with a uniform synaptic strength of w_{ff} from all the excitatory neurons in the preceding module, as illustrated in Fig. 14.6.

Both excitatory and inhibitory neurons are represented by a leaky integrate-and-fire model (Tuckwell, 1988). The basic state variable of a single model neuron is the membrane potential. It decays in time when the neurons receive no synaptic input down to a resting potential. When synaptic input causes the membrane potential to reach a threshold, a spike is emitted and the neuron is set to the reset potential at which it is kept for the refractory period. The emitted action potential is propagated to the other neurons in the network. The excitatory neurons transmit their action potentials via the glutamatergic receptors AMPA and NMDA which are both modeled by their effect in producing exponentially decaying currents in the postsynaptic neuron. The rise time of the AMPA current is neglected, because it is typically very short. The NMDA channel is modeled with an alpha function including both a rise and a decay term. In addition, the synaptic function of the NMDA current includes a voltage dependence controlled by the extracellular magnesium concentration (Jahr and Stevens, 1990). The inhibitory postsynaptic potential is mediated by a $GABA_A$ receptor model and is described by a decay term. A detailed mathematical description is provided by Rolls and Deco (2015a).

Fig. 14.8 A model of syntactic processing. Firing rates of the biased pools in the Subject–Verb–Object modules as a function of time. (After Rolls, E. T. and Deco, G. (2015) Networks for memory, perception, and decision-making, and beyond to how the syntax for language might be implemented in the brain. *Brain Research* 1621: 316–334. © Elsevier B.V.)

14.5.5.3 Spike frequency adaptation mechanism

A specific implementation of the spike-frequency adaptation mechanism using Ca^{2+} -activated K^+ hyper-polarizing currents (Liu and Wang, 2001) was implemented. Its parameters were chosen to produce spike frequency adaptation similar in timecourse to that found in the inferior temporal visual cortex of the behaving macaque (Tovee, Rolls, Treves and Bellis, 1993) (Fig. 2.16). In particular, $[\text{Ca}^{2+}]$ is initially set to be $0 \mu\text{M}$, $\tau_{\text{Ca}} = 300 \text{ ms}$, $\alpha = 0.002$, $V_K = -80 \text{ mV}$ and $g_{\text{AHP}} = 200 \text{ nS}$. (I note that there are a number of other biological mechanisms that might implement the slow transitions from one attractor state to another, some investigated by Deco and Rolls (2005c), and that we use the spike frequency adaptation mechanism to illustrate the principles of operation of the networks.)

14.5.6 Tests of the hypotheses – findings with the model

14.5.6.1 A production system

The operation of the integrate-and-fire system illustrated in Fig. 14.6 is shown in Fig. 14.8 when it is producing a subject – verb – object sequence. The firing rates of attractor pools 1 in Word modules 1 (subject), 2 (verb), and 3 (object) are shown. No other pool had any increase of its firing rate above baseline. The attractor pools 1 in modules 2 and 3 received an increase above the baseline rate of $3.00 \text{ Hz per synapse}$ (or $2400 \text{ spikes/s per neuron}$ given that each neuron receives these inputs through 800 synapses) to $3.03 \text{ Hz per synapse}$ throughout the trial. This itself was insufficient to move any attractor pool in modules 2 and 3 into a high firing rate state, as illustrated, until one of the attractor pools in a preceding module had entered a high firing rate attractor state. At time = 500 ms, the external input into attractor pool 1 of module 1 (subject) was increased to $3.20 \text{ Hz per synapse}$, and maintained at this value for the rest of the trial. This produced after a little delay due to the stochastic recurrent dynamics an increase in the firing of pool 1 in module 1, which peaked at approximately 1000 ms. The initial peak firing rate of approximately 40 spikes/s was followed by a reduction due to the spike frequency adaptation to approximately 25 spikes/s, and this level was maintained for the remainder of the trial, as shown in Fig. 14.8. The parameters for the spike frequency adaptation for all the excitatory neurons in the network were $V_K = -80 \text{ mV}$, $g_{\text{AHP}} = 200 \text{ nS}$, $\alpha_{\text{Ca}} = 0.002$, and $\tau_{\text{Ca}} = 300 \text{ ms}$.

The increase in the firing in attractor pool 1 of module 1 influenced the neurons in module 2 via the feedforward synaptic strength of $w_{\text{ff}12} = 0.55$, and, because attractor pool 1 in module 2 already had a weak external bias from the Deep, semantic, Verb level to help it be selected, it was attractor pool 1 in module 2 that increased its firing, with the peak rate occurring

at approximately 1250 ms, as shown in Fig. 14.8. Again, the peak was followed by low maintained firing in this pool for the remainder of the trial.

The increase in the firing in attractor pool 1 of module 2 influenced the neurons in module 3 via the feedforward synaptic strength of $w_{ff23}=0.4$, and, because attractor pool 1 in module 3 already had a weak external bias from the Deep, semantic, object pool to help it be selected, it was attractor pool 1 in module 3 that increased its firing, with the peak rate occurring at approximately 1650 ms, as shown in Fig. 14.8. Again, the peak was followed by low maintained firing in this pool for the remainder of the trial. The value of w_{ff23} was optimally a little lower than that of w_{ff12} , probably because with the parameters used the firing in module 2 was somewhat higher than that in module 1. All subsequent stages would be expected to operate with $w_{ff}=0.4$.

The network thus shows that the whole system can reliably perform a trajectory that is sequential and delayed at each step through the state space, with the item selected in each module determined by the steady bias being received from a deep structure containing the semantic items to be included in the sentence. However, the order in which the items were produced and which specified the syntax was determined by the connectivity and dynamics of the Word network. In this particular example, the resulting sentence might correspond to ‘James chased John’, which has a completely different syntax and meaning to ‘John chased James’, ‘chased John James’, etc. The peak of firing in each module could be used to produce the appropriate word in the correct order. The lower rate of ongoing firing in each module provided the basis for the items produced in the sentence to be remembered and used for monitoring, with the role of each item in the sentence made explicit by the module in which the attractor pool was still active.

14.5.6.2 A decoding system

In Section 14.5.6.1 the operation of the system when it is operating to produce a subject–verb–object sequence in which the temporal sequence encodes syntactic information is described. In this section, the operation of the system when it decodes a Subject–Verb–Object sentence is considered. The aim is to receive as input the temporal sequence, and to activate the correct attractor in the Subject, Verb, and Object Word attractor modules. The syntactic information in the sequence allows correct decoding of the subject and object nouns in the sentence, when the position in the sequence is the only information that enables a noun to activate a noun attractor in the subject or the object module. The deep semantic attractor modules could then be activated from the Word attractor modules, using selective, associatively modifiable, synaptic connections.

The operation of the system in decoding mode is illustrated in Fig. 14.9. The architecture of the network is the same as that already described. The baseline input to each of the 800 external synapses is maintained at 3 Hz per synapse in all pools in all modules throughout the sentence except where stated. Throughout the trial all pools in module 1 receive a bias of 0.24 Hz on each of the 800 external input synapses. (This corresponds to an extra 192 spikes/s received by every neuron in each of attractor pools.) The aim of this is to prepare all the attractors in module 1, the subject attractor, to respond if an input cue, a word, is received. This bias essentially sets the system into a mode where it is waiting for an input stream to arrive in module 1. All the attractors in module 1 are stable with low firing rates while only this bias is being applied.

At time 500–1000 ms module 1 pool 1 and module 3 pool 1 receive a noun recall cue as an additional input on the external synapses at an additional 0.08 Hz per synapse. (This corresponds to an extra 64 spikes/s received by every neuron in these two pools of neurons.) Module 1 pool 1 goes into an attractor, as illustrated in Fig. 14.9, because it is receiving a noun recall cue and the bias. Module 3 pool 1 does not enter a high firing rate attractor state,

Fig. 14.9 A model of syntactic processing. Decoding the Subject–Verb–Object sequence to produce activation in the Subject (module 1), Verb (module 2), and Object (module 3) modules. A weak bias was applied to all pools in module 1 throughout the trial (see text). Noun 1, the subject, was applied to module 1 pool 1 and module 3 pool 1 during the period 500–1000 ms. Verb 2, was applied to module 2 pool 2 during the period 1000–1500 ms. Noun 3, the object, was applied to module 1 pool 3 and module 3 pool 3 during the period 1500–2000 ms. The firing of module 1 attractor 1 neurons that reflect the decoded subject, of module 2 attractor 2 neurons that reflect the decoded verb, and of module 3 attractor 3 neurons that reflect the decoded object, are shown. None of the other 30 attractor neural populations became active. (After Rolls, E. T. and Deco, G. (2015) Networks for memory, perception, and decision-making, and beyond to how the syntax for language might be implemented in the brain. *Brain Research* 1621: 316–334. © Elsevier B.V.)

even though the word recall cue for its attractor 1 is being applied, because it is not receiving a bias. This shows how the system can decode correctly a noun due to its position in the sequence as a subject or as an object. In the simulations the bias to pool 1 can be left on, or turned off at this stage in the trial, for once an attractor state has been reached by a pool in module 1, it remains with a stable high firing rate for the remainder of the sentence. The continuing firing is implemented to ensure that the subject remains decoded in the system while the rest of the sentence is decoded, and for use even after the end of the sentence. At time 1000 ms, the noun applied to attractor pools 1 in modules 1 and 3 is removed, as it is no longer present in the environment.

At time 1000–1500 ms the verb recall cue is applied to module 2 pool 2, which enters an attractor. The strength of this recall cue alone (the same as before, an additional 0.08 Hz per synapse) is insufficient to cause this pool in module 2 to enter an attractor. However, all pools in module 2 are receiving now via the feed-forward connections w_{ff12} a priming input from the firing now occurring in module 1, and when the verb recall cue is applied to module 2 pool 2, the combined effects of the recall cue and the feedforward inputs cause module 2 pool 2 to enter its correct attractor state to indicate the presence of this verb in the sentence. The intention of the priming forward input from the preceding module is to provide for future expansion of the system, to allow for example correct decoding of two verbs at different positions within the sequence of words in a sentence. Module 2 pool 2 has the Verb recall cue removed at time 1500 ms as it is no longer present in the environment. Module 2 pool 2 however keeps firing in its stable high firing rate attractor state to ensure that the verb remains decoded in the system while the rest of the sentence is decoded, and for use even after the end of the sentence.

At time 1500–2000 ms the object recall cue is applied to module 3 pool 3, and, as a control and test of the syntactic operation of the system, simultaneously also to module 1 pool 3. Module 3 pool 3 enters its correct object attractor, utilising the feedforward priming inputs w_{ff23} . These priming inputs again provide for further expansion of the system, in case there is another object in the sentence in a later clause. Meanwhile module 1 remains in

its pool 1 subject attractor state which is now stable in the face of interfering noun inputs because of its deep low energy basin of attraction. This shows how this noun is forced by its order in the sequence into the Object pool, demonstrating how the system is able to decode information about syntactic role that is present from the position of the item in the sequence. Module 3 pool 3 keeps firing in its stable high firing rate attractor state to ensure that the object remains decoded in the system for use even after the end of the sentence.

As noted, the architecture and overall dynamical principles of operation of the system used for decoding were the same as for encoding. The firing rate adaption was left to operate as before, though it is less useful for the decoding. The only parameters that were adjusted a little for the decoding system were $w_+ = 2.3$ (to help stability of the high firing rate attractor state in the face of for example interfering nouns); $w_{ff12} = w_{ff23} = 0.2$; bias for all pools in module 1 = 0.24 Hz per synapse; and recall cue = 0.08 Hz per synapse.

The results just described and illustrated in Fig. 14.9 illustrate some of the principles of operation of the functional architecture when decoding sentences. Further results were as follows. If during the application of the noun for the subject (time 500–1000 ms in the simulations) an input effective for an attractor in module 2 was also applied, then a pool in module 2 tends to enter a high firing rate attractor state, for it is receiving both a recall cue and the forward bias from the high firing starting in module 1 and applied to module 2 via w_{ff12} . An implication is that only nouns should be applied to Subject and Object attractor modules. Having attractors for verbs that respond to different recall cues (words that are verbs) helps the system to decode the input stream into the correct modules and pools. Thus the semantics, the words being applied to the network, are important in enabling the system to respond correctly.

14.5.7 Evaluation of the hypotheses

The system described here shows how a word production system might operate using neuronal architecture of the type found in the cerebral cortex.

One possible objection to such a computational implementation is how to deal with the passive form. What I propose is that temporal order could again be used, but with different coupling between the attractors appropriate for implementing the passive voice that is again learned by early experience, and is selected instead of the active voice by top-down bias in the general way that we have described elsewhere (Deco and Rolls, 2003, 2005d). The hypothesis is thus that operation of the system for passive sentences would require a different set of connections to be used to generate the correct temporal trajectory through these or possible different modules, with the head of the sentence no longer being (in English) the subject (e.g. James in ‘James chased John’), but instead the object (e.g. ‘John was chased by James’).

In a similar way, it is proposed that different languages are implemented by different forward connectivity between the different modules representing subjects, verbs, and objects in that language, with the connectivity for each language learned by repeated experience and forced trajectories during learning using for example spike-timing-dependent plasticity. Separate neuronal implementation of different languages is consistent with neurological evidence that after brain damage one language but not another may be impaired.

The system would require considerable elaboration to provide for adjectives and adjectival phrases qualifying the subject or the object, and for adverbs or adverbial phrases qualifying the verbs, but a possible principle is stronger synaptic connectivity between the modules in which the qualifiers are represented. To be specific, one type of implementation might have adjectives in modules that qualify subjects connected with relatively stronger synapses to subject modules than to object modules. This should be feasible given that any one attractor

network capable of encoding thousands of words need occupy only 2–3 mm of neocortical area.

In such a system, the problem does arise of how the nouns in the subject attractor module can refer to the same object in the word as the nouns in the object attractor, and of the extent to which when one representation (e.g. in the subject module) is updated by modifying its properties (encoded by which neurons are active in the sparse distributed representation within a module), the representation of the same object in another module (e.g. in the object module) is updated to correspond.

The results on the operation of the system when it is decoding a sentence illustrated in Fig. 14.9 illustrate how the temporal sequence of the words can be used to place them into the appropriate module, for example to place a noun into a subject or an object module. Interestingly, if during the application of the noun for the subject (time 500–1000 ms in the simulations) an input effective for an attractor in module 2 (the verb module) was also applied, then a pool in module 2 tended to enter a high firing rate attractor state, for it was receiving both a recall cue and the forward bias from the high firing starting in module 1 and applied to module 2 via w_{ff12} . An implication is that only nouns should be applied to Subject and Object attractors. Having attractors for verbs that respond to different input cue (words that are verbs) helps the system to decode the input stream into the correct modules and pools. Thus the semantics, the words being applied to the network, are important in enabling the system to respond correctly.

Indeed, overall the system might be thought of as having different modules and pools for different types of word (subject noun, object noun, verb, adverb, adjective, etc) and using the match of the incoming word to the word defined in a module to provide an important cue to which module should have an attractor activated, and then adding to this the temporal sequence sensitivity also considered here to help disambiguate the syntax, for example whether a noun is a subject or an object. Thus the semantics, the word as a noun, verb, or potentially adjective or adverb, help the dynamics because the cue details (adverb, noun, verb, adjective etc) provides constraints on the trajectories and dynamics of the system, and thus on how it decodes input sequences.

Language would thus be brittle if there were not subject-noun, object-noun, verb, adjective, adverb etc pools. It is proposed that the inflections in an inflected language help words to activate the correct pools. For example, if an inflection was present in a word that indicated it was the subject of the sentence, then the inflection suffix acting as a bias on the Word-level Subject attractor network could encourage the Subject attractor network to be activated by and enter an attractor state for that word. If inflections are lost or not present in a language, then the order in a sequence can compensate to some extent, but the system still relies on the words activating selective pools, with the temporal dynamics used for example to disambiguate matters if a noun might otherwise be a subject or an object, or an adjective might qualify a subject vs an object, etc. Moreover, because language is often irregular, particular words must also favour particular dynamics / relations.

In such a stochastic dynamical system (Rolls, 2016b; Rolls and Deco, 2010), speech or writing errors such as words appearing in the incorrect order, word substitution, and repetition of the same word, could be easily accounted for by failures in the stochastically influenced (Rolls, 2016b; Rolls and Deco, 2010) transitions from one attractor to the next, and in the word selected in each attractor. This supports the proposed account of the cortical implementation of language.

Overall, in this Section the coding and dynamical principles of the operation of the cerebral cortex have been considered in the context of how they may be relevant to the implementation of language in the cerebral cortex. It has been proposed that the high capacity of local attractor networks in the neocortex would provide a useful substrate for representations

of words with different syntactical roles, for example subject noun, object noun, adjective modifying a subject, adjective modifying an object, verb, and adverb. With this as a principle of operation, in an inflected language the words produced can have the appropriate suffix (typically) added to specify the module from which it originated and therefore its syntactic role in the sentence. In an inflected language, the inflections added to words can indicate case, person etc, and during decoding of the sentence (when listening or reading) these inflections can be used to help the word to activate attractors in the correct module. In a language without inflections, or that is losing inflections, the order in the sequence can be used to supplement the information present in the word to help activate a representation in the correct attractor. Examples of how cortical dynamics might help in this process both during production and during decoding are provided in the simulations in this Chapter (Rolls and Deco, 2015a).

Interestingly, at least during decoding, temporal dynamics alone was found to be brittle in enabling words to be decoded by the correct module, and the system was found to work much more robustly if words find matches only in different specialized modules, for example with nouns being decodable by only subject noun or object noun modules, verbs only by verb modules, etc. The actual decoding is of course a great strength of the type of attractor neuronal network approach described here, for attractor networks are beautifully suited to performing such decoding based on the vector dot product similarity of the recall cue to what is stored in the network (Rolls, 2016b; Hopfield, 1982; Amit, 1989). The implication is that content addressable specialized word attractor cortical modules are important in the implementation of language, and that temporal dynamics utilizing the order of a word in the sequence can be used to help disambiguate the syntactic role of a word being received by enabling it to activate a representation in the correct module, using mechanisms of the general type described.

This raises the interesting point that in the present proposal, the syntactic role of a representation is encoded in the brain by the particular cortical module that is active, with different cortical modules for different parts of speech. An implication is that for the internal operations of this syntactical system, the syntax is encoded by the module within which the representation is active, and this is a form of place coding. Much may be computed internally by such a system based on this specification of the syntactic role of each module in the thought process. The problem arises when these thoughts must be communicated to others. Then a production system is needed, and in this system the syntactic role of which module the representation arises from can be specified partly by the word itself (with noun words indicating that they arise from a subject or object noun representations, verb words indicating that they arise from a verb module); and this specification is supported by inflection and/or by temporal order information to help disambiguate the module from which the word originates. Then during decoding of a sentence, the word again allows it to match only certain modules, with inflection and/or order in the sequence being used to disambiguate the module that should be activated by the word.

Thus an internal language of thought may be implemented by allocating different cortical modules to different syntactic roles, and using place encoding. However, when language becomes externalized in the process of communication, the way in which language can be used as a computational mechanism may be enhanced. Once a language has the rules that allow syntactic role to be expressed in for example written form, this enables formal syntactic operations including logic to be checked in an extended argument or algorithm or proof, and this then provides language with much greater power, providing a basis for formal reasoned extended argument, which may not be a general property of neuronal network operations (Rolls, 2016b), and which facilitates the use of the reasoned route to action (Rolls, 2014a).

One of the hypotheses considered here is that place coding in quite small cortical modules approximately the size of a cortical column (i.e. a region within which there is a high density of local recurrent collaterals to support attractor functionality, and within which local

inhibitory neurons operate) may be used to encode the syntactic role of a word might not easily reveal itself at the brain lesion or functional neuroimaging levels, which generally operate with less resolution than this. For example, such studies of the effects of brain damage and of activations do not provide clear evidence for segregation by syntactic role, such as noun-selective vs verb-selective areas (Vigliocco et al., 2011). Although effects produced by nouns vs verbs do segregate to some extent into the temporal and frontal lobes, this may be because the semantic associations of nouns with objects, and verbs with actions, will tend to activate different cortical areas because of the semantic not purely because of the syntactic difference (Vigliocco et al., 2011). One of the hypotheses developed here is that nouns as subjects and nouns as objects may use different place coding, and one way that this might become evident in future is if single neuron recordings from language areas support this. Indeed, it is a specific and testable prediction of the approach described here that some neurons in language-related cortical areas will have responses to words that depend on the syntactic role of the word. For example, such a neuron might respond preferentially to a noun word when it is a subject compared to when it is an object.

It will be interesting in future to investigate whether this approach based on known principles of cortical computation can be extended to show whether it could provide at least a part of the biological foundation for the implementation of language in the brain. Because of its use of place coding, the system would not be recursive. But language may not be recursive, and indeed some of the interesting properties but also limitations of language may be understood in future as arising from the limitations of its biological implementation.

I note that there are a number of biological mechanisms that might implement the slow transitions from one attractor state to another, some investigated by Deco and Rolls (2005c), and that we are not wedded to any particular mechanism. The speed with which the trajectory through the state space of attractors is executed will depend on factors such as the magnitude of the inputs including the biasing inputs, the strengths of the synapses between the modules, the NMDA dynamics, the effects of finite size noise which will be influenced by the number of spiking neurons, the dilution of the connectivity, and the graded nature of the firing (Rolls and Deco, 2010; Webb et al., 2011; Rolls and Webb, 2012). An implication is that the speed of speech production might be influenced by factors that influence for example NMDA receptors, such as dopamine via D1 receptors (Rolls and Deco, 2010).

One such extension in the future of the approach taken in this Chapter would be to extend the implementation from a single cortical attractor network for each linguistic type (subject nouns, object nouns, verbs, etc) to a set of attractor networks for each linguistic type. If each single local cortical attractor network could store say S patterns (the p referred to above), then how would the system operate with M such attractor nets or modules? There would be two types of connection in such a system. One would be the synaptic connections between the neurons in each attractor network or module. The other connections would be the typically weaker connections between cortical modules (see Rolls (2016b)). The whole system of coupled interacting attractor nets is known as a Potts attractor (Treves, 2005; Kropff and Treves, 2005; Akrami, Russo and Treves, 2012; Song, Yao and Treves, 2014; Ryom, Stendardi, Ciaramelli and Treves, 2023). In a language system representing for example nouns, one attractor net or 'unit' in Potts terminology might contain properties such as shape, another color, another texture, etc, and the full semantic description of the object might be represented by which attractors in which of the M modules are active, that is in a high firing rate state. One advantage of such a system is that all of the properties of an object could be encoded in this way, so we could specify whether the hat is round, red, smooth in texture, etc. Associated with this advantage, the total capacity of the system, that is the number of possible objects that could be represented, is now proportional to S^2 . Thus if a single attractor network could store $S=10,000$ items (10^4), a Potts system with 5 such modules might be able to represent of

order 5×10^8 such objects. In more detail, the number of patterns P_c that can be represented over the Potts attractor is

$$P_c \approx c_M S^2 / a_M \quad (14.2)$$

where c_M is the number of other modules on average with which a module is connected, S is the number of different attractor states within any one module, and a_M is the proportion of the attractor modules in which there is an active attractor, i.e. a high firing rate attractor state (Treves, 2005; Kropff and Treves, 2005). Such a Potts system only works well if (1) long-range connections between the different modules are non-uniformly distributed and (2) only a sparse set of the modules (measured by a_M) is in a high firing rate attractor state (Treves, 2005). In principle, the dynamical system described here could be replaced by substituting each cortical word type module (e.g. that for subject nouns) with a Potts attractor system each with several attractor network modules coding for different properties of features such as shape, color, texture, etc.

An overview at present is that such a Potts system might be useful for a semantic network (Treves, 2005; Ryom et al., 2023), which might correspond to the deep network that biases the word modules in the architecture described in this Chapter. That semantic system would then bias the word modules (with one cortical module for each type of word, subject noun etc), and this architecture might have the advantage that word representations may be more uncorrelated than are semantic representations, which would keep the word representation capacity high. However, in the Potts system simulated so far to model language, the units corresponded to semantic features not to words; and place coding was not used, with instead the syntactic roles of the semantic representations requiring further Potts units to specify the syntactic roles of the semantic units (Pirmoradian and Treves, 2013).

Treves (2005) also considered how such a Potts system might have dynamics that might display some of the properties of language. Adaptation was introduced into each of the attractor networks. After a population of neurons had been active in a high firing rate state in one attractor module for a short time, due to adaptation in that neuronal population, the system then jumped to another attractor state in the same module, or in another connected module a jump might occur to another attractor state, because its inputs had changed due to the adaptation in the other module. The result was a latching process that resulted in complex dynamics of the overall system (Treves, 2005; Song et al., 2014). Whether that complex dynamics is how language is produced has not been proven yet. My view here is that there are sensory inputs from the world, or remembered states that enter short-term memory, and that these states in the deep, semantic, networks then bias the word networks to produce the sequential stream of language. That keeps the processing not a random trajectory through a state space perhaps biased by the statistics of the correlations within a language, but instead a trajectory useful for communication that reflects the states produced by the world or recalled into memory and that can then be communicated to others as a stream of words.

14.5.8 Further approaches

It has been argued that connectionist approaches to language that rely on Elman-style discrete step recurrent networks (Elman, 1990), which take account only of word sequence and have no representation of global structure, cannot capture typical syntax (Jackendoff, 2002, 2003, 2007).

Jackendoff has proposed a Parallel Architecture approach to the structure of grammar that contrasts with mainstream generative grammar in that (a) it treats phonology, syntax, and semantics as independent generative components whose structures are linked by interface rules; (b) it uses a parallel constraint-based formalism that is non-directional; and (c) it treats words and rules alike as pieces of linguistic structure stored in long-term memory (Jackendoff, 2002,

2003, 2007). He proposes that the following processes are involved, but does not take them as far as to propose how they are implemented in the brain:

1. Phonetic processing provides strings of phonemes in phonological working memory.
2. The phonemic strings initiate a call to the lexicon in long-term memory, seeking candidate words that match parts of the strings.
3. Activated lexical items set up candidate phonological parsings, often in multiple drafts, each draft linked to a lexical item or sequence of lexical items.
4. Activated lexical items also set up corresponding strings of syntactic units and collections of semantic units in the relevant departments of working memory.
5. Syntactic integration proceeds right away, by activating and binding to treelets stored in the lexicon.
6. When semantic integration depends on syntactic constituency, it cannot begin until syntactic integration of the relevant constituents is complete. (However, semantic integration does not have to wait for the entire sentence to be syntactically integrated—only for local constituents.)
7. Semantic disambiguation among multiple drafts requires semantic integration with the context (linguistic or non-linguistic). In general semantic disambiguation will therefore be slower than syntactic disambiguation.
8. The last step in disambiguation is the suppression of phonological candidates by feedback.

Models of reading, mainly at the computational not neuroscience level, are described by Reichle (2021). Neurocomputational models of language processing are reviewed by Hale, Campanelli, Li, Bhattasali, Pallier and Brennan (2022).

In conclusion, I have described new hypotheses in this Chapter about how some of the principles of cortical computation used to implement episodic memory, short-term memory, perception, attention, and decision-making (Rolls, 2016b; Rolls and Deco, 2015a) might contribute to the implementation of language including syntax in the cortex. What I have proposed is quite different in its implementation to the systems that follow formal syntactic rules in many neurolinguistic approaches to syntax and language. My proposal is that a series of linked cortical attractors learn what regularities there are in the use of language to which the listener is exposed; and that such attractor networks can also learn the exceptions to the syntactic rules which apply when perhaps particular keywords trigger the system into a trajectory through a different set of Word-level modules. Thus the system I propose is a mechanism for how the syntactic rules of language could be learned by a set of coupled attractor networks, that is, by a dynamical system.

This is a major frontier in neuroscience, and much remains to be done on how language and syntax may be implemented in the cerebral cortex.

15 The motor cortical areas

15.1 Introduction and overview

Some of the main cortical areas involved in the initiation and control of movement are shown in Fig. 15.1 (Rizzolatti and Kalaska, 2013; Scott and Kalaska, 2021; Giarrocco and Averbeck, 2021). A key feature is the hierarchical organisation, with inputs from parietal cortex areas projecting to premotor cortical areas in BA 6, which project to the primary motor cortex. Although the organisation is hierarchical, motor neurons for output descend to subcortical and spinal cord regions from all of these areas. Area 4 is special in its motor outputs, which make direct connections to spinal cord motor neurons for fine control of the hands. Further, although the organization is overall hierarchical, there is specialization of different parietal and premotor areas for different functions as described in this Chapter. In addition there are separate pathways for the control of eye movements (Goldberg and Walker, 2021).

The somatosensory areas 1, 2, and 3 (described in Section 6.1.2) and area PE provide somatosensory input (including touch and proprioceptive information) to M1 (F1) (area 4). Area M1 (or F1) contains a large sector that controls the fingers, hand, and wrist. The pre-central motor cortical areas include the primary motor cortex (M1, F1); F5, a subdivision of PMv; and the ventral premotor cortex (Fig. 15.1).

In terms of processing streams, the visuomotor transformation necessary for reaching is mediated by the parietofrontal network shown in Fig. 15.1 (Rizzolatti and Kalaska, 2013; Scott and Kalaska, 2021; Giarrocco and Averbeck, 2021). The areas located within the intraparietal sulcus are shown in an unfolded view of the sulcus. Two serial pathways are involved in the organization of reaching movements. The ventral stream has its principal nodes in the ventral intraparietal area (VIP) and area F4 of the ventral premotor cortex, whereas the dorsal stream has synaptic relays in the superior parietal lobe (MIP, V6A) and the dorsal premotor cortex (PMd), which includes area F2. (The parietal areas include AIP, anterior intraparietal area; LIP, lateral intraparietal area; and V6A, the parietal portion of the parieto-occipital area.)

The visuomotor transformation necessary for grasping is mediated by the parietofrontal network shown in Fig. 15.1 (Rizzolatti and Kalaska, 2013; Scott and Kalaska, 2021; Giarrocco and Averbeck, 2021). The AIP and PFG areas are concerned mostly with hand movements, whereas area PF is concerned with mouth movements. Area F5 in PMv is concerned with both hand and mouth motor acts. Some grasping neurons have been found in F2, the ventral part of PMd.

The representations in these cortical areas provide evidence about what is computed in these areas, and are described next.

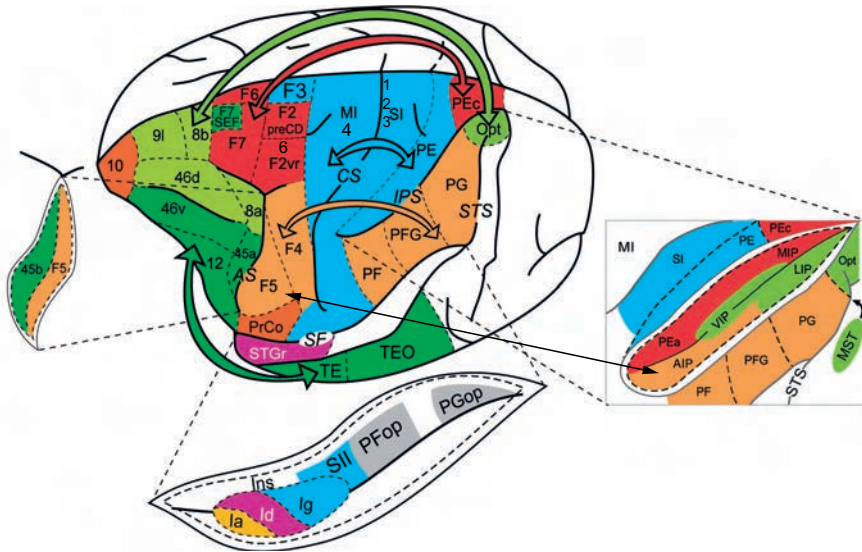

Fig. 15.1 Motor and premotor cortical areas in the macaque and some of their connections. The motor cortex area 4, M1, is anterior to the central sulcus (CS), and is part of the precentral cortex. The premotor cortex area 6 is the area just anterior to this, with subdivisions F2, F4, F5, etc. There are major inputs to premotor cortical areas from the parietal cortex, from areas within the intraparietal sulcus (IPS, opened, right) for reaching, and from more ventral parietal areas such as PF and PFG for grasping. AS, arcuate sulcus; CS, central sulcus; IPS, intraparietal sulcus; SF, Sylvian fissure (opened, below); STS, superior temporal sulcus; F3, supplementary motor cortex; F6, pre-SMA; S1, 1,2,3 - primary somatosensory cortex; Ins, insula; Opt, parietal region Opt. (Adapted from Giarocco, F. and Averbeck, B.B. 2021. Organization of parieto-prefrontal and temporo-prefrontal networks in the macaque. *Journal of Neurophysiology* 126: 1289-1309.)

15.2 What is computed in different cortical motor-related areas

15.2.1 Ventral parietal and ventral premotor cortex F4

One of the ventral parietal areas, the ventral intraparietal cortex (VIP) (Fig. 15.1A), receives projections from MT (medial temporal) and MST (medial superior temporal) (see Chapter 3). Neurons in VIP respond to visual stimuli moving in peripersonal space, and some neurons combine this with tactile somatosensory responses to stimuli in a corresponding part of peripersonal space. The tactile receptive fields are often on the face or hands or arms. These neurons may respond for example to a visual stimulus moving towards a tactile receptive field. This type of visual-tactile responsiveness could be set up by associative learning from much previous experience. There are strong connections from VIP to ventral premotor area F4, in which most of the neurons respond to tactile stimuli, and about half to corresponding visual stimuli. The implication is that the spatial reference frame for these visual neurons might be parts of the body.

15.2.2 Superior parietal areas with activity related to reaching

Neurons in superior parietal areas such as PEc, V6 and MIP (Fig. 15.1) often respond to visual stimuli involved in reaching, and the coordinate frame reflects not only retinal and eye position but also arm posture and hand position. In PEip the neurons are more related to arm posture and hand position. The dorsal premotor neurons to which these parietal areas project are strongly influenced by the direction of movement to the target, rather than by visual stimuli. Some of these neurons respond to the shape of the object depending on how the object can be grasped. These cortical regions are described further in Section 3.6.

Fig. 15.2 Convergence of visual objects, observed actions, and own hand visual and proprioceptive signals in Posterior Parietal Cortex territories devoted to manipulative actions. **A** Own action planning benefits from (1) motor affordances provided by the 3D structure of objects and the environment (blue), (2) social affordances provided by others' observed actions (red), (3) own actions' visual and somatosensory/proprioceptive feedback from the subject's body (orange). Distinct anatomo-functional visual components of observed actions can be identified in the goal-attainment signals (rostral STS) and body movement signals (middle STS) concerning the observed actions of others, which are paralleled by the analysis of visual/proprioceptive feedback from the subject's own actions (conveyed by the STS, PEip, SII, and F5, particularly concerning haptic information about the manipulated object). **B** Schematic view of the different signals that contribute to the encoding of the physical properties of objects and the environment, the subject's own actions, and others' actions. PEip intraparietal area PE; SII secondary somatosensory cortex; STS superior temporal sulcus. (From Orban, G.A., Sepe, A. and Bonini, L. 2021. Parietal maps of visual signals for bodily action planning. *Brain Structure and Function* 226: 2967-2988.)

15.2.3 Inferior parietal areas with activity related to grasping, and ventral premotor cortex F5

Neurons in inferior parietal areas such as AIP and PFG (Fig. 15.1) frequently respond when looking at an object and/or when grasping it, and were made famous by the pioneering studies of Mountcastle, Sakata and colleagues (Mountcastle, Lynch, Georgopoulos, Sakata and Acuna, 1975). These areas project to ventral premotor cortex area F5, where neurons can encode the nature of the grasp needed to grip objects with different shapes (Murata et al., 1997). The pathways implicated in manipulative actions are illustrated in Fig. 15.2 (Orban et al., 2021b,a; Urgen and Orban, 2021).

These cortical regions are described further in Section 3.6.

15.3 The mirror neuron system

Neurons with movement-related activity in for example premotor cortex area F5 and in the parietal cortex respond to the sight of grasping an object, as well as to actually grasping an object, in the mirror neuron system shown in Fig. 15.3 (Rizzolatti and Craighero, 2004; Rizzolatti and Sinigaglia, 2016; Rizzolatti and Rozzi, 2018). It has been suggested that the mirror

Fig. 15.3 The monkey parietofrontal mirror network for hand-grasping actions. Lateral view of the macaque monkey brain localizing the main areas that are involved in action observation with mirror neurons: the ventral premotor cortex (area F5), area PFG, and the anterior intraparietal area (AIP). The intraparietal sulcus (IPS) has been opened to show the areas inside. The parietofrontal network receives high-order visual information from areas that are located inside the superior temporal sulcus (STS) and inferior temporal lobule (IT). Neither of these temporal regions has mirror properties. Area F5 is connected with area F1, which also contains mirror neurons. The parietofrontal circuit is under the control of the frontal lobe (area F6 or pre-supplementary motor area and ventral prefrontal cortex (vPFC)). The inset shows an enlarged view of area F5, displaying its sectors buried inside the arcuate sulcus. The label 'Arm' indicates the area where the arm is represented. IAS, inferior limb of the arcuate sulcus; VIP, ventral intraparietal area; as, arcuate sulcus; cs, central sulcus; ps, principal sulcus; Sf, Sylvian fissure. (Reproduced from Rizzolatti, G. and Sinigaglia, C. (2016) The mirror mechanism: a basic principle of brain function. *Nature Reviews Neuroscience* 17: 757–765. © Springer Nature.)

mechanism transforms sensory representations of others' actions into motor representations of the same actions in the brain of the observer (Rizzolatti and Rozzi, 2018). The implication is that this is useful for observational learning. It has also been suggested that the mirror mechanism plays an important role in understanding actions of others (Rizzolatti and Rozzi, 2018).

As shown in Section 6.1.6 mirror-neuron-like effects are not restricted to systems in which visual and motor representations are found, but can also be produced even in the human primary somatosensory cortex S1 by the sight of touch to the arm, as well as by touch to the arm (McCabe, Rolls, Bilderbeck and McGlone, 2008). Comparison of the sight of an arm being rubbed with cream to a visual control with no contact revealed effects in the inferior frontal gyrus (corresponding probably to F5 in the monkey, a mirror neuron area in which neurons respond to motor actions and to the sight of the action being performed (Rizzolatti and Craighero, 2004)), area 7, and even the primary somatosensory cortex S1, implicating these regions in the imagined or intentional aspects of touch (McCabe et al., 2008). Although neurons in S1 are not activated by most visual or auditory stimuli, effects can be found if these stimuli are relevant to somatosensory processing, such as the sound of a stimulus rubbing the skin (Delhaye et al., 2018). Thus the construct that mirror neurons are present especially for the sight of movements such as grasping and the actual movement of grasping does not seem to be supported by what happens in the somatosensory system. We may be dealing more with anatomical convergence that allows such affects to be learned by association, and that includes the evidence that backprojections in the cortex can learn the correct associations to recall activity in early cortical processing areas (Rolls, 2016b). It was found that the sight of touch did not activate somatosensory regions in the insula, and it was therefore proposed that

this area is especially important in representing that one is being actually touched (McCabe, Rolls, Bilderbeck and McGlone, 2008; Rolls, 2016a).

15.4 How the computations are performed in motor cortical and related areas

Many of the coordinate transforms required for motor behavior are made in the parietal cortex. Some of the computational principles of how the computations are performed are described in Section 3.5.

A parsimonious interpretation of mirror neurons is that they may reflect what has been associatively learned about associations between the sight of objects etc and the actions needed to operate on them such as grasping, and may reflect useful preparation of motor systems for actions that are likely to be performed on the objects.

‘Visual fixation’ and similar neurons in parietal area 7 that respond when objects are visually fixated and when movements are made for the objects were described as ‘command neurons’ (Mountcastle, Lynch, Georgopoulos, Sakata and Acuna, 1975) that reflected goals and motivation. However, when compared with orbitofrontal cortex neurons, the parietal neurons do not reflect reward value, in that they respond as much when a non-reward object is fixated as a reward object, and do not decrease their responses when the value is reduced by feeding to satiety (Rolls, Perrett, Thorpe, Puerto, Roper-Hall and Maddison, 1979a) (Section 6.1.4). The neurons reflect instead whether an action is likely to be performed on the object, independently of its reward value. Actions may be made for example to reject aversive objects, and then parietal neurons are active. Thus many parietal neurons appear to be involved in action rather than reward value.

16 The basal ganglia

16.1 Introduction and overview

1. The basal ganglia provides an evolutionarily old system that receives from many of whatever higher parts of the brain are present, and helps to produce a single output stream of behavior.

2. In mammals, the layer 5 neurons of every part of the neocortex provide the main excitatory inputs to the striatum, which is stage 1 of the computation.

Each part of the cortex projects primarily to its own part of the striatum.

The striatum then sends its outputs to the globus pallidus and substantia nigra pars reticularis, where there is convergence to produce what is largely a single output stream with further selection performed by the mutual inhibition between the principal neurons.

Although earlier in evolution the outputs may have been directed to lower brain output systems, in mammals the outputs return via the thalamus to the cortex.

The probable role in mammals is still to select a single output stream, but for this to exert its effects through influences on the cerebral cortex.

These anatomical pathways are shown schematically Fig. 16.1, with the location of the parts of the basal ganglia shown in Fig. 16.2. These diagrams show the connectivity in primates (including humans), and the treatment here is for primate including human brains, as rodents appear to have such less well developed and computationally separate cortical regions, and because reward processing is so different in rodents, with reward influencing even early sensory processing (see Section 19.10).

3. The response selection is performed by mutual inhibition between the principal neurons in both the striatum and the globus pallidus using the inhibitory transmitter GABA (gamma-amino-butyric acid). There is no recurrent excitation as in the cortex, so short-term memory and planning are beyond the computational capabilities of the basal ganglia.

4. Instead, the functions of the basal ganglia include learning of stimulus-response combinations to produce habits, which are well-learned responses.

5. The learning is facilitated by reinforcement learning in which a third term, dopamine neuron firing, which provides a reward prediction error signal, increases the learning rate for whatever stimulus-response combinations are present just before the reinforcer is received.

6. Because this is stimulus-response learning, and actions are not being produced in order to obtain rewards, the stimulus-response habit continues for some time even when the original reinforcer is devalued, for example by feeding to satiety.

7. At least in primates including humans, the orbitofrontal cortex provides some of the reward-related information to the dopamine neurons, via several routes, including via the ventral striatum, and via the habenula (Fig. 11.4) (Rolls, 2017c).

8. Although some of the dopamine neurons do appear to encode a reward prediction error signal, it has become evident that the signal is more complicated than that, with phasic and sustained or tonic components that the striatum is supposed to understand, and with many dopamine neurons responding to quite different events, including aversive stimuli,

the long-term reward value of stimuli (in contrast to reward prediction error), and movements. The dopamine neurons appear to convey little evidence about the particular reward that has been obtained, making it a somewhat impoverished learning system compared to the orbitofrontal cortex – anterior cingulate cortex system. If there is insufficiency of dopamine, then the transmission through the basal ganglia is impaired and Parkinson's disease occurs, in which there is great difficulty in initiating movements.

9. Computationally, it is proposed that the basal ganglia are a two-stage system with convergence occurring in each stage so that by the second stage, the globus pallidus and substantia nigra, there is sufficient convergence for all the cortical areas that project into the striatum for all these inputs to be combined (see Fig. 16.9). The selection by mutual inhibition at each stage of this two stage process is safe, as there is no danger of runaway excitation and epilepsy as there are no excitatory connections between the principal neurons.
10. The basal ganglia are thus a great contrast with the orbitofrontal cortex to anterior cingulate cortex system, which is much more powerful than the basal ganglia, because it learns associations between actions and outcomes (with the outcome a reward or punisher). For reinforcement learning, the reinforcer is just a modulator of activity that happens to be present when the reinforcement error signal arrives, rather than a direct association between a particular reward outcome and a particular action. This much greater computational power of the orbitofrontal cortex reward to anterior cingulate action learning system than reinforcement learning is brought out further in Section 19.5.

We first consider the anatomical connectivity of the basal ganglia; then what is computed in the basal ganglia as shown by neuronal recording and by the effects of damage to it; and then how the basal ganglia perform their computations, including the role of dopamine in reinforcement learning.

16.2 Systems-level architecture of the basal ganglia

The point-to-point connectivity of the basal ganglia as shown by experimental anterograde and retrograde neuroanatomical path tracing techniques in the primate is indicated in Figs. 16.1 and 16.2. The general connectivity is for cortical or limbic inputs to reach the striatum, which then projects to the globus pallidus and substantia nigra pars reticulata, which in turn project via the thalamus back to the cerebral cortex (DeLong and Wichmann, 2010; Gerfen and Surmeier, 2011; Buot and Yelnik, 2012; Haber, 2016). Within this overall scheme, there is a set of at least partially segregated parallel processing streams, as illustrated in Figs. 16.1 and 16.2 (Rolls and Johnstone, 1992; Rolls, 2014a, 2016b; Haber, 2016; Bostan, Dum and Strick, 2018; Heilbronner, Rodriguez-Romaguera, Quirk, Groenewegen and Haber, 2016).

First, the motor cortex (area 4) and somatosensory cortex (areas 3, 1, and 2) project somatotopically to the putamen, which has connections through the globus pallidus and substantia nigra to the ventral anterior thalamic nuclei and thus to the supplementary motor cortex. Experiments with a virus transneuronal pathway tracing technique have shown that there might be at least partial segregation within this stream, with different parts of the globus pallidus projecting via different parts of the ventrolateral (VL) thalamic nuclei to the supplementary motor area, the primary motor cortex (area 4), and to the ventral premotor area on the lateral surface of the hemisphere (Middleton and Strick, 1996a).

Second, there is an oculomotor circuit (see Fig. 16.1).

Third, the dorsolateral prefrontal and the parietal cortices project to the head and body of the caudate nucleus, which has connections through parts of the globus pallidus and substantia

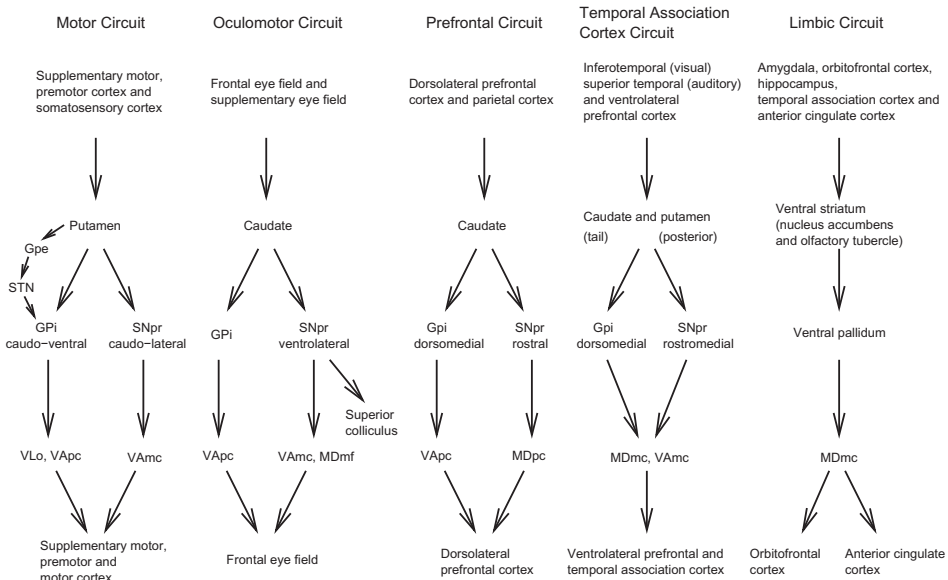

Fig. 16.1 A synthesis of some of the anatomical studies (see text) of the connections of the basal ganglia. GPe, Globus Pallidus, external segment; GPi, Globus Pallidus, internal segment; MD, nucleus medialis dorsalis; SNpr, Substantia Nigra, pars reticulata; VAmc, n. ventralis anterior pars magnocellularis of the thalamus; VApC, n. ventralis anterior pars compacta; VLo, n. ventralis lateralis pars oralis; VLM, n. ventralis pars medialis. An indirect pathway from the striatum via the external segment of the globus pallidus and the subthalamic nucleus (STN) to the internal segment of the globus pallidus is present for the first four circuits (left to right in the figure) of the basal ganglia.

nigra to the ventral anterior group of thalamic nuclei and thus to the dorsolateral prefrontal cortex.

Fourth, the inferior temporal visual cortex and the ventrolateral (inferior convexity) prefrontal cortex to which it is connected project to the posterior and ventral parts of the putamen and the tail of the caudate nucleus (Kemp and Powell, 1970; Saint-Cyr, Ungerleider and Desimone, 1990; Graybiel and Kimura, 1995). Moreover, part of the globus pallidus, perhaps the part influenced by the temporal lobe visual cortex, area TE, may project back (via the thalamus) to area TE (Middleton and Strick, 1996b).

Fifth, and of especial interest in the context of reward mechanisms in the brain, limbic and related structures such as the amygdala, orbitofrontal cortex, and hippocampus project to the ventral striatum (which includes the nucleus accumbens and olfactory tubercle), which has connections through the ventral pallidum to the mediodorsal nucleus of the thalamus and thus to the prefrontal and cingulate cortices (Buot and Yelnik, 2012; Julian et al., 2018; Haber, 2016; Heilbronner et al., 2016, 2018). It is notable that the projections from the amygdala and orbitofrontal cortex are not restricted to the nucleus accumbens, but also reach the adjacent ventral part of the head of the caudate nucleus (Amaral and Price, 1984; Seleman and Goldman-Rakic, 1985; Haber, 2016; Heilbronner, Rodriguez-Romaguera, Quirk, Groenewegen and Haber, 2016). A broadly similar organization is found in humans (Morris et al., 2016). These same reward and memory-related regions may also project to the striosomes or patches (in for example the head of the caudate nucleus), which are set in the matrix formed by the other cortico-striatal systems (Bloem, Huda, Sur and Graybiel, 2017; Friedman, Homma, Gibb, Amemori, Rubin, Hood, Riad and Graybiel, 2015). The striosomes in turn project directly to the dopamine neurons, and via the globus pallidus to the lateral habenula, which in turn projects to the dopamine neurons. As described in Section 11.2.2 and Fig. 11.4, this provides a route for reward-related information from the orbitofrontal cortex and amygdala to influence the dopamine neurons (Rolls, 2017c). But more than that, **these con-**

Fig. 16.2 Some of the striatal and connected regions in which the activity of single neurons is described shown on a lateral view of the brain of the macaque monkey. Gp, globus pallidus; h, hypothalamus; sn, substantia nigra, pars compacta (A9 cell group), which gives rise to the nigrostriatal dopaminergic pathway, or nigrostriatal bundle (nsb); vta, ventral tegmental area, containing the A10 cell group, which gives rise to the mesocortical dopamine pathway (mc) projecting to the frontal and cingulate cortices and to the mesolimbic dopamine pathway (ml), which projects to the nucleus accumbens (nuc acc). There is a route from the nucleus accumbens to the ventral pallidum (vp) which then projects to the mediodorsal nucleus of the thalamus (MD) which in turn projects to the prefrontal cortex. Correspondingly, the globus pallidus projects via the ventral anterior and ventrolateral (VA/VL) thalamic nuclei to cortical areas such as the premotor cortex.

nections to the striosomes or patches allow reward-related information from the orbito-frontal cortex and amygdala to influence the striatum even independently of dopamine inputs.

The striatum then projects to the globus pallidus (including the ventral pallidum) and substantia nigra, where again the principal neurons are mutually directly inhibitory. The globus pallidus and substantia nigra have many fewer neurons, and as shown below, there is an anatomical basis for convergence (see Fig. 16.8). At striatal neurons of the direct pathway (from the striatum directly to the globus pallidus internal segment), dopamine has excitatory effects via the D1 receptor by eliciting or prolonging glutamate excitatory inputs. At striatal neurons in the indirect pathway (from the striatum via the external segment of the globus pallidus via the subthalamic nucleus to the internal segment of the globus pallidus, see Fig. 16.1), D2 receptor activation has inhibitory effects by reducing glutamate release and prolonging membrane down states (hyperpolarization). Both effects of dopamine tend to promote behavioral output (Gerfen and Surmeier, 2011). The pallidal and nigral neurons then project to the thalamus, which in turn projects back to the neocortex (Fig. 16.1). Although the connections return to the separate cortical areas, a key concept developed below is that the basal ganglia enable information from different parts of the cortex to form combinations and also to compete in the basal ganglia, to enable learning of stimulus-response combinations, and to focus on a single stream of output (Fig. 16.9).

16.3 What computations are performed by the basal ganglia?

16.3.1 Effects of striatal lesions

16.3.1.1 Ventral striatum including nucleus accumbens

There is evidence linking the ventral striatum and its dopamine input to reward, for manipulations of this system alter the incentive effects that learned rewarding stimuli have on behavior in the rat (Robbins, Cador, Taylor and Everitt, 1989; Everitt and Robbins, 1992, 2013). The type of task affected is one in which a visual or auditory stimulus is delivered at or just before the delivery of food for which an animal is working. The tone or light becomes associated by learning with the food. Its effects can be measured by whether the rat learns a new operant response to obtain the conditioned reinforcer (the tone or light). This effect in rats is probably produced via the inputs of the amygdala to the ventral striatum, for the effect is abolished by dopamine-depleting lesions of the nucleus accumbens, and amphetamine injections to the nucleus accumbens (which increase the release of dopamine) increase the effects that these learned or secondary reinforcers have on behavior (Robbins et al., 1989).

In primates, neurotoxic lesions of the ventral striatum produced some changes in emotionality, including increased activity and violent and aggressive behavior when reward was no longer available during extinction (frustrative non-reward); but some of the changes found in rats were not apparent, perhaps because the lesions in primates were small (Stern and Passingham, 1995, 1996), and in any case in primates the amygdala projects not only to the ventral striatum, but also to the adjoining part of the caudate nucleus.

In addition to this role in reward related probably to inputs to the ventral striatum from the amygdala and orbitofrontal cortex (see Chapter 11), the ventral striatum is also implicated in effects that could be mediated by the hippocampal inputs to the ventral striatum. For example, spatial learning (Schacter et al., 1989) and locomotor activity elicited by novel stimuli (Iversen, 1984), are influenced by manipulations of the nucleus accumbens.

The nucleus accumbens may not be involved in action–outcome learning, but does allow the affective states retrieved by the basolateral amygdala (BLA) to conditioned stimuli to influence instrumental behavior by for example Pavlovian-instrumental transfer, and facilitating locomotor approach to food which appears to be in rats a Pavlovian process (Cardinal et al., 2002; Cardinal and Everitt, 2004).

16.3.1.2 Dorsal striatum

In humans, depletion of dopamine in the striatum is found in Parkinson's disease, in which there is akinesia, that is a lack of voluntary movement, bradykinesia (slow movement), rigidity, and tremor (Hornykiewicz, 1973; Braak, Ghebremedhin, Rub, Bratzke and Del Tredici, 2004; Armstrong and Okun, 2020; Wang, Cheng, Rolls, Dai, Gong, Du, Zhang, Wang, Liu, Wang, Brown and Feng, 2020d). However, consistent with the anatomical evidence, the effects of damage to different regions of the striatum also suggest that there is functional specialization within the striatum (Divac and Oberg, 1979; Oberg and Divac, 1979). The selective effects may be related to the function of the cortex or limbic structure from which a region of the striatum receives inputs. For example, in the monkey, lesions of the anterodorsal part of the head of the caudate nucleus disrupted delayed spatial alternation performance, a task that requires spatial short-term memory, which is also impaired by lesions of the corresponding cortical region, the dorsolateral prefrontal cortex. Lesions of the ventrolateral part of the head of the caudate nucleus (as of the orbitofrontal cortex which projects to it) impaired object reversal performance, which measures the ability to reverse stimulus–reinforcer associations. Lesions of the tail of the caudate nucleus (as of the inferior temporal visual cortex which

projects to this part of the caudate) produced a visual pattern discrimination deficit (Divac, Rosvold and Szwarcbart, 1967; Iversen, 1979). Analogously, in the rat, lesions of the anteromedial head of the caudate nucleus (or of the medial prefrontal cortex, which projects to it) impaired spatial habit reversal, while lesions of the ventrolateral part of the head of the caudate nucleus (or of the orbital prefrontal cortex from which it receives) impaired the withholding of responses in a Go/No-Go task or in extinction (Dunnett and Iversen, 1982b; Iversen, 1984). Further, in the rat a sensori-motor orientation deficit was produced by damage to a part of the dorsal striatum which receives inputs from lateral cortical areas (Dunnett and Iversen, 1982a; Iversen, 1984). Similar deficits are produced by selective depletion of dopamine using 6-hydroxydopamine in each of these areas (Dunnett and Iversen, 1982b,a; Iversen, 1984).

In rats, the dorsomedial striatum (the equivalent of the primate caudate nucleus) may with its inputs from prelimbic (cingulate) areas be involved in action–outcome learning; the dorsolateral striatum (the equivalent of the primate putamen) with its inputs from sensorimotor cortex in stimulus-response habit behavior; and the ventral striatum may be involved in some effects of rewards and predicted rewards on both directed behavior and habits (Balleine et al., 2009; Balleine and O’Doherty, 2010).

16.3.2 Neuronal activity in different parts of the striatum

Neuronal recording studies in primates and neuroimaging studies in humans show that very different type of information are represented in different parts of the striatum, and reflect the inputs from the cortex to each part of the striatum. We will focus first on neuronal activity in the ventral striatum, because it is particularly relevant to the processing of rewards by the basal ganglia. We again focus on neuronal research in monkeys and activations in neuroimaging studies in humans, because the rodent orbitofrontal cortex (Rolls (2019e) Chapter 8) and brain systems-level organisation (Section 19.10; Rolls (2019e) Chapter 8) are so different.

16.3.2.1 Ventral striatum

To analyze the functions of the ventral striatum, the responses of more than 1000 single neurons were recorded (Rolls and Williams, 1987a; Williams, Rolls, Leonard and Stern, 1993) in a region that included the nucleus accumbens and olfactory tubercle in five macaque monkeys in test situations in which lesions of the orbitofrontal cortex, amygdala, hippocampus, and inferior temporal cortex produce deficits, and in which neurons in these structures respond (Rolls, 2014a, 2016b, 2019e).

One population of ventral striatal neurons was found to respond differently in a visual discrimination task to visual stimuli that indicate that if a lick response is made, the taste of glucose reward will be obtained, and to other visual stimuli that indicate that if a lick response is made, the taste of aversive saline will be obtained (Rolls and Williams, 1987a; Williams, Rolls, Leonard and Stern, 1993). Responses of an example of a neuron of this type are shown in Fig. 16.3. The neuron increased its firing rate to the visual stimulus that indicated that saline would be obtained if a lick was made (the S−), and decreased its firing rate to the visual stimulus that indicated that a response could be made to obtain a taste of glucose (the S+). The differential response latency of this neuron to the reward-related and to the saline-related visual stimulus was approximately 150 ms (see Fig. 16.3), and this value was typical. This neuron thus coded for the valence of the visual stimuli (i.e. whether the visual stimulus was associated with a reward vs a punisher).

Of the neurons that responded to visual stimuli that were rewarding, relatively few responded to all the rewarding stimuli used. That is, only few (1.8%) ventral striatal neurons responded both when food was shown and to the positive discriminative visual stimulus, the

Fig. 16.3 Responses of a ventral striatal neuron in a visual discrimination task. The neuron reduced its firing rate to the visual discriminative stimulus S+ on food reward trials (R), and increased its firing rate to the S- on non-food trials (S) on which aversive saline was obtained if a lick was made. Rastergrams and peristimulus time histograms are shown. The inverted triangles show where lick responses were made on the food reward (R) trials. (Reprinted from Graham V. Williams, Edmund T. Rolls, Christiana M. Leonard, and Chantal Stern (1993) Neuronal responses in the ventral striatum of the behaving macaque. *Behavioural Brain Research* 55: 243–252. © Elsevier B.V.)

S+ (e.g. a triangle shown on a video monitor), in a visual discrimination task. Instead, the reward-related neuronal responses were typically more context or stimulus-dependent, responding for example to the sight of food but not to the S+ which signified food (4.3%), differentially to the S+ or S- but not to food (4.0%), or to food if shown in one context but not in another context. Some neurons were classified as having taste or olfactory responses to food (Williams, Rolls, Leonard and Stern, 1993; Rolls and Williams, 1987a). Some other neurons (1.4%) responded to aversive stimuli. These neurons did not respond simply in relation to arousal, which was produced in control tests by inputs from different modalities, for example by touch of the leg. Thus 13.9% of primate ventral striatal neurons encoded the valence of visual stimuli (Rolls and Williams, 1987a; Williams et al., 1993). Neurons in the ventral striatum (and orbitofrontal cortex) with activity related to the expectation of reward have been confirmed (Schultz, Apicella, Scarnati and Ljungberg, 1992; Schultz, Tremblay and Hollerman, 2000), and as described above reflect inputs from the orbitofrontal cortex (Simmons, Ravel, Shidara and Richmond, 2007). Even ventral striatal interneurons, the activity of which is produced by the principal neurons in the ventral striatum, reflect reward value (Falcone et al., 2019).

Other ventral striatal neurons responded to faces; to other visual stimuli than discriminative stimuli and faces; in relation to somatosensory stimulation and movement; or to cues that signalled the start of a task (Rolls and Williams, 1987a; Williams, Rolls, Leonard and Stern, 1993). The cue-related neurons in the ventral striatum were similar to those found in the head of the caudate nucleus (see Section 16.3.2.4), in that they responded to warning cues that signalled the start of a trial, and stopped responding to the cue if it no longer signalled the start of a trial (see example in Fig. 16.5). 15.9% of ventral striatal neurons had cue-related responses. These can thus be described as encoding the salience of stimuli, and respond independently

of the valence of the stimuli. Thus valence and salience are represented independently by different populations of neurons in the primate ventral striatum.

Another population of ventral striatal neurons responded to novel visual stimuli (Rolls and Williams, 1987a; Williams et al., 1993), as also found in the orbitofrontal cortex (Rolls et al., 2005a).

The neurons with responses to reinforcing or novel visual stimuli may thus reflect the inputs to the ventral striatum from the orbitofrontal cortex, amygdala, and hippocampus, and are consistent with the hypothesis that the ventral striatum provides a route for learned reinforcing and novel visual stimuli to influence behavior. It was notable that although some neurons responded to visual stimuli associated with reward, 1.4% responded to visual stimuli associated with punishment, and 12% responded to arousing visual stimuli or non-specifically to visual stimuli. It was also notable that these neurons were not restricted to the nucleus accumbens, but were found also in the adjacent ventral part of the head of the caudate nucleus (Rolls and Williams, 1987a; Williams, Rolls, Leonard and Stern, 1993; Rolls, Thorpe and Maddison, 1983b), which also receives projections from both the amygdala (Amaral and Price, 1984) and orbitofrontal cortex (Seleman and Goldman-Rakic, 1985).

In human fMRI studies, activations have been described in the ventral striatum that reflect whether monetary rewards can be obtained, and indeed more activation is found for the larger rewards (Knutson et al., 2001). Interestingly, activations in the ventral striatum are not only correlated with the amount of money won in a monetary incentive delay task, but also reflect activations in the medial orbitofrontal cortex (Xie, Jia, Rolls, Robbins, Sahakian, Zhang, Liu, Cheng, Luo, Zac Lo, Wang, Banaschewski, Barker, Bodke, Buchel, Quinlan, Desrivieres, Flor, Grigis, Garavan, Gowland, Heinz, Hohmann, Ittermann, Martinot, Martinot, Nees, Papadopoulos Orfanos, Paus, Poustka, Frohner, Smolka, Walter, Whelan, Schumann, Feng and IMAGEN, 2021). One of the strongest activations that is found in the ventral striatum is produced by reward/punishment prediction errors in Pavlovian (i.e. classical conditioning) tasks (O'Doherty et al., 2003a; McClure et al., 2003; Seymour et al., 2004) and in instrumental decision-making tasks (Hare et al., 2008; Kim et al., 2006). For example, in a classical conditioning task, a first visual stimulus probabilistically predicted high vs low pain, and a second visual stimulus perfectly predicted whether the pain would be high or low on that trial. Activation of the ventral striatum and a part of the insula was related to the temporal difference error, which arose for example at the transition between the first and second visual stimulus if the first visual stimulus had predicted low pain, but the second informed the subject that the pain would be high (Seymour et al., 2004).

The ventral striatum activations may reflect the operation of a 'critic' in reinforcement learning, in that activations in it are related to temporal difference errors in Pavlovian conditions in which actions are not made (O'Doherty et al., 2004). In contrast, activation in the dorsal striatum may be closely related to temporal difference prediction errors used to correct an actor, as these activations occurred during an instrumental version of the task in which the subjects had to choose between two stimuli associated with a high probability or low probability of obtaining juice reward (O'Doherty et al., 2004). (The distinction between a 'critic' and an 'actor' in reinforcement learning is described in Section B.17.3.)

Activations in the ventral striatum related to temporal difference reward/punishment prediction errors in a monetary reward *decision* task are exemplified in the study by Rolls, McCabe and Redoute (2008e). The design of the task meant that sometimes the participants were expecting a low probability of a high reward of 30 pence, and unexpectedly obtained a high reward value of 30 pence. On these trials, the temporal difference prediction error from the expected value part of the trial to the reward value part of the trial when subjects were informed whether they would obtain the large reward was positive. On other trials when the expected value was high but probabilistically no reward was obtained, the temporal differ-

TD error signal in the ventral striatum
in a probabilistic monetary decision-making task

Fig. 16.4 Temporal Difference (TD) error signal in the ventral striatum in a probabilistic monetary decision-making task. The correlation between the TD error and the activation in the nucleus accumbens was significant in a group random effects analysis fully corrected at the cluster level with $p < 0.048$ (voxel $z = 3.84$) at MNI coordinates [8 8 -8]. (Reproduced from E. T. Rolls, C. McCabe, and J. Redoute. (2008) Expected value, reward outcome, and temporal difference error representations in a probabilistic decision task. *Cerebral Cortex* 18: 652–663. © Oxford University Press.)

ence prediction error from the expected value part of the trial to the reward value part of the trial was negative. (Temporal difference (TD) errors are described in Section B.17.3.) It was found that the fMRI BOLD signal in the nucleus accumbens reflected this temporal difference error signal, calculated at the part of the trial when the reward prediction changed from the expected value for that trial block to the actual reward available on that trial, as shown in Fig. 16.4.

Further analyses showed that the activation in the ventral striatum was positively correlated with the reward actually obtained on that trial but not with the expected value. Thus the TD error correlation arose in the nucleus accumbens because at the time that the expected value period ended and the subject was informed about how much reward had been obtained on that trial, the BOLD signal changed to a higher value for large rewards, and to a lower value for low or no reward, from a value that was not a function of the expected value on that trial. A TD error correlation was also found in left cortical area 44 (Broca's area) (as shown in Fig. 16.4), but here the TD correlation arose because the activation became low when the subject was informed that no reward was obtained on a trial, and it appeared that the area was activated especially when the decision was difficult, between two approximately equal values of the expected value. In a part of the midbrain near the dopamine neurons at [14 -20 -16], there was also a correlation with the TD error, but here this was related to a negative correlation between the BOLD signal in the expected value period of each trial and the expected value. (The TD error was thus positive for example whatever reward became available if it was a low expected value trial block, and the TD error was negative if it was a high expected value trial block.) This shows that TD error regressions with functional neuroimaging can arise for a number of different reasons. In this investigation, the reward value on a trial was correlated with the activation in parts of the orbitofrontal cortex, and the expected value was negatively correlated with activations in the anterior insula [-38 24 16], and these cortical areas may be the origins of some of the signals found on other brain areas.

These findings do exemplify the fact that activation of the ventral striatum does reflect the changing expectations of reward (see Appendix 1, Section B.17.3) during the trials of a task, and indeed this is what is illustrated at the neuronal level in Fig. 16.3, where the neuron altered its firing rate within 170 ms of the monkey being shown a visual stimulus that indicated whether reward or saline was available on that trial. Given that ventral striatal neurons of the type illustrated in Fig. 16.3 alter their activity when the visual stimulus is shown informing the macaque about whether reward is available on that trial, it is in fact not surprising that the fMRI correlation analyses do pick up signals during trials that can be interpreted as temporal difference error signals. Whether these fMRI correlations with a temporal difference error reflect more than the activity of single neurons that respond as shown in Fig. 16.3 to the predicted reward value (\hat{v} of Section B.17.3) rather than the phasic temporal difference error (Δ) will be interesting to examine in future neuronal recordings.

Activations of the ventral striatum that reflect the inputs that it receives from the orbito-frontal cortex and amygdala are commonly reported in functional neuroimaging studies, but it will be important to examine the mechanisms at the neuronal level in the ventral striatum to understand better the exact signals represented by neurons, and exactly what computations the ventral striatum performs using its inputs.

16.3.2.2 Tail of the caudate nucleus, and posteroventral putamen

The projections from the inferior temporal cortex and the prestriate cortex to the striatum arrive mainly, although not exclusively, in the tail (and genu) of the caudate nucleus and in the posteroventral portions of the putamen (Kemp and Powell, 1970; Saint-Cyr et al., 1990). The activity of single neurons was analyzed in the tail of the caudate nucleus and adjoining part of the ventral putamen by Caan, Perrett and Rolls (1984). Of 195 neurons analyzed in two macaque monkeys, 109 (56%) responded to visual stimuli, with latencies of 90–150 ms for the majority of the neurons. The neurons responded to a limited range of complex visual stimuli, and in some cases responded to simpler stimuli such as bars and edges. Typically (for 75% of neurons tested) the neurons habituated rapidly, within 1–8 exposures, to each visual stimulus, but remained responsive to other visual stimuli with a different pattern. This habituation was orientation-specific, in that the neurons responded to the same pattern shown at an orthogonal orientation. The habituation was also relatively short term, in that at least partial dishabituation to one stimulus could be produced by a single intervening presentation of a different visual stimulus. These neurons were relatively unresponsive in a visual discrimination task, having habituated to the discriminative stimuli that had been presented in the task on many previous trials. Consistent findings were obtained by Brown et al. (1995).

Given these responses, it may be suggested that these neurons are involved in short-term pattern-specific habituation to visual stimuli. This system would be distinguishable from other habituation systems (involved, for example, in habituation to spots of light) in that it is specialized for patterned visual stimuli that have been highly processed through visual cortical analysis mechanisms, as shown not only by the nature of the neuronal responses, but also by the fact that this system receives inputs from the inferior temporal visual cortex. It may also be suggested that this sensitivity to visual pattern change may have a role in alerting the monkey's attention to new stimuli. This suggestion is consistent with the changes in attention and orientation to stimuli produced by damage to the striatum.

In view of these neurophysiological findings, and the finding that in a visual discrimination task neurons that reflected the reinforcement contingencies of the stimuli were not found, Caan, Perrett and Rolls (1984) suggested that the tail of the caudate nucleus is not directly involved in the development and maintenance of reward or punishment associations to stimuli (and therefore is not closely involved in emotion-related processing), but may aid visual discrimination performance by its sensitivity to change in visual stimuli. Neurons in some other

parts of the striatum may, however, be involved in connecting visual stimuli to appropriate motor responses. For example, in the putamen some neurons have early movement-related firing during the performance of a visual discrimination task (Rolls, Thorpe, Boytim, Szabo and Perrett, 1984); and some neurons in the head of the caudate nucleus respond to environmental cues that signal that reward may be obtained (Rolls, Thorpe and Maddison, 1983b).

If there are long-term differences over several days in the associations of visual stimuli with rewards, it has been found that some tail of caudate neurons respond more to the sight of an object with a high and stable reward value, but these neurons do not reverse rapidly during reversals, so do not reflect the current reward value, nor reward prediction error, but a stable longer term bias to look at highly rewarded objects (Yamamoto, Kim and Hikosaka, 2013; Greve and Fischl, 2009). They may thus reflect habit-based stimulus–response associations, and not stimulus–value associations. These neurons in the tail of the caudate nucleus appear to encode long-term value memories of visual objects and to guide gaze automatically to stably valued objects (Kim, Ghazizadeh and Hikosaka, 2015a; Kim and Hikosaka, 2015; Hikosaka, Ghazizadeh, Griggs and Amita, 2018). A type of dopamine neuron in the monkey caudolateral part of the substantia nigra pars compacta that project to the tail of the caudate nucleus retain past learned reward values stably, and continue to respond differentially to the objects, even when reward is not expected. These dopamine neurons may provide a training signal for the tail of the caudate nucleus (Kim, Ghazizadeh and Hikosaka, 2015a).

16.3.2.3 Postero-ventral putamen

Following these investigations on the caudal striatum which implicated it in visual functions related to a short-term habituation or memory process, a further study was performed to investigate the role of the posterior putamen in visual short-term memory tasks (Johnstone and Rolls, 1990; Rolls and Johnstone, 1992). Both the inferior temporal visual cortex and the prefrontal cortex project to the posterior ventral parts of the putamen (Goldman and Nauta, 1977; Van Hoesen et al., 1981) and these cortical areas are known to subserve a variety of complex functions, including functions related to memory. For example, cells in both areas respond in a variety of short-term memory tasks (Fuster, 1973, 2008; Fuster and Jervey, 1982; Baylis and Rolls, 1987; Miyashita and Chang, 1988).

Two main groups of neurons with memory-related activity were found in the postero-ventral putamen in a delayed match-to-sample (DMS) task. In the task, the monkey was shown a sample stimulus, and had to remember it during a 2–5 s delay period, after which if a matching stimulus was shown he could make one response, but if a non-matching stimulus was shown he had to make no response (Johnstone and Rolls, 1990; Rolls and Johnstone, 1992).

First, 11% of the 621 neurons studied responded to the test stimulus which followed the sample stimulus, but did not respond to the sample stimulus. Of these neurons, 43% responded only on non-match trials (test different from sample), 16% only on match trials (test same as the sample), and 41% to the test stimulus irrespective of whether it was the same or different from the sample. These neuronal responses were not related to the licking motor responses since (i) the neurons did not respond in other tasks in which a lick response was required (for example, in an auditory delayed match-to-sample task which was identical to the visual delayed match-to-sample task except that auditory short-term memory rather than visual short-term memory was required; in a serial recognition memory task; or in a visual discrimination task), and (ii) a periresponse time spike-density function indicated that the stimulus onset better predicted neuronal activity.

Second, 9.5% of the neurons responded in the delay period after the sample stimulus, during which the sample was being remembered. These neurons did not respond in the auditory version of the task, indicating that the responses were visual modality-specific (as were the

Fig. 16.5 Responses of a cue-related neuron in the head of the caudate nucleus in a Go/NoGo visual discrimination task in which the visual stimulus was presented at time 0. Each trial is a single row of the rastergram, each action potential is represented by a single dot, and a lick made to obtain fruit juice is represented by an inverted triangle. R, Reward trials on which fruit juice was obtained. S, Salt trials on which if a lick was made, a small drop of saline was obtained. Tone and light emitting diode cues were provided starting 500 ms before the visual stimulus was shown. Top set of trials: normal performance of the task with the lick tube close to the mouth. Middle set of trials: the lick tube was removed out of reach, but the tone/LED cue, and discriminative visual stimuli, were still provided. Bottom set of trials: normal performance of the task with the lick tube close to the mouth. F, food reward was shown. A, an aversive visual stimulus was shown. (Reprinted from E. T. Rolls, S.J.Thorpe, and S.P.Maddison (1983) Responses of striatal neurons in the behaving monkey. 1. Head of the caudate nucleus. *Behavioural Brain Research* 7:179–210. © Elsevier B.V.)

responses of all other neurons in this part of the putamen with activity related to the delayed match-to-sample task). Given that the visual and auditory tasks were very similar apart from the modality of the input stimuli, this suggests that the activity of the neurons was not related to movements, or to rewards or punishers obtained in the tasks (and is thus not closely linked to emotion-related processing), but instead to modality-specific short-term memory-related processing.

In recordings made from pallidal neurons it was found that some responded in both visual and auditory versions of the task (Johnstone and Rolls, 1990; Rolls and Johnstone, 1992). Of 37 neurons responsive in the visual DMS task that were also tested in the auditory version, seven (19%) responded also in the auditory DMS task. The finding that some of the pallidal neurons active in the DMS task were not modality-specific, whereas only visual modality-specific DMS units were located in the postero-ventral part of the striatum, provides evidence that **the globus pallidus may represent a further stage in information processing in which information from different parts of the striatum can converge.**

16.3.2.4 Head of the caudate nucleus

The activity of 394 neurons in the head of the caudate nucleus and most anterior part of the putamen was analyzed in three behaving rhesus monkeys (Rolls, Thorpe and Maddison, 1983b). Of these neurons, 64.2% had responses related to environmental stimuli, movements, the performance of a visual discrimination task, or eating. However, only relatively small proportions of these neurons had responses that were unconditionally related to visual (9.6%), auditory (3.5%), or gustatory (0.5%) stimuli, or to movements (4.1%). Instead, the majority of the neurons had responses that occurred conditionally in relation to stimuli or movements, in that the responses occurred in only some test situations, *and were often dependent on the performance of a task by the monkeys.* Thus, it was found that in a visual discrimination task

14.5% of the neurons responded during a 0.5 s tone/light cue that signalled the start of each trial (cue-related neurons); 31.1% responded in the period in which the discriminative visual stimuli were shown, with 24.3% of these responding more either to the visual stimulus that predicted food reward or to a stimulus that predicted punishment (by a taste of saline) (reward prediction neurons); and 6.2% responded in relation to lick responses.

An example of a *cue-related* neuron in the head of the caudate nucleus that started responding as soon as a tone/light-emitting diode (LED) cue was presented indicating that a trial was about to start is shown in Fig. 16.5. At time 0 a discriminative visual stimulus was shown, which indicated if for example it was a triangle that reward could be obtained, or if it was a square that saline would be obtained if a lick was made. The reward trials (R) on which a lick could be made to obtain fruit juice, and saline (S) trials on which a lick should not be made otherwise a drop of aversive saline was obtained, each occurred with probability 0.5. This cue-related neuron stopped responding soon after the visual stimulus appeared, and did not discriminate between reward (R) and punishment (S) trials. It was thus a cue neuron and not a reward-predicting neuron. It could be described as encoding *salience* but not valence. Further evidence that the neuron was not reward or punishment related is that it did not respond on trials on which a food reward was shown (F), or an aversive visual stimulus was shown (A).

If the lick tube was moved away from the lips by a few mm so that juice reward could not be obtained (but the tone/LED still sounded, and was followed by a discriminative visual stimulus), the neuron stopped responding to the tone/LED cue, providing evidence that it was only when the tone/LED cue predicted the start of a trial in the visual discrimination task that the head of caudate neuron responded to the cue. This is shown by the middle set of trials in Fig. 16.5.

Approximately half of the cue-related neurons tested showed this learning whereby they only responded to a warning cue normally used to start a trial if it actually did signal the start a trial. It typically took just a few trials for this trial predicting effect of a tone/LED cue to be learned and unlearned by these neurons.

Most of these cue-related neurons learned to respond to whichever cue, either a 500 Hz tone, or a light-emitting diode, signalled the start of a trial (see example in Fig. 16.6).

An example of a *reward-predicting* neuron in the head of the caudate nucleus that started responding as soon as a cue was available that a trial was about to start, and which continued firing after a visual stimulus was shown which indicated that a lick response could be made to obtain juice reward (R), but which stopped firing after a visual stimulus was shown that indicated that if a lick response was made, aversive saline (S) would be obtained, is shown in Fig. 16.7. The reward (R) and saline (S) trials each occurred with probability 0.5. This type of neuron, common in the head of the primate caudate nucleus, thus increased its firing as soon as the probability of reward increased at the start of a trial to 0.5, learned to respond to the first cue that signalled the start of a trial, and stopped responding as soon as the probability of reward decreased to 0 on punishment (S) trials. These neurons typically did not respond in relation to the cue stimuli, to the visual stimuli, or to movements, when these occurred independently of the task or performance of the task was prevented, for example by withdrawing the lick tube from which fruit juice could be obtained (Rolls, Thorpe and Maddison, 1983b) (as illustrated for a cue-related neuron in Fig. 16.5). That is, the responses of these neurons reflected whether reward would be obtained, and more generally, reflect how much reward will be obtained (Cromwell and Schultz, 2003). Similar neurons in the head of the caudate nucleus responded to punishment-predicting stimuli, and indeed approximately as many neurons responded to the saline punishment-associated visual stimulus in the Go/NoGo visual discrimination task as to the juice reward-predicting stimulus (Rolls, Thorpe and Maddison, 1983b; Rolls, Thorpe, Maddison, Roper-Hall, Puerto and Perrett, 1979c; Rolls, 1984).

Fig. 16.6 Responses of a cue-related neuron in the head of the caudate nucleus in a Go/NoGo visual discrimination task in which the visual stimulus was presented at time 0, when a mechanical shutter opened to reveal the discriminative stimulus. Each trial is a single row of the rastergram, each action potential is represented by a single dot, and a lick made to obtain fruit juice on Reward trials only is represented by an inverted triangle. Tone and/or light emitting diode (LED) cues were provided starting 500 ms before the visual stimulus was shown. If no 500 ms warning cue was given for the start of a trial, the neuron responded to the first indication that a trial was beginning, the sound of the shutter opening at time 0. The neuron did not predict whether reward would or would not be obtained, in that there was no differential neuronal response on Reward trials (on which licks were made), compared to non-reward trials (on which licks were correctly not made). The line at the top shows the cusum (cumulative sum) statistic. (Reprinted from E. T. Rolls, S.J.Thorpe, and S.P.Maddison (1983) Responses of striatal neurons in the behaving monkey. 1. Head of the caudate nucleus. *Behavioural Brain Research* 7:179–210. © Elsevier B.V.)

Thus some neurons in the head of the caudate nucleus encode the *valence* of visual stimuli. Consistently, Watanabe, Lauwereyns and Hikosaka (2003) have found that one population of neurons in the primate caudate nucleus responds to rewarded eye movements, and a separate population to unrewarded eye movements.

Similar types of response were found when the neurons were tested outside the visual discrimination task, during feeding. Of the neurons tested during feeding, 25.8% responded when the food was seen by the monkey, 6.2% when he tasted it, and 22.4% during a cue given by the experimenter that a food or non-food object was about to be presented. Further evidence on the nature of these neuronal responses was that many of the neurons with cue-related responses only responded to the tone/light cue stimuli when they were cues for the performance of the task or the presentation of food as described above, and some responded to the different cues used in the task (tone/LED) and feeding test (an arm movement made by the experimenter to reach behind a screen to obtain a food or non-food object) situations (Rolls, Thorpe and Maddison, 1983b).

Similar neurons have been described by Hikosaka and colleagues, who emphasise that head of caudate neurons rapidly change their responses to reflect the current value of a reward stimulus when it changes, and are thus suitable for flexible reward-related behavior when the reward contingencies change (Kim and Hikosaka, 2015; Hikosaka et al., 2018). This is in contrast to tail of caudate neurons that respond to the long-term value of visual stimuli such as objects, even when the contingencies flexibly reverse. These tail of caudate neurons are thus implicated in habitual behavioral responses to objects based on their long-term reward value (Kim and Hikosaka, 2015; Hikosaka et al., 2018).

The finding that such head of caudate neurons may respond to environmental stimuli only when they are significant in predicting for example the onset of a trial (a cue neuron), or the delivery of reward (a reward-predicting neuron) (Rolls, Thorpe, Maddison, Roper-Hall, Puerto and Perrett, 1979c; Rolls, Thorpe and Maddison, 1983b), was confirmed by Evarts and his colleagues. They showed that some neurons in the putamen only responded to the

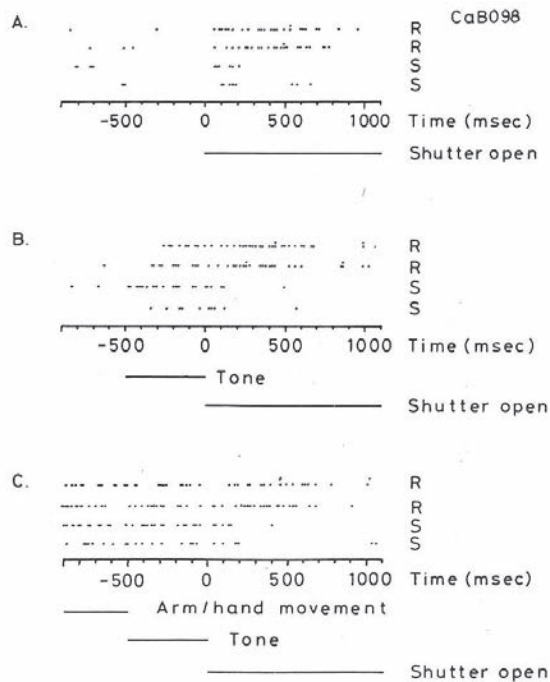

Fig. 16.7 Responses of a reward-predicting neuron in the head of the caudate nucleus in a Go/NoGo visual discrimination task in which the visual stimulus was presented at time 0. Each trial is a single row of the rastergram, each action potential is represented by a single dot, and a lick made to obtain fruit juice is represented by a vertical pair of dots. R, Reward trials on which fruit juice was obtained. S, Salt trials on which if a lick was made, a small drop of saline was obtained. (A) The neuron started to respond approximately 80 ms after the start of the trial when a shutter opened to reveal the discriminative stimulus, continued to respond on reward trials until after the fruit juice was obtained, and stopped responding at approximately 160 ms on trials on which the punisher-related stimulus (S) was shown. (B) The neuron started responding soon after a cue tone sounded indicating the start of a trial. (C) The neuron started responding at the earliest indication that the trial would start, an arm movement made by the macaque to press a button to start the trial. (Reprinted from E. T. Rolls, S.J.Thorpe, and S.P.Maddison (1983) Responses of striatal neurons in the behaving monkey. 1. Head of the caudate nucleus. *Behavioural Brain Research* 7:179–210. © Elsevier B.V.)

click of a solenoid when it indicated that a fruit juice reward could be obtained (Evarts and Wise, 1984). The findings have also been confirmed by Tremblay and Schultz (1998) (see also Schultz, Tremblay and Hollerman (2003)), who reported that macaque caudate neurons come to respond during learning to cues related to the preparation of movement or expectation of reward, and do not respond to cues that do not predict such events.

We have found that this decoding of the significance of environmental events that are signals for the preparation for or initiation of a behavioral response is represented in the firing of a population of neurons in the dorsolateral prefrontal cortex, which projects into the head of the caudate nucleus (E. T. Rolls and G. C. Baylis, unpublished observations 1984). These neurons only respond to the tone cue if it signals the start of a trial of the visual discrimination task, just as do the corresponding population of neurons in the head of the caudate nucleus. The indication that the decoding of significance is performed by the prefrontal cortex, and that the striatum receives only the results of the cortical computation, is considered below and elsewhere (Rolls and Williams, 1987b).

These findings indicate that the head of the caudate nucleus and most anterior part of the putamen contain populations of neurons that respond to predictive sensory cues that enable preparation for the performance of tasks such as feeding and tasks in which movements must be initiated, and others that respond during the performance of such tasks in relation to sensory cue that predict reward, and that the majority of these neurons have no uncondi-

tional sensory or motor responses. It has therefore been suggested (Rolls, Thorpe, Maddison, Roper-Hall, Puerto and Perrett, 1979c; Rolls, Thorpe and Maddison, 1983b) that the anterior neostriatum contains neurons that are important for the utilization of environmental cues for the preparation for behavioral responses, and for particular behavioral responses made in particular situations to particular environmental stimuli, that is in stimulus–motor response habit formation. Different neurons in the cue-related group often respond to different subsets of environmentally significant events, and thus convey some information that would be useful in switching behavior, in preparing to make responses, and in connecting inputs to particular responses (Rolls, Thorpe, Maddison, Roper-Hall, Puerto and Perrett, 1979c; Rolls, Thorpe and Maddison, 1983b; Rolls, 1984). Striatal neurons with similar types of response have also been recorded by Wolfram Schultz and colleagues (Schultz, Apicella, Romo and Scarnati, 1995a; Tremblay and Schultz, 1998; Cromwell and Schultz, 2003; Schultz, Tremblay and Hollerman, 2003). Striatal tonically active interneurons (TANs) which have high spontaneous firing rates and respond by decreasing their firing rates may respond to similar cue-predicting and reward-predicting events (Graybiel and Kimura, 1995), presumably by receiving inhibitory inputs from the principal striatal neurons described above, the medium spiny neurons.

It is of interest, and just as expected, that some dopamine neurons respond to these cue-related inputs, and other salient including novel and aversive stimuli (Bromberg-Martin, Matsumoto and Hikosaka, 2010a) as described in Section 16.4.3, that are found in the head of the caudate nucleus and ventral striatum, for these parts of the striatum provide inputs to the dopamine neurons (Haber and Knutson, 2009).

In a habit-learning, sequential saccade, task, neurons in the head of the caudate nucleus reflected the learning of the task, and the cost-benefit signals that would be consistent with reinforcement learning (Desrochers et al., 2015; Graybiel and Grafton, 2015).

In human fMRI studies, activations have been described in the striatum that reflect whether monetary rewards can be obtained, that is they reflect expected reward value (Delgado, Nystrom, Fissell, Noll and Fiez, 2000; Knutson, Adams, Fong and Hommer, 2001; Haber and Knutson, 2009; Knutson, Delgado and Phillips, 2009; Wu, Sacchet and Knutson, 2012) and also reward outcome value (Rolls, McCabe and Redoute, 2008e). These activations presumably reflect the activity of the reward-predicting striatal neurons (Rolls, Thorpe, Maddison, Roper-Hall, Puerto and Perrett, 1979c; Rolls, Thorpe and Maddison, 1983b; Rolls, 1984). Activations to monetary reward only if it is being worked for instrumentally (Zink et al., 2004) may reflect the type of task dependence illustrated for a cue-related neuron in Fig. 16.5. Human striatal fMRI activations to non-rewarding but salient stimuli (Zink et al., 2003) may reflect the types of trial-predicting (i.e. cue-related) neurons shown in Figs. 16.5 and 16.6 but not reward-predicting neurons of the type shown in Fig. 16.7.

One would expect human striatal activations also to be demonstrable to punishment-predicting stimuli, given that approximately half of the striatal reward/punishment-predicting neurons respond to punishment-predicting stimuli (Rolls, Thorpe, Maddison, Roper-Hall, Puerto and Perrett, 1979c; Rolls, Thorpe and Maddison, 1983b; Rolls, 1984), and there is some human fMRI evidence for this (Seymour et al., 2004). It is a difficulty (Bromberg-Martin, Matsumoto and Hikosaka, 2010a) for the dopamine reward prediction error hypothesis (Schultz et al., 1995b, 1997; Waelti et al., 2001; Schultz, 2004, 2013) that it cannot account for the formation of striatal neurons that fire to predict punishment. [In particular, if dopamine neurons decrease their firing rate if an expected reward is not received or a punishment is received (Mirenovic and Schultz, 1996; Waelti, Dickinson and Schultz, 2001; Tobler, Dickinson and Schultz, 2003), then this would not promote learning in the striatum whereby striatal neurons might respond more to the stimulus (e.g. a discriminative stimulus in a visual discrimination task) that predicted punishment.] However, such reward and punisher predicting information is reflected in the firing of orbitofrontal cortex neurons, some

of which predict reward, and others of which predict punishment (see Chapter 11), and it is presumably by this orbitofrontal cortex route that punishment-predicting neurons in the head of the caudate nucleus receive this information (rather than being reinforced into this type of firing by a dopamine reward error prediction signal).

It is very interesting that the type of head of caudate neuron shown in Fig. 16.7 has certain similarities to the midbrain dopamine neurons described by Schultz and colleagues (Schultz et al., 1995b; Mirenowicz and Schultz, 1996; Waelti et al., 2001), except that the dopamine neurons respond to the transitions in reward probabilities, rather than the reward probabilities themselves which is what appears to be encoded by the type of head of caudate neuron shown in Fig. 16.7. Thus an alternative to the hypothesis that the dopamine neurons provide a reward-prediction error teaching signal (see Section 16.4.3) is that the firing of the dopamine neurons may reflect feedback connections from these striatal regions to the dopamine neurons in the substantia nigra, pars compacta, and ventral tegmental area. These feedback connections would then influence the dopamine neurons for short periods primarily when the firing of the striatal neurons changed, implemented by a high-pass filtering effect. This would leave much more open what the functions of the dopamine neurons are (see Section 16.4.3), in that a simple feedback effect might be being implemented (from striatum to the dopamine neurons and back), perhaps to dynamically reset thresholds or gains in the striatum.

16.3.2.5 Anterior putamen

It is clear that the activity of many neurons in the putamen is related to movements (Anderson, 1978; Crutcher and DeLong, 1984a,b; DeLong et al., 1984; DeLong and Wichmann, 2010). There is a somatotopic organization of neurons in the putamen, with separate areas containing neurons responding to arm, leg, or orofacial movements. Some of these neurons respond only to active movements, and others to active and to passive movements. Some of these neurons respond to somatosensory stimulation, with multiple clusters of neurons responding, for example, to the movement of each joint. Some neurons in the putamen have been shown in experiments in which the arm has been given assisting and opposing loads to respond in relation to the direction of an intended movement, rather than in relation to the muscle forces required to execute the movement (Crutcher and DeLong, 1984b). Also, the firing rate of neurons in the putamen tends to be linearly related to the amplitude of movements (Crutcher and DeLong, 1984b), and this is of potential clinical relevance, since patients with basal ganglia disease frequently have difficulty in controlling the amplitude of their limb movements.

In order to obtain further evidence on specialization of function within the striatum, the activity of neurons in the putamen has been compared with the activity of neurons recorded in different parts of the striatum in the same tasks (Rolls, Thorpe, Boytim, Szabo and Perrett, 1984). Of 234 neurons recorded in the putamen of two macaque monkeys during the performance of a visual discrimination task and the other tests in which other striatal neurons have been shown to respond (Rolls, Thorpe and Maddison, 1983b; Caan, Perrett and Rolls, 1984), 68 (29%) had activity that was phasically related to movements (Rolls, Thorpe, Boytim, Szabo and Perrett, 1984). Many of these responded in relation to mouth movements such as licking. Similar neurons were found in the substantia nigra, pars reticulata, to which the putamen projects (Mora, Mogenson and Rolls, 1977). The neurons did not have activity related to taste, in that they responded, for example, during tongue protrusion made to a food or non-food object. Some of these neurons responded in relation to the licking mouth movements made in the visual discrimination task, and always also responded when mouth movements were made during clinical testing when a food or non-food object was brought close to the mouth. Their responses were thus unconditionally related to movements, in that

they responded in whichever testing situation was used, and were therefore different from the responses of neurons in the head of the caudate nucleus (Rolls, Thorpe and Maddison, 1983b).

Of the 68 neurons in the putamen with movement-related activity in these tests, 61 had activity related to mouth movements, and seven had activity related to movements of the body. Of the remaining neurons, 24 (10%) had activity that was task-related in that some change of firing rate associated with the presentation of the tone cue or the opening of the shutter occurred on each trial (Rolls, Thorpe, Boytim, Szabo and Perrett, 1984), four had auditory responses, one responded to environmental stimuli (Rolls, Thorpe and Maddison, 1983b), and 137 were not responsive in these test situations.

These findings (Rolls, Thorpe, Boytim, Szabo and Perrett, 1984) provide further evidence that differences between neuronal activity in different regions of the striatum are found even in the same testing situations, and also that the inputs that activate these neurons are derived functionally from the cortex which projects into a particular region of the striatum (in this case sensori-motor cortex, areas 3, 1, 2, 4, and 6).

In these four parts of the striatum in which a comparison can be made of processing in the striatum with that in the cortical area that projects to that part of the striatum, it thus appears that the full information represented in the cortex does not reach the striatum, but that rather the striatum receives the output of the computation being performed by a cortical area, and could use this to initiate, switch, or alter behavior.

The hypothesis arises from these findings that some parts of the striatum, particularly the caudate nucleus, ventral striatum, and posterior putamen, receive the output of these cortical memory-related and cognitive computations, but do not themselves perform them. Instead, on receiving the cortical and limbic outputs, the striatum may be involved in switching behavior as appropriate as determined by the different, sometimes conflicting, information received from these cortical and limbic areas. On this view, the striatum would be particularly involved in the selection of behavioral responses, and in producing one coherent stream of behavioral output, with the possibility to switch if a higher priority input was received. This process may be achieved by a laterally spreading competitive interaction between striatal or pallidal neurons, which might be implemented by the direct inhibitory connections between neurons that are close together in the striatum and globus pallidus. In addition, the inhibitory interneurons within the striatum, the dendrites of which in the striatum may cross the boundary between the matrix and striosomes, may play a part in this interaction between striatal processing streams (Groves, 1983; Graybiel and Kimura, 1995; Groves et al., 1995).

Dopamine could play an important role in setting the sensitivity of this response selection function, as suggested by direct iontophoresis of dopamine on to single striatal neurons, which produces a similar decrease in the response of the neuron and in its spontaneous activity in the behaving macaque (Rolls, Thorpe, Boytim, Szabo and Perrett, 1984; Rolls and Williams, 1987b). Consistent with dopamine playing an important role of this type, dopamine acting via D1 receptors in the direct pathway, and via D2 receptors in the indirect pathway, promotes behavioral output (Gerfen and Surmeier, 2011).

In addition to this response selection function by competition, the basal ganglia may, by the convergence discussed, enable signals originating from non-motor parts of the cerebral cortex to be mapped into motor signals to produce behavioral output. In this way, stimulus-response habit learning could be implemented. Indeed, there is considerable agreement that the basal ganglia are involved in stimulus-response habit learning (Graybiel and Grafton, 2015; Robbins and Costa, 2017). The ways in which these computations might be performed are considered next.

16.4 How do the basal ganglia perform their computations?

16.4.1 Interaction between neurons and selection of output

On the hypothesis just raised, different regions of the striatum, or at least the outputs of such regions, would need to interact. Is there within the striatum the possibility for different regions to interact, and is the partial functional segregation seen within the striatum maintained in processing beyond the striatum? For example, is the segregation maintained throughout the globus pallidus and thalamus with projections to different premotor and even prefrontal regions reached by different regions of the striatum, or is there convergence or the possibility for interaction at some stage during this post-striatal processing?

Given the anatomy of the basal ganglia, interactions between signals reaching the basal ganglia could happen in a number of different ways. One would be for each part of the striatum to receive at least some input from a number of different cortical regions. As discussed above, there is evidence for patches of input from different sources to be brought adjacent to each other in the striatum (Van Hoesen et al., 1981; Seleman and Goldman-Rakic, 1985; Graybiel and Kimura, 1995). For example, in the caudate nucleus, different regions of association cortex project to adjacent longitudinal strips (Seleman and Goldman-Rakic, 1985). Now, the dendrites of striatal neurons have the shape of large plates that lie at right angles to the incoming cortico-striatal fibres (Percheron, Yelnik and François, 1984b,a; Percheron, Yelnik, François, Fenelon and Talbi, 1994; Yelnik, 2002; Buot and Yelnik, 2012) (see Figs. 16.8 and 16.9). Thus one way in which interaction may start in the basal ganglia is by virtue of the same striatal neuron receiving inputs on its dendrites from more than just a limited area of the cerebral cortex. This convergence may provide a first level of integration over limited sets of cortico-striatal fibres. The large number of cortical inputs received by each striatal neuron, in the order of 10,000 (Wilson, 1995), is consistent with the hypothesis that convergence of inputs carrying different signals is an important aspect of the function of the basal ganglia. The computation that could be performed by this architecture is discussed below for the inputs to the globus pallidus, where the connectivity pattern is comparable.

The regional segregation of neuronal response types in the striatum described above is consistent with mainly local integration over limited, adjacent sets of cortico-striatal inputs, as suggested by this anatomy. Short-range integration or interactions within the striatum may also be produced by the short length (for example 0.5 mm) of the intra-striatal axons of striatal neurons. These could produce a more widespread influence if the effect of a strong input to one part of the striatum spread like a lateral competition signal (cf. Groves (1983), Groves et al. (1995)). Such a mechanism could contribute to behavioral response selection in the face of different competing input signals to the striatum. The lateral inhibition could operate, for example, between the striatal principal (that is medium spiny) neurons by their direct connections, to inhibit each other. (These neurons receive excitatory connections from the cortex, respond by increasing their firing rates, and could inhibit each other by their local axonal arborizations, which spread in an area as large as their dendritic trees, and which utilize GABA as their inhibitory transmitter to enable the principal neurons of the striatum to directly inhibit each other.) Further lateral inhibition could operate in the pallidum and substantia nigra (see Fig. 16.9). Here again there are local axon collaterals, as widespread as the very large pallidal and nigral dendritic fields. The lateral competition could again operate by direct inhibitory connections between the neurons.

[Note that pallidal and nigral cells have high spontaneous firing rates (often 25–50 spikes/s), and respond (to their inhibitory striatal inputs) by reducing their firing rates below this high spontaneous rate. Such a decrease in the firing rate of one neuron would release inhibition

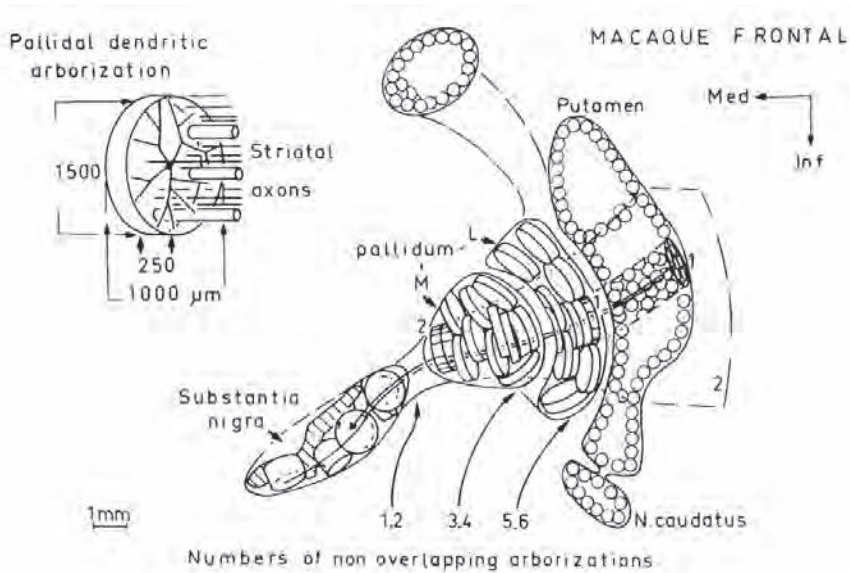

Fig. 16.8 Semi-schematic spatial diagram of the striato-pallido-nigral system (see text). The numbers represent the numbers of non-overlapping arborizations of dendrites in the plane shown. L, lateral or external segment of the globus pallidus; M, medial or internal segment of the globus pallidus. The inserted diagram in the upper left shows the geometry of the dendrites of a typical pallidal neuron, and how the flat dendritic arborization is pierced at right angles by the striatal axons, which make occasional synapses en passage. (Reproduced from Gerard Percheron, Jerome Yelnik, and Chantal Francois (1984) A Golgi analysis of the primate globus pallidus. III. Spatial organization of the striatopallidal complex. *Journal of Comparative Neurology* 227: 214–227. Copyright © Alan R. Liss, Inc.)

on nearby neurons, causing them to increase their firing rates, equivalent to responding less. It is very interesting that direct inhibitory connections between the neurons can implement selection, even though at the striatal level the neurons have low spontaneous firing rates and respond by increasing their firing rates, whereas in the globus pallidus and substantia nigra pars reticulata the neurons have a high spontaneous firing rate, and respond by decreasing their firing rate.]

A selection function of this type between processing streams in the basal ganglia, even without any convergence anatomically between the processing streams implemented by feed-forward inputs, might provide an important computational *raison d'être* for the basal ganglia. As noted, the direct inhibitory local connectivity between the principal neurons within the striatum and globus pallidus would seem to provide a simple, and perhaps evolutionarily old, way in which to implement competition between neurons and processing streams. This might even be a primitive design principle that characterizes the basal ganglia. A system such as the basal ganglia with direct inhibitory recurrent collaterals may have evolved easily because it is easier to make stable than architectures such as the cerebral cortex with recurrent excitatory connections. The basal ganglia architecture may have been especially appropriate in motor systems in which instability could produce movement and co-ordination difficulties (Rolls and Treves, 1998; Rolls, 2014a). Equations that describe the way in which this mutual inhibition between the principal neurons can result in contrast enhancement of neuronal activity in the different competing neurons, and thus selection, are provided by Grossberg (1988), Gurney et al. (2001a), Gurney et al. (2001b), and Grossberg (2021).

This hypothesis of lateral competition between the neurons of the basal ganglia can be sketched simply (see Fig. 16.9 and Rolls and Treves (1998) and Rolls (2014a), where a more detailed neuronal network theory of the operation of the basal ganglia is presented). The inputs from the cortex to the striatum are excitatory, and competition between striatal neurons

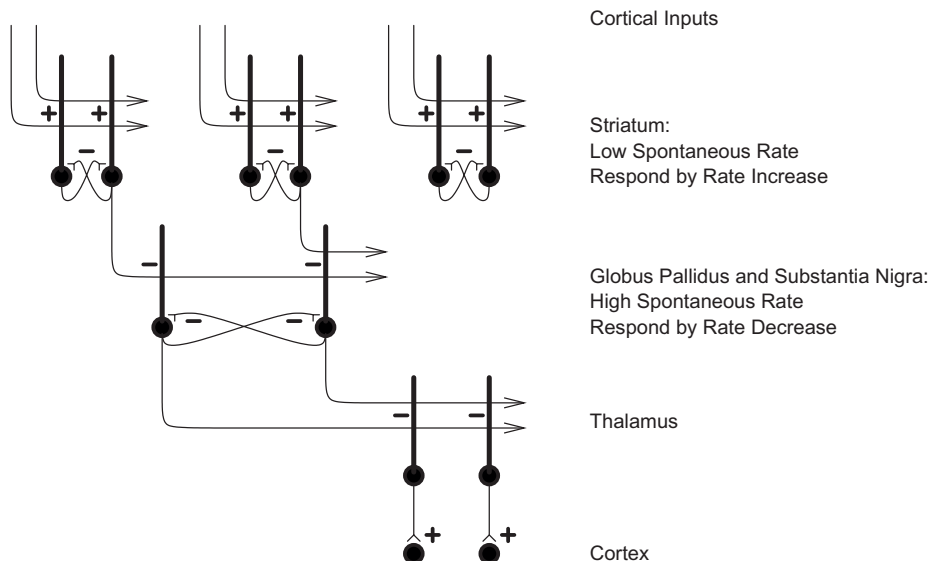

Fig. 16.9 Schematic hypothesis of basal ganglia network architecture. A key aspect is that in both the striatum, and in the globus pallidus and substantia nigra pars reticulata, there are direct inhibitory connections (–) between the principal neurons, as shown. These synapses use GABA as a transmitter. Excitatory inputs to the striatum are shown as +. (Reproduced from E. T. Rolls and A. Treves. (1998) *Neural Networks and Brain Function*. Oxford University Press.)

is implemented by the use of an inhibitory transmitter (GABA), and direct connections between striatal neurons, within an area which is approximately co-extensive with the dendritic arborization. Given that the lateral connections between the striatal neurons are collaterals of the output axons, the output must be inhibitory on to pallidal and nigral neurons. This means that to transmit signals usefully, and in contrast with striatal neurons, the neurons in the globus pallidus and substantia nigra (pars reticulata) must have high spontaneous firing rates, and respond by reducing their firing rates. These pallidal and nigral neurons then repeat the simple scheme for lateral competition between output neurons by having direct lateral inhibitory connections to the other pallidal and nigral neurons. When nigral and pallidal neurons respond by reducing their firing rates, the reduced inhibition through the recurrent collaterals allows the connected pallidal and nigral neurons to fire faster, and also at the same time the main output of the pallidal and nigral neurons allows the thalamic neurons to fire faster. The thalamic neurons then have the standard excitatory influence on their cortical targets.

The simple, and perhaps evolutionarily early, aspect of this basal ganglia architecture is that the striatal, pallidal, and nigral neurons implement competition (for selection) by direct inhibitory recurrent lateral connections of the main output neurons on to other output neurons, with the inputs to each stage of processing (e.g. striatum, globus pallidus) synapsing directly on to the output neurons that inhibit each other (see Fig. 16.9).

Another possible mechanism for interaction within the striatum is provided by the dopaminergic pathway, through which a signal that has descended from, for example, the orbitofrontal cortex via the ventral striatum and habenula to the dopamine neurons in the midbrain (Fig. 11.4, (Rolls, 2017c)) might thereby influence other parts of the striatum. Because of the slow conduction speed of the dopaminergic neurons, this latter system would probably not be suitable for rapid switching of behavior, but only for more tonic, long-term adjustments of connectivity and sensitivity.

Further levels for integration within the basal ganglia are provided by the striato-pallidal and striato-nigral projections (Percheron, Yelnik and François, 1984b,a; Percheron, Yelnik, François, Fenelon and Talbi, 1994; Yelnik, 2002). The afferent fibres from the striatum again

cross at right angles a flat plate or disc formed by the dendrites of the pallidal or nigral neurons (see Fig. 16.8). The discs are approximately 1.5 mm in diameter, and are stacked up one upon the next at right angles to the incoming striatal fibres. The dendritic discs are so large that in the monkey there is room for only perhaps 50 such discs not to overlap in the external pallidal segment, for 10 non-overlapping discs in the medial pallidal segment, and for one overlapping disc in the most medial part of the medial segment of the globus pallidus and in the substantia nigra.

One result of this convergence achieved by this stage of the medial pallidum/substantia nigra is that even if inputs from different cortical regions were kept segregated by specific wiring rules on to different neurons, there might nevertheless well be the possibility for mutual competition between different pallidal neurons, implemented by their mutual inhibitory connections. Given the relatively small number of neurons into which the cortical signals had now been compressed, it would be feasible to have competition (the same effect as lateral inhibition implemented by inhibitory neurons would achieve elsewhere) implemented between the relatively small population of neurons, now all collected into a relatively restricted space, so that the competition could spread widely within these nuclei. This could allow selection by competition between these pathways, that is effectively between information processing originating in different cortical areas. This could be important in allowing each cortical area to control output when appropriate (depending on the task being performed). Even if full segregation were maintained in the return paths to the cerebral cortex, the return paths could influence each cortical area, allowing it to continue processing if it had the strongest 'call'. Each cortical area on a fully segregated hypothesis might thus have its own non-basal ganglia output routes, but might according to the current suggestion utilize the basal ganglia as a system to select a cortical area or set of areas, depending on how strongly each cortical area is calling for output. The thalamic outputs from the basal ganglia (nuclei VA and VLo of the thalamus) might according to this hypothesis have to some extent an activity or gain-controlling function on a cortical area (such as might be mediated by diffuse terminals in superficial cortical layers), rather than the strong and selective inputs implemented by a specific thalamic nucleus such as the lateral geniculate.

16.4.2 Convergence within the basal ganglia, useful for stimulus-response habit learning

In addition to this selection function, it is also useful to consider the further hypothesis that there is some convergent mapping achieved by the basal ganglia. This could allow for example a stimulus reflecting an input or event from any part of the cerebral cortex to be associated together with for example a response of the type represented in the putamen. The anatomical arrangement just described provides a possibility for some convergence on to single striatal neurons of cortical input, and on to single pallidal and nigral (pars reticulata) neurons of signals from relatively different parts of the striatum. For what computation might such anatomy provide a structural basis? Within the pallidum, each dendritic disc is flat, is orthogonal to the input fibres that pierce it, but is not filled with dendritic arborizations. Instead, each dendrite typically consists of 4–5 branches that are spread out to occupy only a small part of the surface area of the dendritic disc (see Fig. 16.8). There are thousands of such sparsely populated plates stacked on top of one another. Each pallidal neuron is contacted by a number of the mass of fibres from the striatum that pass it, and given the relatively small collecting area of each pallidal or nigral neuron (4 or 5 dendritic branches in a plane), each such neuron is thus likely to receive a random combination of inputs from different striatal neurons within its collection field. The thinness of the dendritic sheet may help to ensure that each axon does not make more than a few synapses with each dendrite, and that the combinations of inputs

received by each dendrite are approximately random. This architecture thus appears to be appropriate for bringing together at random on to single pallidal and nigral neurons, inputs that originate from quite diverse parts of the cerebral cortex. (This is a two-stage process, cortex to striatum, and striatum to pallidum and substantia nigra). By the stage of the medial pallidum and substantia nigra, there is the opportunity for the input field of a single neuron to effectively become very wide. Empirical evidence that convergence does occur functionally from striatum to pallidum is the finding that some of the pallidal neurons active in the delayed match to sample task described in Section 16.3.2.3 were not modality-specific, whereas only visual or auditory modality-specific delayed match to sample neurons were located in the postero-ventral part of the striatum (Johnstone and Rolls, 1990; Rolls and Johnstone, 1992).

Given that this architecture could allow individual pallidal and nigral neurons to receive random combinations of inputs from different striatal neurons, the following functional implications arise. Simple associative (Hebbian) learning in the striatum would enable strongly firing striatal neurons to increase the strength of the synapses from the active cortical inputs in what would operate as a competitive network. (Descriptions of competitive networks are provided in Section B.4.) This could enable associations between, for example, stimuli and responses, to be learned. That learning could be made more efficient if a third input increased the associative plasticity, and dopamine could provide that modulating input (Nakahara et al., 2002). The evidence that the firing of dopamine neurons could reflect a reward prediction error (Schultz, 2013; Jiao et al., 2022) could in this reinforcement learning scenario (Schultz, 2016a; Fremaux and Gerstner, 2015) help to enable co-active stimulus and response inputs to striatal neurons that increase the firing of the striatal neurons to be strengthened by the receipt of a reinforcer such as food.

Consistent with this hypothesis (Rolls, 1999a), long-term potentiation (LTP) used to measure an increase of synaptic strength has been demonstrated in at least some parts of the basal ganglia. For example, Pennartz et al. (1993) demonstrated LTP of limbic inputs to the nucleus accumbens, and were able to show that such LTP is facilitated by dopamine. Further, it was shown that coincident cortical input and depolarization in a striatal neuron can induce long-term depression (LTD) of the cortico-striatal synapse if some dopamine is present (Calabresi et al., 1992), and LTP if there is a phasic release of dopamine (Wickens and Kotter, 1995; Wickens et al., 1996; Reynolds and Wickens, 2002). Dopamine can have diverse effects on striatal circuitry (Cox and Witten, 2019; Schultz, 2019; Bamford et al., 2018).

The system just described would not be very efficient, because the dopamine is broadcast throughout the striatum, and so must enable striatal neurons that have just been active to have their input synapses strengthened. The use of a reward prediction error signal would though be useful, for the stimulus-response connections would only be stamped in harder to make the habit stronger if the reward received (the outcome) was better than expected, as described further below in Section 16.4.3.

I suggest that this associative learning in the striatum may not rely only on the dopamine neuron firing: inputs from the orbitofrontal cortex and amygdala that will reflect rewards do reach the striosomes or patches within the striatal matrix (Bloem, Huda, Sur and Graybiel, 2017; Friedman, Homma, Gibb, Amemori, Rubin, Hood, Riad and Graybiel, 2015), and could provide an additional mechanism for guiding learning in the striatum.

In the pallidum, if additional conjunctive learning of coactive inputs occurs, it would be more complex, requiring, for example, a strongly inhibited pallidal neuron to show synaptic strengthening from strongly firing but inhibitory inputs from the striatum. Then, if a particular pallidal or nigral neuron received inputs by chance from striatal neurons that responded to an environmental cue signal that something significant was about to happen, and from striatal neurons that fired because the animal was making a postural adjustment, this conjunction of

events might make that pallidal or nigral neuron become inhibited by (that is respond to) either input alone. Then, in the future, the occurrence of only one of the inputs, for example only the environmental cue, would result in a decrease of firing of that pallidal or nigral neuron, and thus in the appropriate postural adjustment being made by virtue of the output connections of that pallidal or nigral neuron.

This is a proposal that the basal ganglia are able to detect combinations of conjunctively active inputs from quite widespread regions of the cerebral cortex using their combinatorial architecture and a property of synaptic modifiability. In this way it would be possible to trigger any complex pattern of behavioral responses by any complex pattern of environmental inputs, using what is effectively an associative network (operating as a competitive network or pattern associator) to link by learning an antecedent input (for example the environmental salient cue inputs to the striatum) with the succeeding activity (for example a motor signal driving motor responses), especially if these are followed by a reinforcement signal.

It may be noted that the input events need not include only those from environmental stimuli represented in the caudate nucleus and ventral striatum, but also, if the overlapping properties of the dendrites described above provide sufficient opportunity for convergence, of the context of the movement, provided by inputs via the putamen from sensorimotor cortex. This would then make a system appropriate for triggering an appropriate motor response (learned by trial and error, with the final solution becoming associated with the triggering input events) to any environmental input state. As such, this hypothesis provides a suggested neural basis for ‘habit’ learning in which the basal ganglia have been implicated (Phillips et al., 1988; Petri and Mishkin, 1994; Balleine et al., 2009; Graybiel and Grafton, 2015; Robbins and Costa, 2017). The hypothesis could be said to provide a basis for the storage of motor plans in the basal ganglia, which would be instantiated as a series of look-ups of the appropriate motor output pattern to an evolving sequence of input information.

An interesting aspect of this hypothesis is that other parts of the motor system, such as the anterior cingulate cortex action-outcome learning system (Chapter 12), may mediate the control of action in a voluntary, goal-directed, way in the early stages of learning. The input context for the movement and the appropriate motor signals (originating during learning from motor cortical areas) could then be learned by the basal ganglia, until after many trials the basal ganglia can perform the required look-up of the correct motor output in an automated, ‘habit’, or ‘stimulus–response’, mode. In this sense, the cingulate and other cortical learning systems would set up the conditions, which because of their continuing repetition would be learned by the basal ganglia.

The hypothesis introduced above also may provide a basis for the switching between different types of behavior proposed as a function of the basal ganglia, for if a strong new pattern of inputs was received by the basal ganglia, this would result in a different pattern of outputs being associatively ‘looked up’ than that currently in progress.

16.4.3 Dopamine as a reward prediction error signal for reinforcement learning in the striatum

There is considerable evidence that some dopamine neurons (which are located in the mid-brain substantia nigra pars compacta (A9) and ventral tegmental area (A10)) respond to reward prediction error, and project that information to the striatum (Mirenowicz and Schultz, 1996; Schultz, 1998; Glimcher, 2011b; Schultz, 2013, 2016a,b,c, 2017, 2019). Reward prediction error is the reward outcome value minus the expected value, and is illustrated for a midbrain dopamine neuron in Fig. 16.10. Reward prediction error is a key part of the teaching signal in reinforcement learning, which is described in Sections B.17 and 19.5.

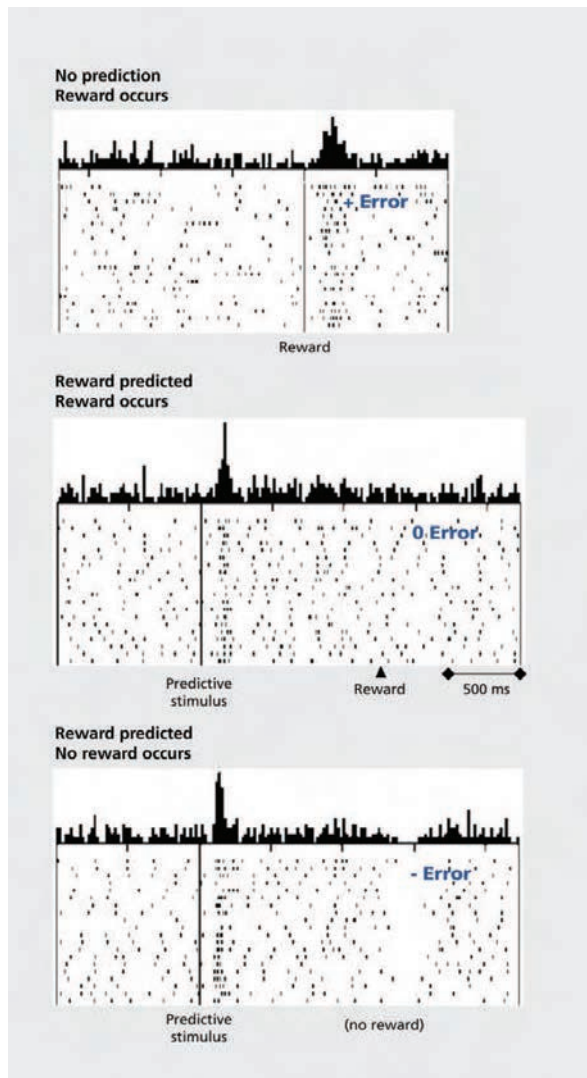

Fig. 16.10 A reward prediction error neuron. The reward outcome is delivered at the time indicated by 'Reward', and is a taste of juice. The Expected Value is signalled by the 'Predictive stimulus'. The neuron fires faster if the reward outcome is larger than expected (top, + Error); does not respond to the reward outcome if it is expected (middle, 0 Error); and fires less if the reward outcome is less than expected (bottom, - Error). The firing is shown on different trials in the rows; and the sum of the firing is represented in the histogram above. (After Schultz, W. 1998. Predictive reward signal of dopamine neurons. *Journal of Neurophysiology* 80: 1–27.)

One type of positive reward prediction error neuron, illustrated in Fig. 16.11A (Matsumoto and Hikosaka, 2009), increases its firing rate to a visual cue that predicts that reward (juice) will be delivered, and decreases its rate to a visual cue that predicts that an aversive stimulus (an air puff) will be delivered (left); and is not activated when a predicted reward is obtained, that is when the juice is delivered (not illustrated in Fig. 16.11A). This type of neuron increases its firing rate to an unpredicted reward outcome, and this is termed a positive reward prediction error response, for the reward outcome is greater than was predicted. This type of neuron decreases its firing if an expected reward stimulus is not received (Fig. 16.11A right), suggesting that it encodes the sign of the prediction error by whether it increases or decreases its firing rate. These neurons encode an accurate prediction error signal, including

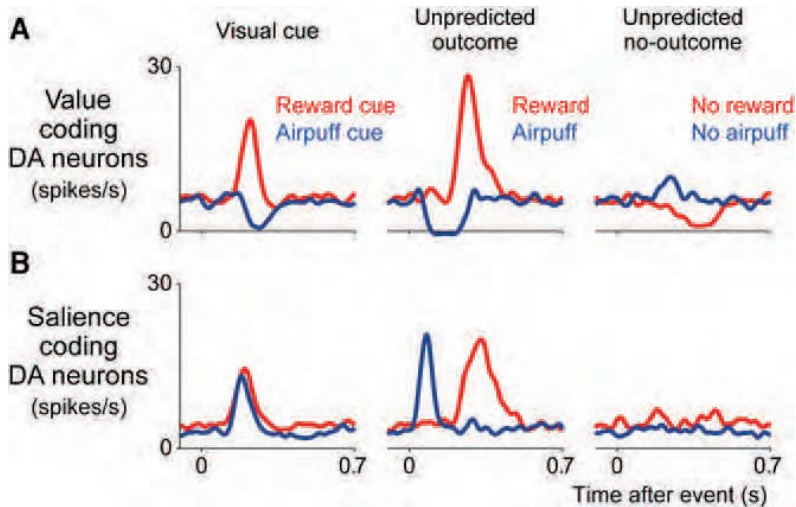

Fig. 16.11 Responses of different types of dopamine neuron. (A) A reward prediction error neuron (see text). The neuron responds to a visual cue that predicts reward (left). It does not respond to the reward outcome if it is as predicted (not illustrated). It does respond if an unpredicted reward is given (middle). It decreases its firing rate if an expected reward is not delivered (right). (B) Neurons activated by aversive and also by rewarding stimuli, sometimes called motivational salience neurons (see text). (Reproduced from Masayuki Matsumoto and Okihide Hikosaka (2009) Two types of dopamine neuron distinctly convey positive and negative motivational signals. *Nature* 459: 7248. © Springer Nature.)

strong inhibition by omission of rewards and mild excitation by omission of aversive events (Fig. 16.11A right). This is the type of dopamine neuron that is generally discussed (Schultz, 2013; Glimcher, 2011a). The neuron illustrated responds in the opposite direction to a visual cue that indicate that a mildly aversive airpuff will be delivered Fig. 16.11A.

Dopamine neurons can perform one-trial rule based reversal (Bromberg-Martin, Matsumoto, Hong and Hikosaka, 2010b), and the origin of this I suggest is the orbitofrontal cortex, which performs this function as described in Section 11.3.4 and projects via the ventral striatum to the dopamine neurons (Fig. 11.4, (Rolls, 2017c)).

Reward prediction error neurons are different to reward outcome neurons in the orbitofrontal cortex, which latter respond vigorously to the delivery of reward, even when it is expected (Section 11.3.1.2). The delivery of a reward is pleasant and produces emotions even when expected, so the dopamine neurons are not related to emotions associated with reward delivery. The reward prediction error signal instead seems more suitable for a learning signal. Moreover, the orbitofrontal cortex reward outcome neurons specify exactly what type of reward has been delivered (taste, oral texture, touch, temperature etc), whereas the reward signal conveyed by dopamine neurons appears to be one-dimensional, that a positive reward prediction error has occurred, but not what the type of reward was.

It should also be noted that these dopamine neurons are completely different to the negative reward prediction error neurons found in the orbitofrontal cortex, which increase their firing rate when an expected reward is not obtained (Thorpe, Rolls and Maddison (1983); see Section 11.3.4) and which has never been found for dopamine neurons.

Dopamine neurons respond not only to the phasic reward prediction error signals just described, but also their firing rate increases steadily during a 2 s period in which another conditioned stimulus is being shown that predicts that reward will be obtained with a probability P of 0.5 (Fiorillo, Tobler and Schultz, 2003). This tonic firing was lower for lower and higher probabilities of reward than 0.5, and so reflects reward uncertainty (see Fig. 16.12). These results are difficult to reconcile with the previously hypothesized (Waelti, Dickinson and Schultz, 2001; Dayan and Abbott, 2001) ‘reward prediction error’ training signal funct-

Fig. 16.12 Recordings from midbrain dopamine neurons by Fiorillo, Tobler and Schultz (2003) in a task in which different visual conditioned stimuli (CS) predicted different probabilities P of juice reward after a delay period when the stimulus switched off. The intertrial interval was variable, so that the conditioned stimulus provided information about reward delivery even when $P = 1.0$. When $P = 1.0$, the neurons responded phasically at the onset of the CS, and did not respond to the delivery of the taste reward. When $P = 0.0$, there was no response to the CS, and no response at the end of the CS unless reward was unexpectedly given (as illustrated). However, when $P = 0.5$, the dopamine neurons responded with gradually increasing and sustained firing during the CS. U indicates the uncertainty of reward. (Reproduced from P. Shizgal and A. Arvanitogiannis (2003) Gambling on dopamine. *Science* 299: 1856–1858. © The American Association for the Advancement of Science.)

ion of the firing of dopamine neurons, for it is difficult to understand how any brain system receiving the phasic (‘prediction error’) and tonic (‘uncertainty of reward’) dopamine signals by the same set of neurons could disentangle them and use them for different functions (Shizgal and Arvanitogiannis, 2003).

It is also an issue that there is an asymmetry in the errors that could be conveyed by dopamine neurons, given their low spontaneous firing rate of a few spikes/s (Niv et al., 2005). As a result of this asymmetry, positive prediction errors could be represented by dopamine neurons by firing rates of $\approx 270\%$ above baseline, while negative errors could be represented by a decrease of only $\approx 55\%$ below baseline (see Fig. 16.11). This asymmetry in prediction errors remains a potential problem for the dopamine error hypothesis.

Another potential problem with the dopamine reward prediction error hypothesis is that there are other types of dopamine neuron, some of which have been studied (Matsumoto and Hikosaka, 2009; Bromberg-Martin, Matsumoto and Hikosaka, 2010a). These neurons, illustrated in Fig. 16.11B, respond to both rewarding and to aversive stimuli, and could not therefore signal reward prediction error. In more detail, these dopamine neurons increase their firing rate to stimuli predicting reward and to stimuli predicting aversive events (left); and also respond when either an unpredicted reward outcome or an unpredicted aversive stimulus is obtained (middle). These are called ‘motivational salience’ neurons (Matsumoto and Hikosaka, 2009; Bromberg-Martin et al., 2010a), in that they encode something about both positive and negative reinforcers, but not a reward prediction error signal. Another type of dopamine neuron responds only to a cue predicting an aversive stimulus, or to an unpredicted aversive outcome.

Another type of dopamine neuron responds to novel stimuli (see Bromberg-Martin et al. (2010a)).

Another type of dopamine neuron responds to alerting cues, for example to the first cue in a trial that indicates that a trial is beginning (Bromberg-Martin et al., 2010a; Horvitz, 2000; Redgrave et al., 1999). These responses are very similar to those that we recorded in the head

of the caudate nucleus (Rolls, Thorpe and Maddison, 1983b) and ventral striatum (Rolls and Williams, 1987a; Williams, Rolls, Leonard and Stern, 1993), which send projections to the dopamine neurons.

Another type of dopamine neuron found in the monkey caudolateral part of the substantia nigra pars compacta that projects to the tail of the caudate nucleus respond not to reward prediction error, but instead respond to objects based on their stable long-term association with rewards and continue to respond differentially to the objects, even when reward is not expected (Kim et al., 2015a). These dopamine neurons may provide a training signal for the tail of the caudate nucleus for habit-based responses, to for example look at objects with stable long-term reward associations (Kim, Ghazizadeh and Hikosaka, 2015a; Kim and Hikosaka, 2015; Hikosaka, Ghazizadeh, Griggs and Amita, 2018).

In rodents, there is also a great diversity of dopamine neuron response types, with some other dopamine neurons responding to the distance to a reward, or to movements (Cox and Witten, 2019).

However, activation of the dopamine neurons projecting to the ventral striatum can induce cue approach and lead the cue to become reinforcing, so it may be that dopamine neurons projecting to different regions have different functions, and some may function to implement a reward prediction error signal for reinforcement learning in the basal ganglia (Cox and Witten, 2019; Schultz, 2019). Indeed, it is now clear that dopamine neurons have far more diverse types of response than signalling reward prediction errors (Schultz, 2019).

Further discussion of the effects of dopamine on behavior is provided in Rolls (2014a). The dopamine system is also implicated in addiction to several types of drug (Everitt et al., 2008; Everitt and Robbins, 2013; Everitt et al., 2018; Luscher et al., 2020), and the habit, stimulus-response functions in habit of the basal ganglia have been related to the addictive properties of drugs that activate the dopamine system (Wise and Jordan, 2021).

Reinforcement learning models (Sections B.17 and 19.5) have been used to model in fMRI studies where reward prediction error may be represented in the brain, with one area in which reward prediction error is represented the ventral striatum (Hare et al., 2008; Colas et al., 2017; O'Doherty et al., 2017).

16.5 Comparison of computations for selection in the basal ganglia and cerebral cortex

The basal ganglia architecture is that the striatal, pallidal, and nigral neurons implement competition (for selection) by direct inhibitory recurrent lateral connections of the main output neurons on to other output neurons. The inputs to each stage of processing (e.g. striatum, globus pallidus) synapse directly on to the output neurons that inhibit each other (see Fig. 16.9). This is a simple and evolutionarily early design in that the basal ganglia were present in the brain before the neocortex evolved. A system such as the basal ganglia with direct inhibitory recurrent collaterals may have evolved easily because it is easier to make stable than architectures such as the cerebral cortex with recurrent excitatory connections. As noted above, the basal ganglia architecture may have been especially appropriate in motor systems in which instability could produce movement and co-ordination difficulties (Rolls and Treves, 1998; Rolls, 2014a, 2016b), and it is important to select motor responses before sending any output to muscles so that the muscles do not oppose each other. Thus a major advantage of this method of selecting outputs is that it is safe, with direct mutual inhibition of neurons, and no excitatory recurrent collaterals as in the neocortex.

This selection performed by the basal ganglia is then fed back to the cortex via the thalamus, and the selection performed in the basal ganglia may help to control many parts of

the cerebral cortex to reflect the selection being performed in the basal ganglia, and also its stimulus-response habit learning.

In contrast, the neocortex with its excitatory recurrent collaterals, can also implement selection, by falling into a basin of attraction in which one mutually excitatory subpopulation of neurons ends up with high firing rates, as described in Section B.3. In this circuitry, the inhibitory neurons perform feedback inhibition to try to keep the system stable, with the very dangerous risk of runaway excitation always present. Indeed, epilepsy may be viewed as the price that is paid for this type of architecture (which applies to neocortex, hippocampal cortex, and pyriform cortex). So what in these circumstances are the advantages of performing the selection using cortical architecture with excitatory recurrent collaterals?

Perhaps the major advantage is that the recurrent collaterals allow a subset of the neurons in the network, once activated, to maintain their activity for some time, in a stable attractor, as described in Section B.3 (Rolls and Deco, 2010; Rolls, 2016b). This allows short-term memory, which has a major advantage of allowing animals to remember what has happened recently, and just as much, to even plan ahead by holding a number of items active simultaneously to form a plan. Thus attractor networks allow both retrospective and prospective memory.

Another major property of the cortical attractor approach is that when used for memory functions, it can complete a memory given a partial retrieval cue (Section B.3). This of course has major adaptive advantages, such as being able to remember where a food was located in response to a food cue or memory of a food (Chapter 9).

Another important property of the cortical attractor approach is that it can be used as a long-term memory system, with quite a high capacity if sparse representations are used (Section B.3). Indeed, in the order of 10,000 memories might be stored in a small cortical region with a diameter of 1–2 mm with 10,000 excitatory recurrent collateral synapses onto each neuron.

Another advantage of the cortical attractor approach is that when used as a decision-making system, the results of the decision can be kept ‘on-line’, by continuing firing of the attractor, to guide actions which may take some time to be performed, or which may need to be delayed.

Another advantage of the cortical attractor approach is that when used for long-term memory, the system can, when influenced by the spiking-related noise, make jumps in different directions on different occasions, and thus implement such important functions as creativity and predator avoidance (Section B.3, Rolls and Deco (2010)).

Another advantage of the cortical attractor approach is that it allows weak interactions between attractors to implement many important cognitive functions, including top-down attention (Chapter 13).

Another advantage of the selection performed by the cerebral cortex is that for action-outcome learning, the exact nature of the outcome provided by the orbitofrontal cortex can be associated with the action that was performed to try to obtain the outcome, and this is likely to be much more powerful than reinforcement learning of stimulus-response associations for habits, as described in Section 19.5.

Given the advantages of attractor networks in the cerebral cortex, it is important to consider further disadvantages than the risk of epilepsy. It appears that variation of the stability of cortical attractor networks is being maintained for natural selection because having relatively low or relatively high stability might confer advantages to some individuals (see Chapter 18). In this context, we must remember that there are many different attractor networks in different cortical areas, and that the stability of every one may be being explored by natural selection, to find combinations that may have high fitness in different environments. For example, having low stability in some cortical attractor networks may contribute to creativity

by facilitating the tendency to jump to new parts of the high-dimensional space (see Section B.3), but if the stability is too low, the low stability may contribute to the cognitive symptoms in schizophrenia such as difficulty in maintaining attention, and also to the positive symptoms in schizophrenia (Loh, Rolls and Deco, 2007a; Rolls, Loh, Deco and Winterer, 2008d; Rolls, 2012c). At the other end of what I see as a continuum, relatively high stability in some networks may help attention to remain focussed on a task (because of the high stability of the controlling attractor network providing the top-down input), but too much stability in some cortical systems may contribute to obsessive compulsive disorders (Rolls, Loh and Deco, 2008c; Rolls, 2012c). In the lateral orbitofrontal cortex, too little stability may contribute to impulsivity, and too much to depression (Rolls, 2016e) (see Chapter 18).

Thus a comparison of the cerebral cortex with the basal ganglia helps to draw out the advantages and disadvantages of these two types of architecture, and highlights the advantages of many of the operational principles of the cerebral cortex that are implemented by its excitatory recurrent collateral connections which can support attractors, which are almost a defining feature of the architecture of the cerebral cortex.

17 Cerebellar cortex

17.1 Introduction

The cerebellar cortex is not cerebral cortex, as it is part of the hindbrain, but its cortical structure is exquisitely developed, and is quite different to that of the cerebral cortex. It is thus very useful to compare its architecture and computational principles of operation to those of the cerebral cortex, for this helps to highlight some of the very different computations performed by different brain areas, that can be related to the major differences in their neuronal network architectures.

In this Chapter, the focus is on the structure of the cerebellar cortex, on the insights this provides into *how* it performs its computations, and on comparing the computational style of the cerebellar cortex with that of the cerebral neocortex.

A comparison with the cerebral cortex also shows how important the architecture and connectivity of a neural system, for example a type of cortex, are to understanding its principles of operation, that is its principles of computation. This goes far beyond trying to produce an arrow diagram to show the flow of information through a set of neurons (Shepherd and Grillner, 2010), which though the fine structure is crucially important, may do little to elucidate our understanding of the function of a type of cortex, as in some canonical microcircuit approaches (see e.g. Figs. 1.15, 1.16, and Rolls (2016b)). The pioneer in taking evidence from the quantitative aspects of the fine structure of the cortex forward to help formulate possible computational principles of operation of the cortex was David Marr (the Cambridge mathematician who came to learn from Giles Brindley in the Physiological Laboratory at Cambridge, when I was a medical student), who produced papers on the cerebellum (Marr, 1969), neocortex (Marr, 1970), and hippocampal cortex (Marr, 1971). My research has followed that pioneering approach, though I have gone beyond the combination of quantitative anatomical and mathematical approaches pioneered by Marr, to include also direct evidence on the neuronal activity at each connected stage of the system, evidence on neuronal encoding, evidence from fMRI in humans, evidence on the effects of damage to the system, and in addition also the approaches of theoretical physics, in collaborations with Alessandro Treves, Gustavo Deco, and many other theoretical physicists (Rolls and Treves, 1998; Rolls, 2008d; Rolls and Deco, 2010; Rolls, 2014a, 2016b).

The cerebellum is involved in the accurate control of movements. If the cerebellum is damaged, movements can still be initiated, but the movements are not directed accurately at the target, and frequently oscillate on the way to the target (Lisberger and Thach, 2013). There is insufficient time during rapid movements for feedback control to operate, and the computational hypothesis is that the cerebellum performs feedforward control by learning to control the motor commands to the limbs and body in such a way that movements are smooth and precise. The cerebellum is thus described as a system for adaptive feedforward motor control (Ito, 1984, 2010). Network theories of cerebellar function are directed at showing how it learns to take the context for a movement, which might consist of a desired movement from the cerebral neocortex and the starting position of the limbs and body, and produce the appropriate output signals. The appropriate output signals are learned as a result of the errors that have occurred on previous trials.

Fig. 17.1 Overall architecture of the cerebellum. Inputs relayed from the pontine nuclei form the mossy fibres which synapse onto dentate granule cells. The dentate granule cells via their parallel fibres form modifiable synapses on the Purkinje cells, from which outputs leave the cerebellar cortex. Each Purkinje cell receives one climbing fibre input. The numbers indicate the approximate numbers of cells of different types, relative to one Purkinje cell (see Ito, 1984). The numbers indicate expansion recoding of the mossy fibre inputs to the parallel fibres. A working hypothesis is that the context for a movement (for example limb state and motor command) reaches the Purkinje cells via the parallel fibres, and that the effect that this input has on the Purkinje cell output is learned through synaptic modification taught by the climbing fibre, so that the cerebellar output produces smooth error-free movements.

However, the human cerebellum is also involved in other functions, including cognitive, emotional, and social functions, as described in Section 17.5.

Much of the fundamental anatomy and physiology of the cerebellum are described by Masao Ito (1984; 2010) with classical neuroanatomy provided by Eccles, Ito and Szentagothai (1967), and pioneering computational neuroscience approaches provided by Marr (1969) and Albus (1971).

Some additional cell types and local circuitry in the cerebellum have been described more recently (Hull and Regehr, 2022). One example is that Purkinje cells have recurrent collaterals that inhibit other Purkinje cells and other cell types, and this may be part of a mechanism to keep the output of the cerebellum under feedback control (Hull and Regehr, 2022). But another possible function is that the mutual inhibition by Purkinje cells may act as a form of competitive interaction to sharpen the tuning of the neurons, in a similar way that is proposed for the striatal neurons and for the pallidal neurons in the basal ganglia (Chapter 16). It is interesting that both of these evolutionarily old brain systems (the basal ganglia and cerebellum) appear to use the same mutual inhibition of the output neurons, which is a safe way to compute, compared to the neocortex with its excitatory recurrent collateral connections between the pyramidal cells that are set up to maintain neuronal activity for functions such as short-term memory. Because there is a risk of runaway self-excitation in the neocortex, extra neuronal types to implement inhibition to keep the activity of the pyramidal cells under control are needed.

Fig. 17.2 Schematic diagram providing a 3D impression of the connectivity of a small part of the cerebellar cortex. Some of the inhibitory interneurons (Golgi, stellate, and basket cells) are shown.

17.2 Architecture of the cerebellum

The overall architecture of the cerebellum and the main hypothesis about the functions of the different inputs it receives are shown schematically in Fig. 17.1. The mossy fibres convey the context or to-be-modified input which is applied, after expansion recoding implemented via the granule cells, via modifiable parallel fibre synapses onto the Purkinje cells, which provide the output of the network. There is a climbing fibre input to each Purkinje cell, and this is thought to carry the teacher or error signal that is used during learning to modify the strength of the parallel fibre synapses onto each Purkinje cell. This network architecture is implemented beautifully in the very regular cerebellar cortex. As cortex, it is a layered system. The cerebellar cortex has great regularity and precision, and this has helped analysis of its network connectivity.

17.2.1 The connections of the parallel fibres onto the Purkinje cells

A small part of the anatomy of the cerebellum is shown schematically in Fig. 17.2. Large numbers of parallel fibres course at right angles over the dendritic trees of Purkinje cells. The dendritic tree of each Purkinje cell has the shape of a flat fan approximately $250\ \mu\text{m}$ by $250\ \mu\text{m}$ by $6\ \mu\text{m}$ thick. The dendrites of different Purkinje cells are lined up as a series of flat plates (see Fig. 17.3). As the parallel fibres cross the Purkinje cell dendrites, each fibre makes one synapse with approximately every fifth Purkinje cell (Ito, 1984). Each parallel fibre runs for approximately 2 mm, in the course of which it makes synapses with approximately 45 Purkinje cells. Each Purkinje cell receives approximately 80,000 synapses, each from a different parallel fibre. The great regularity of this cerebellar anatomy thus beautifully provides for a simple connectivity matrix, with even sampling by the Purkinje cells of the

Fig. 17.3 The connections of the parallel fibres (PF) onto the Purkinje cells. Five rows of Purkinje cells with their fan-shaped dendritic trees are shown. CF, climbing fibre; GR, granule cell; mF, mossy fibre. (Reproduced from Szentagothai, J. (1968) *Structuro-functional considerations of the cerebellar network*. *Proceedings of the IEEE* 56: 960–968. © IEEE.)

parallel fibre input. This architecture provides for only one synapse from any parallel fibre to any one Purkinje cell, and not 2 or 3 synapses occasionally. The significance of this, it is suggested, is that in a perceptron (Section B.11), just as in a pattern association network as analyzed by Rolls (2015a), this maximizes the number of input patterns that can be correctly associated with outputs. The concept here is that if there are any double or triple connections from any input axon (a parallel fibre) to an output neuron (a Purkinje cell), this creates effectively double or triple strength connections between some neurons, which distorts the pattern association computation by emphasizing the contributions of some input neurons more than others (Rolls, 2015a).

17.2.2 The climbing fibre input to the Purkinje cell

The other main input to the Purkinje cell is the climbing fibre. There is one climbing fibre to each Purkinje cell, and this climbing fibre spreads to reach every part of the dendritic tree of the Purkinje cell. (Although the climbing fibre does not reach quite to the end of every dendrite, the effects of it on the Purkinje cell will reach to the apical extremity of every dendrite.) Although each Purkinje cell has an input from only one climbing fibre, each climbing fibre does branch and innervate approximately 10–15 different Purkinje cells in different parts of the cerebellum. The climbing fibres have their cell bodies in the inferior olive.

17.2.3 The mossy fibre to granule cell connectivity

The parallel fibres do not arise directly from the neurons in the pontine and vestibular nuclei (see Fig. 17.1). Instead, axons of the pontine and vestibular cells become the mossy fibres of the cerebellum, which synapse onto the granule cells, the axons of which form the parallel fibres (see Fig. 17.2). There are approximately 450 times as many granule cells (and thus parallel fibres) as mossy fibres (see Ito (1984), p. 116). In the human cerebellum, it is estimated that there are $10^{10} - 10^{11}$ granule cells (see Ito (1984), p. 76), which makes them the most numerous cell type in the brain. What is the significance of this architecture? It was suggested by Marr (1969) that the expansion recoding achieved by the remapping onto granule

cells is to decorrelate or orthogonalize the representation before it is applied to the modifiable synapses onto the Purkinje cells. It is shown in Section B.2.7.3 how such expansion recoding can maximize capacity, reduce interference, and allow arbitrary mappings through a simple associative or similar network.

The granule cells of the cerebellum can therefore be regarded as analogous computationally to the dentate granule cells of the hippocampus, and to the granule / stellate cells in layer 4 of the neocortex, both of which perform pattern separation (Rolls, 2016b). The use again of granule cells for pattern separation in the cerebellum as well as in the hippocampus and neocortex is additional evidence for some of the fundamental computational principles of operation of the cortex described in this book and by Rolls (2016b).

As implied by the numbers given above, and as summarized in Fig. 17.1 in which I show (by extracting numbers from Ito (1984)) estimates of the relative numbers of the cells discussed so far in the cerebellum, there is a massive expansion in the number of cells used to code the same amount of information, in that the ratio of granule cells to mossy fibres is approximately 450. This provides a system comparable to a binary decoder. Consider an 8 bit binary number representation system, which can be used to represent the numbers 0–255 (decimal) (that is 2^8 numbers). Now, the bits that represent these numbers are often highly correlated with each other. For example, the bits that are set in the binary representations of the numbers 127 and 255 are identical apart from the highest order bit. (127 is 01111111 in binary and 255 is 11111111.) These two numbers would thus appear very similar in an associative memory system, such as that described in Section B.2, so there would be great interference between the two numbers in such a memory system. However, if the numbers 0–255 were each represented by a different active axon synapsing onto the output cell, then there would be no interference between the different numbers, that is the representations would be orthogonalized by binary decoding. The 450-fold increase in the number of fibres as information passes from mossy to parallel fibres potentially allows this expansion recoding to take place to implement pattern separation.

This architecture of the brain provides an interesting contrast with that of conventional digital computers. The type of information storage device that has evolved in the brain uses a distributed representation over a large number of input connections to a neuron, and gains from this the useful properties of generalization, graceful degradation, and the capacity to function with low information capacity stores (that is synapses), but pays the penalty that some decorrelation of the inputs is required. The brain apparently has evolved a number of specialized mechanisms to do this. One is exemplified by the granule cell system of the cerebellum, with its enormous expansion recoding. In effect, the brain provides an enormous number of what may be low resolution storage locations, which in the cerebellum are the vast number of parallel fibre to Purkinje cell synapses. It is astounding that the number of storage locations in the (human) cerebellum would thus be approximately 3×10^{10} parallel fibres with every parallel fibre making approximately 300 synapses, or approximately 10^{13} modifiable storage locations. (10 Terabits of storage.)

The recoding that could be performed by the mossy fibre to granule cell system can be understood more precisely by considering the quantitative aspects of the recoding. Each mossy fibre ends in several hundred rosettes, where excitatory contact is made with the dendrites of granule cells. Each granule cell has dendrites in 1–7 mossy rosettes, with an average of four. Thus, on average, each granule cell receives from four mossy fibres. Due to the spacing of the mossy fibres, in almost all cases the four inputs to a granule cell will be from different mossy fibres. Approximately 28 granule cell dendrites contact each rosette. There are approximately 450 times as many granule cells as mossy fibres. The result of this architecture is that the probability that any given granule cell has all its C inputs active, and is therefore likely to fire, is low. It is in fact P^C , where P is the probability that any mossy fibre is active.

Thus if the probability that a mossy fibre is active is 0.1, the probability that all of the average four inputs to a granule cell are active is 0.1^4 or 0.0001. The probability that three of the four inputs to a given granule cell are active would be 0.001. Given that each mossy fibre forms rosettes over a rather wide area of the cerebellum, that is over several folia, cells with three or four active inputs would be dotted randomly, with a low probability, within any one area.

One further aspect of this recoding must be considered. The output of the parallel fibres is sampled by the Golgi cells of the cerebellum via synapses with parallel fibres. Each Golgi cell feeds back inhibitory influences to about 5,000–10,000 granule cells. Neighbouring Golgi cells overlap somewhat in their dendritic fields, which are approximately 300 μm across, and in their axon arborization. Every granule cell is inhibited by at least one Golgi cell. The Golgi cells terminate directly on the mossy rosettes, inhibiting the granule cells at this point. This very broad inhibitory feedback system suggests the function of an automatic gain control. Thus Albus (1971) argued that the Golgi cells serve to maintain granule cell, and hence parallel fibre, activity at a constant rate. If few parallel fibres are active, Golgi inhibitory feedback decreases, allowing granule cells with lower numbers (for example 3 instead of 4) of excitatory inputs to fire. If many parallel fibres become active, Golgi feedback increases, allowing only those few granule cells with many (for example 5 or 6) active mossy inputs to fire. In addition to this feedback inhibitory control of granule cell activity, there is also a feedforward inhibitory control implemented by endings of the mossy fibres directly on Golgi cells. This feedforward inhibition probably serves a speed-up function, to make the overall inhibitory effect produced by the Golgi cells more smooth in time. The net effect of this inhibitory control is probably thus to maintain a relatively low proportion, perhaps 1%, of parallel fibres active at any one time. This relatively low proportion of active input fibres to the Purkinje cell learning mechanism optimizes information storage in the synaptic storage matrix, in that the sparse representation enables many different patterns to be learned by the parallel fibre to Purkinje cell system (see Section B.2).

17.3 Modifiable synapses of parallel fibres onto Purkinje cell dendrites

The climbing fibres take part in determining the modifiability of the parallel fibre to Purkinje cell synapses (Ito et al., 2014). In particular, the parallel fibre to Purkinje cell synapses decrease in strength, that is, they show long-term depression (LTD), when the climbing fibre to a Purkinje cell fires, if the parallel fibre is active (Ito, 1984; Ito et al., 2014). Thus the associative learning is between the parallel fibre and the Purkinje cell, but the ‘teacher’ is the climbing fibre, which produces a plateau potential in the Purkinje cell. This can be thought of as a type of error learning (Ito, 1984, 2013). If a parallel fibre is firing and tending to activate the Purkinje cell when it should not, then firing of the climbing fibre to indicate an error would reduce the strength of the synapse from that parallel fibre. If the climbing fibre does carry an error signal (which is a systems-level question (Ito, 2013), see below), then this would make the computation performed by the cerebellar cortex that of a one-layer perceptron (Ito, 1984, 2006, 2010) (see Section B.11). If the climbing fibre is on average not firing when a parallel fibre is firing, then that parallel fibre to Purkinje cell synapse will become stronger (i.e. show associative long-term potentiation, LTP).

It is interesting to note that despite an early theory that predicted modifiability of the parallel fibre to Purkinje cell synapses (Marr, 1969), experimental evidence for modifiability was only obtained in the 1980s (Ito, 1984). Part of the reason for this was that it was only when the physiology of the inferior olive was understood better, by making recordings from single neurons, that it was found that inferior olive neurons, which give rise to the climbing

fibres, rarely fire at more than a few spikes per second. It was not until such relatively low-frequency stimulation (at 4 Hz) was used by Ito and his colleagues (see Ito (1984)) that the synaptic modifiability was demonstrated. (David Marr had tried with Jack Eccles to obtain evidence for synaptic modification, but they did not know the normally low firing rates of inferior olive neurons. Possibly as a result, David Marr felt that neuroscience methods were not yet available to test his theories on the principles of operation of cortical circuitry, and moved into more abstract theoretical work on vision (Marr, 1982; Rolls, 2011c).)

17.4 The cerebellar cortex as a perceptron

The overall concept that the work of Marr (1969), Albus (1971), and Ito (1984; 2006; 2013) has led towards is that the cerebellum acts as an adaptive feedforward controller with the general form shown in Fig. 17.2. The command for the movement and its context given by the current state of the limbs, trunk, etc., signalled by proprioceptive input would be fed to the intracerebellar (deep cerebellar) nuclei to produce a motor output ('Out' in Fig. 17.2). But in addition the input would be fed via the mossy fibres and then via the granule cells to the parallel fibres. There the appropriate firing of the Purkinje cells to enable the movement to be controlled smoothly would be produced via the parallel fibre to Purkinje cell synapses. These synapses would be set to the appropriate values by error signals received on many previous trials and projected via the climbing fibres to provide the teaching input for modifying the synapses utilizing LTD. The proposal described by Ito (1984) is thus that the cerebellum would be in a sideloop, with the overall gain or output of the system resulting from the direct, relatively unmodifiable output produced through the deep cerebellar nuclei, and the variable gain output contributed by the cerebellar sideloop.

This is a generic model of cerebellar function. Different parts of the cerebellum are concerned with different types of motor output (Ito, 1984; Lisberger and Thach, 2013). One part, the flocculus, is involved in the control of eye movements, and in particular with the way in which eye movements compensate for head movements, helping the images on the retina to remain steady during head movement. This is called the vestibulo-ocular reflex (VOR). Another part of the cerebellum is concerned with the accurate and smooth control of limb movements. Another part is implicated in the classical conditioning of skeletal responses, in which a sensory input such as a tone comes by learning to produce learned reflex responses. In order to assess how the generic circuitry of the cerebellum contributes to these types of adaptive control of motor output, evidence on how the cerebellum contributes to each of these types of motor learning is relevant, and is considered elsewhere (Ito, 1984, 2006, 2013; Lisberger and Thach, 2013).

A proposal that the cerebellum performs a predictive computation to produce an internal forward model for what the cortex is trying to achieve in terms for example of movement fits with earlier concepts, but does yet have any learning mechanism that uses for example the climbing fibres (Tanaka et al., 2020). Further, although the cerebellum is usually considered to implement supervised learning, there is recent interest in the possibility that the climbing fibres carry a signal that would be useful in temporal difference reinforcement learning (Hull, 2020). There is also increasing interest in how the cerebellum is involved in cognitive function, and on its relations with the basal ganglia and cerebral cortex (Sokolov et al., 2017; Caligiore et al., 2017).

One point about the theory that has always intrigued me is how a climbing fibre 'knows' which Purkinje cell to connect to, and therefore to provide the correct error or teaching input for that neuron. Or perhaps it is the other way round: the climbing fibre may determine what functions are being performed by a Purkinje cell, and some connections on the output side

of the cerebellum need to be set up for that Purkinje cell's outputs (via the deep cerebellar nuclei) to act appropriately.

According to the Marr-Albus hypothesis, the cerebellar cortex is a supervised system, with a single teacher (the climbing fibre) for each Purkinje cell. In contrast, the basal ganglia is held to implement reinforcement learning, with a single teaching signal, dopamine release, broadcast to the whole of the striatum (Chapter 16). Neurons that signal reward delivery, expected reward, and non-reward, have now been found in the rodent cerebellum (Kostadinov and Hausser, 2022). Perhaps we should not be surprised, if all parts of the neocortex have connections to the cerebellum, for exactly these signals are found in the orbitofrontal cortex (Thorpe, Rolls and Maddison, 1983; Rolls, 2019f,e). However, this finding has led to the suggestion that the cerebellum may operate not just as a supervised system, but may also make use of reinforcement learning (Kostadinov and Hausser, 2022). However, the cerebellar system is odd, in that some climbing fibers signal violations in reward expectation with an increase in firing, regardless of whether the quality of reward was better or worse than expected – i.e., an unsigned prediction error (Kostadinov and Hausser, 2022). Perhaps the cerebellar error signal is used in the early stages of learning a task where a general reinforcement signal might be useful to guide the system to the correct part of the decision space, and then supervised learning is used to refine the details of the output required from the cerebellum (for example to touch a particular position).

The point of this brief survey has been not only to highlight some of the quantitatively remarkable and precise aspects of the design of the cerebellar cortex, but also to use the differences of its design from that of the cerebral cortex (neocortex, hippocampal cortex, and pyriform cortex) to illuminate the principles of operation and computation of all these types of cortex.

17.5 Cognitive functions of the cerebellum

Although traditionally the cerebellum has been viewed as a brain region with primarily motor functions and with connections with neocortical motor and premotor regions, evidence has started to accumulate that the cerebellum is also involved in cognitive, emotional, and social functions, as described next (Schmahmann et al., 2019; Schmahmann, 2021; Van Overwalle et al., 2020; Guell and Schmahmann, 2020; Stoodley and Tsai, 2021).

17.5.1 Anatomical connections from most neocortical regions

Connections from all neocortical regions via the pontine nuclei in the brainstem reach different parts of the cerebellar cortex (Schmahmann et al., 2019). The return pathways from the cerebellum connect mainly via the ventrolateral thalamic nuclei (VL) but also by the mediodorsal thalamic nuclei (MD) and intralaminar nuclei to all neocortical regions, and the paths are segregated throughout this whole connectivity (Schmahmann et al., 2019). For example, the primary motor cortex connectivity is with cerebellar lobules III–VI and VIII; and the dorsolateral prefrontal cortex area 46 connections are with cerebellar crus II and lobule X (Schmahmann et al., 2019). The cingulate cortex has connectivity that relates it to cerebellar lobule IX, the ventral paraflocculus (Schmahmann, 2021).

17.5.2 Functional connectivity of different cortical systems with different parts of the cerebellum

Different neocortical networks (central executive, default mode, dorsal attention, salience) have resting state functional connectivity with different parts of the cerebellar cortex (Habas, 2021). The polymodal neocerebellum (lobules VII, VIII, and IX) is massively interconnected with associative cortices, as well as with the striatum and amygdala (Habas, 2021). Fig. 17.5a provides further evidence on the parts of the human cerebellum with functional connectivity with different resting state networks in humans.

17.5.3 Activation of different cerebellar cortical regions in different tasks

Task-based fMRI meta-analysis has shown involvement of the neocerebellum, including lobules VI, VII, and VIII, in executive, linguistic, and emotional functions (Schmahmann et al., 2019; Stoodley and Tsai, 2021; Stoodley et al., 2012). Fig. 17.4a shows that different parts of the cerebellar cortex are activated by finger tapping (red), working memory (purple), verb generation (blue), and mental rotation (green) (Stoodley et al., 2010). Fig. 17.4b shows that for lobule VIIb which relates to the neocortical dorsal attention network, in a working memory task the locus of spatial attention encoding is medially situated, and the attentional load content is more laterally situated (Schmahmann et al., 2019). Fig. 17.4d shows that both task activations and changes in task-related functional connectivity provide evidence that several different parts of the cerebellar cortex are activated during three different tasks, a motor task, story listening, and working memory (Schmahmann et al., 2019). Fig. 17.5a shows activations produced in the cerebellum by different types of task.

17.5.4 Damage to different parts of the cerebellum can produce different cognitive, emotional, and motor impairments

In patients with stroke, lesions of different parts of the cerebellar cortex can produce symptoms that may include ataxia or cognitive/emotional deficits. Fig. 17.4c shows that lesions of lobules IV–V of the anterior lobe extending into adjacent lobule VI produce the cerebellar motor syndrome of ataxia. Lesions confined to posterior lobe lobules crus II through lobule IX produce the cerebellar cognitive affective/Schmahmann syndrome but no motor ataxia (Schmahmann et al., 2019; Schmahmann, 2021). The symptoms of the cerebellar cognitive affective/Schmahmann syndrome include impaired executive function (planning, set-shifting, abstract reasoning, verbal fluency, working memory), often with perseveration, distractibility or inattention; visual–spatial disorganization and impaired visual–spatial memory; personality change with blunting of affect or disinhibited and inappropriate behavior; and difficulties with language production including dysprosodia, agrammatism, and mild anomia (Schmahmann, 2021).

17.5.5 Neocortical–cerebellar cortical computations for cognition

One approach is that the cerebellum implements an internal forward model that analyses the causal relationship between a command and the outcomes of that command, predicting the outcome of the performed action given the current context (Stoodley and Tsai, 2021; Ito, 1984). The mossy fiber input may introduce information about the motor command and the present context into the cerebellar circuit, and the climbing fibres need to provide the correct prediction error (Stoodley and Tsai, 2021; Hull, 2020).

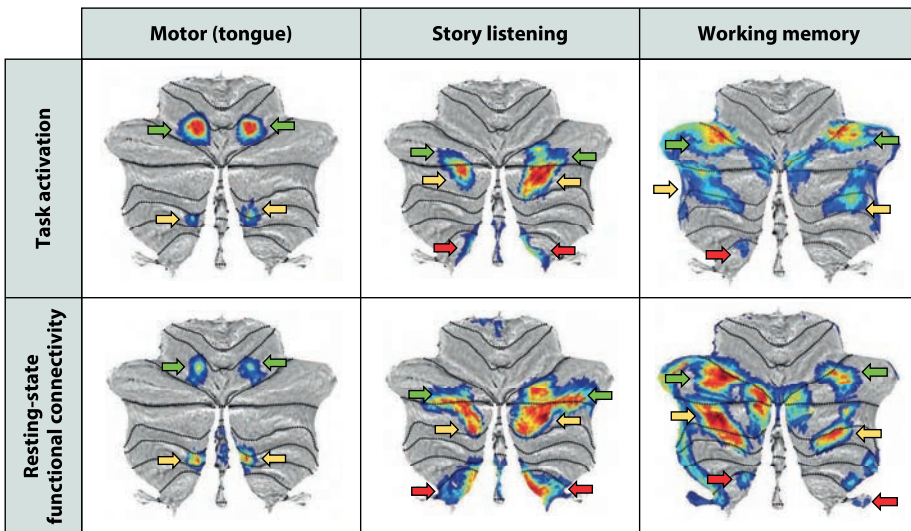

a Single-subject multidomain task topography**b** Intradomain task topography**c** Lesion symptom mapping**d** Task and resting-state activation topography and multiple representations of motor and nonmotor domains

Fig. 17.4 Cerebellar functional topography in humans. (a) Intraindividual topography of task-based activations in the cerebellum for finger tapping (red), working memory (purple), verb generation (blue), and mental rotation (green) (Stoodley et al., 2010). (b) Spatial gradients within the dorsal attention network in lobule VII B on a working memory task. The locus of spatial attention encoding is medially situated; attentional load content is more lateral. Panel b adapted from Brissenden et al. (2018). (c) In patients with stroke, lesions of lobules IV-V of the anterior lobe extending into adjacent lobule VI produce the cerebellar motor syndrome of ataxia. Lesions confined to posterior lobe lobules crus II through lobule IX produce the cerebellar cognitive affective/Schmahmann syndrome but no motor ataxia. Panel c adapted from Stoodley et al. (2016). (d) Task and resting-state activation topography in motor and nonmotor domains. Task activation (top row) reveals a pattern of two motor (first column) and three nonmotor representations (second and third columns). An overlapping pattern was observed when calculating resting-state functional connectivity from cerebral cortical activation peaks for each corresponding task activity contrast (bottom row). First motor (lobules I-VI) or first nonmotor representation (VI/crus I) (green arrows), second motor (VIII) or second nonmotor representation (crus II/lobule VII B) (yellow arrows), and third nonmotor representation (IX/X) (red arrows) are shown. First and second nonmotor representations can be contiguous (as in story listening) or separate (as in working memory). Panel d adapted from Guell et al. (2018a). Abbreviations: CCAS, cerebellar cognitive affective syndrome; Cr, crus; L, left; R, right; VWM, verbal working memory. (From Schmahmann, J.D., Guell, X., Stoodley, C.J. and Halko, M.A. 2019. The theory and neuroscience of cerebellar cognition. *Ann Rev Neurosci* 42:337-364.)

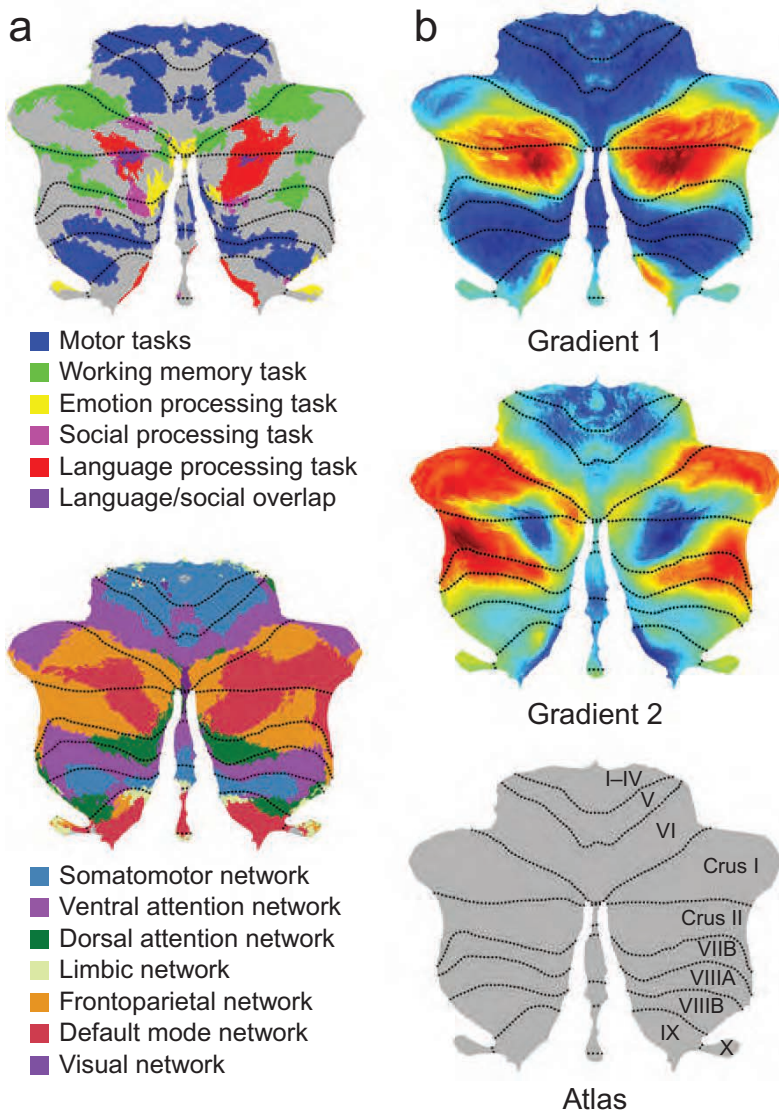

Fig. 17.5 Cerebellar functional topography in humans. (a) Discrete task activity maps (adapted from Guell et al. (2018a)); and resting-state functional connectivity maps (adapted from Buckner et al. (2011)). (b) Cerebellar gradients 1 and 2 and the cerebellum flatmap atlas. Gradient 1 extends from the language task/default mode network to motor regions, and gradient 2 isolates working memory/frontoparietal network areas. Panel b adapted from Guell et al. (2018b). (Modified from Schmahmann, J.D., Guell, X., Stoodley, C.J. and Halko, M.A. 2019. The theory and neuroscience of cerebellar cognition. *Ann Rev Neurosci* 42:337-364.)

With this background, it has been suggested that the cerebellum provides the circuit properties to generate, update, and automatize predictions using both supervised and reinforcement learning (Stoodley and Tsai, 2021). These predictive and adaptive internal models may enable precise performance, timing, and learning of complex behaviors, including those relevant to social interactions. The suggestion is that ‘cerebellar circuits, acting at the implicit level and using social information conveyed through extensive cerebrocerebellar connections, could build internal models of complex behaviors, allowing for automatic information processing and appropriate behaviors in a range of socially relevant processes ranging from perception of biological motion to understanding the mental states of others. For example, an

internal model of the dynamics of a social situation (e.g., a birthday party) would enable one to understand and accurately predict both the order of events (e.g., singing happy birthday prior to cake) and their emotional consequences (e.g., child excited to eat cake)' (Stoodley and Tsai, 2021). This approach is consistent with the evidence that the cerebellum is engaged during social tasks, is functionally connected to neocortical regions critical for social processing, and that cerebellar disruption can be associated with altered social behaviors (Stoodley and Tsai, 2021).

In terms of neocortical design, one feature is that the deep layers of all parts of the neocortex connect to the striatum and enter the basal ganglia circuit with return pathways back to the neocortex via the thalamus (Rolls, 2016b) (Chapters 1 and 16). This basal ganglia circuit may use reinforcement learning utilising dopamine neuron firing reward prediction error to create complex combinations of neocortical inputs that together define a stimulus/context that can be then associated in the basal ganglia with a response to implement stimulus-response habit learning (Rolls, 2016b) (Chapters 1 and 16).

A second feature of neocortical design may be that the deep layers of all parts of the neocortex may be specified to send projections to the pontine nuclei and thereby to gain access to the cerebellum. In evolution, this may have been useful for predictive feed-forward motor control, but given that this genetic specification of this connectivity was once set up between some brain regions (Rolls and Stringer, 2000), it may have been a useful strategy in evolution not to interfere with the genetic specification of connectivity as other neocortical regions were added. The suggestion then is that the cerebellum may perform some predictive feedforward input that is useful to cognitive, emotional, and social neocortical regions. If so, it is an important issue about how the correct training signal is provided to the climbing fibres (Hull, 2020).

These concepts may shed light on neocortical design. A key feature is that outputs are taken from every stage of the neocortex and used for some purpose, and are not just taken from the ends of processing hierarchies (Rolls and Stringer, 2000). It is possible that the deep layers (5,6) of the neocortex are of earlier evolutionary origin than the superficial layers (2, 3), with 2,3 specialised for feedforward computations up hierarchies to build new representations at each stage of the hierarchy. That implies that the design constraints for the superficial and deep layers of the neocortex may be different, and may include more continuous representations for the deep layers (Rolls and Mills, 2017). Another difference may be that the representations in the superficial layers of the neocortex may need to be sparse to facilitate the competitive learning that takes place from cortical stage to stage in a hierarchy. In contrast, in the deep layers of the neocortex the representations might be less sparse, because these layers provide backprojections for memory recall and top-down attentional modulation, and less sparse representations may be useful for these functions in the context of the diluted connectivity of the neocortex (Rolls, 2023e). Possible specialisations of the deep layers of the neocortex that make them appropriate for providing signals for computations to be performed by the cerebellum is a topic of interest.

Another interesting difference is how rewards are used computationally by the cerebellum, basal ganglia, and neocortex. As described above, the cerebellum may operate as a supervised system with a separate teacher for each Purkinje cell, with perhaps some influence by reward-related errors in a type of reinforcement-related learning. This may be appropriate for refining the details of output using predictive feedforward control. The basal ganglia is held to implement reinforcement learning, with a single teaching signal, dopamine release, broadcast to the whole of the striatum to implement stimulus-response habit learning (Chapter 16). This may be appropriate for setting up fixed responses that take into account the activity of all cortical areas channelled through the striatum, and therefore a very large set of possible inputs. In contrast, the neocortex in the orbitofrontal cortex – anterior cingulate cortex system

sends details of the exact reward or punisher received in terms of its value (Chapter 11) to the anterior cingulate cortex where it can be associated with the particular goal-directed action that will obtain the best outcome in terms of its reward-punishment value in action-outcome learning (Chapter 12). This type of action-outcome learning implemented by these neocortical areas is very effective because the actions are always under control of the current value of the goal as received from the orbitofrontal cortex (as shown by devaluing the goal), because the full details of the goal value are specified (e.g. is it this type of food, or that type of food, and is there any sensory-specific satiety for that particular goal), and because the neocortex with its short-term memory capability implemented by recurrent collateral attractor networks can take into account the action-outcome results for the previous few trials.

17.6 Highlights: differences between cerebral and cerebellar cortex microcircuitry

1. First, this comparison does highlight how the design of different types of cortex is very different, and at the same time how precisely types of cortex are designed. The implication is that the quantitative details of the connectivity are important, a point understood by Marr, but hardly emphasized in most ‘canonical models’ of the microcircuitry of the cerebral cortex, most of which may not even show recurrent collateral connections between classes of pyramidal cells, let alone consider their number, and what the computational significance may be (see e.g. Figs. 1.15 and 1.16, but compare Fig. 1.17 and Rolls (2016b)).
2. Second, the cerebellar cortex does not have excitatory recurrent collaterals, and the cerebral cortex does. This helps to make excitatory recurrent collaterals what is probably the most fundamental aspect of the design of the cerebral cortex, which provides the ability to maintain information by positive excitatory feedback, to enable short-term memory, long-term memory, decision-making, top-down attention, etc, as described throughout this book and by Rolls (2016b).
3. Third, analysis of the cerebellum shows how important the quantitative aspects of the connectivity are for brain computation, with large numbers of parallel fibre synapses for example onto each Purkinje cell. The importance of this is that the number of synapses onto each neuron is the leading factor in the number of memories that can be stored in pattern associators, perceptrons, and autoassociation networks, so these numbers are just as important for the cerebral cortex (Appendix B).
4. Fourth, analysis of the cerebellum shows how important it is for associative memories to have relatively orthogonal patterns presented to the network, with this being implemented by the 10^{10} or more granule cells in the cerebellum. In the same way, the hippocampus has granule cells in the dentate gyrus to perform pattern separation, and the neocortex has stellate cells in layer 4 to do the same, especially where it appears that much orthogonalization is required, in primary sensory cortical areas such as the primary visual cortex, V1 (see Rolls (2016b)).
5. Fifth, a major difference from the cerebral cortex is that each Purkinje cell has its own teacher, its climbing fibre. There appears to be nothing like this in the cerebral cortex. Instead, the hypothesis developed by Rolls (2016b) and in this book is that in the neocortex the correct neocortical pyramidal cells are selected by which ones win in an unsupervised, competitive network, style of computation for any given input pattern. Further, the hypothesis is that in the hippocampus, the selection of which CA3 cells should be activated is performed by random selection, using the mossy fibres, as described in Chapter 9. The

difference from the neocortex is that the computation performed by the hippocampal CA3 network is to store large numbers of memories separately, and for this, picking neurons at random to be part of each memory is appropriate. In contrast, in the neocortex, the aim of the computation is much more sophisticated, to build useful representations for categorising complex inputs, and for this purpose competitive learning is used to produce neocortical neurons that respond to different non-linear combinations of their inputs (Section B.4 and Rolls (2016b)).

6. Sixth, the human cerebellum is also involved in other functions, including cognitive, emotional, and social functions, as described in Section 17.5. Different neocortical regions have connectivity with different parts of the cerebellum, and the different parts of the human cerebellum are activated during the performance of different tasks. Moreover, damage to some parts of the human cerebellum can produce clinically relevant cognitive, emotional, or social problems. It has been suggested that cerebellar circuits could build internal models of complex behaviors that facilitate predictions, allowing for automatic information processing and appropriate behaviors in a range of processes ranging from perception of biological motion to understanding the mental states of others (Stoodley and Tsai, 2021).

18 Cortical attractor dynamics and connectivity, stochasticity, psychiatric disorders, and aging

18.1 Introduction and overview

18.1.1 Introduction

The cerebral neocortex has highly developed local recurrent collateral connections allowing neurons within 2–3 mm to have a probability of approximately 0.1 of connecting with each other, and given associative synaptic modifiability, these can form local attractor networks (Section B.3) (Rolls, 2016b). These attractor networks provide a foundation for *what* is computed in many cortical systems, including short-term memory (Section 13.6.1), decision-making (Section 11.5.1), language (Section 14.5), episodic memory (Chapter 9), and visual perception by contributing to a trace of previous neuronal firing (Chapter 2). The operation of attractor or autoassociation networks is described in Sections B.3 and 11.5.1.

In this chapter we consider *how* the operation of attractor networks in the brain is influenced by noise in the brain produced by the random firing times of neurons for a given mean firing rate; how this can in fact be beneficial to the operation of the brain; and how the stability of these systems and how they are influenced by noise in the brain is relevant to understanding a number of mental disorders. These concepts can inform understanding of the brain that is relevant not only to its operation in health, but also in disease, and how it may be possible to ameliorate some of the effects found in these mental and other disorders, which is a key aim of this book.

18.1.2 Overview

1. The stability of attractor networks in the face of the random spiking times of neurons for a given mean neuronal firing rate is analyzed. The stability of attractor networks is increased if the receptor conductances, or at a different level the synaptic weights, or at another level the functional connectivity, is increased. Such networks with this higher stability can have more persistent short-term memory, and are less distractible.
2. Hypotheses are described about how increased or decreased stability of different cortical networks may contribute to psychiatric disorders and to the memory changes in normal aging.
3. In schizophrenia, the positive symptoms such as hallucinations and intrusive thoughts may be associated with too little stability of attractor networks caused by reduced inhibition (and/or increased glutamatergic function) in the temporal lobe cortex and related areas. The reduction of stability results in some networks entering high firing rate attractor states even with no or little input.
4. In schizophrenia, the cognitive symptoms such as impaired attention and working memory may be related to reduced efficacy of NMDA glutamate receptors and/or decreased numbers of spines introducing excitatory input to neurons in the prefrontal cortex involved in

short-term memory and attention. The reduced firing rate would decrease the stability of high firing rate attractor network states involved in maintaining stable working memory and attention.

5. In schizophrenia, the same changes as in (4) in the orbitofrontal cortex would decrease the firing rates of neurons involved in reward, punishment, emotion, and motivation, and thus produce the negative symptoms of decreased mood and motivation.
6. Going beyond the disconnectivity hypothesis of schizophrenia, it is shown using effective connectivity that although the forward (stronger) connections between cortical areas are decreased, the backprojections are much less reduced. This produces an imbalance, with internally generated states becoming more prevalent compared to states elicited by bottom-up inputs from the world.
7. In addition, in schizophrenia there is reduced functional connectivity and therefore increased temporal variability of the thalamic inputs for visual and auditory stimuli, which is related to decreased efficacy of inputs from the world relative to internally generated processing related to increased backprojections from the precuneus and posterior cingulate gyrus which have been identified in schizophrenia.
8. In obsessive-compulsive disorder, enhanced glutamatergic activity may make a number of different cortical attractor networks overstable. The details of which attractor networks are overstable may be different in different patients. Overactivity of some frontal cortical attractor networks might produce over-stability and perseveration of plans. Overstability of other frontal cortical attractor networks might produce obsessive actions.
9. In depression, oversensitivity, overactivity and increased functional connectivity of a lateral orbitofrontal cortex network involved in non-reward and punishment may lead it to enter too often and remain too long in high firing rate attractor states, leading to the symptoms of persistent sadness that can be produced by non-reward. This higher connectivity is normalised by conventional antidepressant drugs (e.g. SSRIs). In depression, the medial orbitofrontal cortex reward system has reduced sensitivity to reward and reduced functional connectivity with medial temporal lobe memory systems, resulting in anhedonia and fewer happy memory states (see *The Brain, Emotion, and Depression* (Rolls, 2018a) and Zhang, Rolls et al (2023a)). The medial orbitofrontal cortex is a site where ketamine acting as an antidepressant may act (Zhang et al., 2023a).
10. In normal aging, reduced neuronal firing rates in attractor memory networks may contribute to the reduced working memory. The reduction of firing rates may be related to decreased synaptic efficacy and learning, and to increased cortical adaptation. Decreasing cholinergic function in aging may contribute to the memory problems in normal aging by reducing long-term synaptic modification, and by increasing neuronal adaptation thereby decreasing the firing rates in attractor networks used in memory. The orbitofrontal cortex has connectivity to the cholinergic systems, and may also thereby be involved in the memory problems that can occur in normal aging. This applies to both hippocampal episodic memory and to prefrontal cortex short-term / working memory.
11. All these hypotheses have implications for potential treatments, and provide a new way to conceptualize some psychiatric disorders, and the effects of normal aging on memory.
12. Part of the value of the approach is that it links changes at the neuronal and synaptic level, and how they are influenced by treatments, to the symptoms, through understanding the computational principles of operation of neuronal networks in the cerebral cortex.

18.2 The noisy cortex: stochastic dynamics, decisions, and memory

The spiking of the neurons in the brain is almost random in time for a given mean firing rate, i.e. the spiking is approximately Poissonian, and this randomness introduces noise into the system, which makes the system behave stochastically. The effect that this stochasticity has on a neural system, and more generally the dynamics of the system, for example how long it takes to respond, and how long it remains in a given state, can be investigated using integrate-and-fire neuronal network simulations, which model how the currents through the different synaptic receptor-activated ion channels are integrated to produce the membrane potential of a neuron, which fires an action potential when the threshold is reached. The integrate-and-fire neuronal network approach is described in Section B.6, and as used here dynamically models the membrane potential of point neurons, and the dynamics of the opening and closing of different receptor-activated ion channels. Each of the simulated neurons shows spiking that is very much like that of neurons recorded in the brain. From such integrate-and-fire models it is possible to make predictions not only about synaptic and neuronal activity, but also about the signals recorded in functional neuroimaging experiments, and the behavior of the system, in terms for example of its probabilistic choices, its reaction times, and its stability. This makes a close link with human behavior possible (Rolls, Grabenhorst and Deco, 2010b,c). The theory as to how networks operate stochastically (Rolls and Deco, 2010; Deco et al., 2013) has implications throughout the cortex, some of which are described in this chapter.

First we consider the sources of the noise in the cortex (Section 18.2.1). Then we consider how the spiking-related noise influences the stability of short-term memory mechanisms in the cortex (Section 18.2.2). How the spiking-related noise influences decision-making mechanisms in the cortex has been described in Section 11.5.1. Some advantages of noise in the brain, and how these play out in some different ways in the cortex, are described in Sections 18.2.5–18.2.8. Fundamental approaches to stochastic dynamics in the cortex, including equations, are provided in Sections B.6–B.8.

18.2.1 Reasons why the brain is inherently noisy and stochastic

Why is the spiking activity of neurons probabilistic, and what are the advantages that this may confer? The answer suggested (see Rolls (2016b) and Rolls and Deco (2010)) is that the spiking activity is approximately Poisson-like (as if generated by a random process with a given mean rate, both in the brain and in the integrate-and-fire simulations I describe), because the neurons are held close to (just slightly below) their firing threshold, so that any incoming input can rapidly cause sufficient further depolarization to produce a spike. It is this ability to respond rapidly to an input, rather than having to charge up the cell membrane from the resting potential to the threshold, a slow process determined by the time constant of the neuron and influenced by that of the synapses, that enables neuronal networks in the brain, including attractor networks, to operate and retrieve information so rapidly (Treves, 1993; Rolls and Treves, 1998; Battaglia and Treves, 1998a; Rolls, 2016b; Panzeri, Rolls, Battaglia and Lavis, 2001; Rolls and Deco, 2010). The spike trains are essentially Poisson-like because the cell potential hovers noisily close to the threshold for firing (Dayan and Abbott, 2001), the noise being generated in part by the Poisson-like firing of the other neurons in the network (Jackson, 2004). The noise and spontaneous firing help to ensure that when a stimulus arrives, there are always some neurons very close to threshold that respond rapidly, and then communicate their firing to other neurons through the modified synaptic weights, so that an attractor process can take place very rapidly (Rolls, 2016b; Rolls and Deco, 2010).

The implication of these concepts is that the operation of networks in the brain is inherently noisy because of the Poisson-like timing of the spikes of the neurons, which itself is related to the mechanisms that enable neurons to respond rapidly to their inputs (Rolls, 2016b). However, the consequence of the Poisson-like firing is that, even with quite large attractor networks of thousands of neurons with hundreds of neurons representing each pattern or memory, the network inevitably settles probabilistically to a given attractor state. This results, *inter alia*, in decision-making being probabilistic. Factors that influence the probabilistic behavior of the network include the strength of the inputs (with the difference in the inputs / the magnitude of the inputs being relevant to decision-making and Weber's Law as described in Section 11.5.1); the depth and position of the basins of attraction, which if shallow or correlated with other basins will tend to slow the network; noise in the synapses due to probabilistic release of transmitters (Koch, 1999; Abbott and Regehr, 2004); and the mean firing rates of the neurons during the decision-making itself, the firing rate distribution (Webb, Rolls, Deco and Feng, 2011), and the dilution of the connectivity (Rolls and Webb, 2012). In terms of synaptic noise, if the probability of release, p , is constant, then the only effect is that the releases in response to a Poisson presynaptic train at rate r are described by a Poisson process with rate pr , rather than r . However, if the synapse has short-term depression or facilitation, the statistics change (Fuhrmann et al., 2002b; Abbott and Regehr, 2004). A combination of these factors contributes to the probabilistic behavior of the network becoming poorer and slower as the difference between the inputs divided by the base frequency is decreased (Deco and Rolls, 2006).

In signal-detection theory, behavioral indeterminacy is accounted for in terms of noisy input (Green and Swets, 1966). In the present approach, indeterminacy is accounted for in part in terms of internal noise inherent to the operation of spiking neuronal circuitry (Rolls, 2016b; Rolls and Deco, 2010) (see also Wang (2008) and Faisal, Selen and Wolpert (2008)).

In fact, there are many sources of noise, both external to the brain and internal (Faisal, Selen and Wolpert, 2008). A simple measure of the variability of neuronal responses is the Fano factor, which is the ratio of the variance to the mean. A Poisson process has a Fano factor of 1, and neurons often have Fano factors close to one, though in some systems and for some neurons they can be lower (less variable than a Poisson process), or higher (Faisal et al., 2008). The sources of noise include the following, with citations to original findings provided by Faisal et al. (2008).

First, there is sensory noise, arising external to the brain. Thermodynamic noise is present for example in chemical sensing (including smell and gustation) because molecules arrive at the receptor at random rates owing to diffusion. Quantum noise can also be a factor, with photons arriving at the photoreceptor at a rate governed by a Poisson process. The peripheral nervous system (e.g. the retina, and in the olfactory bulb the glomeruli) often sums inputs over many receptors in order to limit this type of noise. In addition to these processes inherent in the transduction and subsequent amplification of the signals, there may of course be variation in the signal itself arriving from the world.

Second, there is cellular or neuronal noise arising even in the absence of variation in synaptic input. This cellular noise arises from the stochastic opening and closing of voltage or ligand-gated ion channels, the fusing of synaptic vesicles, and the diffusion and binding of signalling molecules to the receptors. The channel noise becomes appreciable in small axons and cell bodies (where the number of channels and molecules involved becomes relatively small). This channel noise can affect not only the membrane potential of the cell body and the initiation of spikes, but also spike propagation in thin axons. There may also be some cross-talk between neurons, caused by processes such as ephaptic coupling, changes in extracellular ion concentration after electrical signalling, and spillover of neurotransmitters between adjacent unrelated synapses.

Third, there is synaptic noise evident for example as spontaneous miniature postsynaptic currents (mPSCs) that are generated by the ‘quantal’ (discrete) nature of released neurotransmitter vesicles (Fatt and Katz, 1950; Manwani and Koch, 2001). This synaptic noise can be produced by processes that include spontaneous opening of intracellular Ca^{2+} stores, synaptic Ca^{2+} -channel noise, spontaneous triggering of the vesicle-release pathway, and spontaneous fusion of a vesicle with the membrane. In addition, at the synapses there is variation in the number of transmitter molecules in a released vesicle, and there are random diffusion processes of the molecules (Franks et al., 2003). In addition, there is randomness in whether an action potential releases a vesicle, with the probability sometimes being low, and being influenced by factors such as synaptic plasticity and synaptic adaptation (Faisal et al., 2008; Abbott and Regehr, 2004; Manwani and Koch, 2001).

The sources of noise in the brain arise from the effects described earlier that make the firing properties of neurons very often close to Poisson-like. If the system were infinitely large (as the mean field approach described here assumes) then the Poisson firing would average out to produce a steady average firing rate averaged across all the neurons. However, if the system has a finite number of neurons, then the Poisson or semirandom effects will not average out, and the average firing rate of the population will fluctuate statistically. These effects are referred to as coherent fluctuations. The magnitude of these fluctuations decreases with the square root of the size of the network (the number of neurons in the population in a fully connected network, and the number of connections per neuron in a network with diluted connectivity) (Mattia and Del Giudice, 2002). The magnitude of these fluctuations is described by the standard deviation of the firing rates divided by the mean rate, and this can be used to measure the noise in the network. These effects are described in detail in the Appendix of *The Noisy Brain: Stochastic Dynamics as a Principle of Brain Function* (Rolls and Deco, 2010) (available for download at <https://www.oxcns.org>).

The signal-to-noise ratio can be measured in a network by the average firing rate change produced by the signal in the neuronal population divided by the standard deviation of the firing rates. Non-linearities in the system will affect how the signal-to-noise ratio described in this way is reflected in the output of the system. Another type of measure that reflects the signal-to-noise ratio is the stability of the system as described by its trial to trial variability, as described in Sections 18.2.2 and 18.2.4 and by Rolls, Loh, Deco and Winterer (2008d).

Although many approaches have seen noise as a problem in the brain that needs to be averaged out or resolved (Faisal, Selen and Wolpert, 2008), and this is certainly important in sensory systems, the thrust of *The Noisy Brain* (Rolls and Deco, 2010) is to show that in fact noise inherent in brain activity has a number of advantages by making the dynamics stochastic, which allows for many remarkable features of the brain, including creativity, probabilistic decision-making, stochastic resonance, unpredictability, conflict resolution, symmetry breaking, allocation to discrete categories, and many other important properties described later in this Chapter.

The size of a network is an important factor in influencing how noisy the network is in relation to the statistical fluctuations related to the Poisson nature of the neuronal spiking. An infinite size network would have no noise, and its performance can be calculated analytically using mean field methods and checked with numerical simulations (Hopfield, 1982; Amit, 1989; Treves and Rolls, 1991; Treves, 1991b, 1990; Rolls, Treves, Foster and Perez-Vicente, 1997c; Rolls, 2012b) (Section B.3.3.7). In terms of relevance to cortical function, attractor networks with even thousands of neurons show probabilistic behavior, showing that the spiking-related noise of neurons does influence cortical networks of biologically relevant size. For example, even when a fully connected recurrent attractor network has 4,000 neurons, the operation of the network is still probabilistic (Deco and Rolls, 2006). Under these conditions, the probabilistic spiking of the excitatory (pyramidal) cells in the recurrent col-

lateral firing, rather than variability in the external inputs to the network, is what makes the major contribution to the noise in the network (Deco and Rolls, 2006). Thus, once the firing in the recurrent collaterals is spike-implemented by integrate-and-fire neurons, the probabilistic behavior seems inevitable, even up to quite large attractor network sizes.

The graded nature of the sparse distributed representations in the cortex tends to increase the noise (Webb, Rolls, Deco and Feng, 2011). Representations in the cortex are often distributed with graded firing rates in the neuronal populations. The firing rate probability distribution of each neuron to a set of stimuli is often exponential or gamma (see Section C.3.1.1) (Webb et al., 2011). In integrate-and-fire simulations of an attractor decision-making network, we showed that the noise is indeed greater for a given sparseness of the representation for graded, exponential, than for binary firing rate distributions. The greater noise was measured by faster escaping times from the spontaneous firing rate state when the decision cues are applied, and this corresponds to faster decision or reaction times. The greater noise was also evident as less stability of the spontaneous firing state before the decision cues are applied. The implication is that spiking-related noise will continue to be a factor that influences processes such as decision-making, signal detection, short-term memory, and memory recall even with the quite large networks found in the cerebral cortex. In these networks there are several thousand recurrent collateral synapses onto each neuron. The greater noise with graded firing rate distributions has the advantage that it can increase the speed of operation of cortical circuitry (Webb, Rolls, Deco and Feng, 2011).

Dilution of the connectivity within an attractor network can have the effect of decreasing the noise compared to a fully connected network with the same number of connections onto each neuron and therefore the same memory capacity (Rolls and Webb, 2012). The connectivity of the cerebral cortex is diluted, with the probability of excitatory connections between even nearby pyramidal cells rarely more than 0.1, and in the hippocampus 0.04 (Chapter 9 and Rolls (2016b)). To investigate the extent to which this diluted connectivity affects the dynamics of attractor networks in the cerebral cortex, we simulated an integrate-and-fire attractor network taking decisions between competing inputs with diluted connectivity of 0.25 or 0.1, and with the same number of synaptic connections per neuron for the recurrent collateral synapses within an attractor population as for full connectivity. The results indicated that there was less spiking-related noise with the diluted connectivity, in that the stability of the network when in the spontaneous state of firing increased, and the accuracy of the correct decisions increased. The decision times were a little slower with diluted than with complete connectivity. Given that the capacity of the network is set by the number of recurrent collateral synaptic connections per neuron, on which there is a biological limit, the findings indicate that the stability of cortical networks, and the accuracy of their correct decisions or memory recall operations, can be increased by utilizing diluted connectivity and correspondingly increasing the number of neurons in the network, with little impact on the speed of processing of the cortex (Rolls and Webb, 2012).

18.2.2 Attractor networks, energy landscapes, and stochastic neurodynamics

Attractor networks can be used for short-term memory and long-term memory, and for decision making (Section B.3). This section considers approaches to the stability of these networks. This section can be thought of as explaining the stability of memory networks, though the principles apply just as much to the decision-making networks considered in Section 11.5.1.

Autoassociation attractor systems (described in Section B.3) can have two types of stable fixed points: a spontaneous state with a low firing rate, and one or more attractor states with

Fig. 18.1 Stability and noise in an attractor network: an energy landscape. The noise influences when the system will jump out of the spontaneous firing stable (low energy) state S, and whether it jumps into the high firing rate state labelled P (with persistent or continuing firing in a state which is even more stable with even lower energy), which might correspond to a short-term memory, or to a decision.

high firing rates in which the positive feedback implemented by the recurrent collateral connections maintains a high firing rate. We sometimes refer to this latter state as the persistent state, because the high firing normally persists to maintain a set of neurons active, which might implement a short-term memory, or the recall of a long-term memory that persists for a short time.

The stable points of the system can be visualized in an energy landscape (see Fig. 18.1). The area in the energy landscape within which the system will move to a stable attractor state is called its basin of attraction. The attractor dynamics can be pictured by energy landscapes, which indicate the basins of attraction by valleys, and the attractor states or fixed points by the bottom of the valleys (see Fig. 18.1).

The stability of an attractor is characterized by the average time in which the system stays in the basin of attraction under the influence of noise. The noise provokes transitions to other attractor states. One source of noise results from the interplay between the Poissonian character of the spikes and the finite-size effect due to the limited number of neurons in the network.

Two factors determine the stability. First, if the depths of the attractors are shallow (as in the left compared to the right valley in Figure 18.1), then less force is needed to move a ball from one valley to the next. Second, high noise will make it more likely that the system will jump over an energy boundary from one state to another. We envision that the brain as a dynamical system has characteristics of such an attractor system including statistical fluctuations (see further Rolls and Deco (2010), where the effects of noise are defined quantitatively). The noise could arise not only from the probabilistic spiking of the neurons which has significant effects in finite size integrate-and-fire networks (Deco and Rolls, 2006), but also from any other source of noise in the brain or the environment (Faisal et al., 2008), including the effects of distracting stimuli.

In an attractor network in which a retrieval cue is provided to initiate recall but then removed, a landscape can be defined in terms of the synaptic weights. An example is shown in Fig. 18.2a. The basins in the landscape can be defined by the strengths of the synaptic weights which describe the stable operating points of the system, where the depth of the basins can be defined in terms of the synaptic weight space, in terms defined by an associative rule operating on the firing rates of pairs of neurons during the learning as follows

$$w_{ij} = y_i y_j \quad (18.1)$$

where y_i is the firing rate of the postsynaptic neuron, y_j is the firing rate of the presynaptic neuron, and w_{ij} is the strength of the synapses connecting these neurons.

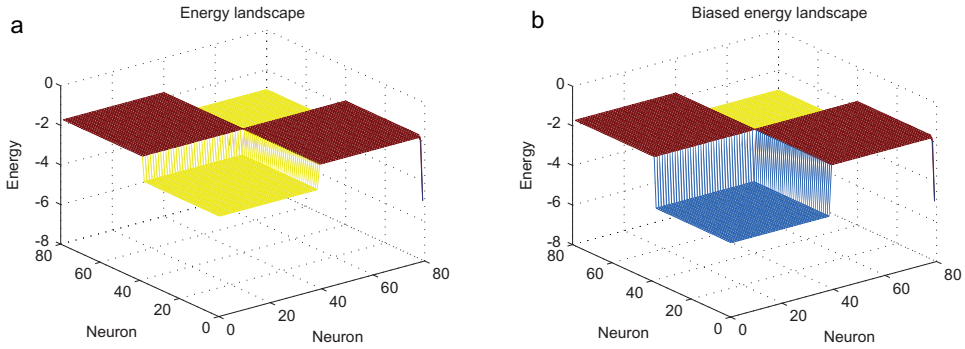

Fig. 18.2 Stability and noise in an attractor network. (a) Energy landscape without any differential bias applied. The landscape is for a network with neurons 1–40 connected by strengthened synapses so that they form attractor 1, and neurons 41–80 connected by synapses strengthened (by the same amount) so that they form attractor 2. The energy basins in the two-dimensional landscape are calculated by Equation 18.2. In this two-dimensional landscape, there are two stable attractors, and each will be reached equally probably under the influence of noise. This scenario might correspond to decision-making where the input λ_1 to attractor 1 has the same value as the input λ_2 to attractor 2, and the network is equally likely under the influence of the noise to fall into attractor 1 representing decision 1 as into attractor 2 representing decision 2. (b) Energy landscape with bias applied to neurons 1–40. This makes the basin of attraction deeper for attractor 1, as calculated with Equation 18.2. Thus, under the influence of noise caused by the randomness in the firing of the neurons, the network will reach attractor 1 more probably than it will reach attractor 2. This scenario might correspond to decision-making, where the evidence for decision 1 is stronger than for decision 2, so that a higher firing rate is applied as λ_1 to neurons 1–40. The scenario might also correspond to memory recall, in which memory 1 might be probabilistically more likely to be recalled than memory 2 if the evidence for memory 1 is stronger. Nevertheless, memory 2 will be recalled sometimes in what operates as a non-deterministic system. (From Rolls, E. T. and Deco, G. (2010) *The Noisy Brain: Stochastic Dynamics as a Principle of Brain Function*. Oxford University Press: Oxford.)

Hopfield (1982) showed how many stable states a simple attractor system might contain, and this is the capacity of the network described in Section B.3.3.7. He showed that the recall process in his attractor network can be conceptualized as movement towards basins of attraction, and his equation defines the energy at a given point in time as being a function of the synaptic weights and the current firing rates as follows

$$E = -\frac{1}{2} \sum_{i,j} w_{ij} (y_i - \langle y \rangle)(y_j - \langle y \rangle). \quad (18.2)$$

where y_i is the firing rate of the postsynaptic neuron, y_j is the firing rate of the presynaptic neuron, w_{ij} is the strength of the synapse connecting them, and $\langle y \rangle$ is the mean firing rate of the neurons. I note that the system defined by Hopfield had an energy function, in that the neurons were connected by symmetric synaptic weights (produced for example by associative synaptic modification of the recurrent collateral synapses) and there was no self-coupling (Hertz, Krogh and Palmer, 1991; Moreno-Bote, Rinzel and Rubin, 2007; Hopfield and Herz, 1995). (Equation 18.2 can be understood as showing that the system will be stable if high firing rate neurons are connected by strong synaptic weights, and a stable fixed point can be thought of as having low energy so that the system does not jump somewhere else in the energy landscape.)

The situation is more complicated in an attractor network if it does not have a formal energy function. One such condition is when the connectivity is randomly diluted, for then the synaptic weights between pairs of neurons will not be symmetric. Indeed, in general, neuronal systems do not admit such an energy function. (This is the case in that it is not in general possible to define the flow in terms of the gradient of an energy function. Hopfield defined first an energy function, and from there derived dynamics.) However, such diluted

connectivity systems can still operate as attractor systems (Treves, 1993, 1991a,b; Treves and Rolls, 1991; Treves, Rolls and Simmen, 1997; Rolls and Treves, 1998; Battaglia and Treves, 1998a), and the concept of an energy function and landscape is useful for discussion purposes. In practice, a Lyapunov function can be used to prove analytically that there is a stable fixed point such as an attractor basin (Khalil, 1996), and even in systems where this can not be proved analytically, it may still be possible to show numerically that there are stable fixed points, to measure the flow towards those fixed points which describes the depth of the attractor basin as we have done for this type of network (Loh, Rolls and Deco, 2007a), and to use the concept of energy or potential landscapes to help visualize the properties of the system (Rolls and Deco, 2010).

If an external input remains on during the retrieval process, this will influence the energy function of such a network, and its stable points, as implied by Equation 18.2, and as illustrated in Fig. 18.2b. In this situation, the external inputs bias the stable points of the system. Indeed, in this situation, a landscape, though not necessarily formally an energy landscape, can be specified by a combination of the synaptic weights and external inputs that bias the firing rates. The noise introduced into the network by for example the random neuronal spiking can be conceptualized as influencing the way that the system flows across this fixed landscape shaped by the synaptic weights, and by the external inputs if they remain on during operation of the network, in what is referred to as a ‘clamped’ condition, the normal condition that applies during decision-making (see Section 11.5.1).

In more detail, the flow, which is the time derivative of the neuronal activity, specifies the landscape in an attractor system. The flow is defined in the mean field analysis in terms of the effects of the synaptic weights between the neurons and the external inputs (Loh, Rolls and Deco, 2007a; Rolls and Deco, 2010). The flow is the force that drives the system towards the attractor given a parameter value in phase space, i.e. the firing rates of the pools (populations) of neurons. This is measured by fixing the value of the firing rate of the selective pool and letting the other values converge to their fixed point. The flow can then be computed with this configuration (Mascaro and Amit, 1999). This landscape is thus fixed by the synaptic and the external inputs. The noise, produced for example by the almost Poissonian spiking of the neurons, can be conceptualized as influencing the way that the system flows across this fixed landscape. Moreover, the noise can enable the system to jump over a barrier in this fixed landscape, as illustrated in Figs. 18.1 and 11.33.

In Fig. 18.2a (and in Fig. 11.33) the decision basins of attraction are equally deep, because the inputs λ_1 and λ_2 to the decision-making network are equal, that is, ΔI the difference between them is zero. If λ_1 is greater than λ_2 , the basin will be deeper for λ_1 . The shape of the landscape is thus a function of the synaptic weights and the biasing inputs to the system. This is illustrated in Fig. 18.2b. Noise can be thought of as provoking movements across the ‘effective energy landscape’ conceptualized in this way.

The way in which we conceptualise the operation of an attractor network used for noise-driven stochastic decision-making, stimulus detection, etc. is as follows. The noise in the system (caused for example by statistical fluctuations produced by the Poisson-like neuronal firing in a finite-sized system as described in Section 18.2.1) produces changes in neuronal firing. These changes may accumulate stochastically, and eventually may become sufficiently large that the firing is sufficient to produce energy to cause the system to jump over an energy barrier (see Fig. 18.3). Opposing this noise-driven fluctuation will be the flow being caused by the shape and depth of the fixed energy landscape defined by the synaptic weights and the applied external input bias or biases. The noisy statistical fluctuation is a diffusion-like process. If the spontaneous firing rate state is stable with the decision cues applied (see Fig. 18.4 middle), eventually the noise may provoke a transition over the energy barrier in an escaping time, and the system will drop, again noisily, down the valley on the other side of the hill.

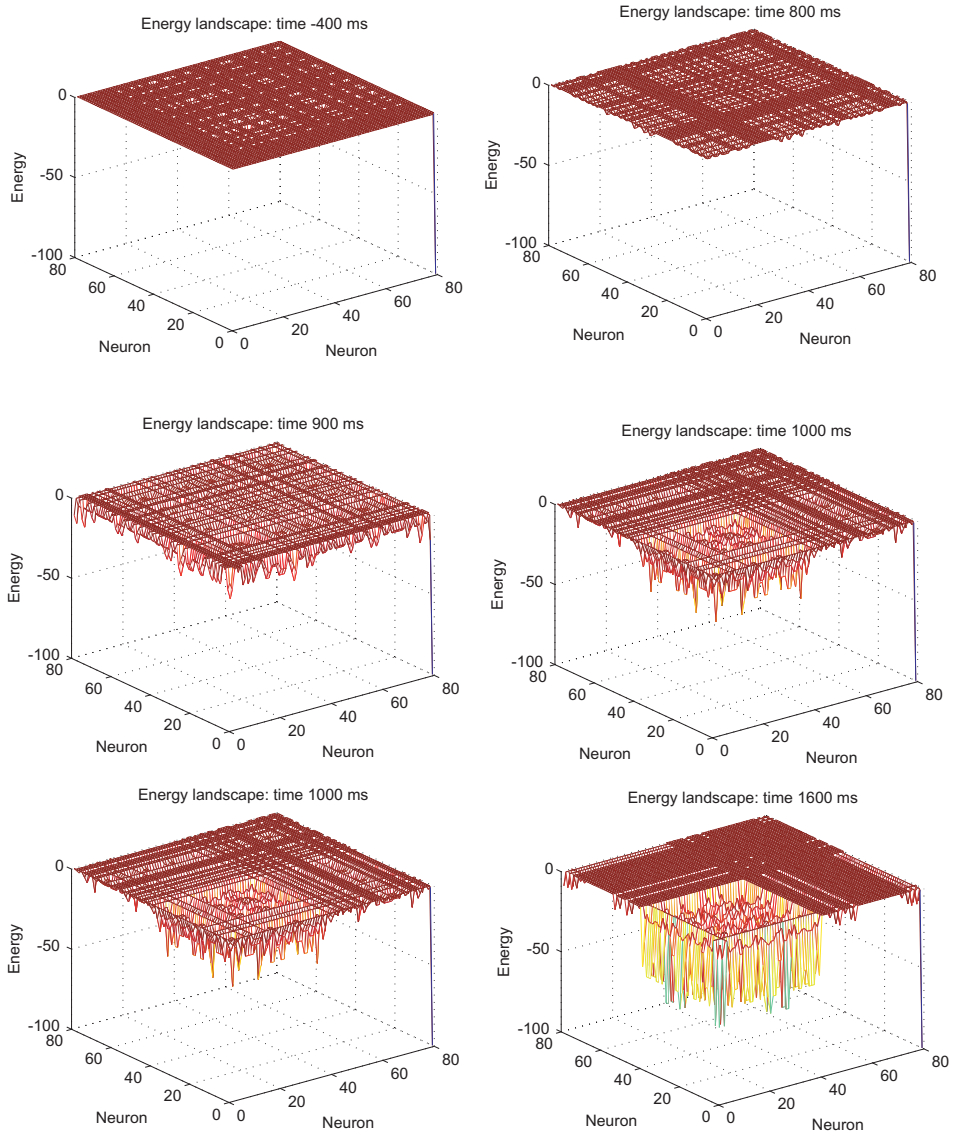

Fig. 18.3 Stability and noise in an attractor network. Energy states shown at different times after the decision cues were applied. Neurons 1–40 are in attractor 1 and are connected by strong weights with each other; and neurons 41–80 are in attractor 2 and are connected by strong weights with each other. The energy state is defined in Equation 18.2, and the energy between any pair of neurons is a product of the firing rates of each neuron and the synaptic weight that connects them. These are the energy states for the trial shown in Fig. 11.35b and c on page 550. Time 0 is the time when the decision stimuli were applied (and this corresponds to time 2 s in Fig. 11.35). (From Rolls, E. T. and Deco, G. (2010) *The Noisy Brain: Stochastic Dynamics as a Principle of Brain Function*. Oxford University Press: Oxford.)

The rate of change of the firing rate is again measured by the flow, and is influenced by the synaptic weights and applied biases, and by the statistical fluctuations. In this scenario, the reaction times will depend on the amount of noise, influenced by the size of the network, and by the fixed ‘effective energy landscape’ as determined by the synaptic weights and applied biasing inputs λ , which will produce an escaping time as defined further in the Appendix of Rolls and Deco (2010).

If the spontaneous state is not stable (see Fig. 18.4 right), the reaction times will be influenced primarily by the flow as influenced by the gradient of the energy landscape, and by the noise caused by the random neuronal firings. A noise-produced escaping time from a stable spontaneous state attractor will not in this situation contribute to the reaction times.

The noise-driven escaping time from the stable spontaneous state is important in understanding long and variable reaction times, and such reaction times are present primarily in the scenario when the parameters make the spontaneous state stable, as described further by Marti et al. (2008). While in a spontaneous stable state the system may be thought of as being driven by the noise, and it is primarily when the system has reached a ridge at the edge of the spontaneous valley and the system is close to a bifurcation point into a high firing rate close to the ridge that the attractor system can be thought of as accumulating evidence from the input stimuli (Deco et al., 2007). While in the spontaneous state valley (see Fig. 18.4 middle), the inputs can be thought of as biasing the ‘effective energy landscape’ across which the noise is driving the system stochastically.

An interesting aspect of the model is that the recurrent connectivity, and the relatively long time constant of the NMDA receptors (Wang, 2002), may together enable the attractor network to accumulate evidence over a long time period of several hundred milliseconds. Important aspects of the functionality of attractor networks are that they can accumulate and maintain information.

18.2.3 A multistable system with noise

In the situation illustrated in Figs. 18.1 and 11.33, there is multistability, in that the spontaneous state and a large number of high firing rate persistent states are stable. More generally, and depending on the network parameters including the strengths of the inputs, a number of different scenarios can occur. These are illustrated in Fig. 18.4. Let us consider the activity of a given neuronal population while inputs are being applied.

In Fig. 18.4 (left) we see a situation in which only the spontaneous state S is stable. This might occur if the external inputs λ_1 and λ_2 are weak.

On the right we have a situation in which our neuronal population is either in a high firing rate stable state $C2$, or in a low firing rate state $C1$ because another population is firing fast and inhibiting our neuronal population. There is no stable spontaneous state.

In the middle of Fig. 18.4 we see a situation in which our population may be either in $C1$, or in $C2$, or in a spontaneous state of firing S when no population has won the competition. We emphasize that this can be a scenario even when the decision cues λ_1 and λ_2 are being applied during the decision-making period. We refer to this system as a multistable system.

The differences between these scenarios are of interest in relation to how noise influences the decision-making. In the scenario shown in the middle of Fig. 18.4 we see that there are three stable states when the inputs λ_1 and λ_2 are being applied, and that it is the stochastic noise that influences whether the system jumps from the initial spontaneous state to a high firing rate state in which one of the decision-state populations fires fast, producing either $C2$ if our population wins, or $C1$ if our population loses. The statistical properties of the noise (including its amplitude and frequency spectrum), and the shape of the different basins in the energy landscape, influence whether a decision will be taken, the time when it will be

Fig. 18.4 Computational principles underlying the different dynamical regimes of the decision-making attractor network (see text). The x -axis represents the neuronal activity of one of the populations (ν_i) and the landscape represents an energy landscape ('potential') regulating the evolution of the system. S is a stable state of spontaneous activity, C2 is a high firing rate state of this neuronal population corresponding to the decision implemented by this population, and C1 is a low firing rate state present when the other population wins the competition.

taken, and which high firing rate decision attractor wins. In contrast, in the scenario shown in Fig. 18.4 (right) the energy landscape when the stimuli are being applied is such that there is no stable spontaneous state, so the system moves to one of the high firing rate decision attractors without requiring noise. In this case, the noise, and the shape of the energy landscape, influence which high firing rate decision state attractor will win.

A more detailed analysis suggests that there are two scenarios that are needed to understand the time course of processes such as decision-making and memory retrieval (which are very similar processes involving an attractor network driven by one input, or by several inputs) (Marti, Deco, Mattia, Gigante and Del Giudice, 2008).

First, in the scenario investigated by Wang (2002), the spontaneous state is unstable when the decision cues are applied. The network, initially in the spontaneous state, is driven to a competition regime by an increase of the external input (that is, upon stimulus presentation) that destabilizes the initial state. The decision process can then be seen as the relaxation from an unstable stationary state towards either of the two stable decision states (Fig. 18.4 (right)). When the system is completely symmetric (i.e. when there is no bias in the external inputs that favours one choice over the other), this destabilization occurs because the system undergoes a pitchfork bifurcation for sufficiently high inputs. The time spent by the system to evolve from the initial state to either of the two decision states is determined by the actual stochastic trajectory of the system in the phase space. In particular, the transition time increases significantly when the system wanders in the vicinity of the saddle that appears when the spontaneous state becomes unstable. Reaction times in the order of hundreds of ms may be produced in this way, and are strongly influenced by the long time constants of the NMDA receptors (Wang, 2002). The transition can be further slowed down by setting the external input slightly above the bifurcation value. This tuning can be exploited to obtain realistic decision times.

Second, there is a scenario in which the stimuli do not destabilize the spontaneous state, but rather increase the probability for a noise-driven transition from a stable spontaneous state to one of the decision states (see Fig. 18.4 (centre) and Section 18.2.3). Due to the presence of finite-size noise in the system there is a nonzero probability that this transition occurs and hence a finite mean transition rate between the spontaneous and the decision states. It has been shown that in this scenario mean decision times tend to the Van't Hoff-Arrhenius exponential dependence on the amplitude of noise in the limit of infinitely large networks. As a consequence, in this limit, mean decision times increase exponentially with the size of the network (Marti, Deco, Mattia, Gigante and Del Giudice, 2008). Further, the decision events

become Poissonian in the limit of vanishing noise, leading to an exponential distribution of decision times. For small noise a decrease in the mean input to the network leads to an increase of the positive skewness of decision-time distributions.

These results suggest that noise-driven decision models as in this second scenario provide an alternative dynamical mechanism for the variability and wide range of decision times observed, which span from a few hundred milliseconds to more than one second (Marti et al., 2008). In this scenario, there is an escaping time from the spontaneous firing state (Rolls and Deco, 2010). In this time the information can be thought of as accumulating in the sense that the stochastic noise may slowly drive the firing rates in a diffusion-like way such that an energy barrier is jumped over and escaped (see Fig. 18.1 on page 715 and Fig. 18.2). In this situation, a landscape can be specified by a combination of the synaptic weights and external decision-related input evidence that biases the firing rates of the decision attractors, as described in Section 18.2.2. The noise introduced into the network by for example the random neuronal spiking can be conceptualized as influencing the way that the system flows across this fixed landscape shaped by the synaptic weights, and by the external inputs if they remain on during operation of the network.

The model for the second scenario, with a stable spontaneous state even when the decision cues are being applied, makes specific predictions about reaction times. The analysis shows that there will be a gamma-like distribution with an exponential tail of long reaction times in the reaction time distribution with this second scenario (Marti et al., 2008).

For the reasons just described, all of the research that I have performed with integrate-and-fire networks has been with the second scenario, termed a multistable system, in which the spontaneous firing state is stable even when the decision cues (or recall cue) are being applied, and shown in 18.4 (centre). This is in contrast to the situation studied by Wang (2002), which corresponds to the bistable system shown in the right of Fig. 18.4.

18.2.4 Stochastic dynamics and the stability of short-term memory

I now introduce concepts on how noise produced by neuronal spiking, or noise from other sources, influences short-term memory, with illustrations drawn from Loh, Rolls and Deco (2007a) and Rolls, Loh and Deco (2008c).

The noise caused by the probabilistic firing of neurons can influence the stability of short-term memory. To investigate this, it is necessary to use a model of short-term memory which is a biophysically realistic integrate-and-fire attractor network with spiking of the neurons, so that the properties of receptors, synaptic currents and the statistical effects related to the noisy probabilistic spiking of the neurons can be analyzed. Loh, Rolls and Deco (2007a) and Rolls, Loh and Deco (2008c) used a minimal architecture, a single attractor or autoassociation network (Hopfield, 1982; Amit, 1989; Hertz et al., 1991; Rolls and Treves, 1998; Rolls, 2016b) (see Section B.3), to investigate how spiking-related stochastic noise influences the stability of short-term memory. They chose a recurrent (attractor) integrate-and-fire network model which includes synaptic channels for AMPA, NMDA and GABA_A receptors (Brunel and Wang, 2001). The integrate-and-fire model was necessary to characterize and exploit the effects of the spiking noise produced by the neurons in a finite-sized network. However, to initialize the parameters of the integrate-and-fire model such as the synaptic connection strengths to produce stable attractors, and to ensure that the spontaneous activity is in the correct range, they used a mean-field approximation consistent with the integrate-and-fire network, as described in Section B.8.2. Both excitatory and inhibitory neurons were represented by a leaky integrate-and-fire model (Tuckwell, 1988) described in detail in Section B.6.3.

The single attractor network contained 400 excitatory and 100 inhibitory neurons, which

Fig. 18.5 The attractor network model for short-term memory, attention, and decision-making. The excitatory neurons are divided into two selective pools S1 and S2 (with 40 neurons each) with strong intra-pool connection strengths w_+ , and one non-selective pool (NS) (with 320 neurons). The other connection strengths are 1 or weak w_- . The network contains 500 neurons, of which 400 are in the excitatory pools and 100 are in the inhibitory pool IH. Each neuron in the network also receives inputs from 800 external neurons, and these neurons increase their firing rates to apply a stimulus or distracter to one of the pools S1 or S2. The synaptic connection matrices are shown in Tables 18.1 and 18.2. (Reproduced from Loh, M., Rolls, E. T. and Deco, G. (2007) A Dynamical Systems hypothesis of Schizophrenia. *PLoS Computational Biology* 3: e228.)

is consistent with the observed proportions of pyramidal cells and interneurons in the cerebral cortex (Abeles, 1991; Braitenberg and Schüz, 1991). The connection strengths were adjusted using mean-field analysis (see Brunel and Wang (2001) and Section B.8.2), so that the excitatory and inhibitory neurons exhibited a spontaneous activity of 3 Hz and 9 Hz respectively (Koch and Fuster, 1989; Wilson et al., 1994a). The recurrent excitation mediated by the AMPA and NMDA receptors is dominated by the long time constant NMDA currents to avoid instabilities during the delay periods (Wang, 1999, 2002).

The cortical network model featured a minimal architecture to investigate stability (and also distractibility), and consisted of two selective pools (or populations of neurons) S1 and S2, as shown in Fig. 18.5. Pool S1 is used for the short-term memory item to be remembered, sometimes called the target; and pool S2 is used for a distracter stimulus. The non-selective pool NS modelled the spiking of other cortical neurons and served to generate an approximately Poisson spiking dynamics in the model (Brunel and Wang, 2001), which is what is observed in the cortex. The inhibitory pool IH contained 100 inhibitory neurons. There were thus four populations or pools of neurons in the network, and the connection weights were set up using a mean-field analysis to make S1 and S2 have stable attractor properties. The connection weights between the neurons within each selective pool or population were called the intra-pool connection strengths w_+ . The increased strength of the intra-pool connections was counterbalanced by the other excitatory connections (w_-) to keep the average input to a neuron constant. The actual synaptic strengths are shown in Tables 18.1 and 18.2 where $w_- = \frac{0.8 - f_{S1} w_+}{0.8 - f_{S1}}$, and f_{S1} is the fraction of the total number of excitatory neurons in pool S1. For these investigations, $w_+ = 2.1$ was selected, because with the default values of the NMDA and GABA conductances this yielded relatively stable dynamics with some effect of the noise being apparent, that is, a relatively stable spontaneous state if no retrieval cue was applied, and a relatively stable state of persistent firing after a retrieval cue had been applied and removed.

Each neuron in the network received Poisson input spikes via AMPA receptors which are envisioned to originate from 800 external neurons at an average spontaneous firing rate of 3 Hz from each external neuron, consistent with the spontaneous activity observed in the cerebral cortex (Wilson et al., 1994a; Rolls and Treves, 1998; Rolls, 2016b) (see Section B.6.3).

Table 18.1 The attractor network model: Connection matrix for AMPA and NMDA – [from, to]

	S1	S2	NS	IH
S1	w_+	w_-	1	1
S2	w_-	w_+	1	1
NS	w_-	w_-	1	1
IH	0	0	0	0

Table 18.2 The attractor network model: Connection matrix for GABA – [from, to]

	S1	S2	NS	IH
S1	0	0	0	0

NS	0	0	0	0
IH	1	1	1	1

Fig. 18.6 The attractor network model for the stability of short-term memory and attention: The simulation protocols. Stimuli to either S1 or S2 are applied at different times depending on the type of simulations. The spontaneous simulations include no input. The 'persistent' simulations assess how stably a stimulus is retained in short-term memory by the network. The distractor simulations add a distractor stimulus to further address the stability of the network activity in the face of a distracting stimulus, and thus both the stability of attention, and the shifting of attention. (Reproduced from Loh, M., Rolls, E. T. and Deco, G. (2007) A Dynamical Systems hypothesis of Schizophrenia. *PLoS Computational Biology* 3: e228.)

18.2.4.1 Analysis of the stability of short-term memory

The analyses (Loh, Rolls and Deco, 2007a; Rolls, Loh and Deco, 2008c) aimed to investigate the stability of the short-term memory implemented by the attractor network. Simulations were performed for many separate trials, each run with a different random seed to analyze the statistical variability of the network as the noise varied from trial to trial. We focussed on simulations of two different conditions: the spontaneous, and persistent, conditions.

In spontaneous simulations (see Fig. 18.6), we ran spiking simulations for 3 s without any extra external input. The aim of this condition was to test whether the network was stable in maintaining a low average firing rate in the absence of any inputs, or whether it fell into one of its attractor states without any external input.

In persistent simulations, an external cue of 120 Hz above the background firing rate of 2400 Hz was applied to each neuron in pool S1 during the first 500 ms to induce a high activity state and then the system was run without the additional external cue of 120 Hz for another 2.5 s, which was a short-term memory period. The 2400 Hz was distributed across the 800 synapses of each S1 neuron for the external inputs, with the spontaneous Poisson spike trains received by each synapse thus having a mean rate of 3 Hz. The aim of this condition was to investigate whether once in an attractor short-term memory state, the network can maintain its activity stably, or whether it fell out of its attractor, which might correspond to an inability to maintain short-term memory.

Fig. 18.7 The attractor network model for the stability of short-term memory. Example trials of the Integrate-and-Fire attractor network simulations of short-term memory. The average firing rate of all the neurons in the S1 pool is shown. Top: Normal operation. On a trial in which a recall stimulus was applied to S1 at 0–500 ms, firing continued normally until the end of the trial in the ‘persistent’ simulation condition. On a trial on which no recall stimulus was applied to S1, spontaneous firing continued until the end of the trial in the ‘spontaneous’ simulation condition. Bottom: Unstable operation. On this persistent condition trial, the firing decreased during the trial as the network fell out of the attractor because of the statistical fluctuations caused by the spiking dynamics. On the spontaneous condition trial, the firing increased during the trial because of the statistical fluctuations. In these simulations the network parameter was $w_+ = 2.1$. (After Rolls, E. 18.2.4.2 Stability and noise in a model of short-term memory

To clarify the concept of stability, we show examples of trials of spontaneous and persistent simulations in which the statistical fluctuations have different impacts on the temporal dynamics. Fig. 18.7 shows the possibilities, as follows.

In the spontaneous state simulations, no cue was applied, and we are interested in whether the network remains stably in the spontaneous firing state, or whether it is unstable and on some trials due to statistical fluctuations entered one of the attractors, thus falsely retrieving a memory. Figure 18.7 (top) shows an example of a trial on which the network correctly stayed in the low spontaneous firing rate regime, and (bottom) another trial (labelled spontaneous unstable) in which statistical spiking-related fluctuations in the network caused it to enter a high activity state, moving into one of the attractors even without a stimulus.

In the persistent state simulations (in which the short-term memory was implemented by the continuing neuronal firing), a strong excitatory input was given to the S1 neuronal population between 0 and 500 ms. Two such trials are shown in Fig. 18.7. In Fig. 18.7 (top), the S1 neurons (correctly) keep firing at approximately 30 Hz after the retrieval cue is removed at 500 ms. However, due to statistical fluctuations in the network related to the spiking activity, on the trial labelled persistent unstable the high firing rate in the attractor for S1 was not stable, and the firing decreased back towards the spontaneous level, in the example shown starting after 1.5 s (Fig. 18.7 bottom). This trial illustrates a failure to maintain a stable short-term memory state.

When an average was taken over many trials, for the persistent run simulations, in which the cue triggered the attractor into the high firing rate attractor state, the network was still in the high firing rate attractor state in the baseline condition on 88% of the runs. The noise had thus caused the network to fail to maintain the short-term memory on 12% of the runs.

The spontaneous state was unstable on approximately 10% of the trials, that is, on 10% of the trials the spiking noise in the network caused the network run in the condition without any initial retrieval cue to end up in a high firing rate attractor state. This is of course an error that is related to the spiking noise in the network.

We emphasise that the transitions to the incorrect activity states illustrated in Fig. 18.7 are caused by statistical fluctuations (noise) in the spiking activity of the integrate-and-fire neurons. Indeed, we used a mean-field approach with an equivalent network with the same parameters but without noise to establish parameter values where the spontaneous state and the high firing rate short-term memory ('persistent') state would be stable without the spiking noise, and then in integrate-and-fire simulations with the same parameter values examined the effects of the spiking noise (Loh, Rolls and Deco, 2007a; Rolls, Loh and Deco, 2008c). The mean-field approach used to calculate the stationary attractor states of the network for the delay period (Brunel and Wang, 2001) is described in Section B.7. These attractor states are independent of any simulation protocol of the spiking simulations and represent the behavior of the network by mean firing rates to which the system would converge in the absence of statistical fluctuations caused by the spiking of the neurons and by external changes. Therefore the mean-field technique is suitable for tasks in which temporal dynamics and fluctuations are negligible. It also allows a first assessment of the attractor landscape and the depths of the basin of attraction which then need to be investigated in detail with stochastic spiking simulations. Part of the utility of the mean-field approach is that it allows the parameter region for the synaptic strengths to be investigated to determine which synaptic strengths will on average produce stable activity in the network, for example of persistent activity in a delay period after the removal of a stimulus. For the spontaneous state, the initial conditions for numerical simulations of the mean-field method were set to 3 Hz for all excitatory pools and 9 Hz for the inhibitory pool. These values correspond to the approximate values of the spontaneous attractors when the network is not driven by stimulus-specific inputs. For the persistent state, the network parameters resulted in a selective pool having a high firing rate value of approximately 30 Hz when in its attractor state (Loh, Rolls and Deco, 2007a; Rolls, Loh and Deco, 2008c).

I note that there are two sources of noise in the simulated integrate-and-fire spiking networks that cause the statistical fluctuations: the randomly arriving external Poisson spike trains, and the statistical fluctuations caused by the spiking of the neurons in the finite sized network. Some of the evidence that the statistical fluctuations caused by the neuronal spiking do provide an important source of noise in attractor networks in the brain is that factors that affect the noise in the network such as the number of neurons in the network have clear effects on the operation of integrate-and-fire attractor networks, as considered further in Section 11.5.1. Indeed, the magnitude of these fluctuations increases as the number of neurons in the network becomes smaller (Mattia and Del Giudice, 2004).

The ways in which alterations in the inputs to the different synapse types in the different neurons in the network influence the stability of the network, and their applications to understanding psychiatric disorders and normal aging, are described next.

18.2.5 Stochastic dynamics in decision-making, and the evolutionary utility of probabilistic choice

Attractor decision-making networks are described in Sections 11.5.1 and B.6–B.8. Here we consider some advantages of the stochastic dynamics in the decision-making process (see further Rolls and Deco (2010)).

Probabilistic decision-making can be evolutionarily advantageous in that sometimes taking a decision that is not optimal based on previous history may provide information that

is useful, and that may contribute to learning. Consider for example a probabilistic decision task in which choice 1 provides rewards on 80% of the occasions, and choice 2 on 20% of the occasions. A deterministic system with knowledge of the previous reinforcement history would always make choice 1. But this is not how animals including humans behave. Instead (especially when the overall probabilities are low and the situation involves random probabilistic baiting, and there is a penalty for changing the choice), the proportion of choices made approximately matches the outcomes that are available, in what is called the matching law (Sugrue, Corrado and Newsome, 2005; Corrado, Sugrue, Seung and Newsome, 2005; Rolls, McCabe and Redoute, 2008e). By making the less favoured choice sometimes, the organism can keep obtaining evidence on whether the environment is changing (for example on whether the probability of a reward for choice 2 has increased), and by doing this approximately according to the matching law minimizes the cost of the disadvantageous choices in obtaining information about the environment.

This probabilistic exploration of the environment is very important in trial-and-error learning, and indeed has been incorporated into a simple reinforcement algorithm in which noise is added to the system, and if this improves outcomes above the expected value, then changes are made to the synaptic weights in the correct direction (in the associative reward-penalty algorithm) (Sutton and Barto, 1981; Barto, 1985; Rolls, 2016b).

In perceptual learning, probabilistic exploratory behavior may be part of the mechanism by which perceptual representations can be shaped to have appropriate selectivities for the behavioral categorization being performed (Sigala and Logothetis, 2002; Szabo et al., 2006).

Another example is in food foraging, which probabilistically may reflect the outcomes (Krebs and Davies, 1991; Kacelnik and Brito e Abreu, 1998), and is a way to keep sampling the environment and exploring the space of possible choices. Foraging can be performed optimally in terms of the costs and benefits of staying, or of moving on to forage elsewhere. Some noise in the system may help the amount of foraging to be optimally adjusted.

Another sense in which probabilistic decision-making may be evolutionarily advantageous is with respect to detecting signals that are close to threshold in the process termed stochastic resonance (Rolls and Deco, 2010; Deco, Rolls, Albantakis and Romo, 2013).

Intrinsic indeterminacy may be essential for unpredictable behavior (Glimcher, 2005). For example, in interactive games like matching pennies or rock–paper–scissors, any trend that deviates from random choice by an agent could be exploited to his or her opponent's advantage.

18.2.6 Selection between conscious vs unconscious decision-making, and free will

Another application of this type of model of stochastic decision-making is to taking decisions between the implicit (unconscious) and explicit (conscious) systems in emotional decision-making (see Rolls (2014a), Rolls (2016b) and Rolls (2020a)), where again the two different systems could provide the biasing inputs λ_1 and λ_2 to the model. An implication is that noise will influence with probabilistic outcomes which system, the implicit or the conscious reasoning system, takes a decision (Rolls, 2016b, 2020a).

When decisions are taken, sometimes confabulation may occur, in that a verbal account of why the action was performed may be given, and this may not be related at all to the environmental event that actually triggered the action (Gazzaniga and LeDoux, 1978; Gazzaniga, 1988, 1995; Rolls, 2014a; LeDoux, 2008). It is accordingly possible that sometimes in normal humans when actions are initiated as a result of processing in a specialized brain region such as those involved in some types of rewarded behavior, the language system may subsequently elaborate a coherent account of why that action was performed (i.e. confabulate)

(Rolls, 2020a). This would be consistent with a general view of brain evolution in which, as areas of the cortex evolve, they are laid on top of existing circuitry connecting inputs to outputs, and in which each level in this hierarchy of separate input–output pathways may control behavior according to the specialized function it can perform.

This raises the issue of free will in decision-making (Rolls, 2016b, 2020a).

First, we can note that in so far as the brain operates with some degree of randomness due to the statistical fluctuations produced by the random spiking times of neurons, brain function is to some extent non-deterministic, as defined in terms of these statistical fluctuations. That is, the behavior of the system, and of the individual, can vary from trial to trial based on these statistical fluctuations, in ways that are described in this book. Indeed, given that each neuron has this randomness, and that there are sufficiently small numbers of synapses on the neurons in each network (between a few thousand and 20,000) that these statistical fluctuations are not smoothed out, and that there are a number of different networks involved in typical thoughts and actions each one of which may behave probabilistically, and with 10^{11} neurons in the brain each with the number of synapses noted above, the system has so many degrees of freedom that it operates effectively as a non-deterministic system. (Philosophers may wish to argue about different senses of the term deterministic, but it is being used here in a precise, scientific, and quantitative way, which has been clearly defined.)

Second, do we have free will when both the implicit and the explicit systems have made the choice? Free will would in Rolls' view (Rolls, 2014a, 2008a, 2016b, 2010c, 2011b, 2020a) involve the use of language to check many moves ahead on a number of possible series of actions and their outcomes, and then with this information to make a choice from the likely outcomes of different possible series of actions. (If, in contrast, choices were made only on the basis of the reinforcement value of immediately available stimuli, without the arbitrary syntactic symbol manipulation made possible by language, then the choice strategy would be much more limited, and we might not want to use the term free will, as all the consequences of those actions would not have been computed.) It is suggested that when this type of reflective, conscious, information processing is occurring and leading to action (see Section 19.6.3), the system performing this processing and producing the action would have to believe that it could cause the action, for otherwise inconsistencies would arise, and the system might no longer try to initiate action. This belief held by the system may partly underlie the feeling of free will. At other times, when other brain modules are initiating actions (in the implicit systems), the conscious processor (the explicit system) may confabulate and believe that it caused the action, or at least give an account (possibly wrong) of why the action was initiated. The fact that the conscious processor may have the belief even in these circumstances that it initiated the action may arise as a property of it being inconsistent for a system that can take overall control using conscious verbal processing to believe that it was overridden by another system. This may be the underlying computational reason why confabulation occurs (Rolls, 2020a).

The interesting view we are led to is thus that when probabilistic choices influenced by stochastic dynamics are made between the implicit and explicit systems, we may not be aware of which system made the choice. Further, when the stochastic noise has made us choose with the implicit system, we may confabulate and say that we made the choice of our own free will, and provide a guess at why the decision was taken. In this scenario, the stochastic dynamics of the brain plays a role even in how we understand free will (Rolls, 2010c, 2016b, 2020a).

18.2.7 Stochastic dynamics and creative thought

Another way in which probabilistic decision-making may be evolutionarily advantageous is in creative thought, which is influenced in part by associations between one memory, representation, or thought, and another. If the system were deterministic, i.e. for the present purposes without noise, then the trajectory through a set of thoughts would be deterministic and would tend to follow the same furrow each time. However, if the recall of one memory or thought from another were influenced by the statistical noise due to the random spiking of neurons, then the trajectory through the state space would be different on different occasions, and we might be led in different directions on different occasions, facilitating creative thought (Rolls, 2016b; Rolls and Deco, 2010).

Of course, if the basins of attraction of each thought were too shallow, then the statistical noise might lead one to have very unstable thoughts that were too loosely and even bizarrely associated to each other, and to have a short-term memory and attentional system that is unstable and distractible, and indeed this is an account that we have proposed for some of the symptoms of schizophrenia (Rolls, 2014a, 2016b; Loh, Rolls and Deco, 2007a,b; Rolls, Loh, Deco and Winterer, 2008d) (see Section 18.3).

The stochastic noise caused by the probabilistic neuronal spiking plays an important role in these hypotheses, because it is the noise that destabilizes the attractors when the depth of the basins of attraction is reduced. If the basins of attraction were too deep, then the noise might be insufficient to destabilize attractors, and this leads to an approach to understanding obsessive-compulsive disorders (Rolls, Loh and Deco, 2008c) (see Section 18.4).

It is key to this hypothesis of an important mechanism of human creativity that the noise promotes a jump in an associative semantic (or similar) network, so that the jump is to a location in the attractor network that is associated with the starting point, and is thus not just to a random point in the space. This promotes finding solutions similar to some that may have been useful before and are not too far away within the associative space. This is a very different use to the noise that is sometimes used in artificial neural networks to avoid becoming stuck in a local minimum during gradient descent using error correction. It is proposed that use of noise in associative semantic networks to influence jumps to nearby locations in the energy landscape is likely to be useful in increasing creativity in Artificial Intelligence networks.

In an fMRI investigation of these hypotheses, the starting point was that creative individuals exhibit the ability to switch between different modes of thinking and shift their mental focus (Sun, Liu, Rolls, Chen, Yao, Yang, Wei, Zhang, Zhang, Feng and Qiu, 2019b). This suggests a connection between creativity and dynamic interactions of brain networks. We found that individuals' verbal creativity correlates with the temporal variability of the functional connectivity patterns of the lateral prefrontal cortex, the precuneus, and the parahippocampal gyrus. High variability of these regions indicates flexible connectivity patterns which may facilitate executive functions. In addition, verbal creativity was correlated with the temporal variability of functional connectivity patterns within the default mode network (DMN), between the DMN and attention/sensorimotor network, and between control and sensory networks. High variability of flexible connectivity patterns between the DMN and attention networks may characterize frequent adjustments of attention. This investigation (Sun et al., 2019b) revealed that there is a close relationship between verbal creativity and high variability of cortical networks involved in spontaneous thought, attention and cognitive control, consistent with the stochastic dynamics approach described here.

18.2.8 Stochastic dynamics and unpredictable behavior

An area where the spiking-related noise in the decision-making process may be evolutionarily advantageous is in the generation of unpredictable behavior, which can be advantageous in a number of situations, for example when a prey is trying to escape from a predator, and perhaps in some social and economic situations in which organisms may not wish to reveal their intentions (Maynard Smith, 1982, 1984; Dawkins, 1995). I note that such probabilistic decisions may have long-term consequences. For example, a probabilistic decision in a ‘war of attrition’ such as staring down a competitor e.g. in dominance hierarchy formation, may fix the relative status of the two individual animals involved, who then tend to maintain that relationship stably for a considerable period of weeks or more (Maynard Smith, 1982, 1984; Dawkins, 1995).

Thus intrinsic indeterminacy may be essential for unpredictable behavior. I also note the example provided by Glimcher (2005): in interactive games like matching pennies or rock–paper–scissors, any trend that deviates from random choice by an agent could be exploited to his or her opponent’s advantage.

18.3 Attractor dynamics and schizophrenia

18.3.1 Introduction

Schizophrenia is a major mental illness, which has a great impact on patients and their environment. One of the difficulties in proposing models for schizophrenia is the complexity and heterogeneity of the illness. We propose that part of the reason for the inconsistent symptoms may be a reduced signal-to-noise ratio and increased statistical fluctuations in different cortical brain networks. The novelty of the approach described here is that instead of basing our hypothesis purely on biological mechanisms, we develop a top-down approach based on the different types of symptoms and relate them to instabilities in attractor neural networks (Rolls, 2005a; Loh, Rolls and Deco, 2007a,b; Rolls, Loh, Deco and Winterer, 2008d; Rolls, 2016b; Deco, Rolls and Romo, 2009; Rolls and Deco, 2011a; Rolls, 2012c, 2014a, 2016b, 2021a).

The main assumption of our hypothesis is that attractor dynamics are important in cognitive processes. Our hypothesis is based on the concept of attractor dynamics in a network of interconnected neurons which in their associatively modified synaptic connections store a set of patterns, which could be memories, perceptual representations, or thoughts (Hopfield, 1982; Amit, 1989; Rolls, 2016b; Rolls and Deco, 2010). The attractor states are important in cognitive processes such as short-term memory, attention, and action selection (Deco and Rolls, 2005a; Rolls, 2016b). The network may be in a state of spontaneous activity, or one set of neurons may have a high firing rate, each set representing a different memory state, normally recalled in response to a retrieval stimulus. Each of the states is an attractor in the sense that retrieval stimuli cause the network to fall into the closest attractor state, and thus to recall a complete memory in response to a partial or incorrect cue. Each attractor state can produce stable and continuing or persistent firing of the relevant neurons. The concept of an energy landscape (Hopfield, 1982) is that each pattern has a basin of attraction, and each is stable if the basins are far apart, and also if each basin is deep, caused for example by high firing rates and strong synaptic connections between the neurons representing each pattern, which together make the attractor state resistant to distraction by a different stimulus (Section 18.2). The spontaneous firing state, before a retrieval cue is applied, should also be stable. Noise in the network caused by statistical fluctuations in the stochastic spiking of different neurons can contribute to making the network transition from one state to another, and we

take this into account by performing integrate-and-fire simulations with spiking activity, and relate this to the concept of an altered signal-to-noise ratio in schizophrenia (Winterer et al., 2000, 2004, 2006).

Schizophrenia is characterized by three main types of symptom: cognitive dysfunction, negative symptoms, and positive symptoms (Liddle, 1987; Baxter and Liddle, 1998; Mueser and McGurk, 2004; Owen, Sawa and Mortensen, 2016; Rolls, Lu, Wan, Yan, Wang, Yang, Tan, Li, Chinese-Schizophrenia-Collaboration, Yu, Liddle, Palaniyappan, Zhang, Yue and Feng, 2017). We consider how the basic characteristics of these three categories might be produced in a neurodynamical system, as follows.

Dysfunction of working memory, the core of the cognitive symptoms, may be related to instabilities of persistent attractor states (Durstewitz et al., 2000b; Wang, 2001) which we show can be produced by reduced firing rates in attractor networks, in brain regions such as the prefrontal cortex.

The negative symptoms such as flattening of affect or reduction of emotions may be caused by a consistent reduction in firing rates of neurons in regions associated with emotion such as the orbitofrontal cortex (Rolls, 2014a, 2016b, 2019e,f, 2023b). These hypotheses are supported by the frequently observed hypofrontality, a reduced activity in frontal brain regions in schizophrenic patients during cognitive tasks (Ingvar and Franzen, 1974; Kircher and Thienel, 2005; Scheuerecker et al., 2008).

The positive symptoms are characterized by phenomenologically overactive perceptions or thoughts such as hallucinations or delusions which are reflected for example by higher activity in the temporal lobes (Shergill et al., 2000; Scheuerecker et al., 2008). We relate this category of symptoms to a spontaneous appearance of activity in attractor networks in the brain and more generally to instability of both the spontaneous and persistent attractor states (Loh, Rolls and Deco, 2007a; Rolls, 2021a).

18.3.2 A dynamical systems hypothesis of the symptoms of schizophrenia

There is evidence on GABA-mediated inhibition impairments in schizophrenia, and also of decreased spine density that would reduce excitatory transmission in attractor networks (Lewis, 2014; Gonzalez-Burgos, Hashimoto and Lewis, 2010; Gonzalez-Burgos and Lewis, 2012; Glausier and Lewis, 2018; MacDonald, Alhassan, Newman, Richard, Gu, Kelly, Sampson, Fish, Penzes, Wills, Lewis and Sweet, 2017; Hoftman, Datta and Lewis, 2017; Dienel, Schoonover and Lewis, 2022; Smucny, Dienel, Lewis and Carter, 2022). This is an indication that the stability of cortical circuits is likely to be impaired in schizophrenia. In this section, models are described that show some of the effects that would be produced by altered levels of excitatory and inhibitory transmission on the stability of cortical circuitry, and how this might influence processes such as working memory and attention and lead to some of the symptoms of schizophrenia.

We relate the three types of symptoms of schizophrenia to the dynamical systems attractor framework described earlier as follows (Loh, Rolls and Deco, 2007a,b; Rolls, Loh, Deco and Winterer, 2008d; Rolls, 2016b; Deco, Rolls and Romo, 2009; Rolls and Deco, 2011a; Rolls, 2012c, 2014a).

The *cognitive symptoms* of schizophrenia include distractibility, poor attention, and the dysexecutive syndrome (Liddle, 1987; Green, 1996; Mueser and McGurk, 2004; Owen et al., 2016). The core of the cognitive symptoms is a working memory deficit in which there is a difficulty in maintaining items in short-term memory (Goldman-Rakic, 1994, 1999; Glausier and Lewis, 2018; Dienel, Schoonover and Lewis, 2022; Smucny, Dienel, Lewis and Carter, 2022), which could directly or indirectly account for a wide range of the cognitive symptoms.

We propose that these symptoms may be related to instabilities of persistent states in attractor neural networks, consistent with the body of theoretical research on network models of working memory (Durstewitz, Seamans and Sejnowski, 2000b). The neurons are firing at a lower rate, leading to shallower basins of attraction of the persistent states, and thus a difficulty in maintaining a stable short-term memory, normally the source of the bias in biased competition models of attention (Rolls and Deco, 2002; Deco and Rolls, 2005a; Rolls, 2008d, 2016b). The shallower basins of attraction would thus result in working memory deficits, poor attention, distractibility, and problems with executive function and action selection (Deco and Rolls, 2003, 2005a; Rolls, 2016b).

The *negative symptoms* refer to the flattening of affect and a reduction in emotion. Behavioral indicators are blunted affect, emotional and passive withdrawal, poor rapport, lack of spontaneity, motor retardation, and disturbance of volition (Liddle, 1987; Mueser and McGurk, 2004; Owen et al., 2016). The negative symptoms are a major source of difference between schizophrenic patients, and show a continuous gradation in magnitude between different people with schizophrenia (Rolls, Lu, Wan, Yan, Wang, Yang, Tan, Li, Chinese-Schizophrenia-Collaboration, Yu, Liddle, Palaniyappan, Zhang, Yue and Feng, 2017). Moreover, we have found in a large-scale study that the negative symptoms, as well as the positive and general symptoms, are reduced by treatment with antipsychotic drugs (Rolls et al., 2017). We propose that the negative symptoms are related to decreases in firing rates in the orbitofrontal cortex and/or anterior cingulate cortex (Rolls, 2014a, 2016b), where neuronal firing rates and activations in fMRI investigations are correlated with reward value and pleasure (Rolls, 2014a, 2006b, 2007f; Rolls and Grabenhorst, 2008; Rolls, 2008c, 2019e,c). Consistent with this, imaging studies have identified a relationship between negative symptoms and prefrontal hypometabolism, i.e. a reduced activation of frontal areas (Wolkin et al., 1992; Aleman and Kahn, 2005).

The *positive symptoms* of schizophrenia include bizarre (psychotic) trains of thoughts, hallucinations, and (paranoid) delusions (Liddle, 1987; Mueser and McGurk, 2004; Owen, Sawa and Mortensen, 2016; Rolls, Lu, Wan, Yan, Wang, Yang, Tan, Li, Chinese-Schizophrenia-Collaboration, Yu, Liddle, Palaniyappan, Zhang, Yue and Feng, 2017). We propose that these symptoms are related to shallow basins of attraction of both the spontaneous and persistent states in the temporal lobe semantic memory networks and to the statistical fluctuations caused by the probabilistic spiking of the neurons. This could result in activations arising spontaneously, and thoughts moving too freely round the energy landscape, loosely from thought to weakly associated thought, leading to bizarre thoughts and associations, which may eventually over time be associated together in semantic memory to lead to false beliefs and delusions. Consistent with this, neuroimaging studies suggest higher activation especially in areas of the temporal lobe (Weiss and Heckers, 1999; Shergill et al., 2000; Scheuerecker et al., 2008).

To further investigate our hypothesis, we used an attractor network, as this is likely to be implemented in many parts of the cerebral cortex by the recurrent collateral connections between pyramidal cells, and has short-term memory properties with basins of attraction which allow systematic investigation of stability and distractibility. The particular neural network implementation we adopted includes channels activated by AMPA, NMDA and GABA_A receptors and allows not only the spiking activity to be simulated, but also a consistent mean-field approach to be used (Brunel and Wang, 2001). The network, and some of the simulations performed with it, are described in Section 18.2 and Section B.6.

The main findings were as follows, and are summarized in Fig. 18.8 (Loh, Rolls and Deco, 2007a,b; Rolls, Loh, Deco and Winterer, 2008d).

A reduction of the NMDA receptor activated synaptic conductances ($-NMDA$) reduces

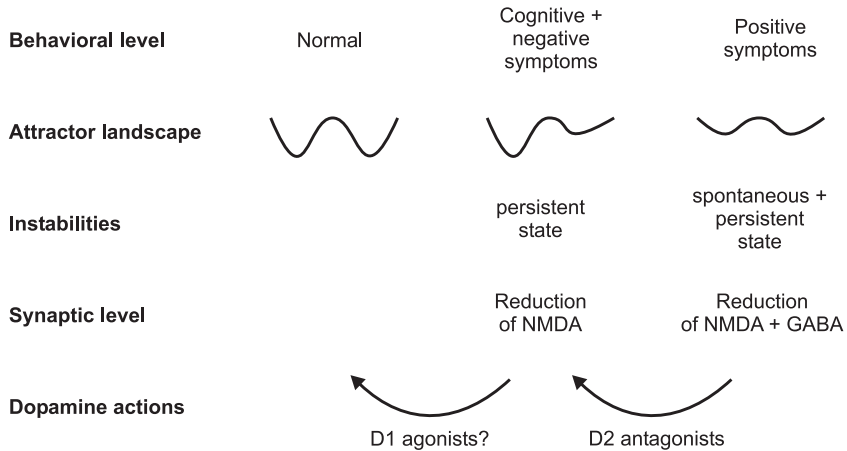

Fig. 18.8 Summary of attractor hypothesis of schizophrenic symptoms and simulation results (see text). The first basin (from the left) in each energy landscape is the spontaneous state, and the second basin is the persistent attractor state. The vertical axis of each landscape is the energy potential. (After Loh, M., Rolls, E. T. and Deco, G. (2007) A dynamical systems hypothesis of schizophrenia. *PLoS Computational Biology* 3: e228.)

the stability of the persistent state drastically. We hypothesized that this type of change might be related to the cognitive symptoms, since it shows a reduced stability of the working memory properties. The network was also more sensitive to a weak external stimulus, and we related this to increased distractibility. Consistent with this, there is a reduced spine density on excitatory neurons in the prefrontal cortex (Glausier and Lewis, 2013; Konopaske et al., 2014; Glantz and Lewis, 2000; Dienel et al., 2022). If present also in the orbitofrontal and anterior cingulate cortex, this could reduce the firing rates of these cortical neurons, and thus produce the negative symptoms of schizophrenia. This simulation relates directly to the glutamate hypothesis of schizophrenia, and particularly to hypofunction of the NMDA receptor (Uno and Coyle, 2019; Coyle, Ruzicka and Balu, 2020).

When both NMDA and GABA synaptic conductances are reduced, the stability of the high firing rate attractor state was reduced, and so was the stability of the spontaneous low firing rate state. We relate this pattern to the positive symptoms of schizophrenia, in which both the spontaneous and attractor states are shallow, and the system by the influence of statistical fluctuations wanders between the different (spontaneous and high firing rate attractor) states, as illustrated in Fig. 18.9.

The positive symptoms (Fig. 18.8, right column) of schizophrenia include delusions, hallucinations, thought disorder, and bizarre behavior. Examples of delusions are beliefs that others are trying to harm the person, impressions that others control the person's thoughts, and delusions of grandeur. Hallucinations are perceptual experiences, which are not shared by others, and are frequently auditory but can affect any sensory modality. These symptoms may be related to activity in the temporal lobes (Liddle, 1987; Epstein et al., 1999; Mueser and McGurk, 2004). The attractor framework approach taken here hypothesizes that the basins of attraction of both spontaneous and persistent states are shallow (Fig. 18.8). Due to the shallowness of the spontaneous state, the system can jump spontaneously up to a high activity state causing hallucinations to arise and leading to bizarre thoughts and associations. This might be the cause for the higher activations in schizophrenics in temporal lobe areas which are identified in imaging experiments (Shergill et al., 2000; Scheuerecker et al., 2008).

We relate the positive symptoms to not only a reduction in NMDA conductance (cf. Coyle, Ruzicka and Balu (2020)), but especially also to a reduction in what we modelled as GABA conductance, but more generally to any reduction of inhibitory neuron efficacy that might lead to higher firing rates of cortical excitatory neurons (Loh, Rolls and Deco, 2007a,b; Rolls,

Fig. 18.9 Wandering between attractor states by virtue of statistical fluctuations caused by the randomness of the spiking activity. We simulated a single long trial (60 s) in the spontaneous test condition for the synaptic modification (—NMDA, —GABA). The two curves show the activity of the two selective pools over time smoothed with a 1 s sliding averaging window. The activity moves noisily between the attractor for the spontaneous state and the two persistent states S1 and S2. (After Loh, M., Rolls, E. T. and Deco, G. (2007) A dynamical systems hypothesis of schizophrenia. *PLoS Computational Biology* 3: e228.)

Loh, Deco and Winterer, 2008d). This is consistent with the fact that the positive symptoms usually follow the cognitive and negative ones and represent a qualitative worsening of the illness (Mueser and McGurk, 2004). Alterations in GABA receptors have been identified in schizophrenia (Lewis, 2014; Gonzalez-Burgos et al., 2010; Gonzalez-Burgos and Lewis, 2012; Glausier and Lewis, 2018), and the hippocampus has increased metabolism and activity in schizophrenia (Wegrzyn, Juckel and Faissner, 2022).

The evidence on GABA-mediated inhibition impairments in schizophrenia, and also of decreased spine density that would reduce excitatory transmission (Lewis, 2014; Gonzalez-Burgos et al., 2010; Gonzalez-Burgos and Lewis, 2012; MacDonald et al., 2017; Hoftman et al., 2017; Glausier and Lewis, 2018; Rolls, 2021a; Dienel et al., 2022), is an indication that the stability of cortical attractor networks is likely to be impaired in schizophrenia. The models described here have shown some of the effects that would be produced by altered levels of excitatory and inhibitory transmission on the stability of cortical circuitry, and how this might influence processes such as working memory and attention, and produce some of the symptoms of schizophrenia.

18.3.3 Reduced functional connectivity of some brain regions in schizophrenia

One way to investigate further the hypothesis that some networks in the brain are less stable in schizophrenia is to measure whether the functional connectivity between some brain regions is lower in schizophrenia. Functional connectivity can be measured by the Pearson correlation between the BOLD signal for each pair of brain regions over a time period of several minutes. A higher correlation is interpreted as showing that the nodes (the brain regions) are more strongly connected, in that they are influencing each other's BOLD signals, or have a common input.

In one such investigation, the functional connectivity in a group of 123 patients with chronic schizophrenia compared to 136 matched healthy controls is shown in Fig. 18.10B (Rolls, Cheng and Feng, 2021b). The matrix shows the functional connectivity differences for pairs of brain areas from the automated anatomical labelling atlas 3 (AAL3) (Rolls, Huang, Lin, Feng and Joliot, 2020d). First, it is evident that many of the functional connectivities are significantly lower in schizophrenia. This is consistent with the hypothesis that the level of excitation between cortical areas is lower in schizophrenia, which is equivalent in the simulations described above to a reduction in the NMDA synaptic conductances. This is consistent with the disconnectivity hypothesis of schizophrenia (Friston and Frith, 1995).

Moving beyond the disconnectivity hypothesis, the reduced functional connectivities evident in Fig. 18.10B might lead us to expect that there might be signs of less stability in the BOLD signal in schizophrenia. This was shown to be the case, in that the temporal variability of the functional connectivities of many of the brain regions was higher in schizophrenia, as shown in Fig. 18.10A²¹. The higher temporal variability was especially clear for some early visual cortical areas (Inferior Occipital and Fusiform), the temporal lobe areas connected to these, and the orbitofrontal cortex. This is an indication of increased instability of these brain regions in schizophrenia (Rolls, Cheng and Feng, 2021b,a).

Very interestingly, this higher temporal variability reflecting instability of some early visual cortical areas, the temporal lobe areas connected to these, and the orbitofrontal cortex could be related to lower functional connectivities of especially these areas, as shown in Fig. 18.10B. Especially interesting was that the functional connectivities of the thalamic sensory visual relay, the lateral geniculate nucleus, and the thalamic sensory auditory relay, the medial geniculate nucleus, were lower in schizophrenia (Fig. 18.10B). This was in interesting contrast to the association thalamic nuclei, which had increased functional connectivity in schizophrenia. This finding was cross-validated in a different set of patients with first-episode schizophrenia, who had similar though somewhat smaller differences from controls (Rolls et al., 2021b).

These findings are consistent with the hypothesis that a factor in schizophrenia is a reduction in the connectivity and therefore excitability of some brain regions, which destabilizes attractor networks in these regions because the firing rates are insufficient to maintain the networks in a high firing rate state. In particular, we propose that in schizophrenia these differences bias processing away from external visual and auditory inputs, and towards internal cognitive processing in associative cortical areas such as the prefrontal and temporal cortical areas. We relate this to the tendency for people with schizophrenia to be disconnected from the world, and to be unable to maintain attention (Rolls, Cheng and Feng, 2021b).

18.3.4 Beyond the disconnectivity hypothesis of schizophrenia: reduced forward but not backward connectivity

It has been possible to go beyond the disconnectivity hypothesis of schizophrenia (Friston and Frith, 1995), not only in terms of reduced dynamical stability of early visual cortical and

²¹The temporal variability measures how much the functional connectivity of a brain region k with other brain regions changes across time. The temporal variability of a given brain region was obtained as follows. We first segmented all BOLD signals into n non-overlapping windows with length l . The whole-brain FC network F_i (an $m * m$ matrix, with $m = 132$ nodes) in the i th time window was then constructed, with the Pearson correlation being the measure of Functional Connectivity. The Functional Connectivity profile of region k at time window i is denoted by $F_i(k, :)$ (shortened as $F_{i,k}$, which is an m -dimensional vector that represents all the functional connections of region k). The variability of a region k is defined as:

$$V_k = 1 - (\text{corcoef}(F_{(i,k)}, F_{(j,k)})) \quad i, j = 1, 2, 3, \dots, n, i \neq j \quad (18.3)$$

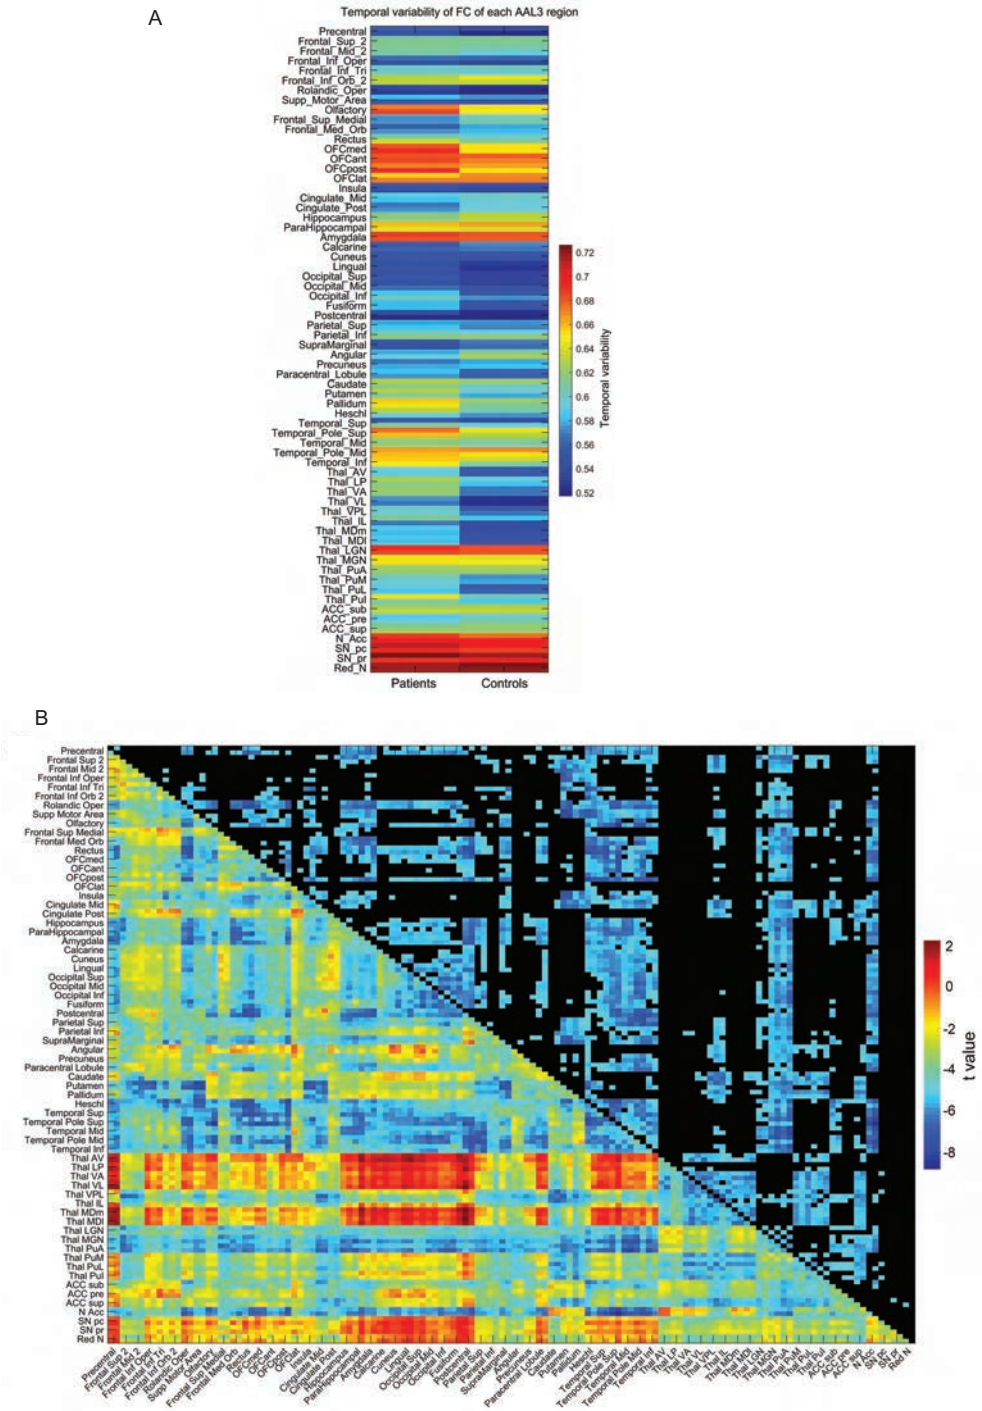

Fig. 18.10 A) The temporal variability of different AAL3 regions in the chronic schizophrenic and control groups. B) The functional connectivity of AAL3 regions for the chronic schizophrenic group minus controls. The lower left shows the t value for the difference in functional connectivity of patients - controls; the upper right shows the significance after Bonferroni correction. (After Rolls, E. T., Cheng, W. and Feng, J. (2021) Brain dynamics: the temporal variability of connectivity, and differences in schizophrenia and ADHD. *Translational Psychiatry* 11: 70.)

related areas as described above (Rolls, Cheng and Feng, 2021b), but also in terms of the direction of the connectivities that are decreased, as described next (Rolls, Cheng, Gilson, Gong, Deco, Lo, Yang, Tsai, Liu, Lin and Feng, 2020c).

In hierarchical cortical systems, the forward connectivities up through the hierarchy are strong, to drive the processing up through the hierarchy; and the backprojections are weaker, as they are used for memory recall and for top-down attentional bias (Rolls, 2016b). Measurements can be made of the connectivity in each of these directions, by making use of differences in the signals between successive timesteps. The connectivity in each direction is termed the *effective connectivity*. To investigate how the directed or effective connectivities are different in schizophrenia, to see whether they are different for particular brain areas, or in particular directions, we have analyzed effective connectivity in schizophrenia, comparing the resting state effective connectivity in 181 participants with schizophrenia and 208 controls (Rolls et al., 2020c).

It is difficult to apply directed connectivity algorithms to the fMRI BOLD signal, which is fairly slow, but an approach called Dynamic Causal Modelling (DCM) has been developed (Marreiros et al., 2008; Stephan et al., 2010). However, DCM is generally limited to a relatively small number of brain regions. We therefore adopted an approach (Gilson, Moreno-Bote, Ponce-Alvarez, Ritter and Deco, 2016) that can allow effective connectivity measurements between the 94 areas in the automated anatomical labelling atlas 2 (Rolls et al., 2015a).

The first key finding was that for the significantly different effective connectivities in schizophrenia, on average the forward (stronger) effective connectivities were smaller, but the backward connectivities tended to be larger, in schizophrenia, and the difference was significant (Rolls et al., 2020c). An implication of this is that the feedforward sensory inputs from the world are less effective in schizophrenia; and that the top-down backward connectivities that mediate the effects of memory recall and attention (Rolls, 2016b) show little difference in schizophrenia. This would tend to disconnect the individual from the world; and enclose the patient in an imaginary world too dominated by internal representations not corrected towards reality by sensory information from the world. Put in another way, if top-down signals are increased relative to bottom-up signals this would increase the importance of priors, ie, beliefs, at the cost of sensory signals, representing a possible mechanism for the emergence of hallucinations and delusions (Tschacher et al., 2017).

A second key finding in schizophrenia was the high effective connectivity directed away from the precuneus and the closely related posterior cingulate cortex (Fig. 18.11) (Rolls et al., 2020c). The connectivity in the strong (or forward) direction in schizophrenia to the precuneus is similar to that in the healthy controls, and it is in the weaker (backprojection) direction that the effective connectivity is higher in schizophrenia than in controls. It is suggested that by influencing other areas too much by its backprojections, the precuneus may contribute to the symptoms of schizophrenia. The regions to which the backprojections from the posterior cingulate cortex are higher in schizophrenia than in controls include the parahippocampal and temporal cortices (Rolls et al., 2020c).

I therefore consider how these differences in the connectivity of the precuneus and posterior cingulate cortex are involved in schizophrenia. The precuneus is a medial parietal cortex region implicated in the sense of self, agency, autobiographical memory, and spatial function (Cavanna and Trimble, 2006; Freton et al., 2014), and this may relate to the altered sense of self that is a feature of schizophrenia. The precuneus and the adjoining retrosplenial cortex (areas 29 and 30) (Kobayashi and Amaral, 2007) are key regions related to spatial function, memory, and navigation (Bubb et al., 2017; Cavanna and Trimble, 2006; Freton et al., 2014; Rolls and Wirth, 2018; Rolls, 2020b, 2021f; Rolls et al., 2023i; Rolls, 2023c) (Chapters 10 and 9). The retrosplenial cortex provides connections to and receives connections from the hippocampal system, connecting especially with the parahippocampal gyrus areas TF and

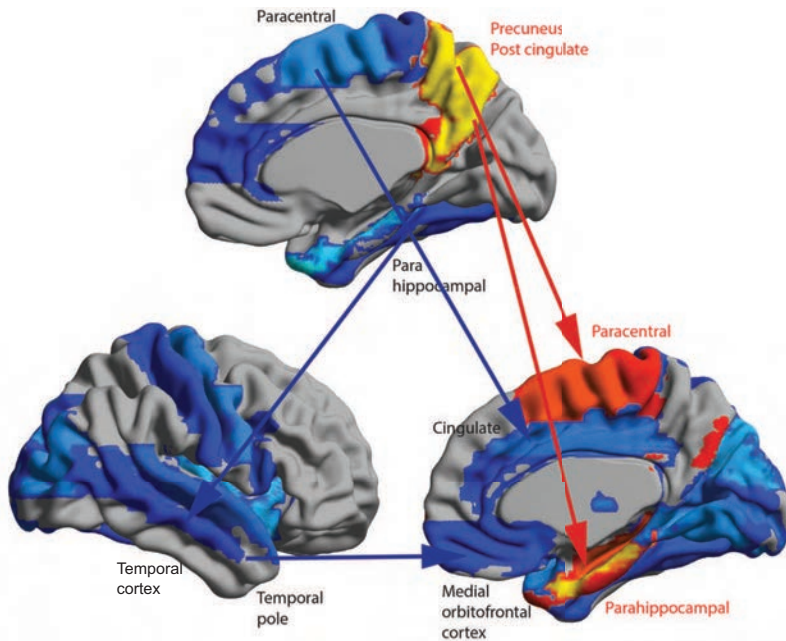

Fig. 18.11 Differences in effective connectivity in schizophrenia. The source regions (Region 1) are shown in the upper view of the brain, and the target regions (Region 2) in the two lower views of the brain. The Automated Anatomical Labelling atlas 2 regions with these differences show higher effective connectivity in red to yellow; and lower effective connectivity in blue. (After Rolls, E. T., Cheng, W., Gilson, M., Gong, W., Deco, G., Zac Lo, C-Y., Yang, A.C., Tsai, S-J., Liu, M-E., Lin, C-P. and Feng, J. (2020) Beyond the disconnectivity hypothesis of schizophrenia. *Cerebral Cortex* 30: 1213–1233. © Oxford University Press.)

TH, and with the subiculum (Bubb et al., 2017; Kobayashi and Amaral, 2007; Rolls et al., 2023i; Rolls, 2023c) (Fig. 9.1). The precuneus can be conceptualized as providing access to the hippocampus for spatial and related information from the parietal cortex (given the rich connections between the precuneus and parietal cortex (Vogt, 2009; Kobayashi and Amaral, 2007; Rolls et al., 2023i,d). This increased effective connectivity from the precuneus to the hippocampal system is of special interest as it may contribute to the overactivity of the hippocampus in schizophrenia (Wegrzyn et al., 2022), which is consistent with the high Sigma parameter reflecting signal variance in schizophrenia also found for the hippocampus (Rolls, Cheng, Gilson, Gong, Deco, Lo, Yang, Tsai, Liu, Lin and Feng, 2020c). Further, the precuneus has rich connectivity with the posterior cingulate cortex (Vogt, 2009; Rolls et al., 2023i), which provides a pathway into the hippocampal memory system (Rolls and Wirth, 2018; Rolls, 2019c, 2020b, 2021f; Rolls et al., 2023i; Rolls, 2023c). The precuneus is part of the default mode network, which becomes more active when tasks are not being performed in the world, and instead internal thoughts and processing are occurring.

The posterior cingulate cortex is also a key region of the default mode network with strong connectivity in primates with the entorhinal cortex and parahippocampal gyrus, and thus with the hippocampal memory system (Bubb et al., 2017; Vogt, 2009; Rolls, 2019c; Rolls et al., 2023i). The posterior cingulate region (including the retrosplenial cortex) is consistently engaged by a range of tasks that examine episodic memory including autobiographical memory, and imagining the future; and also spatial navigation and scene processing (Auger and Maguire, 2013; Leech and Sharp, 2014; Rolls, 2019c; Rolls et al., 2023i; Rolls, 2022b).

The proposal made based on the findings described here and the evidence about the functions of the precuneus and posterior cingulate cortex is that the high backprojection effective connectivities from the precuneus may relate to increased internal thoughts about the self in

schizophrenia, the world in which the self exists, and the relatively greater role of these internal thoughts which are not dominated by the sensory inputs from the world which normally keep the self in contact with the real world and with real-world inputs. Correspondingly, it was proposed that the high backprojection effective connectivities from the posterior cingulate cortex in schizophrenia may relate to increased memory-related internal thoughts involving relatively higher dominance of memories over the normal forward real-world sensory inputs that normally keep us in contact with the real world (Rolls et al., 2020c).

Thus overall we have seen in this section (18.3) how concepts about the stability and connectivity of cortical networks can be applied to help understand some important aspects of a key mental disorder, schizophrenia (Rolls et al., 2021b,a; Rolls, 2021a).

18.4 Attractor dynamics and obsessive-compulsive disorder

18.4.1 Introduction

Obsessive-compulsive disorder (OCD) is a chronically debilitating disorder with a lifetime prevalence of 2–3% (Karno, Golding, Sorenson and Burnam, 1988; Weissman, Bland, Canino, Greenwald, Hwu, Lee, Newman, Oakley-Browne, Rubio-Stipec, Wickramaratne et al., 1994; Pauls, Abramovitch, Rauch and Geller, 2014; Stein, Kogan, Atmaca, Fineberg, Fontenelle, Grant, Matsunaga, Reddy, Simpson, Thomsen, van den Heuvel, Veale, Woods and Reed, 2016; Robbins, Vaghi and Banca, 2019; Fineberg and Robbins, 2021). It is characterized by two sets of symptoms, obsessive and compulsive. Obsessions are unwanted, intrusive, recurrent thoughts or impulses that are often concerned with themes of contamination and ‘germs’, checking household items in case of fire or burglary, order and symmetry of objects, or fears of harming oneself or others (Chamberlain, Solly, Hook, Vaghi and Robbins, 2021). Compulsions are ritualistic, repetitive behaviors or mental acts carried out in relation to these obsessions e.g. washing, household safety checks, counting, rearrangement of objects in symmetrical arrays or constant checking of oneself and others to ensure no harm has occurred (Menziez et al., 2008; Stein et al., 2016; Robbins et al., 2019). Patients with OCD experience the persistent intrusion of thoughts that they generally perceive as foreign and irrational but which cannot be dismissed. The anxiety associated with these unwanted and disturbing thoughts can be extremely intense; it is often described as a feeling that something is incomplete or wrong, or that terrible consequences will ensue if specific actions are not taken. Many patients engage in repetitive, compulsive behaviors that aim to discharge the anxieties associated with these obsessional thoughts. Severely affected patients can spend many hours each day in their obsessional thinking and resultant compulsive behaviors, leading to marked disability (Pittenger et al., 2006; Stein et al., 2016). While patients with OCD and related disorders exhibit a wide variety of obsessions and compulsions, the symptoms tend to fall into specific clusters. Common patterns include obsessions of contamination, with accompanying cleaning compulsions; obsessions with symmetry or order, with accompanying ordering behaviors; obsessions of saving, with accompanying hoarding; somatic obsessions; aggressive obsessions with checking compulsions; and sexual and religious obsessions (Pittenger et al., 2006; Stein et al., 2016; van den Heuvel et al., 2016; Grant and Chamberlain, 2019; Robbins et al., 2019; Fineberg and Robbins, 2021).

In this section a theory is described of how obsessive-compulsive disorders arise, and of the different symptoms. The theory (Rolls, Loh and Deco, 2008c; Rolls, 2012c) is based on the proposal that there is overstability of attractor neuronal networks in some cortical and related areas in obsessive-compulsive disorders.

18.4.2 A hypothesis about the increased stability of attractor networks and the symptoms of obsessive-compulsive disorder

We hypothesized (Rolls, Loh and Deco, 2008c) that cortical and related attractor networks become too stable in obsessive-compulsive disorder, so that once in an attractor state, the networks tend to remain there too long (Rolls, Loh and Deco, 2008c; Rolls, 2012c). The hypothesis is that the depths of the basins of attraction become deeper, and that this is what makes the attractor networks more stable. We further hypothesize that part of the mechanism for the increased depth of the basins of attraction is increased glutamatergic transmission, which increases the depth of the basins of attraction by increasing the firing rates of the neurons, and by increasing the effective value of the synaptic weights between the associatively modified synapses that define the attractor, as is made evident in Equation B.12. The synaptic strength is effectively increased if more glutamate is released per action potential at the synapse, or if in other ways the currents injected into the neurons through the NMDA (N-methyl-d-aspartate) and/or AMPA synapses are larger. In addition, if NMDA receptor function is increased, this could also increase the stability of the system because of the temporal smoothing effect of the long time constant of the NMDA receptors (Wang, 1999). This increased stability of cortical and related attractor networks, and the associated higher neuronal firing rates, could occur in different brain regions, and thereby produce different symptoms, as follows. If these effects occurred in high order motor areas, the symptoms could include inability to move out of one motor pattern, resulting for example in repeated movements or actions. In parts of the cingulate cortex and dorsal medial prefrontal cortex, this could result in difficulty in switching between actions or strategies (Rushworth et al., 2007a,b), as the system would be locked into one action or strategy. If an action was locked into a high order motor area due to increased stability of an attractor network, then lower order motor areas might thereby not be able to escape easily what they implement, such as a sequence of movements, so that the sequence would be repeated.

A similar account, of becoming locked in one action and having difficulty in switching to another action, can be provided for response inhibition deficits, which have been found in OCD. The response inhibition deficit has been found in tasks such as go/no-go and stop-signal reaction time (SSRT) which examine motor inhibitory processes, and also the Stroop task, a putative test of cognitive inhibition (Hartston and Swerdlow, 1999; Bannon et al., 2002; Penades et al., 2005; Bannon et al., 2006; Chamberlain et al., 2006, 2007; Penades et al., 2007; Robbins et al., 2019). For example, response inhibition deficits have been reported in OCD patients when performing the SSRT, which measures the time taken to internally suppress pre-potent motor responses (Chamberlain et al., 2006). Unaffected first-degree relatives of OCD patients are also impaired on this task compared with unrelated healthy controls, suggesting that response inhibition may be an endophenotype (or intermediate phenotype) for OCD (Chamberlain et al., 2007; Menzies et al., 2008).

If occurring in the lateral prefrontal cortex (including the dorsolateral and ventrolateral parts), the increased stability of attractor networks could produce symptoms that include a difficulty in shifting attention and in cognitive set shifting. These are in fact important symptoms that can be found in obsessive-compulsive disorder (Menzies, Chamberlain, Laird, Thelen, Sahakian and Bullmore, 2008; Chamberlain, Solly, Hook, Vaghi and Robbins, 2021). Two different forms of shifting have been investigated: affective set shifting, where the affective or reward value of a stimulus changes over time (e.g. a rewarded stimulus is no longer rewarded) (intradimensional or ID set shifting); and attentional set shifting, where the stimulus dimension (e.g. shapes or colors) to which the subject must attend is changed (extradimensional or ED set shifting). Deficits of attentional set shifting in OCD have been found in several neurocognitive studies using the CANTAB ID/ED set shifting task (Veale, Sahakian,

Owen and Marks, 1996; Watkins, Sahakian, Robertson, Veale, Rogers, Pickard, Aitken and Robbins, 2005; Chamberlain, Fineberg, Blackwell, Robbins and Sahakian, 2006; Chamberlain, Fineberg, Menzies, Blackwell, Bullmore, Robbins and Sahakian, 2007; Robbins, Vaghi and Banca, 2019; Chamberlain, Solly, Hook, Vaghi and Robbins, 2021). This deficit is most consistently reported at the ED stage (in which the stimulus dimension, e.g. shape, color or number, alters and subjects have to inhibit their attention to this dimension and attend to a new, previously irrelevant dimension). The ED stage is analogous to the stage in the Wisconsin Card Sorting Task where a previously correct rule for card sorting is changed and the subject has to respond to the new rule (Berg, 1948; Chamberlain et al., 2021). This ED shift impairment in OCD patients is considered to reflect a lack of cognitive or attentional flexibility and may be related to the repetitive nature of OCD symptoms and behaviors (Chamberlain et al., 2021). Deficits in attentional set shifting are considered to be more dependent upon dorsolateral and ventrolateral prefrontal regions than the orbital prefrontal regions included in the orbitofronto-striatal model of OCD (Pantelis et al., 1999; Rogers et al., 2000; Nagahama et al., 2001; Hampshire and Owen, 2006; Robbins et al., 2019; Chamberlain et al., 2021), suggesting that cognitive deficits in OCD may not be underpinned exclusively by orbitofrontal cortex pathology. Indeed, intradimensional or affective set shifting may not be consistently impaired in OCD (Menzies et al., 2008; Chamberlain et al., 2021).

Planning may also be impaired in patients with OCD (Menzies et al., 2008), and this could arise because there is too much stability of attractor networks in the dorsolateral prefrontal cortex concerned with holding in mind the different short-term memory representations that encode the different steps of a plan (Rolls, 2016b). Indeed, there is evidence for dorsolateral prefrontal cortex (DLPFC) dysfunction in patients with OCD, in conjunction with impairment on a version of the Tower of London, a task often used to probe planning aspects of executive function (van den Heuvel et al., 2005). Impairment on the Tower of London task has also been demonstrated in healthy first-degree relatives of OCD patients (Delorme et al., 2007).

An increased firing rate of neurons in the orbitofrontal cortex, and anterior cingulate cortex, produced by hyperactivity of glutamatergic transmitter systems, would increase emotionality, which is frequently found in obsessive-compulsive disorder. Part of the increased anxiety found in obsessive-compulsive disorder could be related to an inability to complete tasks or actions in which one is locked. But part of our unifying proposal is that part of the increased emotionality in OCD may be directly related to increased firing produced by the increased glutamatergic activity in brain areas such as the orbitofrontal and anterior cingulate cortex. The orbitofrontal cortex and anterior cingulate cortex are involved in emotion, in that they are activated by primary and secondary reinforcers that produce affective states (Rolls, 2004a, 2014a, 2016b; Rolls and Grabenhorst, 2008; Rolls, 2019e, 2023b), and in that damage to these regions alters emotional behavior and emotional experience (Rolls, Hornak, Wade and McGrath, 1994a; Hornak, Rolls and Wade, 1996; Hornak, Bramham, Rolls, Morris, O'Doherty, Bullock and Polkey, 2003; Hornak, O'Doherty, Bramham, Rolls, Morris, Bullock and Polkey, 2004; Berlin, Rolls and Kischka, 2004; Berlin, Rolls and Iversen, 2005; Rolls, 2019e, 2021h) (Chapter 11). Indeed, negative emotions as well as positive emotions activate the orbitofrontal cortex, with the emotional states produced by negative events tending to be represented in the lateral orbitofrontal cortex and dorsal part of the anterior cingulate cortex (Kringelbach and Rolls, 2004; Rolls, 2014a, 2016b, 2009a; Grabenhorst and Rolls, 2011; Rolls, 2019e; Rolls et al., 2020a; Zhang et al., 2023a; Rolls et al., 2023b). We may note that stimulus-reinforcer reversal tasks (also known as intra-dimensional shifts or affective reversal) are not generally impaired in patients with OCD (Menzies et al., 2008), and this is as predicted, for the machinery for the reversal including the detection of non-reward (Rolls, 2014a, 2019e) (Chapter 11) is present even if the system is hyperglutamatergic.

If the increased stability of attractor networks occurred in temporal lobe semantic memory

networks, then this would result in a difficulty in moving from one thought to another, and possibly in stereotyped thoughts, which again may be a symptom of obsessive-compulsive disorder (Menzies et al., 2008; Robbins et al., 2019; Fineberg and Robbins, 2021). The obsessional states are thus proposed to arise because cortical areas concerned with cognitive functions have states that become too stable. The compulsive states are proposed to arise partly in response to the obsessional states, but also partly because cortical areas concerned with actions have states that become too stable. The theory provides a unifying computational account of both the obsessional and compulsive symptoms, in that both arise due to increased stability of cortical attractor networks, with the different symptoms related to overstability in different cortical areas. The theory is also unifying in that a similar increase in glutamatergic activity in the orbitofrontal and anterior cingulate cortex could increase emotionality, as described earlier.

18.4.3 Glutamate and increased depth of the basins of attraction of attractor networks

To demonstrate how alterations of glutamate as a transmitter for the connections between the neurons may influence the stability of attractor networks, Rolls, Loh and Deco (2008c) performed integrate-and-fire simulations of the stability of a short-term memory attractor network of the type described in Section 13.6.1 and Section 18.3. A feature of these simulations is that we simulated the currents produced by activation of NMDA and AMPA receptors in the recurrent collateral synapses, and took into account the effects of the spiking-related noise, which is an important factor in determining whether the attractor stays in a basin of attraction, or jumps over an energy barrier into another basin (Loh, Rolls and Deco, 2007a; Rolls, Loh, Deco and Winterer, 2008d; Deco, Rolls and Romo, 2009).

We found that increasing the NMDA receptor-activated synaptic currents by 3% or the AMPA by 10% increased the stability of the high firing rate short-term memory state of the network. Thinking about possible treatments, we showed that increasing the inhibition in the network by increasing the GABA receptor-mediated currents by 10% could ameliorate the overstability produced by increased glutamate-related effects. We also showed that the increased NMDA-receptor mediated effects produced less distractibility of the short-term memory state by another stimulus, which is a further sign of overstability.

This provides a new approach to the symptoms of obsessive-compulsive disorder, for it deals with the symptoms in terms of overstability of attractor networks in the cerebral cortex (Rolls, Loh and Deco, 2008c; Rolls, 2012c). Consistent with this approach, hyperactivity of the lateral orbitofrontal cortex is found during symptom provocation, and this normalized over the course of behavioral therapy for OCD (Robbins et al., 2019). If the same generic change in activity and therefore in stability were produced in different cortical areas, then we have indicated how different symptoms might arise. Of course, if these changes were more evident in some areas than in others in different patients, this would help to account for the different symptoms in different patients. Having proposed a generic hypothesis for the disorder, we recognize of course that the exact symptoms that arise if stability in some systems is increased will be subject to the exact effects that these will have in an individual patient, who may react to these effects, and produce explanatory accounts for the effects, and ways to deal with them, that may be quite different from individual to individual.

This simulation evidence, that an increase of glutamatergic synaptic efficacy can increase the stability of attractor networks and thus potentially provide an account for some of the symptoms of obsessive-compulsive disorder, is consistent with evidence that glutamatergic function may be increased in some brain systems in obsessive-compulsive disorder (Rosenberg et al., 2000, 2001, 2004; Pittenger et al., 2006; Rolls, 2012c; Pittenger et al., 2011; Pit-

tenger, 2015; Karthik et al., 2020) and that cerebro-spinal-fluid glutamate levels are elevated (Chakrabarty et al., 2005), though the evidence is still tentative (Pittenger, 2021). Consistent with this, agents with antiglutamatergic activity such as memantine and riluzole, which can decrease glutamate transmitter release, may be efficacious in obsessive-compulsive disorder (Pittenger et al., 2006; Bhattacharyya and Chakraborty, 2007; Pittenger et al., 2011; Pittenger, 2015, 2021).

Further evidence for a link between glutamate as a neurotransmitter and OCD comes from genetic studies. There is evidence for a significant association between the SLC glutamate transporter genes and OCD (Stewart et al., 2007; Pauls et al., 2014). These transporters are crucial in terminating the action of glutamate as an excitatory neurotransmitter and in maintaining extracellular glutamate concentrations within a normal range (Bhattacharyya and Chakraborty, 2007; Pauls et al., 2014). In addition, it has been postulated that N-methyl-d-aspartate (NMDA) receptors are involved in OCD, and specifically that polymorphisms in the 3' untranslated region of GRIN2B (glutamate receptor, ionotropic, N-methyl-d-aspartate 2B) were associated with OCD in affected families (Arnold et al., 2004; Pittenger et al., 2011), and more recent evidence has also found some association to glutamate-related genes (Pauls et al., 2014). However, genetic studies of OCD have not yet produced robust conclusions (Fernandez, Leckman and Pittenger, 2018; Pittenger, 2021).

18.5 Depression and attractor dynamics

18.5.1 Introduction

Major depressive disorder is ranked by the World Health Organization as the leading cause of years-of-life lived with disability, with more than 300 million people having major depressive disorder (Drevets, 2007; Gotlib and Hammen, 2009; Hamilton et al., 2013; WHO, 2017). Major depressive episodes, found in both major depressive disorder and bipolar disorder are pathological mood states characterized by persistently sad or depressed mood. Major depressive disorders are generally accompanied by: (1) altered incentive and reward processing, evidenced by amotivation, apathy, and anhedonia; (2) impaired modulation of anxiety and worry, manifested by generalized, social and panic anxiety, and oversensitivity to negative feedback; (3) inflexibility of thought and behavior in association with changing reinforcement contingencies, apparent as ruminative thoughts of self-reproach, pessimism, and guilt, and inertia toward initiating goal-directed behavior; (4) altered integration of sensory and social information, as evidenced by mood-congruent processing biases; (5) impaired attention and memory, shown as performance deficits on tests of attention set-shifting and maintenance, and autobiographical and short-term memory; and 6) visceral disturbances, including altered weight, appetite, sleep, and endocrine and autonomic function (Drevets, 2007; Gotlib and Hammen, 2009; Rolls, 2018a; Thapar et al., 2022). This section describes an attractor-based theory of some of the brain mechanisms that are related to depression (Rolls, 2016e), and tests of the theory (Rolls, Cheng and Feng, 2020a; Zhang, Rolls, Wang, Xie, Cheng and Feng, 2023a).

The attractor theory of depression starts with the evidence that the orbitofrontal cortex contains a population of error neurons that respond to non-reward and maintain their firing for many seconds after the non-reward, providing evidence that they have entered an attractor state that maintains a memory of the non-reward (Thorpe, Rolls and Maddison, 1983; Rosenkilde, Bauer and Fuster, 1981; Rolls, 2014a, 2018a, 2019e) (Section 11.3.4). An example of such a neuron is shown in Fig. 11.14. The human lateral orbitofrontal cortex is activated by non-reward during reward reversal (Kringelbach and Rolls, 2003) (Fig. 11.16), by losing

money (O'Doherty et al., 2001a) or not winning (Xie et al., 2021) (Fig. 11.9), and by many other aversive stimuli (Grabenhorst and Rolls, 2011) (Fig. 11.18). Further evidence that the orbitofrontal cortex is involved in changing rewarded behavior when non-reward is detected is that damage to the human orbitofrontal cortex impairs reward reversal learning, in that the previously rewarded stimulus is still chosen during reversal even when no reward is being obtained (Rolls, Hornak, Wade and McGrath, 1994a; Hornak, O'Doherty, Bramham, Rolls, Morris, Bullock and Polkey, 2004; Fellows and Farah, 2003; Fellows, 2011). Further, the right lateral orbitofrontal cortex is strongly activated by non-reward in a one-trial rule-based reward reversal task (Rolls, Vatansever, Li, Cheng and Feng, 2020e), which is the same brain region with increased functional connectivity in depression as described below.

Now it is well established that not receiving expected reward, or receiving unpleasant stimuli or events, can produce feelings of depression (Beck, 2008; Drevets, 2007; Harmer and Cowen, 2013; Price and Drevets, 2012; Pryce et al., 2011; Eshel and Roiser, 2010; Rolls, 2018a). A clear example is that if a member of the family dies, then this is the removal of reward (in that we would work to try to avoid this), and the result of the removal of the reward can be depression. More formally, in terms of learning theory, the omission or termination of a reward can give rise to sadness or depression, depending on the magnitude of the reward that is lost, if there is no action that can be taken to restore the reward (Rolls, 2005a, 2013d, 2014a, 2018a) (Fig. 11.20). If an action can be taken, then frustration and anger may arise to the same reinforcement contingency (Rolls, 2014a, 2018a, 2019e,f, 2023b) (Section 11.3.8). This relates the current approach to the learned helplessness approach to depression, in which depression arises because no actions are being taken to restore rewards (Forgeard et al., 2011; Pryce et al., 2011; Maier and Seligman, 2016).

18.5.2 A non-reward attractor theory of depression

The theory has been proposed that in depression, the lateral orbitofrontal cortex non-reward / punishment attractor network system is more easily triggered, and maintains its attractor-related firing for longer (Rolls, 2016e, 2017c, 2019f, 2018a). The greater attractor-related firing of the non-reward / punishment system triggers negative cognitive states held on-line in other cortical systems such as the language system and in the dorsolateral prefrontal cortex which is implicated in attentional control. These other cortical systems then in turn have top-down effects on the orbitofrontal non-reward system that bias it in a negative direction (Rolls, 2013a) (see Section 4.3.5 and Fig. 4.16), and thus increase the sensitivity of the lateral orbitofrontal cortex to non-reward and maintain its overactivity (Rolls, 2016e) (Fig. 18.12). It is proposed that the interaction of non-reward and language / attentional brain systems of these types accounts for the ruminating and continuing depressive thoughts, which occur as a result of a positive feedback cycle between these types of brain system (Rolls, 2016e).

Indeed, we have shown that cognitive states can have 'top-down' effects on affective representations in the orbitofrontal cortex (De Araujo, Rolls, Velazco, Margot and Cayeux, 2005; Grabenhorst, Rolls and Bilderbeck, 2008a; McCabe, Rolls, Bilderbeck and McGlone, 2008; Rolls, 2013a). Further, top-down selective attention can also influence affective representations in the orbitofrontal cortex (Rolls et al., 2008b; Grabenhorst and Rolls, 2008; Ge et al., 2012; Luo et al., 2013; Rolls, 2013a), and paying attention to depressive symptoms when depressed may in this way exacerbate the problems in a positive feedback way.

More generally, the presence of the cognitive ability that is afforded by language to think ahead and see the implications of recent events may be a computational development in the brain that exacerbates the vulnerability of the human brain to depression (Rolls, 2014a, 2018a). For example, with language we can think ahead and see that perhaps the loss of an

Interaction of non-reward and language networks in depression

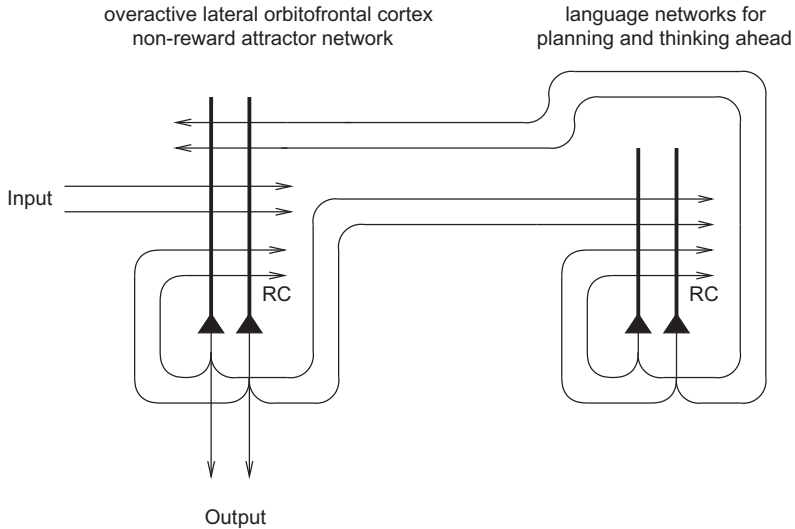

Fig. 18.12 Interaction of orbitofrontal cortex non-reward networks with language networks in depression. Illustration of how an overactive non-reward attractor network in the lateral orbitofrontal cortex could send excitatory information forward to networks for language and planning ahead; which could in turn send excitatory ‘top-down’ feedback back down to the orbitofrontal non-reward network to maintain its over-activity. It is suggested that such a system with mutual ‘long loop’ re-excitation contributes to the persistent ruminating thoughts in depression. (After Rolls, E. T. (2016) A non-reward attractor theory of depression. *Neuroscience and Biobehavioral Reviews* 68: 47–58. © Elsevier.)

individual in one’s life may be long-term, and this thought and its consequences for our future can become fully evident.

The theory is that one way in which depression could result from over-activity in this lateral orbitofrontal cortex system is if there is a major negatively reinforcing life event that produces reactive depression and activates this system, which then becomes self-re-exciting based on the cycle between the lateral orbitofrontal cortex non-reward / punishment attractor system and the cognitive / language system, which together operate as a systems-level attractor (Fig. 18.12). (The generic cortical architecture for such reciprocal feedforward and feedback excitatory effects is illustrated by Rolls (2016b).)

The theory is that a second way in which depression might arise is if this lateral orbitofrontal cortex non-reward / punishment system is especially sensitive in some individuals. This might be related for example to genetic predisposition, or to the effects of stress (Gold, 2015). In this case, the orbitofrontal system would over-react to normal levels of non-reward or punishment, and start the local attractor circuit in the lateral orbitofrontal cortex (Section 11.3.4) (Rolls, 2016e; Rolls and Deco, 2016), which in turn would activate the cognitive system, which would feed back to the over-reactive lateral orbitofrontal cortex system to maintain now a systems-level attractor with ruminating thoughts. This is described as a ‘systems-level’ attractor because it includes mutual excitations between different brain areas.

Given that the activations of the lateral and medial orbitofrontal cortex often appear to be reciprocally oppositely related (O’Doherty, Kringelbach, Rolls, Hornak and Andrews, 2001a; Rolls, Kringelbach and De Araujo, 2003c; Xie, Jia, Rolls, Robbins, Sahakian, Zhang, Liu, Cheng, Luo, Zac Lo, Wang, Banaschewski, Barker, Bodke, Buchel, Quinlan, Desrivieres, Flor, Grigis, Garavan, Gowland, Heinz, Hohmann, Ittermann, Martinot, Martinot, Nees, Papadopoulos Orfanos, Paus, Poustka, Frohner, Smolka, Walter, Whelan, Schumann, Feng and IMAGEN, 2021; Zhang, Rolls, Wang, Xie, Cheng and Feng, 2023a), the other part of the theory of depression is that in depression there may be underactivity, under-sensitivity, or

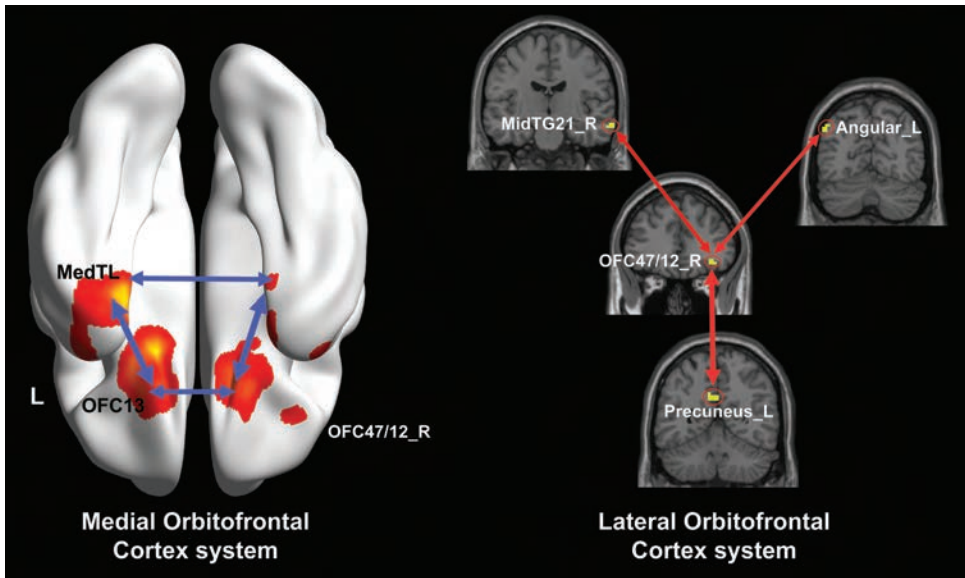

Fig. 18.13 Resting state functional connectivity in depression. The medial orbitofrontal cortex has reduced functional connectivity (blue) in depression with medial temporal lobe memory systems. The lateral orbitofrontal cortex has increased functional connectivity (red) in depression with the angular gyrus, precuneus, and middle temporal gyrus. MedTL – medial temporal lobe from the parahippocampal gyrus to the temporal pole; MidTG21R – middle temporal gyrus area 21 right; OFC13 – medial orbitofrontal cortex area 13; OFC12/47R – lateral orbitofrontal cortex area 12/47 right. The lateral orbitofrontal cortex cluster in OFC12/47 is visible on the ventral view of the brain anterior and lateral to the OFC13 clusters. (After Cheng,W., Rolls,E.T., Qiu,J., Liu,W., Tang,Y., Huang,C-C., Wang,XF., Zhang,J., Lin,W., Zheng,L., Pu,J.C., Tsai,S-J., Yang,AC., Lin,C-P., Wang,F., Xie,P. and Feng,J. (2016) Medial reward and lateral non-reward orbitofrontal cortex circuits change in opposite directions in depression. *Brain* 139: 3296–3309. © Oxford University Press.)

under-connectivity of the (reward-related) medial orbitofrontal cortex in depression (Rolls, 2016e, 2018a; Uran et al., 2022). The theory is further that under-responsiveness of the medial orbitofrontal cortex could contribute to other aspects of depression, such as anhedonia.

18.5.3 The orbitofrontal cortex, and the theory of depression

There is some evidence for altered structure and function of the lateral orbitofrontal cortex in depression (Drevets, 2007; Ma, 2015; Price and Drevets, 2012; Zhang, Rolls, Wang, Xie, Cheng and Feng, 2023a). For example, reductions of grey-matter volume and cortex thickness have been demonstrated in the posterolateral OFC (BA 12/47, caudal BA 11 and the adjoining BA 45), and also in the subgenual cingulate cortex (BA 24, 25) (Drevets, 2007; Nugent et al., 2006; Schmaal et al., 2017), and in the medial orbitofrontal cortex (Schmaal et al., 2017). In depression, there is increased cerebral blood flow in areas that include the ventrolateral orbitofrontal cortex (which is a prediction of the theory), and also in regions such as the subgenual cingulate cortex and amygdala, and these increases appear to be related to the mood change, in that they become more normal when the mood state remits (Drevets, 2007; Lally, Nugent, Luckenbaugh, Niciu, Roiser and Zarate, 2015; Zhang, Rolls, Wang, Xie, Cheng and Feng, 2023a).

In the first brain-wide voxel-level resting state functional connectivity neuroimaging analysis of depression (with 421 patients with major depressive disorder and 488 controls), we have found that one major circuit with altered functional connectivity involved the medial orbitofrontal cortex BA 13, which had reduced functional connectivity in depression with memory systems in the parahippocampal gyrus and medial temporal lobe (Cheng, Rolls, Qiu, Liu, Tang, Huang, Wang, Zhang, Lin, Zheng, Pu, Tsai, Yang, Lin, Wang, Xie and Feng,

2016a) (Fig. 18.13). The lateral orbitofrontal cortex BA 12/47, involved in non-reward and punishing events, did not have this reduced functional connectivity with memory systems, so that there is an imbalance in depression towards decreased reward-related memory system functionality.

A second major circuit change was that the lateral orbitofrontal cortex area BA 12/47 had increased functional connectivity with the precuneus, the angular gyrus, and the temporal visual cortex BA 21 (Cheng et al., 2016a) (Fig. 18.13). This enhanced functional connectivity of the non-reward/punishment system (BA 12/47) with the precuneus (involved in the sense of self and agency), and the angular gyrus (involved in language) is thus related to the explicit affectively negative sense of the self, and of self-esteem, in depression.

The differences in orbitofrontal connectivity with these brain regions were related to the depression by evidence that the symptoms of depression were correlated with these differences of functional connectivity; and that the lateral orbitofrontal cortex functional connectivity links described were less high if the patients were receiving antidepressant medication (Cheng et al., 2016a).

The reduced functional connectivity of the medial orbitofrontal cortex, implicated in reward, with memory systems provides a new way of understanding how memory systems may be biased away from pleasant events in depression. The increased functional connectivity of the lateral orbitofrontal cortex, implicated in non-reward and punishment, with areas of the brain implicated in representing the self, language, and inputs from face and related perceptual systems provides a new way of understanding how unpleasant events and thoughts, and lowered self-esteem, may be exacerbated in depression (Cheng et al., 2016a; Rolls et al., 2018a).

These differences of functional connectivity are related to the orbitofrontal cortex attractor theory of depression, because increased functional connectivity of the non-reward lateral orbitofrontal cortex would increase the stability and persistence of its negative attractor mood-related states; and decreased functional connectivity of the reward-related medial orbitofrontal cortex would decrease the stability and persistence of its positive mood states (Rolls, 2018a).

These advances have stimulated many other large-scale voxel-level investigations of functional connectivity in depression, described in Section 18.5.4. A recent large-scale activation investigation of the role of the orbitofrontal cortex in depressive symptoms is described in Section 18.5.5. Implications for treatments are considered in Section 18.5.6.

18.5.4 Altered connectivity of the orbitofrontal cortex in depression

Further investigations have provided more evidence for different functional connectivity of the orbitofrontal cortex in depression, as described next, with a summary of some of the differences shown in Fig. 18.14 (Rolls, Cheng and Feng, 2020a). **These differences of functional connectivity all relate to altered stability of the circuits involved, which help to account for some of the symptoms of depression.**

18.5.4.1 Precuneus: higher connectivity with the lateral orbitofrontal cortex

The precuneus is a medial parietal cortex region implicated in the sense of self and agency, autobiographical memory, spatial function, and navigation (Cavanna and Trimble, 2006; Fretton et al., 2014). The retrosplenial cortex provides connections to and receives connections from the hippocampal system, connecting especially with the parahippocampal gyrus areas TF and TH, and with the subiculum (Bubb et al., 2017; Kobayashi and Amaral, 2007; Rolls et al., 2023i) (Fig. 9.1). The precuneus can be conceptualized as providing access to the hippo-

Fig. 18.14 Functional connectivity (FC) differences of the medial and lateral orbitofrontal cortex in major depressive disorder. Higher functional connectivity in depression is shown in red, and includes higher functional connectivity of the non-reward / punishment-related lateral orbitofrontal cortex with the precuneus, posterior cingulate cortex (PCC), subgenual anterior cingulate cortex (ACC subgenual), angular gyrus, and inferior frontal gyrus. Lower functional connectivity in depression is shown in blue, and includes lower functional connectivity of the medial orbitofrontal cortex with the parahippocampal gyrus memory system (PHG), amygdala, and temporal cortex. The part of the medial orbitofrontal cortex shown are as defined in the automated anatomical labelling atlas 2 (Rolls, Joliot and Tzourio-Mazoyer, 2015), although the investigations that form the basis for the summary were at the voxel level. (After Rolls, E. T., Cheng, W. and Feng, J. (2020) The orbitofrontal cortex: reward, emotion, and depression. *Brain Communications* 2: fcaa196.)

campus for spatial and related information from the parietal cortex (given the rich connections between the precuneus and parietal cortex) (Rolls, 2018a; Rolls et al., 2023i).

To further analyze the functioning of the precuneus in depression, resting state functional connectivity was measured in 282 patients with major depressive disorder and 254 controls (Cheng, Rolls, Qiu, Yang, Ruan, Wei, Zhao, Meng, Xie and Feng, 2018c). In 125 patients not receiving medication, voxels in the precuneus had significantly higher functional connectivity with the lateral orbitofrontal cortex (Fig. 18.14). In patients receiving medication, the functional connectivity between the lateral orbitofrontal cortex and precuneus was decreased back towards that in the controls (Cheng et al., 2018c).

These findings support the theory that the non-reward system in the lateral orbitofrontal cortex has increased effects on areas in which the self is represented including the precuneus, which could relate to the low self-esteem in depressed patients (Rolls, 2016e, 2018a; Rolls et al., 2020a).

18.5.4.2 Parahippocampal gyrus / medial temporal lobe memory system, and temporal lobe visual cortex: lower connectivity with the medial orbitofrontal cortex

We found that voxels in the medial orbitofrontal cortex had lower functional connectivity with the parahippocampal gyrus / medial temporal lobe memory system (Cheng et al., 2016a) (Fig. 18.13), and interpreted this as resulting in fewer happy memories being recalled, as the medial orbitofrontal cortex has activations that correlate with subjective pleasantness, as described above, and the parahippocampal gyrus is a pathway in the hippocampal episodic memory system (Kesner and Rolls, 2015; Rolls, 2016b, 2018b; Rolls and Wirth, 2018; Rolls et al., 2023e, 2022a; Rolls, 2023c). The reduced connectivity with temporal cortex areas in which objects and faces are represented was interpreted as contributing to the reduced positive valuation of signals involved in emotion such as the sight of face expressions, and of people (Hasselmo et al., 1989a; Critchley et al., 2000).

In a further analysis, which also investigated the effects of antidepressant medication (Rolls, Cheng, Du, Wei, Qiu, Dai, Zhou, Xie and Feng, 2020b), medial orbitofrontal cortex voxels had lower functional connectivity with temporal cortex areas, the parahippocampal gyrus, fusiform gyrus, and supplementary motor area, and medication did not result in these functional connectivities being closer to controls. This is consistent with the anhedonia of depression and reduced happy memories being related to these low functional connectivities of the medial orbitofrontal cortex with temporal lobe and memory systems. What is especially interesting is that these low functional connectivities are not normalized by treatment with antidepressant drugs (Rolls et al., 2020b), suggesting that one goal of future treatment for depression might be to increase the functionality of the medial orbitofrontal cortex (Rolls et al., 2020a).

18.5.4.3 Posterior cingulate cortex: higher functional connectivity with the lateral orbitofrontal cortex in depression

The posterior cingulate cortex is a region with strong connectivity in primates with the entorhinal cortex and parahippocampal gyrus (areas TF and TH), and thus with the hippocampal memory system (Vogt, 2009; Bubb et al., 2017; Rolls and Wirth, 2018; Rolls, 2019c) (Fig. 9.1). The posterior cingulate cortex also has connections with the orbitofrontal cortex (Vogt and Pandya, 1987; Vogt, 2009; Hsu et al., 2020), and the posterior cingulate cortex has high functional connectivity with the parahippocampal regions that are involved in memory (Cheng et al., 2018b; Rolls, 2019c). The posterior cingulate region (including the retrosplenial cortex) is consistently engaged by a range of tasks that examine episodic memory including autobiographical memory, and imagining the future; and also spatial navigation and scene processing (Leech and Sharp, 2014; Auger and Maguire, 2013). Self-reflection and self-imagery activate the ventral part of the posterior cingulate cortex (vPCC, the part with which we will be mainly concerned here) (Kircher et al., 2002, 2000; Johnson et al., 2002; Sugiura et al., 2005; Rolls, 2019c; Rolls et al., 2023i).

To analyze the functioning of the posterior cingulate cortex in depression, we performed a fully voxel-level resting-state functional connectivity neuroimaging analysis of depression of the posterior cingulate cortex, with 336 patients with major depressive disorder and 350 controls (Cheng, Rolls, Qiu, Xie, Wei, Huang, Yang, Tsai, Li, Meng, Lin, Xie and Feng, 2018b). In depression, the posterior cingulate cortex had significantly higher functional connectivity with the lateral orbitofrontal cortex (Fig. 18.14). In patients receiving medication, the functional connectivity between the lateral orbitofrontal cortex and the posterior cingulate cortex was decreased back towards that in the controls.

These findings are consistent with the hypothesis that the non-reward system in the lateral orbitofrontal cortex has increased effects on memory systems, which contribute to the rumination about sad memories and events in depression (Cheng et al., 2018b).

18.5.4.4 Anterior cingulate cortex: higher connectivity with the orbitofrontal cortex in depression

The orbitofrontal cortex projects to the anterior cingulate cortex (Vogt, 2009; Bubb et al., 2017; Rolls, 2019c; Vogt, 2019b; Rolls et al., 2023c; Zhang et al., 2023a). As shown in Chapter 12, the supracallosal anterior cingulate cortex is activated by many aversive stimuli, and has strong connectivity with the lateral orbitofrontal cortex (Rolls, Cheng, Gong, Qiu, Zhou, Zhang, Lv, Ruan, Wei, Cheng, Meng, Xie and Feng, 2019; Hsu, Rolls, Huang, Chong, Lo, Feng and Lin, 2020; Du, Rolls, Cheng, Li, Gong, Qiu and Feng, 2020). The pregenual anterior cingulate cortex is activated by many pleasant, rewarding, stimuli, and has strong functional connectivity with the medial orbitofrontal cortex (Rolls et al., 2019; Hsu et al., 2020; Du et al., 2020; Rolls et al., 2023c). However, the dorsal or supracallosal anterior cingulate cortex appears to be involved in learning actions to obtain rewards (action-outcome learning), where the outcome refers to the reward or punisher for which an action is being learned (Rolls, 2019c). In contrast, the medial orbitofrontal cortex is implicated in reward-related processing and learning, and the lateral orbitofrontal cortex in non-reward and punishment-related processing and learning. These involve stimulus-stimulus associations, where the second stimulus is a reward (or its omission), or a punisher (Rolls, 2019f,e). Now given that emotions can be considered as states elicited by rewarding and punishing stimuli, and that moods such as depression can arise from prolonged non-reward or punishment (see above and Chapter 11), the part of the brain that processes these stimulus-reward associations, the orbitofrontal cortex, is more likely to be involved in depression than the action-related parts of the cingulate cortex, although the anterior cingulate cortex and other regions related to action such as the right inferior frontal gyrus could contribute to depression as it is an output region for the orbitofrontal cortex (Rolls et al., 2023c,b).

However, the subgenual (or subcallosal) cingulate cortex has been implicated in depression, and electrical stimulation in that region may relieve depression (Lujan et al., 2013; Laxton et al., 2013; Lozano et al., 2012; Hamani et al., 2011, 2009; Mayberg, 2003) (although it has not been possible to confirm this in a double-blind study (Holtzheimer et al., 2017)). The subgenual cingulate cortex is also implicated in autonomic function (Gabbott et al., 2003), and this could be related to some of the effects found in this area that are related to depression. Whether the subgenual cingulate cortex is activated because of inputs from the orbitofrontal cortex, or performs separate computations is not yet clear. Further, the possibility is considered that electrical stimulation of the subcallosal region, which includes parts of the ventromedial prefrontal cortex (Laxton et al., 2013), that may relieve depression, may do so at least in part by activating connections involving the orbitofrontal cortex, other parts of the anterior cingulate cortex, and the striatum (Lujan et al., 2013; Hamani et al., 2009; Johansen-Berg et al., 2008; Elias et al., 2022a; Zhang et al., 2023a).

In a study of depression, overall the anterior cingulate cortex (ACC) had significantly higher functional connectivity with the orbitofrontal cortex, inferior frontal gyrus, superior parietal lobule, and with early cortical visual areas (Fig. 18.14) (Rolls, Cheng, Gong, Qiu, Zhou, Zhang, Lv, Ruan, Wei, Cheng, Meng, Xie and Feng, 2019). A pregenual ACC subdivision had high functional connectivity with medial orbitofrontal cortex areas, and a supracallosal ACC subdivision had high functional connectivity with the lateral orbitofrontal cortex and inferior frontal gyrus. The high FC in depression between the lateral orbitofrontal cortex and the subcallosal (subgenual) parts of the ACC may provide a mechanism for more non-reward information transmission to the ACC, contributing to depression. The high functional

connectivity between the medial orbitofrontal cortex and supracallosal ACC in depression may also contribute to depressive symptoms. These higher functional connectivities in unmedicated patients were ameliorated by treatment with antidepressants (Rolls et al., 2019).

18.5.4.5 Inferior frontal gyrus: increased connectivity with the lateral orbitofrontal cortex in depression

The lateral orbitofrontal cortex projects to the inferior frontal gyrus (Hsu et al., 2020; Rolls et al., 2023c,b), and very interestingly higher functional connectivity was found in depression of voxels in the right inferior frontal gyrus with voxels in the lateral and medial orbitofrontal cortex, cingulate cortex, inferior and middle temporal gyrus and temporal pole, the angular gyrus, precuneus, hippocampus and mid- and superior frontal gyrus connectivity with the orbitofrontal cortex, temporal lobe areas, the parahippocampal gyrus and hippocampus, and motor areas (Fig. 18.14) (Rolls, Cheng, Du, Wei, Qiu, Dai, Zhou, Xie and Feng, 2020b). In medicated patients these functional connectivities of the inferior frontal gyrus were lower and towards those in controls.

The hypothesis was proposed (Rolls et al., 2020b,a) that one way in which the orbitofrontal cortex influences behavior in depression is via the right inferior frontal gyrus, which projects in turn to premotor cortical areas (Du, Rolls, Cheng, Li, Gong, Qiu and Feng, 2020; Rolls, Deco, Huang and Feng, 2023f). Consistent with the consequent hypothesis that the inferior frontal gyrus route may allow non-reward signals to have too great an effect to inhibit behavior in depression, lesions of the right inferior frontal gyrus impair stopping in the stop-signal task, and produce impulsiveness (Aron, Robbins and Poldrack, 2014; Dalley and Robbins, 2017). Also consistent with the hypothesis, successful stopping in the stop-signal task is associated with high activation of the inferior frontal gyrus and lateral orbitofrontal cortex (Deng, Rolls et al (2017)).

18.5.4.6 Amygdala: reduced connectivity with the orbitofrontal cortex in depression

The amygdala is involved in emotion, though as shown in Chapter 11, it may be overshadowed in humans by the orbitofrontal cortex (LeDoux and Pine, 2016; Rolls, 2019e; Rolls et al., 2023b). In a large scale study of depression, amygdala voxels had decreased functional connectivity with the medial orbitofrontal cortex (involved in reward); the lateral orbitofrontal cortex (involved in non-reward and punishment); temporal lobe areas (involved in visual and auditory perception including face expression analysis (Perrett, Rolls and Caan, 1982; Rolls, 2011d, 2012d; Leonard, Rolls, Wilson and Baylis, 1985); and the parahippocampal gyrus (involved in memory) (Fig. 18.14) (Cheng, Rolls, Qiu, Xie, Lyu, Li, Huang, Yang, Tsai, Lyu, Zhuang, Lin, Xie and Feng, 2018a). This disconnectivity of the amygdala may contribute to particularly some of the changed behavioral and autonomic responses in depression, and perhaps not to the depressed subjective feelings (Rolls et al., 2023b).

18.5.4.7 Sleep, depression, and increased lateral orbitofrontal cortex connectivity

Sleep is frequently impaired in depression (Becker et al., 2017). To advance understanding of the brain regions involved in sleep and depression, the relation between functional connectivity, depressive symptoms (the Adult Self-Report Depressive Problems scores), and poor sleep quality was measured in 1017 participants from the general population in the Human Connectome Project (Cheng, Rolls, Ruan and Feng, 2018d). The brain areas with increased functional connectivity of these common links related to both sleep and depressive scores included the lateral orbitofrontal cortex; the dorsolateral prefrontal cortex; the anterior and posterior cingulate cortex; the insula; the parahippocampal gyrus and hippocampus; the

amygdala; the temporal cortex; and the precuneus. A mediation analysis showed that these functional connectivities in the brain contribute to the relation between depression and poor sleep quality.

Evidence was also found in this general population that the Depressive Problems scores were correlated with functional connectivities between areas that included the lateral orbitofrontal cortex, cingulate cortex, precuneus, angular gyrus, and temporal cortex (Cheng, Rolls, Ruan and Feng, 2018d). Part of the importance of this is that it provides strong support for a role of the lateral orbitofrontal cortex in depression in a general population in the U.S.A. in which a tendency to have depressive problems could be assessed. This cross-validation in a completely different population and in people not selected to have depression (Cheng et al., 2018d) provides support for the theory that the lateral orbitofrontal cortex is a key brain area that might be targeted in the search for treatments for depression (Rolls, 2016e). (Further validation is provided by a European cohort of 1,877 adolescents (Xie et al., 2021).) Low sleep duration and high depressive scores are also related to lower cortical area of the orbitofrontal cortex in a sample of 11,067 participants (Cheng, Rolls, Gong, Du, Zhang, Zhang, Li and Feng, 2021).

18.5.4.8 Effective connectivity in depression

Effective connectivity measures the effect of one brain region on another in a particular direction, and can in principle therefore provide information related to the causal processes that operate in brain function, that is, how one brain region influences another.

In a resting state fMRI investigation, effective connectivity directed to the medial orbitofrontal cortex from areas including the parahippocampal gyrus, temporal pole, inferior temporal gyrus, and amygdala was decreased in depression (Rolls, Cheng, Gilson, Qiu, Hu, Ruan, Li, Huang, Yang, Tsai, Zhang, Zhuang, Lin, Deco, Xie and Feng, 2018a). This implies less strong positive driving influences of these input regions on the medial and middle orbitofrontal cortex, regions implicated in reward, and thus helps to elucidate part of the decreased feelings of happy states in depression (Rolls, 2016e). The links from temporal cortical areas to the precuneus were increased in depression, and this may relate to representations of the sense of self (Cavanna and Trimble, 2006), which become more negative in depression (Rolls, 2016e; Cheng et al., 2016a). The lateral orbitofrontal cortex, implicated in non-reward and punishment, had an increased level of activity as reflected in the analysis in the depressed group. In addition, activity in the analysis was also higher in the right and left hippocampus of patients with depression, implying heightened memory-related processing (Rolls et al., 2018a).

18.5.5 Increased activations to non-reward of the lateral orbitofrontal cortex, and decreased sensitivity to reward of the medial orbitofrontal cortex, are related to depression scores

In 1140 adolescents at age 19 and 1877 at age 14 in the monetary incentive delay task, we found that the medial orbitofrontal cortex had graded increases in activation as the reward (Win) value increased (Xie, Jia, Rolls et al (2021)). The lateral orbitofrontal cortex had graded increases of activation as the reward value dropped to zero (the No-Win condition) (Fig. 11.9).

In a subgroup with a high score on the Adolescent Depression Rating Scale at age 19 and 14, the medial orbitofrontal cortex activations had reduced sensitivity to the different reward conditions; and the lateral orbitofrontal cortex activation showed high activation to the No-Win (i.e. Non-reward) condition (Xie et al., 2021) (Fig. 18.15). These new findings provide support for the hypothesis that those with symptoms of depression have increased sensitivity to non-reward in the lateral orbitofrontal cortex, and decreased sensitivity for differences

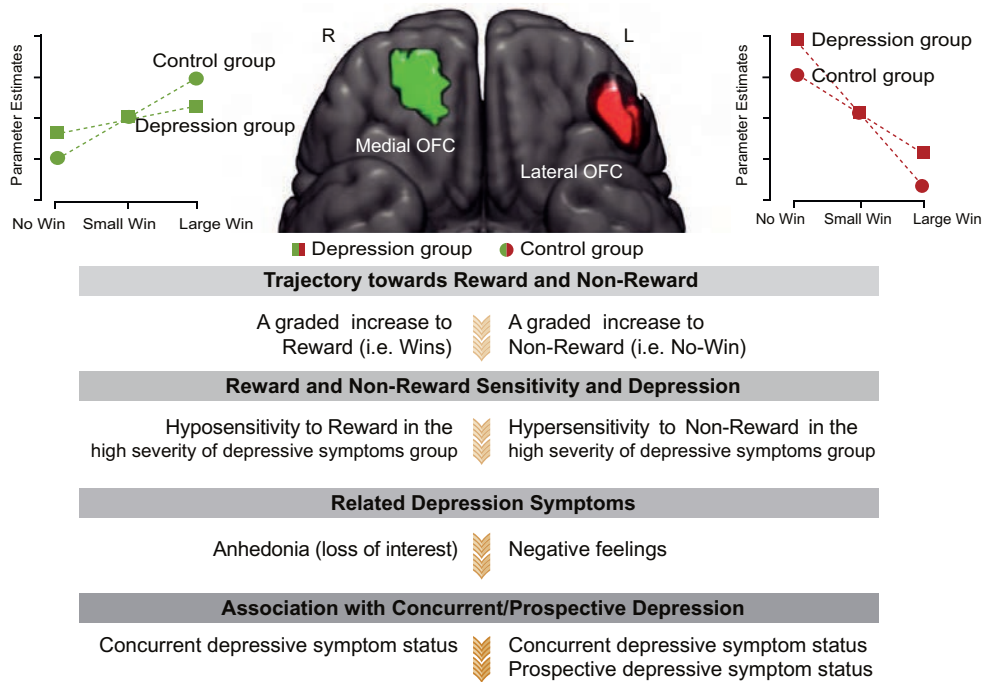

Fig. 18.15 Reduced sensitivity to reward of the medial orbitofrontal cortex, and increased sensitivity of the lateral orbitofrontal cortex to non-reward (No Win) in individuals with high scores on the Adolescent Depression Rating Scale (squares) compared to a control group (circles) in the Monetary Incentive Delay task. The summary is based on findings in 1140 adolescents at age 19 and 1877 at age 14. L, left; R, right. (After Xie, C., Jia, T., Rolls, E. T. et al (2021) Reward versus Nonreward sensitivity of the Medial versus Lateral Orbitofrontal Cortex relates to the severity of depressive symptoms. *Biological Psychiatry: Cognitive Neuroscience and Neuroimaging* 6: 259-269.)

in reward of the medial orbitofrontal cortex. Moreover, these differences are evident at an age as early as 14 years old (Xie et al., 2021). This increase in Non-reward sensitivity of the lateral orbitofrontal cortex in depression, and decreased Reward sensitivity of the medial orbitofrontal cortex, may act together with the altered functional connectivity of these regions just described, to make some individuals susceptible to depression (Rolls et al., 2020a; Zhang et al., 2023a).

It is hypothesized that as part of the process of evolution, variation of the sensitivity of individuals to specific types of Reward and Non-Reward may be present (Rolls, 2014a). Individuals with high sensitivity to Non-Reward may be susceptible to depression, and individuals with low sensitivity to Non-Reward may be impulsive because they are little affected by non-reward (Rolls, 2014a, 2018a). Individuals with high sensitivity to Reward may be sensation-seekers (Wan, Rolls, Cheng and Feng, 2020) and risk-takers (Rolls, Wan, Cheng and Feng, 2022c) (with increased functional connectivity of the medial orbitofrontal cortex with for example the anterior cingulate cortex, and for that reason also impulsive (Wan, Rolls, Cheng and Feng, 2020; Rolls, Wan, Cheng and Feng, 2022c)); and individuals with low sensitivity to Reward may have reduced goal-seeking behavior and reduced motivation (Rolls, 2014a, 2018a; Zhang, Rolls, Wang, Xie, Cheng and Feng, 2023a). These types of natural variation may be important foundations for different types of personality (Rolls, 2014a, 2012e, 2023b).

18.5.6 Implications, and possible treatments, and subtypes of depression

The differences of functional connectivity described in this section (18.5) all relate to altered stability of the circuits involved, which help to account for some of the symptoms of depression. I now consider some of the implications of these advances (Rolls, Cheng and Feng, 2020a; Zhang, Rolls, Wang, Xie, Cheng and Feng, 2023a).

Because the lateral orbitofrontal cortex responds to many punishing and non-rewarding stimuli (Grabenhorst and Rolls, 2011; Rolls, 2014a,b, 2019e; Zhang et al., 2023a; Rolls, 2023b) that are likely to elicit autonomic/visceral responses, as does the supracallosal anterior cingulate cortex, and in view of connections from these areas to the anterior insula which is implicated in autonomic/visceral function (Critchley and Harrison, 2013; Rolls, 2016c), the anterior insula would also be expected to be overactive in depression, which it is (Drevets, 2007; Hamilton et al., 2013; Ma, 2015).

A notable discovery is that ketamine, a N-methyl-D-aspartate (NMDA) receptor antagonist, in subanaesthetic doses, produces rapid (within hours) antidepressant responses in patients who are resistant to typical antidepressants, and that the effects may last for two weeks or longer (Zanos and Gould, 2018; Iadarola et al., 2015; Maltbie et al., 2017; Zanos et al., 2016; Wilkinson et al., 2018; Rhee et al., 2022). Clinically, ketamine may be useful with a single dose, or doses may be repeated (Rhee et al., 2022). The short-term effects of ketamine include blocking excitatory NMDA receptors on cortical pyramidal cells which reduces the excitatory effect produced by the excitatory transmitter glutamate; and blocking excitatory receptors on GABA inhibitory neurons, which will tend to decrease GABAergic neuron firing, resulting in a potential increase in pyramidal cell firing. However, ketamine produces further effects, such as inducing synaptogenesis on excitatory neurons, increased glutamate transmission, reversing the synaptic deficits caused by chronic stress, and effects mediated by a ketamine metabolite hydroxynorketamine (Duman and Aghajanian, 2012; Ghasemi et al., 2017; Zorumski et al., 2016; Abdallah et al., 2016; Aleksandrova et al., 2017; Zanos and Gould, 2018; Zhang et al., 2023a). Another way in which ketamine may be effective in depression is by reducing inflammatory processes, which are sometimes related to depression (Ghasemi et al., 2017).

Ketamine may act in part by quashing the attractor state in the lateral orbitofrontal cortex at least for a number of days. Evidence consistent with this is that the activity (metabolism) of the inferior frontal gyrus and orbitofrontal cortex was decreased by a single dose of ketamine, which reduced the anhedonia of depression (see further below) (Lally et al., 2015). This NMDA receptor blocker may act at least in part by decreasing the high firing rate state of attractor networks by reducing transmission in the recurrent collateral excitatory connections between the neurons (Rolls, 2016b; Rolls, Loh, Deco and Winterer, 2008d; Rolls and Deco, 2010; Rolls, 2012c; Deco, Rolls, Albantakis and Romo, 2013; Rolls and Deco, 2015b). Treatment with conventional antidepressant drugs (e.g. SSRIs) decreases the activity and connectivity of this lateral orbitofrontal cortex system (Ma, 2015; Rolls et al., 2020a; Rolls, 2018a; Rolls et al., 2020a). Electroconvulsive therapy may have antidepressant effects, may and might knock the non-reward system out of its attractor state.

Given that a ketamine metabolite, hydroxynorketamine, may be related to the antidepressant effects of ketamine and may act via facilitating effects mediated by AMPA receptors (Zanos et al., 2016), the effects of ketamine might be mediated by increasing the activity of the medial orbitofrontal cortex reward-related system (which tends to be reciprocally inversely related to the lateral orbitofrontal cortex non-reward system), or the functional connectivity of the medial orbitofrontal cortex reward system with the hippocampal system which is reduced in depression (Fig. 18.13). There is now some evidence for an action of ketamine to

increase activity or connectivity in the medial orbitofrontal cortex, as follows (Zhang, Rolls, Wang, Xie, Cheng and Feng, 2023a).

A pharmacological investigation tested 10 treatment resistant depression (TRD) patients with a monetary incentive delay task before and after ketamine infusions. The study showed that ketamine administration induced a sustained increase in medial orbitofrontal cortex and nucleus accumbens activation during both the anticipation of positive reward cues and during the receipt of positive feedback (the outcome phase). The enhanced reactivity of the medial orbitofrontal cortex and nucleus accumbens was accompanied by decreased depression symptoms and better behavioral performance to positive items (Sterpenich et al., 2019). Consistent with this, in one of the first clinical studies to investigate the anti-anhedonic mechanisms of ketamine in depression, 52 TRD patients received a single ketamine infusion. The primary outcome indicated that ketamine rapidly reduced levels of anhedonia, with a substantial effect within 40 minutes which lasted up to 3 days post-infusion (Lally et al., 2015). Importantly, in a subgroup of patients who received PET scans, the single ketamine infusion decreased glucose metabolism within medial orbitofrontal cortex regions, and the reduced magnitude of the orbitofrontal cortex metabolism was positively correlated with the changes in the anhedonia symptoms (i.e., changes in SHAPS scores) (Lally et al., 2015). In addition, a double-blind, placebo-controlled, crossover trial in TRD and healthy controls also showed that ketamine infusion increased the functional connectivity between the right medial orbitofrontal cortex and ventral rostral putamen for the TRD patients toward the levels observed in healthy controls, and the increased magnitude of orbitofrontal cortex-putamen connectivity was correlated with improved levels of anhedonia symptoms (i.e., reductions in SHAPS scores) (Mkrtchian, Evans, Kraus, Yuan, Kadriu, Nugent, Roiser and Zarate, 2021). Taken together, these findings provide evidence that ketamine has acute and chronic anti-anhedonic effects in major depressive disorder by acting in part to restore activity and sensitivity to reward, and increasing functional connectivity, of the medial orbitofrontal cortex.

A very interesting possibility arises. Ketamine may act at least in part to increase sensitivity to reward and connectivity of the medial orbitofrontal cortex, and thereby ameliorate the anhedonia and motivational symptoms of depression (Zhang, Rolls, Wang, Xie, Cheng and Feng, 2023a). Conventional antidepressants such as the selective serotonin reuptake inhibitors may act in part on the non-reward-related lateral orbitofrontal cortex to decrease its elevated sensitivity to non-reward and connectivity in depression, and thereby treat the symptoms of sadness related to non-reward over-efficacy (Rolls et al., 2020a; Zhang et al., 2023a). It is suggested that low doses of both types of treatment would be useful to explore.

Deep brain stimulation of the orbitofrontal cortex may be useful in the treatment of mood disorders and depression. The macaque orbitofrontal cortex is a key brain site at which deep brain electrical stimulation is rewarding (Rolls et al., 1980b; Rolls, 2005a, 2019e). Electrical stimulation of the human orbitofrontal cortex can also produce reward and raise mood (Rao et al., 2018), and many of the sites were in the middle part of the orbitofrontal cortex, areas 13 and 11, which are categorised as medial orbitofrontal cortex, the area activated by rewards (Rolls, 2019e). It is likely that these medial orbitofrontal cortex sites will produce better reward in humans than stimulation in the lateral orbitofrontal cortex BA12/47, for these lateral sites are activated by unpleasant stimuli and by not obtaining expected rewards. The medial (/middle) orbitofrontal cortex may for the reasons described here and elsewhere (Rolls, 2019e) be a key area of interest for deep brain stimulation to help relieve depression (Rolls et al., 2020a).

The anterior cingulate cortex, including the subcallosal cingulate cortex, is a key brain region to which the orbitofrontal cortex projects (Hsu et al., 2020; Du et al., 2020; Rolls et al., 2019; Rolls, 2019e; Rolls et al., 2023c). It is possible that brain stimulation of the subcallosal cingulate cortex might be useful in the treatment of at least some patients with

depression (Riva-Posse et al., 2018; Holtzheimer et al., 2017; Dunlop et al., 2017; Lujan et al., 2013; Johansen-Berg et al., 2008), and it is possible that the subcallosal cingulate stimulation affects pathways that connect with the orbitofrontal cortex (Riva-Posse et al., 2018; Dunlop et al., 2017; Lujan et al., 2013; Johansen-Berg et al., 2008; Elias et al., 2022b,a). Given that the anterior cingulate cortex is an output region of the orbitofrontal cortex, it may be that treatments of the orbitofrontal cortex, where emotion-related processing is implemented, may be a better target for potential treatments for depression (Rolls et al., 2020a).

This non-reward / punishment attractor network sensitivity theory of depression has implications for treatments. These implications can be understood and further explored in the context of investigations of the factors that influence the stability of attractor neuronal networks with integrate-and-fire neurons with noise introduced by the close to Poisson spiking times of the neurons (Section 18.2) (Wang, 2002; Rolls, 2016b; Deco et al., 2009; Rolls and Deco, 2010; Deco et al., 2013; Loh et al., 2007a; Rolls and Deco, 2015b; Rolls, 2016b).

One implication is that anti-anxiety drugs, by increasing inhibition, might reduce the stability of the high firing rate state of the non-reward attractor, thus acting to quash the depression-related attractor state.

A second implication is that it might be possible to produce agents that decrease the efficacy of NMDA receptors in the lateral orbitofrontal cortex, thereby reducing the stability of the depression-related attractor state. The evidence that there are genes that are selective for NMDA receptors for the neurons in different populations is that there are separate knock-outs for NMDA receptors in the CA3 and CA1 regions of the hippocampus (Nakazawa et al., 2002; Tonegawa et al., 2003; Nakazawa et al., 2003, 2004). The present theory suggests that searching for ways to influence the attractor networks in the lateral orbitofrontal cortex by decreasing excitatory or increasing inhibitory transmission in this region may be of considerable interest. It should be noted that the present theory is a theory specifically of non-reward and punishment-related attractor networks in the lateral orbitofrontal cortex and related areas in relation to depression, and of reduced efficacy of the medial orbitofrontal cortex, and that alterations of attractor networks in other cortical areas may be related to other psychiatric disorders (Rolls, 2012c).

In terms of the implications of the attractor-based aspect of the present theory, an important point is that the attractor dynamics must be kept stable in the face of the randomness or noise introduced into the system by the almost Poisson firing times of neurons for a given mean firing rate. Moreover, the spontaneous firing rate state of the non-reward attractor must be maintained stable when no non-reward inputs are present (or otherwise the non-reward attractor would jump into a high firing rate non-reward state for no external reason, contributing to depression). The inhibitory transmitter GABA may be important in maintaining this type of stability (Rolls and Deco, 2010). Moreover, the high firing rate state produced by non-reward must not reach too high a firing rate, as this would cause over-stability of the non-reward / depression state. In a complementary way, if the high firing rate attractor state is insufficiently high, then that attractor state might be unstable, and the individual might be relatively insensitive to non-reward, not depressed, and impulsive because of not responding sufficiently to non-reward or punishment. The excitatory transmitter glutamate acting at NMDA or AMPA receptors may be important in setting the stability of the high firing rate attractor state. In this respect and in this sense, the tendency to become depressed or to be impulsive may be reciprocally related to each other. Predictions for treatments follow from understanding these noisy attractor-based dynamics (Rolls and Deco, 2010; Rolls, 2012c).

There is growing interest in possible subtypes of depression, for it may be possible to treat different subtypes differently, for example by targeting different brain systems, or by different types of cognitive therapy (Drysdale et al., 2017). In one investigation, the subtypes appeared to reflect different combinations of depression and anxiety (Drysdale et al., 2017).

A subtype with anxiety may be especially helped by repetitive transcranial stimulation of the right lateral orbitofrontal cortex (Feffer, Fettes, Giacobbe, Daskalakis, Blumberger and Downar, 2018).

The approach to understanding depression does suggest that differences in depression in different people could relate to the different systems described here (Rolls, 2019e; Drysdale et al., 2017; Fettes et al., 2017; Rolls et al., 2020a). One subtype may relate to reduced functioning of the reward-related medial orbitofrontal cortex and related brain systems such as the ventral striatum, and could be related to anhedonia, a reduction in pleasure, and a reduction in reward-related learning.

A second subtype may relate to increased sensitivity of networks in the lateral orbitofrontal cortex non-reward / punishment system, and may related to prominent and persistent (almost compulsive) negative thoughts, and to increased anxiety and neuroticism, and to suicidal ideation.

A third subtype may relate to decreased connectivity of the orbitofrontal cortex with the anterior cingulate cortex, which by breaking the link between value / outcome representations in the orbitofrontal cortex and the action-outcome learning system in the anterior cingulate cortex (Rolls, 2019c) could lead to reduced motivation to perform actions, and to reduced learning by receiving reward outcomes for actions. Consistent with the way in which this subsystem may operate is that the functional connectivity between only the reward-related orbitofrontal cortex and the anterior cingulate cortex can be used to predict sensation-seeking in a large population of individuals (Wan, Rolls, Cheng and Feng, 2020), showing how important the connectivity between these two brain regions is likely to be in how individuals respond to rewards in the world.

Strengths of the approach to understanding depression described here are that it has its foundations in an understanding of the brain systems involved in normal emotions and mood states (Rolls, 2014a, 2018a, 2019f; Rolls et al., 2020a; Rolls, 2023b); and that it incorporates concepts of the stability of attractor networks in the cortex, which are a key feature of cortical design (Rolls and Deco, 2010; Rolls, 2016b).

18.5.7 Mania and bipolar disorder

So far in this Section 18.5, we have been considering unipolar depression.

Bipolar disorder includes periods of mania in addition to periods of depression (Kato, 2019). The severity of the mania is greatest in bipolar I disorder, moderate in bipolar II disorder, and lower in cyclothymia. During depression, people feel helplessness, reduced energy, and risk aversion, while with mania behaviors include grandiosity, increased energy, less sleep, and risk preference / impulsivity.

What is the relation between mania and depression? Could it be that in mania, there is something that in terms of reward/non-reward systems, is almost the opposite of depression? Might there be in mania *increased sensitivity to reward, and decreased sensitivity to non-reward / punishment*? The latter might manifest itself as increased impulsiveness in mania. That is a suggestion that might be considered to be the opposite of what has been described for depression in the previous part of this Section 18.5.

It turns out that there is support for this hypothesis. It indeed appears that the risk for mania is characterized by a hypersensitivity to goal- and reward-relevant cues (Nusslock et al., 2014). This hypersensitivity can lead to an excessive increase in approach-related affect and motivation during life events involving rewards or goal striving and attainment. In the extreme, this excessive increase in reward-related affect is reflected in manic symptoms, such as pursuit of rewarding activities without attention to risks, elevated or irritable mood, decreased need for sleep, increased psychomotor activation, and extreme self-confidence.

Some evidence consistent with the hypothesis is that patients with bipolar I disorder and their relatives showed greater activation of the medial orbitofrontal cortex in response to reward delivery (Wessa et al., 2014). Also, reduced deactivation of the medial orbitofrontal cortex (where rewards are represented) during reward reversal might reflect a reduced error signal in bipolar disorder patients and their relatives in the lateral orbitofrontal cortex. (The activation of the lateral orbitofrontal cortex by non-reward in healthy individuals is illustrated in Fig. 11.16.) This type of responsiveness has been found to be very different in mania, with apparently decreasing activations in the lateral orbitofrontal cortex during expectation of increasing loss, the opposite of what is found in healthy participants (Berpohl et al., 2010) which we discovered in the orbitofrontal cortex (O'Doherty, Kringelbach, Rolls, Hornak and Andrews, 2001a). In this context, of potentially reduced sensitivity or even abnormal function of the lateral orbitofrontal cortex non-reward system in mania, it is relevant that manic bipolar patients continue to pursue immediate rewards despite negative consequences (Wessa et al., 2014). Further, impulsivity in mania is pervasive, encompassing deficits in attention and behavioral inhibition. In addition, impulsivity is greater if the illness is severe (with for example frequent episodes, substance use disorders, and suicide attempts) (Swann, 2009). The significance of this is that impulsivity may reflect decreased sensitivity to non-reward, which is represented by activations in the lateral orbitofrontal cortex, where non-reward is represented (see above).

Thus mania may reflect a state in which there is decreased sensitivity of non-reward systems and hence increased impulsiveness due to reduced sensitivity of the lateral orbitofrontal cortex, and at the same time, increased sensitivity to reward reflected in activations in the medial orbitofrontal cortex and pregenual cingulate cortex. Although these medial and lateral orbitofrontal cortex systems may show reciprocally related activations within an individual, with for example increasing activations in the medial orbitofrontal cortex to increasing monetary gains and decreasing activations in the lateral orbitofrontal cortex, and vice versa to increasing monetary loss (O'Doherty et al., 2001a), the reward and non-reward systems could be, and indeed are likely to, have their sensitivity set by independent genes, providing a basis for some patients to be depressed, and others to show both mania and depression. Indeed, Rolls' theory of emotion (Rolls, 2014a) (Chapter 11) would go beyond this, and suggest that the sensitivity to many different rewards (e.g. food when hungry, water when thirsty, pleasant touch, sensitivity to reputation), and correspondingly to many different non-rewards, may be set by genes somewhat independently. This provides a relation to personality (Rolls, 2014a), with the implication that people with depression may be particularly sensitive to certain non-rewards or punishers, and people with mania may be particularly sensitive to particular rewards. This has important implications for therapy, which might be well-directed towards particular sensitivities to particular non-rewards and particular rewards in different individuals.

The question then arises of the extent to which attractor network operations contribute to mania. In terms of responses to inputs that increase the expectancy of reward, a short-term attractor system, probably in the orbitofrontal cortex, is likely to be present, to bridge any temporal interval between the expected reward signal and the actual outcome. This could in principle be oversensitive in mania. When the reward, the outcome, is delivered, it might also be useful to have a short-term attractor, to help reset a rule attractor for which stimulus is currently rewarding. However, it would be maladaptive if these reward-expectancy or reward-outcome attractors normally operated for more than perhaps 10 s, for this would tend to break the important contingency between input stimuli and outcomes. In addition to these short-term attractors, there also needs to be a longer term attractor process to reflect mood state, which typically operates on a much longer time scale. This might again be an attractor (with separate competing attractors for different mood states), and this attractor might be

re-activated by the longer loop through the language / planning system, which by recalling a recent reward might calculate the long-term benefits, helping to keep the mood state prolonged. This whole ‘long-loop’ attractor might also be more sensitive in mania. These are interesting concepts for future empirical exploration. There is much left to understand about bipolar disorder (Kato, 2019).

18.6 Attractor stochastic dynamics, aging, and memory

In Section 18.3 I considered how some cognitive symptoms such as poor short-term memory and attention could arise due to reduced depth in the basins of attraction of prefrontal cortical networks, and the effects of noise. The hypothesis is that the reduced depth in the basins of attraction would make short-term memory unstable, so that sometimes the continuing firing of neurons that implement short-term memory would cease, and the system under the influence of noise would fall back out of the short-term memory state into spontaneous firing.

Given that top-down attention requires a short-term memory to hold the object of attention in mind, and that this is the source of the top-down attentional bias that influences competition in other networks that are receiving incoming signals, then disruption of short-term memory is also predicted to impair the stability of attention.

These ideas are elaborated in Section 18.3, where the reduced depth of the basins of attraction in schizophrenia is related to down-regulation of NMDA receptors, or to factors that influence NMDA receptor generated ion channel currents such as dopamine D1 receptors.

Could similar processes, in which the stochasticity of the dynamics is increased because of a reduced depth in the basins of attraction, contribute to the changes in short-term memory and attention that are common in aging? Reduced short-term memory and less good attention are common in aging, as are impairments in episodic memory (Grady, 2008; Dahan et al., 2020). What changes in aging might contribute to a reduced depth in the basins of attraction? Computational approaches to the memory problems in aging are considered next (Rolls and Deco, 2015b; Rolls, 2019a). Some of the changes in the aging brain include impaired synaptic plasticity, and impaired neurogenesis in the dentate gyrus of the hippocampal system (Dahan et al., 2020). The ways in which impaired synaptic plasticity could influence memory are described below in Section 18.6.3. Neurogenesis, considered in Section 9.3.6.6, would if impaired reduce the ability of new items to generate separate patterns of firing in the CA3 neurons of the hippocampal episodic memory system, and thereby impair the formation of new episodic memories.

18.6.1 NMDA receptor hypofunction

One factor is that NMDA receptor functionality tends to decrease with aging (Kelly et al., 2006; Temido-Ferreira et al., 2019; Ploux et al., 2020; Orzylowski et al., 2021). This would act, as investigated in detail in Section 18.3, to reduce the depth of the basins of attraction, both by reducing the firing rate of the neurons in the active attractor, and effectively by decreasing the strength of the potentiated synaptic connections that support each attractor as the currents passing through these potentiated synapses would decrease. These two actions are clarified by considering Equation B.12 on page 835, in which the Energy E reflects the depth of the basin of attraction.

An example of the reductions of firing rate in an attractor network produced by even a small downregulations of the NMDA receptor activated ion channel conductances is shown in Fig. 18.16. The effect of these reductions would be to decrease the depth of the basins of

Fig. 18.16 Aging: reductions of NMDA receptor conductances reduce the firing rates (and therefore the stability) of short-term memory networks. Effects of reductions of NMDA receptor conductance on the firing rates of neurons in the short-term memory integrate-and-fire network during the short-term memory period of 4–5 s in the simulations. The firing rates are shown for correct trials only, that is when the spontaneous firing state was stable, and when the firing rate remained high in pool S1 (i.e. greater than 10 spikes/s more than in pool 2) until the end of the trial. (For the reduction of NMDA receptor activated synaptic conductance of 10%, there were no trials on which the memory was correctly maintained during this period, and the rates reflect a value close to the spontaneous firing rate before the memory retrieval cue was applied.) (From Rolls, E.T. and Deco, G. (2015) Stochastic cortical neurodynamics underlying the memory and cognitive changes in aging. *Neurobiology of Learning and Memory* 118: 150–161. © Elsevier Inc.)

attraction, both by reducing the firing rate, and by producing an effect similar to weakened synaptic strengths, as shown in Equation B.12.

The reduced depth in the basins of attraction could have a number of effects that are relevant to cognitive changes in aging.

First, the stability of short-term memory networks would be impaired, and it might be difficult to hold items in short-term memory for long, as the noise might push the network easily out of its shallow attractor.

Second, top-down attention would be impaired, in two ways. In one, the short-term memory network holding the object of attention in mind would be less stable, so that the source of the top-down bias for the biased competition in other cortical areas might disappear. In a second, and very interestingly, even when the short-term memory for attention is still in its persistent attractor state, it would be less effective as a source of the top-down bias, because the firing rates would be lower, as shown in Fig. 18.16.

Third, the recall of information from episodic memory systems in the temporal lobe (Rolls, 2016b; Dere et al., 2008; Rolls, 2008e) would be impaired. This would arise because the positive feedback from the recurrent collateral synapses that helps the system to fall into a basin of attraction, representing in this case the recalled memory, would be less effective, and so the recall process would be more noisy overall.

Fourth, any reduction of the firing rate of the pyramidal cells caused by NMDA receptor hypofunction (Fig. 18.16) would itself be likely to impair new learning involving LTP.

In addition, if the NMDA receptor hypofunction were expressed not only in the prefrontal cortex where it would affect short-term memory, and in the temporal lobes where it would affect episodic memory, but also in the orbitofrontal cortex, then we would predict some reduction in emotion and motivation with aging, as these functions rely on the orbitofrontal cortex (see Rolls (2019e) and Section 18.3).

Although NMDA hypofunction may contribute to cognitive effects such as poor short-term memory and attention in aging and in schizophrenia, the two states are clearly very different. Part of the difference lies in the positive symptoms of schizophrenia (the psychotic

symptoms, such as thought disorder, delusions, and hallucinations) which may be related to the additional downregulation of GABA in the temporal lobes, which would promote too little stability of the spontaneous firing rate state of temporal lobe attractor networks, so that the networks would have too great a tendency to enter states even in the absence of inputs, and to not be controlled normally by input signals (Loh, Rolls and Deco, 2007a,b; Rolls, Loh, Deco and Winterer, 2008d) (see Section 18.3). However, in relation to the cognitive symptoms of schizophrenia, there has always been the fact that schizophrenia is a condition that often has its onset in the late teens or twenties, and I suggest that there could be a link here to changes in NMDA and related receptor functions that are related to aging. In particular, short-term memory is at its peak when young, and it may be the case that by the late teens or early twenties NMDA and related receptor systems (including dopamine) may be less efficacious than when younger, so that the cognitive symptoms of schizophrenia are more likely to occur at this age than earlier.

Possible ways to minimize the effects of reduction in NMDA receptor efficacy with aging may be caffeine (Temido-Ferreira et al., 2019), and d-serine (Ploux et al., 2020).

18.6.2 Dopamine and norepinephrine

D1 receptor blockade in the prefrontal cortex can impair short-term memory (Sawaguchi and Goldman-Rakic, 1991, 1994; Goldman-Rakic, 1999; Castner et al., 2000). Part of the reason for this may be that D1 receptor blockade can decrease NMDA receptor activated ion channel conductances, among other effects (Seamans and Yang, 2004; Durstewitz et al., 1999, 2000a; Brunel and Wang, 2001; Durstewitz and Seamans, 2002) (see further Section 18.3). Thus part of the role of dopamine in the prefrontal cortex in short-term memory can be accounted for by a decreased depth in the basins of attraction of prefrontal attractor networks (Loh, Rolls and Deco, 2007a,b; Rolls, Loh, Deco and Winterer, 2008d). The decreased depth would be due to both the decreased firing rate of the neurons, and the reduced efficacy of the modified synapses as their ion channels would be less conductive (see equation B.12). The reduced depth of the basins of attraction can be thought of as decreasing the signal-to-noise ratio (Loh, Rolls and Deco, 2007b; Rolls, Loh, Deco and Winterer, 2008d). Given that dopaminergic function in the prefrontal cortex may decline with aging (Sikström, 2007), and in conditions in which there are cognitive impairments such as Parkinson's disease, the decrease in dopamine could contribute to the reduced short-term memory and attention in aging.

In attention deficit hyperactivity disorder (ADHD), in which there are attentional deficits including too much distractibility, catecholamine function more generally (dopamine and noradrenaline (i.e. norepinephrine)) may be reduced (Arnsten and Li, 2005), and I suggest that these reductions could produce less stability of short-term memory and thereby attentional states by reducing the depth of the basins of attraction. Indeed, treatment with guanfacine, an adrenoceptor agonist (i.e. working on receptors activated by norepinephrine) can improve cognitive including working memory functions implemented in the dorsolateral prefrontal cortex (Arnsten and Wang, 2016), and this may be helpful in healthy aging.

18.6.3 Impaired synaptic modification

Another factor that may contribute to the cognitive changes in aging is that long-lasting associative synaptic modification as assessed by long-term potentiation (LTP) is more difficult to achieve in older animals and decays more quickly (Barnes, 2003; Burke and Barnes, 2006; Kelly et al., 2006; Dahan et al., 2020; Orzylowski et al., 2021). This would tend to make the synaptic strengths that would support an attractor weaker, and weaken further over the

course of time, and thus directly reduce the depth of the attractor basins. This would impact episodic memory, the memory for particular past episodes, such as where one was at breakfast on a particular day, who was present, and what was eaten (Rolls, 2016b, 2008e; Dere et al., 2008). The reduction of synaptic strength over time could also affect short-term memory, which requires that the synapses that support a short-term memory attractor be modified in the first place using LTP, before the attractor is used (Kesner and Rolls, 2001). Part of the mechanism involving the decrease in synaptic plasticity in aging may be a decrease in D-serine, which is a cofactor required for normal operation of the NMDA receptor in synaptic plasticity (Orzylowski et al., 2021).

In view of these changes, boosting glutamatergic transmission is being explored as a means of enhancing cognition and minimizing its decline in aging. Several classes of AMPA receptor potentiators have been described. These molecules bind to allosteric sites on AMPA receptors, slow desensitization, and thereby enhance signalling through the receptors. Some AMPA receptor potentiator agents have been explored in rodent models and are now entering clinical trials (Lynch and Gall, 2006; O'Neill and Dix, 2007). These treatments might increase the depth of the basins of attraction. Agents that activate the glycine or serine modulatory sites on the NMDA receptor (Coyle, 2006; Uno and Coyle, 2019; Ploux et al., 2020) would also be predicted to be useful in healthy aging, and there is some evidence that D-serine administration or agents that influence D-serine can reverse some of the memory problems in aging in humans and in animal models (Orzylowski et al., 2021).

Another factor is that Ca^{2+} -dependent processes affect Ca^{2+} signaling pathways and impair synaptic function in an aging-dependent manner, consistent with the Ca^{2+} hypothesis of brain aging and dementia (Kelly et al., 2006). In particular, an increase in Ca^{2+} conductance can occur in aged neurons, and CA1 pyramidal cells in the aged hippocampus have an increased density of L-type Ca^{2+} channels that might lead to disruptions in Ca^{2+} homeostasis, contributing to the plasticity deficits that occur during aging (Burke and Barnes, 2006; Orzylowski et al., 2021).

18.6.4 Cholinergic function and memory

18.6.4.1 Cholinergic function, memory, and aging

Another factor is acetylcholine. Acetylcholine in the neocortex has its origin largely in the cholinergic neurons in the basal magnocellular forebrain nuclei of Meynert (Mesulam, 1990; Zaborszky et al., 2018, 2008; Galvin et al., 2020). The correlation of clinical dementia ratings with the reductions in a number of cortical cholinergic markers such as choline acetyltransferase, muscarinic and nicotinic acetylcholine receptor binding, as well as levels of acetylcholine, suggested an association of cholinergic hypofunction with cognitive deficits, which led to the formulation of the cholinergic hypothesis of memory dysfunction in senescence and in Alzheimer's disease (Bartus, 2000; Schliebs and Arendt, 2006). Could the cholinergic system alter the function of the cerebral cortex in ways that can be illuminated by stochastic neurodynamics? The dorsolateral prefrontal cortex is a key brain area in working memory (Chapter 13), and acetylcholine working mainly through nicotinic receptors is important in enabling neurons to maintain their firing in attractor states to implement working memory (Galvin et al., 2020). In addition, acetylcholine is important in hippocampal synaptic plasticity and memory (Hasselmo and Giocomo, 2006; Giocomo and Hasselmo, 2007; Hasselmo and Sarter, 2011; Newman et al., 2012; Zaborszky et al., 2018; Rolls, 2021b), as described in Chapter 9.

18.6.4.2 The responses of basal magnocellular forebrain nuclei cholinergic neurons

The cells in the basal magnocellular forebrain nuclei of Meynert lie just lateral to the lateral hypothalamus in the substantia innominata, and extend forward through the preoptic area into the diagonal band of Broca (Mesulam, 1990). These cells, many of which are cholinergic, project directly to the cerebral cortex (Divac, 1975; Kievit and Kuypers, 1975; Mesulam, 1990; Zaborszky et al., 2018; Galvin et al., 2020). These cells provide the major cholinergic input to the cerebral cortex, in that if they are lesioned the cortex is depleted of acetylcholine (Mesulam, 1990). Loss of these cells does occur in Alzheimer's disease, and there is consequently a reduction in cortical acetylcholine in this disease (Mesulam, 1990; Schliebs and Arendt, 2006). This loss of cortical acetylcholine may contribute to the memory loss in Alzheimer's disease, although it may not be the primary factor in the aetiology.

In order to investigate the role of the basal forebrain nuclei in memory, Aigner et al. (1991) made neurotoxic lesions of these nuclei in monkeys. Some impairments on a simple test of recognition memory, delayed non-match-to-sample, were found. Analysis of the effects of similar lesions in rats showed that performance on memory tasks was impaired, perhaps because of failure to attend properly (Muir et al., 1994). Damage to the cholinergic neurons in this region in monkeys with a selective neurotoxin was also shown to impair memory (Easton and Gaffan, 2000; Easton et al., 2002).

There are quite limited numbers of these basal forebrain neurons (in the order of thousands). Given that there are relatively few of these neurons, it is not likely that they carry the information to be stored in cortical memory circuits, for the number of different patterns that could be represented and stored is so small. (The number of different patterns that could be stored is dependent in a leading way on the number of input connections on to each neuron in a pattern associator, see e.g. Rolls (2016b)). With these few neurons distributed throughout the cerebral cortex, the memory capacity of the whole system would be impractically small. This argument alone indicates that these cholinergic neurons are unlikely to carry the information to be stored in cortical memory systems. Instead, they could modulate storage in the cortex of information derived from what provides the numerically major input to cortical neurons, the glutamatergic terminals of other cortical neurons. This modulation may operate by setting thresholds for cortical cells to the appropriate value, or by more directly influencing the cascade of processes involved in long-term potentiation (Rolls, 2016b). There is indeed evidence that acetylcholine is necessary for cortical synaptic modifiability, as shown by studies in which depletion of acetylcholine and noradrenaline impaired cortical LTP/synaptic modifiability (Bear and Singer, 1986). However, non-specific effects of damage to the basal forebrain cholinergic neurons are also likely, with cortical neurons becoming much more sluggish in their responses, and showing much more adaptation, in the absence of cholinergic inputs (Markram and Tsodyks, 1996; Abbott, Varela, Sen and Nelson, 1997) (see later).

The question then arises of whether the basal forebrain cholinergic neurons tonically release acetylcholine, or whether they release it particularly in response to some external influence. To examine this, recordings have been made from basal forebrain neurons, at least some of which project to the cortex (see Rolls (2005a)) and will have been the cholinergic neurons just described.

It has been found that some of these basal forebrain neurons respond to visual stimuli associated with rewards such as food (Rolls, 1975, 1981b,a, 1982, 1986c,a,b, 1990c, 1993, 1999a; Rolls, Burton and Mora, 1976; Burton, Rolls and Mora, 1976; Mora, Rolls and Burton, 1976; Wilson and Rolls, 1990b,a), or with punishment (Rolls, Sanghera and Roper-Hall, 1979b), that others respond to novel visual stimuli (Wilson and Rolls, 1990c), and that others

respond to a range of visual stimuli. For example, in one set of recordings, one group of these neurons (1.5%) responded to novel visual stimuli while monkeys performed recognition or visual discrimination tasks (Wilson and Rolls, 1990c).

A complementary group of neurons more anteriorly responded to familiar visual stimuli in the same tasks (Rolls, Perrett, Caan and Wilson, 1982d; Wilson and Rolls, 1990c).

A third group of neurons (5.7%) responded to positively reinforcing visual stimuli in visual discrimination and in recognition memory tasks (Wilson and Rolls, 1990b,a).

In addition, a considerable proportion of these neurons (21.8%) responded to any visual stimuli shown in the tasks, and some (13.1%) responded to the tone cue that preceded the presentation of the visual stimuli in the task, and was provided to enable the monkey to alert to the visual stimuli (Wilson and Rolls, 1990c). None of these neurons responded to touch to the leg which induced arousal, so their responses did not simply reflect arousal.

Neurons in this region receive inputs from the amygdala (Mesulam, 1990; Amaral et al., 1992; Russchen et al., 1985) and orbitofrontal cortex (Rolls et al., 2023c; Rolls, 2022b), and it is probably via the amygdala and orbitofrontal cortex that the information described here reaches the basal forebrain neurons. For example, neurons with similar response properties have been found in the amygdala, and the amygdala appears to be involved in decoding visual stimuli that are associated with reinforcers, or are novel (Rolls, 1990c, 1992b; Davis, 1992; Wilson and Rolls, 1993; Rolls, 2000c; LeDoux, 1995; Wilson and Rolls, 2005; Rolls, 2005a, 2016b). Further, similar neurons responding to rewarding stimuli, aversive stimuli, and to novel stimuli are found in the orbitofrontal cortex (Thorpe, Rolls and Maddison, 1983; Rolls, Browning, Inoue and Hernadi, 2005a; Rolls, 2019f,e) (see Chapter 11).

18.6.4.3 Basal magnocellular forebrain nuclei cholinergic neurons as a cortical strobe to facilitate memory

On the basis of these findings, it is suggested that the normal physiological function of these basal forebrain neurons is to send a general activation signal to the cortex when certain classes of environmental stimulus occur. These stimuli are often stimuli to which behavioral activation is appropriate or required, such as positively or negatively reinforcing visual stimuli, or novel visual stimuli. The effect of the firing of these neurons on the cortex is excitatory, and in this way produces activation. This cortical activation may produce behavioral arousal, and may thus facilitate concentration and attention, which are both impaired in Alzheimer's disease. The reduced arousal and concentration may themselves contribute to the memory disorders. But the acetylcholine released from these basal magnocellular neurons may in addition be more directly necessary for memory formation, for Bear and Singer (1986) showed that long-term potentiation, used as an indicator of the synaptic modification which underlies learning, requires the presence in the cortex of acetylcholine as well as noradrenaline. For comparison, acetylcholine in the hippocampus makes it more likely that LTP will occur, probably through activation of an inositol phosphate second messenger cascade (Markram and Segal, 1992; Seigel and Auerbach, 1996; Hasselmo and Bower, 1993; Hasselmo et al., 1995; Hasselmo, 1999).

The adaptive value of the cortical strobe provided by the basal magnocellular neurons may thus be that it facilitates memory storage especially when significant (e.g. reinforcing) environmental stimuli are detected. This means that memory storage is likely to be conserved (new memories are less likely to be laid down) when significant environmental stimuli are not present. In that the basal forebrain projection spreads widely to many areas of the cerebral cortex, and in that there are relatively few basal forebrain neurons (in the order of thousands), the basal forebrain neurons do not determine the actual memories that are stored. Instead the actual memories stored are determined by the active subset of the thousands of cortical afferents on to a strongly activated cortical neuron (Treves and Rolls, 1994; Rolls and Treves,

1998; Rolls, 2016b). The basal forebrain magnocellular neurons would then according to this analysis when activated increase the probability that a memory would be stored. Impairment of the normal operation of the basal forebrain magnocellular neurons would be expected to interfere with normal memory by interfering with this function, and this interference could contribute in this way to the memory disorder in Alzheimer's disease.

Interesting new evidence is that in humans the cholinergic septal neurons that project to the hippocampus receive inputs in humans from the pregenual anterior cingulate cortex, which in turn receives from the orbitofrontal and ventromedial prefrontal cortex; and the basal forebrain cholinergic neurons that project to the neocortex receive from the medial orbitofrontal cortex (Rolls et al., 2023c). This places the human orbitofrontal cortex in a key position to influence memory consolidation, and indeed to be the origin of the cortical strobe that can increase memory consolidation (Rolls et al., 2023c; Rolls, 2022b). Consistent with this, damage to the ventromedial prefrontal cortex / pregenual anterior cingulate cortex impairs memory consolidation (Rolls, 2022b) (see Section 9.2.8.5). It is accordingly proposed that an additional factor in any decline in memory function in aging could relate to a less strong cortical strobe from the reward / punishment / novelty system in the orbitofrontal cortex, which might itself be less responsive to these emotion-provoking stimuli in some individuals as part of the normal aging process.

Thus one way in which impaired cholinergic neuron function is likely to impair memory is by reducing the depth of the basins of attraction of cortical networks, in that these networks store less strongly the representations that are needed for episodic memory and for short-term memory, thus making the recall of long-term episodic memories less reliable in the face of stochastic noise, and the maintenance of short-term memory less reliable in the face of stochastic noise. Such changes would thereby also impair attention.

18.6.4.4 Basal magnocellular forebrain nuclei cholinergic neurons reduce cortical adaptation

Another property of cortical neurons is that they tend to adapt with repeated input (Abbott, Varela, Sen and Nelson, 1997; Fuhrmann, Markram and Tsodyks, 2002a; Rolls, 2016b). However, this adaptation is most marked in slices, in which there is no acetylcholine. One effect of acetylcholine is to reduce this adaptation (Power and Sah, 2008). The mechanism is understood as follows. The afterpolarization (AHP) that follows the generation of a spike in a neuron is primarily mediated by two calcium-activated potassium currents, I_{AHP} and sI_{AHP} (Sah and Faber, 2002), which are activated by calcium influx during action potentials. The I_{AHP} current is mediated by small conductance calcium-activated potassium (SK) channels, and its time course primarily follows cytosolic calcium, rising rapidly after action potentials and decaying with a time constant of 50 to several hundred milliseconds (Sah and Faber, 2002). In contrast, the kinetics of the sI_{AHP} are slower, exhibiting a distinct rising phase and decaying with a time constant of 1–2 s (Sah, 1996). A variety of neuromodulators, including acetylcholine (ACh), noradrenaline, and glutamate acting via G-protein-coupled receptors, suppress the sI_{AHP} and thus reduce spike-frequency adaptation (Nicoll, 1988).

When recordings are made from single neurons operating in physiological conditions in the awake behaving monkey, peristimulus time histograms of inferior temporal cortex neurons to visual stimuli show only limited adaptation. There is typically an onset of the neuronal response at 80–100 ms after the stimulus, followed within 50 ms by the highest firing rate. There is after that some reduction in the firing rate, but the firing rate is still typically more than half-maximal 500 ms later (see example in Fig. 2.16). Thus under normal physiological conditions, firing rate adaptation can occur, but does not involve a major adaptation, even when cells are responding fast (at e.g. 100 spikes/s) to a visual stimulus. One of the factors that keeps the response relatively maintained may however be the presence of acetylcholine.

The depletion of acetylcholine in aging and some disease states (Schliebs and Arendt, 2011) could lead to less sustained neuronal responses (i.e. more adaptation), and this may contribute to the symptoms found. In particular, the reduced firing rate that may occur as a function of time if acetylcholine is low would gradually over a few seconds reduce the depth of the basin of attraction, and thus destabilize short-term memory when noise is present, by reducing the firing rate component shown in Equation B.12. I suggest that such changes would thereby impair short-term memory, and thus also top-down attention.

This adaptation can be studied by including a time-varying intrinsic (potassium like) conductance in the cell membrane, as described in Section B.6.2. A specific implementation of the spike-frequency adaptation mechanism using Ca^{2+} -activated K^+ hyperpolarizing currents (Liu and Wang, 2001) as follows was used, and was also used by Deco and Rolls (2005c) (who also describe two other approaches to adaptation).

We assume that the intrinsic gating of K^+ after-hyper-polarizing current (I_{AHP}) is fast, and therefore its slow activation is due to the kinetics of the cytoplasmic Ca^{2+} concentration. This can be introduced in the model by adding an extra current term in the integrate-and-fire model, i.e. by adding I_{AHP} to the right hand of Equation 18.4, which describes the evolution of the subthreshold membrane potential $V(t)$ of each neuron:

$$C_m \frac{dV(t)}{dt} = -g_m(V(t) - V_L) - I_{\text{syn}}(t) \quad (18.4)$$

where $I_{\text{syn}}(t)$ is the total synaptic current flow into the cell, V_L is the resting potential, C_m is the membrane capacitance, and g_m is the membrane conductance. The extra current term that is introduced into this equation is as follows:

$$I_{\text{AHP}} = -g_{\text{AHP}}[\text{Ca}^{2+}](V(t) - V_K) \quad (18.5)$$

where V_K is the reversal potential of the potassium channel. Further, each action potential generates a small amount (α) of calcium influx, so that I_{AHP} is incremented accordingly. Between spikes the $[\text{Ca}^{2+}]$ dynamics is modelled as a leaky integrator with a decay constant τ_{Ca} . Hence, the calcium dynamics can be described by the following system of equations:

$$\frac{d[\text{Ca}^{2+}]}{dt} = -\frac{[\text{Ca}^{2+}]}{\tau_{\text{Ca}}} \quad (18.6)$$

If $V(t) = \theta$, then $[\text{Ca}^{2+}] = [\text{Ca}^{2+}] + \alpha$ and $V = V_{\text{reset}}$, and these are coupled to the previously-mentioned modified equations. The $[\text{Ca}^{2+}]$ is initially set to be $0 \mu\text{M}$, $\tau_{\text{Ca}} = 600$ ms, $\alpha = 0.005$, $V_K = -80$ mV and $g_{\text{AHP}} = 7.5$ nS.

On the basis of these hypotheses, it is predicted that enhancing cholinergic function will help to reduce the instability of attractor networks involved in short-term memory and attention that may occur in aging.

Part of the interest of this stochastic dynamics approach to aging (Rolls and Deco, 2015b; Rolls, 2019a) is that it provides a way to test combinations of pharmacological treatments, that may together help to minimize the cognitive symptoms of aging. Indeed, the approach facilitates the investigation of drug combinations that may together be effective in doses lower than when only one drug is given. Further, this approach may lead to predictions for effective treatments that need not necessarily restore the particular change in the brain that caused the symptoms, but may find alternative routes to restore the stability of the dynamics.

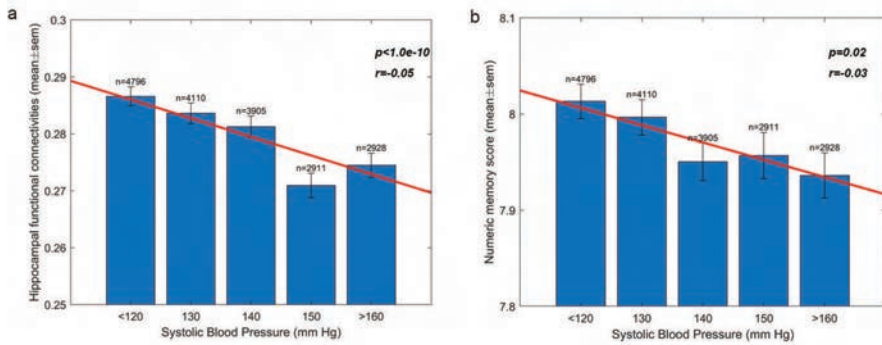

Fig. 18.17 The hippocampus, blood pressure, and memory. a. For 19,507 participants with neuroimaging data from the UK Biobank, there was a graded reduction in the functional connectivity of 88 hippocampal functional connectivity links and systolic blood pressure. The mean functional connectivity \pm the sem is shown, together with the number of participants. The line shows the linear regression computed over all 19,507 participants, with age regressed out, and was significant at $p < 10^{-10}$. b. For the same participants there was a graded reduction in the numeric memory score with higher values of blood pressure, with the linear regression coefficient significant at $p < 10^{-10}$ and age regressed out. (From Feng, R., Rolls, E. T., Cheng, W. and Feng, J. (2020) Hypertension is associated with reduced hippocampal connectivity and impaired memory. *EBioMedicine* 61: 103082.)

18.7 High blood pressure, reduced hippocampal functional connectivity, and impaired memory

In another investigation to help to relate the advances in the computational approaches described in this book to disorders of brain function, we discovered that in the general population (with 19,507 participants in the UK Biobank), there was a linear relation between higher blood pressure, reduced hippocampal functional connectivity with other brain regions, and impaired numeric and prospective memory (all $p < 10^{-10}$) (see Fig. 18.17) (Feng, Rolls, Cheng and Feng, 2020). Effects of this type are probably related to a number of neurovascular changes that occur in hypertension (Iadecola and Gottesman, 2019), but part of the interest of the new discovery is that effects are found throughout the range of systolic blood pressure on both decreased functional connectivity of the hippocampus and decreased memory performance. These findings have implications for the treatment of hypertension, because the findings show more about the effects of even small increases in blood pressure. It is also of interest and potential clinical relevance that these effects were more evident for systolic blood pressure than for diastolic blood pressure (Feng, Rolls, Cheng and Feng, 2020).

18.8 Brain development, and structural differences in the brain

The differences in functional connectivity described in this Chapter that could produce different dynamics of different brain systems in some mental disorders could be partly related to genetic differences, and partly to the environment. It has recently been shown in several very large-scale studies with thousands of participants that in children or adolescents, there may even be structural differences in the brain that relate to psychiatric and cognitive problems, though again, we do not yet know whether these are related to genetic or environmental effects, or to a combination.

We have discovered that a set of different factors can be associated with reduced area or volume of the orbitofrontal cortex, anterior cingulate and medial prefrontal cortex, the medial temporal lobe, and some related areas; and with behavioral and psychiatric problems including difficult behavior and depression. In one study, this syndrome was associated with

prolonged nausea and vomiting during pregnancy of the mothers (Wang, Rolls, Du, Du, Yang, Li, Li, Cheng and Feng, 2020c). In another study, family conflict was associated with a similar reduction of the area and volume of the same brain areas and similar behavioral, psychiatric and cognitive problems; and high parental monitoring (care) of the children with the opposite brain and behavioral differences (Gong, Rolls, Du, Feng and Cheng, 2021). In a third study, reduced area and volume of similar brain areas in the children, and behavioral and psychiatric problems, were associated with a low age of the mother when the child was born (Du, Rolls, Gong, Cao, Vatansever, Zhang, Kang, Cheng and Feng, 2022).

19 Computations by different types of brain, and by artificial neural systems

19.1 Introduction and overview

In this Chapter a comparison is made between computations in the brain and computations performed in computers (Section 19.3). This is intended to be helpful to those engineers, computer scientists, AI specialists and others interested in designing new computers that emulate aspects of brain function. In fact, the whole of this book is intended to be useful for this aim, by setting out what is computed by different brain systems, and what we know about how it is computed. It is essential to know this if an emulation of brain function is to be performed, and this is important to enable this group of scientists to bring their expertise to help understand brain function, and its disorders, better.

The comparison between computation in the brain and computation in computers in Section 19.3 is also intended to be of interest to neuroscientists to emphasize the differences in the implementations of computation in the brain and in computers.

Part of the interest here is that many computer implementations of ‘neural networks’ implement very different algorithms to those implemented in the brain. This means that there is a lot left not only to learn about the brain, but also to learn from the brain. For example, Section 19.4 specifically compares deep learning in artificial neural networks to the type of self-organising learning implemented in the brain; and Section 19.5 compares reinforcement learning in the brain (and in computers) to other learning systems in the brain.

Section 19.6 raises an important issue for understanding brains (and computers): the relation between explanations at different levels (neurons, networks, the computation that is performed, etc) of how brains and computers work, which is relevant to the mind-brain problem (Rolls, 2020a). Section 19.6.4 considers in particular the levels of investigation that are essential in order to understand how the brain performs its computations.

Section 19.7 considers the pioneering approach taken in this book to biologically plausible computations performed by each of many brain regions.

Section 19.8 is on Brain-Inspired Intelligence: how we can learn from the brain to implement new applications in computers.

Section 19.9 is on Brain-Inspired Medicine: how our developing understanding of how the brain computes has many implications not only for understanding how we as humans operate in health, but also what happens in for example mental disorders (considered in Chapter 18) and in other types of behavior, including behavior driven by our reward systems that can result in overeating and obesity.

Finally, Section 19.10 makes it clear why the focus of this book is on computations in primate (and that very much includes human) brains, rather than on rodent (rat and mice) brains. It is because the systems-level organization of primate including human brains is quite different from that in rodents.

We start in Section 19.2 by making the point that to understand how the brain works, a way forward is to understand how its different systems operate; and how that provides the foundation for how different systems operate together to produce a particular behavior.

That is also an important way forward when aiming to emulate in a computer how the brain performs a particular function.

19.2 Computations that combine different computational systems in the brain to produce behavior

By understanding what is computed in each brain system, how the information is represented, and how each system connects to other systems, we have a foundation for understanding how different brain systems operate together to perform behavioral functions. The ability to understand computationally what each part of the brain computes, and how the results of its computations are represented, is crucial to this aim. Studying each of these systems when the same behavior is being performed is also key to this aim. This approach is feasible, to understand the computations performed by each brain system separately, but while the same behavior is being performed, because there is considerable localisation of function in the brain, as set out by Rolls (2016b).

To model how the brain implements a function such as visual object recognition, or episodic memory, the strategy can next be to combine together the computations performed by several brain systems using information of the type presented in the different Chapters of this book, and in the Appendices. When moving forward to do this, it is suggested that a twofold strategy will be useful. The first part is to utilize the information provided in this book about what is computed in different brain systems, and how it is computed. The second part towards the implementation is to take into account the principles of operation of the cerebral cortex, as set out for example in *Cerebral Cortex: Principles of Operation* (Rolls, 2016b). In that book I did not attempt to produce a theory of how particular different brain systems compute, but instead focussed on the principles of operation and computation of the cortex. Thus what is in these two books complements each other in understanding the computations performed by the brain, and together they provide a foundation for further developments in our understanding, and in applying that understanding. Important applications of these advances are to understanding brain operation in disease, and developing new machines with what might be described as ‘**Brain-Inspired Intelligence**’.

19.3 Brain computation compared to computation on a digital computer

An important component of the approach taken in this book is to describe what computations are performed, and then how they may be performed. This enables the different levels of analysis in neuroscience to be brought together in a multilevel causal account.

However, the types of computation that are performed by the brain, and the computational style, are very different from the type of computation performed by a digital computer, which performs specified logical / syntactic operations on exact data retrieved from memory, and then stores the exact result back in memory. To highlight some of the principles of brain computation described in this book, and to emphasize how the type of computation is very different from that performed by digital computers, the principles of computation by the brain are compared next with those of a digital computer, with a summary of some of the differences in Table 19.1.

Data addressing. An item of data is retrieved from the memory of a digital computer by providing the address of the data in memory, and then the data can be manipulated (moved,

Table 19.1 Brain computation vs Digital computer computation

Brain Computation	Digital computer computation
1. Dot product similarity followed by a threshold	vs logical functions e.g. AND, NAND, OR
2. 10,000 inputs per neuron	vs several inputs to a logic gate
3. Content-addressable memory	vs data accessed by address
4. Fault tolerant: dot product	vs no inherent fault tolerance
5. Generalization and completion	vs only exact match in the hardware
6. Fast: parallel update of a neuron and of neurons in a network	vs serial processing with fast components
7. Approximate, low precision	vs high precision 64 bit
8. Stochastic spiking noise: probabilistic computation helps originality, creativity	vs noise free implemented by non-linearities
9. Dynamics are parallel e.g. an attractor network retrieves in 1–2 time constants of the synapses	vs inherently serial
10. Heuristics, e.g. Invariant object recognition analyzes only part of a scene.	vs attempt to understand a whole scene
11. Syntax: none inherent	vs syntactical operations on data at an address
12. The architecture adapts by learning to implement the computation.	vs fixed architecture with different software
13. Sparse distributed representation	vs binary encoding in a computer word
14. Mind vs brain	vs software vs hardware

compared, added to the data at another address in the computer etc.) using typically a 32-bit or 64-bit binary word of data. Pointers to memory locations are thus used extensively. In contrast, in the cortex, the data are used as the access key (in for example a pattern associator, autoassociator, and competitive network, see Appendix B), and the neurons with synaptic weights that match the data respond. Memory in the brain is thus **content-addressable**. In one time constant of the synapses / cell membranes, the brain has thus found the correct output. In contrast, in a digital computer a serial search is required, in which the data at every address must be retrieved and compared in turn to the test data to discover if there is a match.

Vector similarity vs logical operations. Cortical computation including that performed by associative memories and competitive networks operates by vector similarity – the dot (inner) product of the input and of the synaptic weight vector of each neuron are produced, and the neurons with the highest dot product will be most activated (Section 1.4 and Appendix B). Even if an exact match is not found, some output is likely to result. In contrast, in a digital computer, logical operations (such as AND, OR, XOR) and exact mathematical operations (such as addition, subtraction, multiplication, and division) are computed. (There is no bit-wise similarity between the binary representations of 7 (0111) and 8 (1000).) The similarity computations performed by the brain may be very useful, in enabling similarities to be seen and parallels to be drawn, and this may be an interesting aspect of human creativity, realized for example in *Finnegans’s Wake* by James Joyce in which thoughts reached by associative thinking abound. However, the lateral thinking must be controlled, to prevent bizarre similarities being found, and this is argued to be related to the symptoms of schizophrenia in Section 18.3.

Fault tolerance. Because exact computations are performed in a digital computer, there is no in-built fault tolerance or graceful degradation. If one bit of a memory has a fault, the whole memory chip must be discarded. In contrast, the brain is naturally fault tolerant, because it uses vector similarity (by neurons using their input firing rate vectors and synaptic weight vectors) in its calculations, and linked to this, distributed representations. This makes the brain robust developmentally with respect to ‘missing synapses’, and robust with respect

to later losing some synapses or neurons (see Appendix B).

Word length. To enable the vector similarity comparison to have high capacity (for example memory capacity) the ‘word length’ in the brain is typically long, with between 10,000 and 50,000 synapses onto every neuron being common in cortical areas. (Remember that the leading term in the factor that determines the storage capacity of an associative memory is the number of synapses per neuron – see Sections B.2 and B.3.) In contrast, the word length in typical digital computers at 32 or 64 bits is much shorter, though with the binary and exact encoding used this allows great precision in a digital computer.

Readability of the code. To comment further on the encoding: in the cortex, the code must not be too compact, so that it can be read by neuronally plausible dot product decoding and can use vector similarity to generalize to similar patterns (Rolls, 2016b), as shown in Sections 1.7, B.2.4.3 and C.3.1, and throughout Appendices B and C. In contrast, the binary encoding used in a digital computer is optimally efficient, with one bit stored and retrievable for each binary memory location. However, the computer binary code cannot be read by neuronally plausible dot-product decoding.

Precision. The precision of the components in a digital computer is that every modifiable memory location must store one bit accurately. In contrast, it is of interest that synapses in the brain need not work with exact precision, with for example typically less than one bit per synapse being usable in associative memories (Treves and Rolls, 1991; Rolls and Treves, 1998). The precision of the encoding of information in the firing rate of a neuron is likely to be a few bits – perhaps 3 – as judged by the standard deviation and firing rate range of individual cortical neurons (Appendix C).

The speed of computation. This brings us to the speed of computation. In the brain, considerable information can be read in 20 ms from the firing rate of an individual neuron (e.g. 0.2 bits), leading to estimates of 10–30 bits/s for primate temporal cortex visual neurons (Rolls, Treves and Tovee, 1997b; Rolls and Tovee, 1994), and 2–3 bits/s for rat hippocampal cells (Skaggs, McNaughton, Gothard and Markus, 1993; Rolls, 2016b; Rolls and Treves, 2011) (Appendix C). Though this is very slow compared to a digital computer, the brain does have the advantage that a single neuron receives spikes from thousands of individual neurons, and computes its output from all of these inputs within a period of approximately 10–20 ms (determined largely by the time constant of the synapses) (Rolls, 2016b). Moreover, each neuron, up to at least the order of tens of neurons, conveys independent information, as described in Appendix C.

Parallel vs serial processing. Computation in a conventional digital computer is inherently serial, with a single central processing unit that must fetch the data from a memory address, manipulate the word of data, and store it again at a memory address. In contrast, brain computation is parallel in at least three senses.

First, an individual neuron in performing a dot product between its input firing rate vector and its synaptic weight vector does operate in an analog way to sum all the injected currents through the thousands of synapses to calculate the activation h_i , and fire if a threshold is reached, in a time in the order of the synaptic time constant. To implement this on a digital computer would take $2C$ operations (C multiply operations, and C add operations, where C is the number of synapses per neuron – see Equation 1.1).

Second, each neuron in a single network (e.g. a small region of the cortex with of the order of hundreds of thousands of neurons) does this dot product computation in parallel, followed

by interaction through the GABA inhibitory neurons, which again is fast. (It is in the order of the time constant of the synapses involved, operates in continuous time, and does not have to wait at all until the dot product operation of the pyramidal cells has been completed by all neurons given the spontaneous neuronal activity that allows some neurons to reflect their changed inputs rapidly by when the next spike occurs.) This interaction sets the threshold in associative and competitive networks, and helps to set the sparseness of the representation of the population of neurons.

Third, different brain areas operate in parallel. An example is that the ventral visual stream computes object representations, while simultaneously the dorsal visual stream computes (inter alia) the types of global motion described by Rolls and Stringer (2006a) (Section 3.3), including for example a wheel rotating in the same direction as it traverses the visual field. Another example is that within a hierarchical system in the brain, every stage operates simultaneously, as a pipeline processor, with a good example being V1–V2–V4–IT (inferior temporal visual cortex), which can all operate simultaneously as the data are pipelined through (Chapter 2).

We could refer to the computation that takes place in different modules, that is in networks that are relatively separate in terms of the number of connections between modules relative to those within modules, such as those in the dorsal and ventral visual streams, as being parallel computation. Within a single module or network, such as the CA3 region of the hippocampus, or inferior temporal visual cortex, we could refer to the computation as being *parallel distributed computation*, in that the closely connected neurons in the network all contribute to the result of the computation. For example, with distributed representations in an attractor network, all the neurons interact with each other directly and through the inhibitory interneurons to retrieve and then maintain a stable pattern of neuronal firing in short-term memory (Section B.3). In a competitive network involved in pattern categorization, all the neurons interact through the inhibitory interneurons to result in an active population of neurons that represents the best match between the input stimulus and what has been learned previously by the network, with neurons with a poor match being inhibited by neurons with a good match (Section B.4). In a more complicated scenario with closely connected interacting modules, such as the prefrontal cortex and the inferior temporal cortex during top-down attention tasks and more generally forward and backward connections between adjacent cortical areas, we might also use the term parallel distributed computation, as the bottom-up and top-down interactions may be important in how the whole dynamical system of interconnected networks settles (see examples in Sections 13.6.1, 13.4, 2.12, and Appendix B).

Stochastic dynamics and probabilistic computation. Digital computers do not have noise to contend with as part of the computation, as they use binary logic levels, and perform exact computation. In contrast, brain computation is inherently noisy, and this gives it a non-exact, probabilistic, character. One of the sources of noise in the brain is the spiking activity of each neuron. Each neuron must transmit information by spikes, for an all-or-none spike carried along an axon ensures that the signal arrives faithfully, and is not subject to the uncertain cable transmission line losses of analog potentials. But once a neuron needs to spike, then it turns out to be important to have spontaneous activity, so that neurons do not all have to charge up from a hyperpolarized baseline whenever a new input is received. The fact that neurons are kept near threshold, with therefore some spontaneous spiking, is inherent to the rapid operation of for example autoassociative retrieval, as described in Section B.3. But keeping the neurons close to threshold, and the spiking activity received from other neurons, results in spontaneous spike trains that are approximately Poisson, that is with spikes randomly timed for a given mean firing rate. The result of the interaction of all these randomly timed inputs is that in a network of finite size (i.e. with a limited number of neurons) there will be statis-

tical fluctuations, that influence which memory is recalled, which decision is taken, etc. as described in Section 11.5.1 and Chapter 18. Thus brain computation is inherently noisy and probabilistic, and this has many advantages, as described in Section 11.5.1, Chapter 18, and by Rolls and Deco (2010) and Rolls (2016b).

Syntax. Digital computers can perform arbitrary syntactical operations on operands, because they use pointers to address each of the different operands required (corresponding even for example to the subject, the verb, and the object of a sentence). In contrast, as data are not accessed in the brain by pointers that can point anywhere, but instead just having neurons firing to represent a data item, a real problem arises in specifying which neurons firing represent for example the subject, the verb, and the object, and distributed representations potentially make this even more difficult. The brain thus inherently finds syntactical operations difficult (as explained in Section 14.5). We do not know how the brain implements the syntax required for language. But we do know that the firing of neurons conveys ‘meaning’ based on spatial location in the brain. For example, a neuron firing in V1 indicates that a bar or edge matching the filter characteristic of the neuron is present at a particular location in space. Another neuron in V1 encodes another feature at another position in space. A neuron in the inferior temporal visual cortex indicates (with other neurons helping to form a distributed representation) that a particular object or face is present in the visual scene. Perhaps the implementation of the syntax required for language that is implemented in the brain also utilizes the spatial location of the network in the cortex to help specify what syntactical role the representation should perform. This is a suggestion I make, as it is one way that the brain could deal with the implementation of the syntax required for language (Section 14.5).

Modifiable connectivity. The physical architecture (what is connected to what) of a digital computer is fixed. In contrast, the connectivity of the brain alters as a result of experience and learning, and indeed it is alterations in the strength of the synapses (which implement the connectivity) that underlie learning and memory. Indeed, self-organization in for example competitive networks has a strong influence on how the brain is matched to the statistics of the incoming signals from the world, and of the architecture that develops. In a digital computer, every connection must be specified. In contrast, in the brain there are far too few genes (of order 25,000) for the synaptic connections in the brain (of order 10^{15} , given approximately 10^{11} neurons each with in the order of 10^4 synapses) for the genes to specify every connection²². The genes must therefore specify some much more general rules, such as that each CA3 neuron should make approximately 12,000 synapses with other CA3 neurons, and receive approximately 48 synapses from dentate granule cells (see Chapter 9). The actual connections made would then be made randomly within these constraints, and then strengthened or weakened as a result of self-organization based on for example conjunctive pre- and postsynaptic activity. Some of the rules that may be specified genetically have been suggested on the basis of a comparison of the architecture of different brain areas (Rolls and Stringer, 2000; Rolls, 2016b). Moreover, it has been shown that if these rules are selected by a genetic algorithm based on the fitness of the network that self-organizes and learns based on these rules, then architectures are built that solve different computational problems in one-layer networks, including pattern association learning, autoassociation memory, and competitive learning (Rolls and Stringer, 2000; Rolls, 2016b) (see Section B.20). The architecture of the brain is thus interestingly adaptive, but guided in the long term by genetic selection of the

²²For comparison, a computer with 1 Gb of memory has approximately 10^{10} modifiable locations, and if it had a 100 Gb disk that would have approximately 10^{12} modifiable locations.

building rules.

Logic. The learning rules that are implemented in the brain that are most widely accepted are associative, as exemplified by LTP and LTD. This, and the vector similarity operations implemented by neurons, set the stage for processes such as pattern association, autoassociation, and competitive learning to occur naturally, but not for logical operations such as XOR and NAND or arithmetic operations. Of course, the non-linearity inherent in the firing threshold of neurons is important in many of the properties of associative memories and competitive learning, as described in Appendix B, and indeed are how some of the non-linearities that can be seen with attention can arise (Deco and Rolls, 2005b).

Dynamical interaction between modules. Because the brain has populations of neurons that are simultaneously active (operating in parallel), but are interconnected, many properties arise naturally in dynamical neural systems, including the interactions that give rise to top-down attention (Sections 13.4 and 2.12), the effects of mood on memory (Rolls and Stringer, 2001b; Rolls, 2014a) etc. Because simultaneous activity of different computational nodes does not occur in digital computers, these dynamical systems properties that arise from interacting subsystems do not occur naturally in digital computers, though they can be simulated.

The cortex has recurrent excitatory connections within a cortical area, and reciprocal, forward and feedback, connections between adjacent cortical areas in a hierarchy. The excitatory connections enable cortical activity to be maintained over short periods, making short-term memory an inherent property of the cortex. They also provide the autoassociative long-term memory with completion from a partial cue (given associative synaptic modifiability in these connections). However, completion on a digital computer is a difficult and serial process to identify a possible correct partial match. Another comparison is that the short-term memory property of the cortex is part of what makes the cortex a dynamical interacting system, with for example what is in short-term memory in the prefrontal cortex acting to influence memory recall, perception, and even what decision is taken, in other networks, by top-down biased competition (see Sections 13.4 and 2.12). There is a price that the brain pays for this positive feedback inherent in its recurrent cortical circuitry, which is that this circuitry is inherently unstable, and requires strong control by inhibitory interneurons to minimize the risk of epilepsy and other disorders (Chapter 18).

Modular organization. Brain organization is modular, with many relatively independent modules each performing a different function, whereas digital computers typically have a single central processing unit connected to memory. The cortex has many localized modules with dense connectivity within a module, and then connections to a few other modules. The reasons for the modularity of the brain are considered by Rolls (2016b).

Hierarchical organization. As described by Rolls (2016b), many cortical systems are organized hierarchically. A major reason for this is that this enables the connectivity to be kept within the limits of which neurons appear capable (up to 50,000 synapses per neuron), yet also enables global computation (such as the presence of a particular object anywhere in the visual field) to be achieved, as exemplified by VisNet, a model of invariant visual object recognition (see Fig. 2.2 and Chapter 2). Another important reason is that hierarchical organization simplifies the learning that is required at each stage and enables it to be a local operation, in contrast to backpropagation of error networks where similar problems could in principle be solved in a two-layer network (with one hidden layer), but would require training with a non-local learning rule (Appendix C) as well as potentially neurons with very large numbers of connections. Another feature of cortical organization is that the number of areas

or levels in any hierarchy in the brain is not more than 4 or 5, because each area requires 20–30 ms of computation and transmission time. (This of course contrasts with the hundreds of successive layers being explored with artificial neural networks, as described in Section B.14, which is completely biologically implausible in terms of response times.)

19.4 A comparison of brain computation with learning in artificial deep learning networks using error backpropagation

Learning in deep networks with error backpropagation (LeCun, Bengio and Hinton, 2015; Lillicrap, Santoro, Marris, Akerman and Hinton, 2020) is described in Section B.12. Attempts to compare the operation of hierarchical convolutional deep neural networks to the operation of the ventral visual cortical stream (Yamins and DiCarlo, 2016; Rajalingham, Issa, Bashivan, Kar, Schmidt and DiCarlo, 2018) are evaluated in Section 2.9.4. Here the biological plausibility and advantages and disadvantages of this deep learning compared with brain computation are considered.

A first problem in terms of biological plausibility of deep networks trained by error backpropagation is that these are typically supervised systems, with a separate teacher for each output neuron informing it how each output neuron should be responding for a given input pattern at the bottom layer of the network (LeCun et al., 2015; Lillicrap et al., 2020). There is no architecture that looks remotely like this in the cerebral cortex, with a separate teacher for each neuron. The only part of the brain where there is what might be a teacher for each neuron is in the cerebellum, where there is a single climbing fibre for each Purkinje cell, and a network with no hidden layers (Chapter 17). Progress is being made in unsupervised training of deep convolutional neural networks (Zhuang, Yan, Nayebi, Schrimpf, Frank, DiCarlo and Yamins, 2021) using for example principles utilised in autoencoders in which higher layers aim to reconstruct the signals in the input layer and update the connections based on the differences (the errors) (Lillicrap et al., 2020), but these still implement convolution and deep learning using non-local learning rules including backpropagation of error to optimize representations, so are still biologically implausible.

But the problem is deeper than that there is no teacher for each output neuron (and the other problems that appear to make deep learning biologically implausible described below). A bigger problem for backpropagation of error networks is that someone has to know what the output should be, for every neuron, that is, backprop is a supervised learning system in that error correction is performed. The great beauty of the brain in contrast is that it is a largely self-organizing system, without a teacher telling each neuron what to do, as is made evident throughout this book, with a simple example of such a system a hierarchically organised set of competitive networks with convergence from stage to stage, as described in Chapter 2. Such self-organizing networks learn what categories to form based on the statistics of the inputs arriving from the world. They often use special adaptations to learn those statistics in a useful way, such as the trace short-term memory learning rule described in Chapter 2 that enables invariant representations to be learned because over short time periods it is likely to be the same object that is being viewed. And they may benefit from guidance (mild supervision) provided by top-down signals from higher layers, as described in Section B.4.5.

In essence, a deep network trained by backpropagation of error tries to achieve an optimal mapping between input patterns and output patterns of neural activity. The number of neurons in each deep layer must be carefully adjusted to ensure that the system does not become just a look-up table, yet has sufficient neurons to enable the mapping and generalization required,

and the number of layers is often adjusted to be 100 or more to help to minimize overall errors. But a problem that arises is that what is being represented at each intermediate layer is very difficult to understand, and is likely to yield very little useful information to help understand the brain. There may be a lesson here, as follows:

At each stage of cortical processing, some output is always taken and directed to structures such as the striatum and basal ganglia for use in behavioral output. That is a key aspect of cortical design (Rolls, 2016b). It may reflect an interesting way in which the cortex evolves, by adding new areas each of which can produce useful output. That is not true of deep backprop networks.

An important point is that the brain does not solve a predetermined mapping problem from input to output, as in deep learning. Instead, the general architecture of the brain is specified by a relatively small number of genes that appear to specify what type of neuron connects to what other type to generate the architecture within and between cortical areas (Section B.20 and Chapter 19 of Rolls (2016b)). The brain then builds the details of its synaptic connectivities using self-organizing learning based on the environment in which it finds itself. This view has been developed by comparing the connectivity of different cortical areas, and then allowing genetic algorithms to select different combinations of the connectivity rules to build neural networks in computer simulations that can successfully solve different types of computational problem for which different architectures are needed (Rolls and Stringer, 2000; Rolls, 2016b) (Section B.20).

Another key feature of cortical design is that with its self-organizing principles rather than being taught what to compute, the cortex is able to solve complex problems with just a few layers, e.g. four, as described in Chapter 2 and by Rolls (2016b). The cortex is constrained to a few layers in the hierarchy, because each layer takes about 15 ms to compute including recurrent attractor operations, and the total compute time needs to be kept to less than 100 ms for biological utility. More layers could be tried in artificial self-organizing neural networks.

I hope that those interested in brain-inspired intelligence will look carefully at what the computational problems are that are solved by different parts of the brain, and will not only learn from our current understanding of how the brain performs its computations, but will also suggest new ways in which those computations may be performed. In this context, *Cerebral Cortex: Principles of Operation* (Rolls, 2016b) does set out principles of the organization of the brain many of which underlie its computational abilities and style.

There are other factors that make deep networks trained by backprop biologically implausible. Given that the signed error for a hidden neuron in an error backpropagation network is calculated by propagating backwards information based on the errors of all the output neurons to which a hidden neuron is connected, and all the relevant synaptic weights, and the activations of the output neurons to define the part of the activation function on which they are operating, it is implausible to suppose that the correct information to provide the appropriate signed error for each hidden neuron is propagated backwards between real neurons. A hidden neuron would have to ‘know’, or receive information about, the errors of all the neurons to which it is connected, and its synaptic weights to them, and their current activations (Section B.12). If there were more than one hidden layer, this would be even more difficult.

To expand on the difficulties: first, there would have to be a mechanism in the brain for providing an appropriate error signal to each output neuron in the network. With the possible exception of the cerebellum, an architecture where a separate error signal could be provided for each output neurons is difficult to identify in the brain. Second, as noted in Chapter 9 and by Rolls (2016b), the backprojection pathways that are present in the cortex seem suited to perform recall (Chapter 9) and to implement top-down attention (Sections 2.12 and B.8.4), and this might make it difficult for them also to have the correct strength to carry the correct error signal.

A problem with the backpropagation of error approach in a biological context is thus that in order to achieve their competence, backpropagation networks use what is almost certainly a learning rule that is much more powerful than those that could be implemented biologically, and achieve their excellent performance by performing the mapping through a minimal number of hidden neurons (Lillicrap, Santoro, Marris, Akerman and Hinton, 2020). In contrast, real neuronal networks in the brain probably use much less powerful learning rules, in which errors are not propagated backwards, and at the same time have very large numbers of hidden neurons, without the bottleneck that helps to provide backpropagation networks with their good performance. A consequence of these differences between backpropagation and biologically plausible networks may be that the way in which biological networks solve difficult problems may be rather different from the way in which backpropagation networks find mappings. Thus the solutions found by connectionist systems may not always be excellent guides to how biologically plausible networks may perform on similar problems. Part of the challenge for future work is to discover how more biologically plausible networks than backpropagation networks can solve comparably hard problems, and then to examine the properties of these networks, as a perhaps more accurate guide to brain computation (Lillicrap, Santoro, Marris, Akerman and Hinton, 2020).

As stated above, it is a major challenge for brain research to discover whether there are algorithms that will solve comparably difficult problems to backpropagation, but with a local learning rule (see also Lillicrap, Santoro, Marris, Akerman and Hinton (2020)). Such algorithms may be expected to require many more hidden neurons than backpropagation networks, in that the brain does not appear to use information bottlenecks to help it solve difficult problems. The issue here is that much of the power of backpropagation algorithms arises because there is a minimal number of hidden neurons to perform the required mapping using typically a final one-layer delta-rule network. Useful generalization arises in such networks because with a minimal number of hidden neurons, the net sets the representation they provide to enable appropriate generalization. The danger with more hidden neurons is that the network becomes a look-up table, with one hidden neuron for every required output, and generalization when the inputs vary becomes poor. The challenge is to find a more biologically plausible type of network that operates with large numbers of neurons, and yet that still provides useful generalization. An example of such an approach is described in Chapter 2 (Rolls, 2021d).

Another key difference between artificial deep learning approaches and real networks in humans and other primates is in the training. For deep learning with supervision, a very large number of exemplars, typically visual images, is presented each with a label to state its category. In contrast primates including humans experience a continuous world in which first one object is encountered for typically many seconds as it is held in the hand and viewed from different angles, or the individual moves round the world for example by crawling and sees the world gradually change as obstacles are moved round or bumped into or grasped. The latter type of real-world training allows temporal and spatial continuities about objects in the world to be learned, and that is the style of training used with VisNet (Chapter 2) in which continuities about visually transforming objects are used to help learn about the properties of objects and how they transform in the real world. With such different styles of training, it is likely to be difficult to use artificial deep learning networks trained by thousands of different labelled exemplars to understand how the real primate including human brain learns about the rules of perception, visual object recognition, etc. It is not clear what would be learned for example if a primate or human brain was trained only on thousands of labelled exemplars, rather than on the continuous input from the world in which the properties of objects and space can be learned as they continuously transform. It is not clear that whatever such an

individual learned would be at all like what is learned and is present in a real brain trained in a real natural environment.

What is described here and elsewhere (Rolls, 2016b, 2021d,b) may it is hoped be useful for developing better artificial neural networks and artificial intelligence. For example, convolutional neural networks are typically trained on very large numbers of single training image exemplars (snapshots) of the classes to be learned, and can fail if a few pixels are altered, implying that they learn pixel-level representations. It is proposed that training such networks with different transforms of objects with statistics of how objects transform in short time periods in the real world as in trace rule learning (Chapter 2) would much better enable transform-invariant shape-based representations to be learned, leading to much more powerful performance.

Limitations of current understanding of deep learning networks and how different they are from the computations performed by the brain, and how difficult it would be to implement a backprop equivalent in the brain perhaps with autoencoders without raising many further difficulties, have been highlighted by others (Plebe and Grasso, 2019; Sejnowski, 2020; Lillicrap, Santoro, Marris, Akerman and Hinton, 2020; Bowers, Malhotra, Dujmovic, Montero, Tsvetkov, Biscione, Puebla, Adolphi, Hummel, Heaton, Evans, Mitchell and Blything, 2023). The mild guidance of competitive learning by cortico-cortical backprojections described in Section B.4.5 may provide a brain-feasible and at least biologically plausible approach.

19.5 Reinforcement Learning

Reinforcement learning is another approach to understanding the function of some brain areas that has its origin in the machine learning literature (Sutton and Barto, 1998). Reinforcement learning is described in Section B.17, and evidence that the dopamine neurons encode a reward prediction error signal is described in Section 16.4.3 (Schultz, 2013, 2016c,b, 2017, 2019). Some evaluation about how it fits in with brain design follows.

Reinforcement learning utilizes a single reward or reinforcement signal to train a whole network. This is in contrast with backpropagation of error networks, which typically specify what the output should be of every output neuron for a given input pattern, which is a much more information-rich training signal. Reinforcement learning is thus in a sense simpler in terms of evolutionary design, because the single training signal can be broadcast widely in the neural network, without having to tell individual neurons how to respond, which is biologically implausible.

Reinforcement learning uses a widely broadcast reward prediction error signal to systems in the brain such as the basal ganglia. If there has been very recent neuronal activity at synapses that reflect coactivity of for example stimulus encoding and response encoding neurons, then those synaptic connections are strengthened if the dopamine input is high (see Chapter 16). In this way, stimulus-response habits may be set up in the basal ganglia. A property is that the reward is not part of what is learned, just the stimulus-response connection. So if the reward is devalued, the stimulus-response connection is still there, and the response is elicited when the stimulus occurs, even though the stimulus is no longer a goal for action. A further property is that the dopamine neurons seem to convey just a reward prediction error signal, and do not specify the type of reward, such as food, water, novelty, money etc. So lots of habits may be set up without the goal for which the habit may have been set up specified in the stimulus-response habit.

This is very different from the type of learning implemented in the orbitofrontal cortex to anterior cingulate cortex learning system to perform actions to obtain goals (with the goals the rewards specified by the orbitofrontal cortex) (Rolls, 2019c) (Chapter 12). Here there is

a potentially very precise specification of the outcome, and different actions can be learned to obtain different goals, even if the actions are very similar, but the outcomes are different. That is, a precise association is learned between a particular action and a particular outcome. To put it another way: the orbitofrontal cortex provides the anterior cingulate cortex with a high-dimensional reward signal with each type of reward specified as being different to other rewards, and this makes for a much more efficient learning system to enable any of a wide range of actions to be associated rapidly with any of a wide range of reward (see Section 12.2.2). Because the cingulate cortex initiates actions to obtain the goals or rewards specified by the orbitofrontal cortex (Rolls, 2019c), if the reward/goal stimulus is devalued, actions will not be performed. Moreover, the stimulus value can be reset in the orbitofrontal cortex by for example relearning or reversal of a stimulus-reward association, and that learning can be on one trial, again allowing great flexibility of action-outcome learning as implemented in the orbitofrontal cortex / anterior cingulate cortex system (Chapter 12 and Rolls (2019c)).

In comparison, with reinforcement learning and its very general reward prediction error signal, the learning tends to be slow, so that regular associations between a stimulus and a response can be evaluated, and stamped in by the dopamine modulator. If the system is not slow, then the reinforcement learning system risks setting up incorrect stimulus-response associations, because of chance stimulus and response co-occurrence, or because of noise-related effects in the brain.

The orbitofrontal cortex reward evaluation system, followed by an action-outcome system (Rolls, 2019c), thus appears to be a much more powerful learning system than reinforcement learning using a general reward prediction error signal. The reinforcement learning in which the basal ganglia and dopamine system are implicated (Schultz (2016c) and Chapter 16) may have been appropriate at early stages of evolution as it does not require a memory of the response that has just been made apart from a simple eligibility signal for synapses that have recently been active. The striatum and globus pallidus do not implement a short-term memory that could be used for a longer term ‘eligibility trace’, because the basal ganglia have no recurrent collateral connections to support a short-term memory (Chapter 16). On the other hand, the cingulate cortex as it is neocortex has a highly developed set of recurrent collaterals, and may therefore be much better suited to learning, when the actions may be followed by a delay before the outcome (reward) arrives, and where the results of the previous few choices can be accumulated (Chapter 12 and Rolls (2019c)).

A comparison of the computations involved in reversal learning helps to show why reinforcement learning as implemented in the basal ganglia using dopamine for stimulus–response habit learning is much less efficient than the orbitofrontal cortex – cingulate cortex action–outcome learning system. The learning considered is a visual discrimination task in which a choice of one visual stimulus leads to reward, and of the other to punishment / loss. When this occurs for the dopamine system, the reward prediction errors change, but new stimulus–response connections need to be learned. This may even mean a return to trial and error learning, where many different responses may be tried until a response is found that when following the stimulus leads to a positive reward prediction error. This then takes some time to train the system, for the reasons given above. In contrast, for the orbitofrontal cortex – cingulate cortex action–outcome system, when the reward association of the visual stimuli reverses, on the very next trial after an error, the orbitofrontal cortex expected value representations reverse. Accordingly, the next time a visual stimulus is shown, the correct expected value is sent to the cingulate cortex, which then performs the same action that it has already learned for that expected value input received from the orbitofrontal cortex. (This is described in Chapter 11.) So part of the power of the orbitofrontal cortex – cingulate cortex system is that it is a two stage learning process, and the visual stimulus to reward association process,

a stimulus–stimulus learning process implemented in the orbitofrontal cortex, can reverse in one trial, with no new action learning needed.

Additionally, as described above, the cingulate cortex is likely to be able to remember actions for longer times until the outcome becomes known when new actions need to be learned to obtain rewards; and can match actions to particular outcomes (such as food, water, money etc), whereas the reinforcement learning system uses just a single general reward prediction error. It also seems likely that the cingulate cortex has a repertoire of previously learned actions, which can rapidly be associated with new different outcomes by rapid associative learning between actions and outcomes (Rolls, 2019c).

For these reasons, I argue that the orbitofrontal cortex – cingulate cortex action–outcome learning system is a much more powerful way that the brain uses to deal with reward-related learning than the reinforcement learning stimulus-response dopamine reward prediction error habit system. Consistent with this, it is damage to the orbitofrontal cortex that has a great influence on our emotional and reward-related behavior and their disorders including depression, as described in Chapter 11 and elsewhere (Rolls, 2018a, 2019e), whereas the effects of damage to the dopamine system produce major motor problems including Parkinson’s disease. In this context, we should remember that stimulus-response learning is a simple type of motor learning.

I have also argued that reward prediction error neurons do not themselves relate to emotion, because emotions can still occur to rewarding or punishing stimuli even when there is no new learning and no reward prediction error (Rolls, 2018a, 2019e) (Chapter 11). That is, emotions are states elicited by rewards or punishers, not by reward prediction errors (Rolls, 2014a, 2018a, 2019e) (Chapter 11).

I thus argue that reinforcement learning in the brain involving dopamine neurons, despite great interest in it (Schultz, 2013, 2016c,b, 2017; O’Doherty et al., 2017), is a rather specialized brain system, and that other processes, described in Chapters 11 and 12 are involved in much reward and goal-related behavior, and in emotion.

The reinforcement learning algorithm can be applied in deep networks (Botvinick et al., 2019), that is, in a network with one or more hidden layers (see Appendix B). Indeed, artificial neural networks of this type have become popular in Artificial Intelligence, and can perform well in Atari video games, Go, and Capture the Flag (Botvinick et al., 2019). However, such systems do require a great deal of training, so produce slow learning. Variations have been tried, such as incorporation of a type of episodic memory about rewards received in previous similar situations, and that can speed up the learning (Botvinick et al., 2019). However, if reinforcement learning in the brain is used mainly in the basal ganglia, then the type of problem to which it is applied is at least usually rather simple, stimulus-response habit learning (see Chapter 16). On the other hand, use of a hippocampal episodic memory system to remember the outcome when a previous situation occurred might be a solution that could be used that would not require reinforcement learning.

19.6 Levels of explanation, and the mind-brain problem

19.6.1 A levels of explanation theory of causality, and the relation between the mind and the brain

We can now understand brain processing from the level of ion channels in neurons, through neuronal biophysics, to neuronal firing, through the computations performed by populations of neurons, and how their activity is reflected by functional neuroimaging, to behavioral and

cognitive effects (Rolls, 2016b; Rolls and Deco, 2010; Rolls, 2014a, 2021b). Activity at any one level can be used to understand activity at the next. This raises the philosophical issue of how we should consider causality with these different levels (Rolls, 2020a, 2012e, 2021g,e). Does the brain cause effects in the mind, or do events at the mind level cause brain activity?

What is the relation between the mind and the brain? This is the mind–brain or mind–body problem. Do mental, mind, events cause brain events? Do brain events cause mental effects? What can we learn from the relation between software and hardware in a computer about mind–brain interactions and how causality operates? Neuroscience shows that there is a close relation between mind and matter (captured by the following inverted saying: ‘Never matter, no mind’).

My view (Rolls, 2016b, 2020a, 2021g,e) is that the relationship between mental events and neurophysiological events is similar to the relationship between the program running in a computer and the hardware of the computer. Does the program (the software loaded onto the computer usually written in a high-level language such as C or Matlab) ‘cause’ the logic gates (TTL, transistor-transistor logic) of the hardware to move to the next state? And does this hardware state change ‘cause’ the program to move to its next step or state?

I propose that one way to think about this is that when we are looking at different levels of what is overall the operation of a system, causality can usefully be understood as operating within levels (causing one step of the program to move to the next; or the neurons to move from one state to another), but not between levels (e.g. software to hardware and vice versa). That is, if the events at the different levels of explanation are occurring simultaneously, without a time delay, then my view is that we should not think of causality as operating between levels, but just that what happens at a higher level may be an emergent property of what happens at a lower level. This is the solution I propose to this aspect of the mind-brain problem (Rolls, 2020a, 2021g,e).

Following this thinking, when one step of a process at one level of explanation moves to the next step in time, we can speak of causality that would meet the criteria for Granger causality where one time series, including the time series being considered, can be used to predict the next step in time (Section 13.4) (Granger, 1969; Ge, Feng, Grabenhorst and Rolls, 2012; Bressler and Seth, 2011). In contrast, when we consider the relationship between processes described at different levels of explanation, such as the relation between a step in the hardware in a computer and a step in the software, then these processes may occur simultaneously, and be inextricably linked with each other, and just be different ways of describing the same process, so that temporal (Granger) causality does not apply to this relation between levels, but only within levels. The whole processing can now be specified from the mechanistic level of neuronal firings, etc. up through the computational level to the cognitive and behavioral level.

In the neuroscience-based approach that I propose for the relation between the mind and the brain, the proposal is that events at the sub-neuronal, neuronal, and neuronal network levels take place simultaneously to perform a computation that can be described at a high level as a mental state, with content about the world (Rolls, 2021g). It is argued that as the processes at the different levels of explanation take place at the same time, they are linked by a non-causal relationship: causality can best be described in brains as operating within but not between levels. This mind-brain theory allows mental events to be different in kind from the mechanistic events that underlie them; but does not lead one to argue that mental events cause brain events, or vice versa: they are different levels of explanation of the operation of the computational system (Rolls, 2021g).

The proposal has been developed further (Rolls, 2021e), and it is proposed that causality, at least as it applies to the brain, should satisfy three conditions. First, interventionist tests for causality (Kim, 2011; Woodward, 2015, 2005, 2021b,a, 2020; Craver and Bechtel, 2007)

must be satisfied. If one intervenes to remove a potential cause, and the putative effect no longer occurs, then that makes it more likely that the potential cause does cause the putative effect. More formally, where X and Y are variables, X causes Y *iff* there are some possible interventions that would change the value of X and if such intervention were to occur, a regular change in the value of Y would occur (Woodward, 2021b, 2020). Second, the causally related events should be at the same level of explanation. The bases of the argument include the point that the processes that occur at the different levels can occur simultaneously (for example the mental and brain event, or the mathematical or logic operation performed by a computer and the current flow within its arithmetic logic unit), whereas causal processes can be understood to involve sequences of events in time with the operations performed within a level (Rolls, 2021g,e). Third, a temporal order condition must be satisfied, with a suitable time scale in the order of 10 ms for brain processing (to exclude application to quantum physics; and a cause cannot follow an effect) (Rolls, 2021e). Next, although it may be useful for different purposes to describe causality involving the mind and brain at the mental level, or at the brain level, it is argued that the brain level may sometimes be more accurate, for sometimes causal accounts at the mental level may arise from confabulation by the mentalee, whereas understanding exactly what computations have occurred in the brain that result in a choice or action will provide the correct causal account for why a choice or action was made (Rolls, 2021e) (see Section 11.3.9).

19.6.2 Downward or Upward Causality?

In addition, it is argued that possible cases of ‘downward causation’ (or ‘upward causation’) can be accounted for by a within-levels-of-explanation account of causality (Rolls, 2021e). One example might be that excessive synaptic pruning or reductions in synaptic transmission produced by lower NMDA receptor efficacy may causally contribute to some of the cognitive and behavioral symptoms of schizophrenia (Rolls, 2021a). As these changes in synaptic transmission relate to the symptoms (which involve the whole person), should this be considered as a case of across-level causation (Woodward, 2021b,a)? (In this case, it would be upward causation, from synapses to cognitive symptoms.) In the present case, my account is that reduced synaptic transmission (caused for example by high synaptic pruning or reduced NMDA receptor conductances) reduces the firing rates of populations of neurons, which destabilizes the attractor neuronal networks in the prefrontal cortex (Rolls, 2021a,b). Now these prefrontal cortex attractor networks are involved in maintaining items in short-term memory, and in holding on-line in short-term memory the top-down bias required to bias processing in some parts of the brain thus providing a mechanism for top-down attention (Rolls, 2021b; Deco and Rolls, 2005b,a; Luo et al., 2013). The computational level of events in the brain thus provides a causal, computational, account of how these synaptic events alter behavior so that attention and short-term memory change. But the causal level is within-level in this approach, at the level of synapses, transmitters, receptors, and neuronal networks; and the behavioral changes occur at the same time, but are descriptions at a higher level of explanation. In such systems we can describe necessary relations between levels, or superveniences between levels of operation of the system, but the mechanistic, causal, computational account is best dealt with in this case at the brain level of explanation.

Another possible case considered as ‘downward causation’ in physics is when a higher level Law ‘causes’ an effect at a lower level (Ellis, 2020). Let us take as an example the interaction between neurons in a population that falls into a low energy attractor basin (Hopfield, 1982; Amit, 1989; Amit et al., 1985). This happens to be a system that is highly relevant to understanding the operation of the cerebral cortex, as the most characteristic attribute of cerebral cortex is the highly developed excitatory recurrent collateral local connections between

pyramidal cells that enable local attractor networks to be implemented for short-term memory, long-term memory, top-down attention, decision-making, etc. (Rolls, 2016b, 2021b). The interaction between the neurons (equivalent to spins in a physics model) can be analyzed at the population level (but not at the single neuron level) to show how the whole network can fall into an attractor state, and to specify the number of possible attractor states, for example the maximum number of different memory patterns, that can be stored and correctly retrieved.

One concept of causality that has been advanced for systems with different levels is that because a Law can be specified for a system such as the number of stable memory states and hence memory capacity at a high level (the population of neurons level), then that Law or rule of operation formulated at the high level provides ‘downward causation’ to the lower level (Ellis, 2020), to in this case result in the number of stable attractor basins being limited to what is shown by mathematical analysis using the methods of theoretical physics to be possible (Hopfield, 1982; Amit, 1989; Amit et al., 1985; Treves, 1991b; Treves and Rolls, 1991).

But that is not how I see the system as operating in terms of causality. The individual neurons at the lower level do not wait for a top-down signal from the population level to tell them what to do next. Instead, it just is a property of the whole system that the individual neurons at the lower level operate as neurons each with a certain number of connections to the other neurons, and the result of the lower level interactions between the neurons is that only a certain number of stable states can be stored and correctly retrieved. To elucidate further, when we simulate such an attractor network in a computer, we set up for example neurons with threshold linear activation functions, and modify the synaptic connections between the neurons to store the memory patterns, and then we let the system run (Rolls, 2012b, 2021b). We find that as we increase the number of memory patterns stored in the system, at some point, the critical capacity, the recalled memories become very poor, and the system no longer works as a memory system (Rolls, 2012b). But we do not include in the program that we write that the neuron-level implementation should check up to some higher level to find out if the number of patterns specified by the Law specifying the critical capacity has been exceeded, and if so fall into a random neuronal firing (or spin) state. Nor is there a high-level part of the program that knows about the equations that specify the capacity and checks if the number of memories to be stored is too high for the critical capacity, and if so causes the lower level to fall into a random spin state (i.e. a random set of neurons firing). So the operation of the system is implemented only at the lower level, and that is where causality acts, by the firing of individual neurons influencing other neurons through the modified synaptic weights. Now of course the operation of the system in terms of its storage capacity can be explained, and analyzed, at the higher level, where the interactions between the whole population of neurons can be understood, and specified as rules or Laws of the operation of the system. But that does not mean that the higher level rules or Laws that describe the operation of the whole system have to act down to the lower level to cause effects there at the low level, whether synchronously, or after a time delay. Thus I reject the concept (Ellis, 2020), at least in relation to the operation of the brain, that Laws that apply at a high level act by ‘downward causation’ to control the operation of the system at a lower level. The high level Laws just express some properties of the system.

Thus my view of the mind–brain issue is that we are considering the process as a mechanism with different levels of explanation. As described above, we can now understand brain processing from the level of ion channels in neurons, through neuronal biophysics, to neuronal firing, through the computations performed by populations of neurons, to behavioral and cognitive effects, and even perhaps to the phenomenal (feeling) aspects of consciousness (Rolls, 2020a, 2016b). The whole processing is now specified from the mechanistic level of neuronal firings, etc. up through the computational level to the cognitive and behavioral level.

Sometimes the cognitive effects seem remarkable, for example the recall of a whole memory from a part of it, and we describe this as an ‘emergent property’, but once understood from the mechanistic level upwards, the functions implemented are elegant and wonderful, but understandable and not magical or poorly understood (Rolls, 2016b, 2012e, 2021g,e).

This computational neuroscience levels of explanation approach to causality provides an opportunity to proceed beyond Cartesian dualism (Descartes, 1644) and physical reductionism (Carruthers, 2019) in considering the relations between the mind and the brain. What I propose (Rolls, 2021g,e) is that a necessary relation between the different levels of explanation needs to be established, and that can be done using interventionist tests (Kim, 2011; Woodward, 2015, 2005, 2021b,a, 2020; Craver and Bechtel, 2007) as described above (Section 19.6.1). But because the transitions at the different levels take place simultaneously, we should not think of different levels as causing effects in each other, for the reasons described earlier in this subsection 19.6.2. Instead, we should think of causality as operating within each level, and identifiable by time delays in the causal chain of events within each level of explanation and analysis. In this analysis, time delays (post hoc, ergo propter hoc, ‘after that, therefore because of that’) are an important property of causality (at the macro not subatomic level). So there is a necessary relation between some brain and mental events, but the relation should be thought of as necessary (when established), but not causal.

The point I make is that however one thinks about causality in such a mechanistic system with interesting ‘emergent’ computational properties, the system is now well-defined, is no longer mysterious or magical, and we have now from a combination of neuroscience and analyses of the type used in theoretical physics a clear understanding of the properties of neural systems and how cognition emerges from neural mechanisms. There are of course particular problems that remain to be resolved with this approach, such as that of how language is implemented in the brain, but my point is that this mechanistic approach, supported by parsimony, appears to be capable of leading us to a full understanding of brain function, cognition, and behavior. However, the property of phenomenal consciousness is a big step for an ‘emergent property’, and that hard problem is therefore considered elsewhere (Rolls, 2020a, 2012e, 2021g,e, 2016b, 2004b). A summary follows.

19.6.3 Consciousness - a Higher Order Syntactic Thought theory

The global workspace hypothesis of consciousness holds that many different brain systems need to interact to account for consciousness (Dehaene, 2014; Dehaene et al., 2017; van Vugt et al., 2018; Lau, 2022). However, there are problems with this approach, for example about exactly how global the workspace needs to be for consciousness to suddenly be present (Rolls, 2020a; Lau, 2022). Humans can perform many complex tasks, including apparently driving a car for a short period, without being able to report about the driving if they were thinking about something else, which they can report about. Yet driving a car might be thought to require a rather large workspace. Problems are also raised (Rolls, 2020a) with a version that excludes conceptual (categorical or discrete) representations, and in which phenomenal consciousness can be reduced to physical processes (Carruthers, 2019).

Instead a different levels of explanation approach to the relation between the brain and the mind has been advocated (Rolls, 2020a; Rolls et al., 2022b; Rolls and Deco, 2015a). Further, a different theory of phenomenal consciousness is described, in which there is a particular computational system involved in which Higher Order Syntactic Thoughts (HOSTs) are used to perform credit assignment on first order thoughts of multiple step plans to correct them by manipulating symbols in a syntactic type of working memory (Rolls, 2020a). This provides a

good evolutionary reason for the evolution of this kind of computational module, with which, it is proposed, phenomenal consciousness is associated (Rolls, 2020a).

Some advantages of this HOST approach to phenomenal consciousness compared to other Higher Order Thought (HOT) theories (Rosenthal, 2012; Lau and Rosenthal, 2011) have been described (Rolls, 2020a). For example, a multi-step thought or planning system has a potential credit assignment problem (which step in the multistep process caused the process to fail), and the incorrect step needs to be identified, for which a natural method is to think about the plan, and work out which step may have produced the error (Rolls, 2020a). It is hypothesized that the HOST system which requires the ability to manipulate first (or lower) order symbols in working memory might utilize parts of the prefrontal cortex implicated in working memory, and especially the left inferior frontal gyrus, which is involved in language and probably syntactical processing (Rolls, 2020a; Rolls et al., 2022b; Rolls and Deco, 2015a). Overall, the approach advocated is to identify the computations that are linked to consciousness, and to analyze the neural bases of those computations (Rolls, 2020a).

This Higher Order Syntactic Thought theory of consciousness (Rolls, 2020a) differs from that of Lau (2022), who proposes that consciousness involves a higher order monitoring of perceptual reality that could be used to correct problems such as an incorrect threshold for perceptual input. However, that type of problem could include a signal-to-noise ratio problem, which need have nothing to do with consciousness. A simple algorithm can separate neural noise (Lau's source of interference) from a signal. And it is not clear how a Higher Order Thought could correct the engineering issue of a signal to noise ratio problem by adjusting the threshold by just thinking about it. But if the theory (Lau, 2022) is that one needs to reason about the sensory (or any other processing) to see whether it needs to be corrected, then it becomes a theory very much like my HOST theory of consciousness (Rolls, 2020a), except that I argue that the monitoring that is needed and that would be computationally useful is that of thoughts, in which a credit assignment problem could arise, and which could be corrected by a higher order syntactic thought about a lower order syntactic thought, and this would be very useful for any multistep planning (Rolls, 2020a).

I then argue that it is plausible to think that a system that was performing this type of computation, thinking about its own thoughts, with the lower order thoughts grounded in the world, would feel conscious. That is of course a plausibility argument, but a plausible one (Rolls, 2020a, 1997b,a, 2004b, 2007a,b, 2008a, 2010c, 2011b, 2014a). And the HOST theory is testable, for example by intervening by temporary inactivation of this type of computation in the brain, to test whether consciousness is affected by this intervention.

19.6.4 Levels of explanation, and levels of investigation

It will be evident from the approach taken in this book that to understand how the brain works, we need to understand what is computed in each brain area, as well as how it is computed. It should be evident that the level at which information is exchanged between the computing elements of the brain is the firing of single neurons, with the evidence set out by Rolls (2016b) and elsewhere (Rolls, 2021g,e).

It is important to investigate this at the level of single neurons, and populations of single neurons, because neurons often have relatively independent responses as is made clear in Appendix C, so that it is only possible to know what is represented in a brain area by utilising evidence from neuronal firing.

Operating at a higher level, such as the signals measured in functional neuroimaging that reflect the activity of thousands of neurons, does not lend itself well to making computational models of how the brain works, because one does not know exactly what is represented at each successive stage. Thus methods such as fMRI may be useful for obtaining some evidence

on the functions of different brain areas, but do need to be complemented where possible by evidence on the firing of neurons (which of course is often not possible in humans).

The architecture of the cerebral cortex is also considerably localised, with among the evolutionary reasons that this design minimises the connection length between neurons, and also the genetic information needed to specify cortical design, as set out in *Cerebral Cortex* (Rolls, 2016b). Those are among the reasons why there are hierarchically organised networks in the brain, with the major connections between adjacent cortical areas in the hierarchy. The level of granularity here corresponds to for example V1, V2, V4, posterior inferior temporal cortex, and anterior inferior temporal cortex, with frequently cytoarchitectural differences between such areas leading to classifications at about the level of Brodmann areas. There is also a finer level of granularity, specified by the radial extents of cortical pyramidal cell dendrites and their axons, which have a high density with a radius of 2–3 mm, and provide a basis for local cortical attractor networks (Rolls, 2016b).

The level of analysis just described, in which the different computational roles of each brain area are addressed using methods such as comparing neuronal activity in different stages of the processing, and double dissociation of the effects of brain lesions or inactivation of neuronal populations, sits uncomfortably with brain networks identified with some neuroimaging approaches in which correlations between the BOLD signals of many brain areas are found, leading to identification of a few brain networks (Ryali, Supekar, Chen, Kochalka, Cai, Nicholas, Padmanabhan and Menon, 2016). If these reflect just descriptions of correlations, that is one thing, but when simple functions are attributed to such networks, then that may be an oversimplification (or indeed misdiagnosis) of exactly what is computed in each brain region, which is the different approach taken here.

For example, these large-scale networks identifiable with neuroimaging correlation-based measures have been described as follows: “The Saliency Network (SN) (Menon and Uddin, 2010) is a limbic-paralimbic network anchored in the anterior insula and dorsal anterior cingulate cortex with prominent subcortical nodes in affective and reward processing regions including the amygdala and ventral striatum. The Saliency Network plays an important role in orienting attention to behaviorally and emotionally salient and rewarding stimuli and facilitating goal-directed behavior. The fronto-parietal Central Executive Network (CEN) is anchored in the dorsolateral prefrontal cortex and supramarginal gyrus and is critical for actively maintaining and manipulating information in working memory. The Default Mode Network (DMN) is anchored in the posterior cingulate cortex, medial prefrontal cortex, medial temporal lobe, and angular gyrus and is involved in self-referential mental activity and autobiographical memory” (Ryali, Supekar, Chen, Kochalka, Cai, Nicholas, Padmanabhan and Menon, 2016).

To take the Saliency Network (Menon and Uddin, 2010) as an example, it is clear that the dorsal anterior insula is the primary taste cortex, and that there is an area ventral to it that is probably visceral/autonomic cortex (Rolls, 2016c; Critchley and Harrison, 2013; Hassanpour et al., 2018), and is shown in the ventral parts of the anterior insula in Fig. 2 of Baylis, Rolls and Baylis (1995). The autonomic cortex during salient and emotional events is likely to produce autonomic output (alterations of heart rate and variability, sweating, and skin conductance), and far from ‘altering attention to behaviorally and emotionally salient and reward stimuli’ (Menon and Uddin, 2010), it is likely to receive outputs about such stimuli from the orbitofrontal cortex, which has strong connections to it, so that the anterior insular cortex provides a pathway to autonomic output (Rolls, 2016c, 2019e). The taste insula of primates is not involved in taste reward according to the experimental evidence (Rolls, 2016c, 2019e) (Chapter 4). And much of the rest of the insula is involved in somatosensory processing (Chapter 6). And the anterior cingulate cortex receives reward and punishment information from the

orbitofrontal cortex, and uses this reward outcome information for action-outcome learning (Rolls, 2019c) (Chapter 12).

So it appears that a lot is lost if simple functions are ascribed to these large-scale human cortical networks such as the saliency network, and such concepts may not have much explanatory value. Instead the goal that I advocate is to identify what computations are performed by each cortical area. Each area will of course transmit information to other specialised cortical areas. And together in their complementary ways they will produce a particular computation of a brain system. The brain regions to which I refer might previously have been defined as for example Brodmann areas based on cytoarchitecture (Section 1.11). But now the Human Connectome Project has moved the enterprise forward, by delineating 360 cortical regions each defined by multiple, multimodal, methods including anatomy, functional connectivity, and task-related activations (Glasser, Coalson, Robinson, Hacker, Harwell, Yacoub, Ugurbil, Andersson, Beckmann, Jenkinson, Smith and Van Essen, 2016a) (Section 1.12), and this now provides a useful current approach to defining cortical regions each of which may have different computational functions. 66 subcortical regions have been added in an extended version of this atlas (Huang, Rolls, Feng and Lin, 2022).

19.7 Biologically plausible computation in the brain: a grand unifying theory?

In an interesting and perceptive review in the journal *Brain* of *Brain Computations: What and How* (Rolls, 2021b), Manohar (2022) raised the question of whether the book provides ‘a grand unifying theory’ of brain function with the computational neuroscience approach taken in that book. My response to that is that the approach taken in *Brain Computations: What and How* and in the present book *Brain Computations and Connectivity* is indeed aiming to provide exactly that, a comprehensive theory of the operation of the brain, and is pioneering in that it forges and provides the foundation of a biologically plausible computational approach to brain function.

The approach taken is a biologically plausible approach to how the brain computes, rather than invoking the artificial intelligence approach of deep learning to try to account for brain computation. The approach to how the brain computes in this book is biologically plausible in that it utilises only local synaptic modification rules to set up the synaptic connections between neurons, and primarily unsupervised learning, yet considers how far this can take us in understanding how the brain operates. This approach is quite different to the deep learning approach used now in much machine learning and AI, which typically backpropagates an error back down through the network to correct every synaptic weight in all preceding layers of the network (LeCun et al., 2015; Lillcrap et al., 2020), but that is not easily consistent with cortical connectivity and function, as described in Section 19.4. Moreover, the learning in the brain is largely unsupervised, whereas deep learning approaches typically require a supervisor for each output neuron, which in turn requires what must be computed for each output neuron to be specified by the designer of the deep network. The point is developed (in Section 19.4) that machine learning might benefit from understanding some of the unsupervised approaches used by the brain to solve complex problems, including navigation, attention, semantics, and even syntax. The title of this book, *Brain Computations and Connectivity*, refers to the concept that the actual connectivity at the local level of neurons and synapses that is found in the brain, and between brain regions, is important in understanding what and how the brain computes.

In this book, much new evidence has been provided that is important to this biologically plausible computational neuroscience approach in that the connectivity studies of the 360

cortical areas defined in the Human Connectome Project Multimodal Parcellation atlas (HCP-MMP) (Glasser et al., 2016a; Huang et al., 2022) that are described in this book (Huang et al., 2021; Ma et al., 2022a; Rolls et al., 2022a, 2023c,i,d, 2022b, 2023e,h,f,b,a) provide a framework to help understand better what computation is being performed in each of these brain regions, and how the results of that computation are fed primarily to a limited set of further cortical regions to which strong effective connectivity is directed. This book therefore helps to bring the computational neuroscience approach developed in *Cerebral Cortex: Principles of Operation* (Rolls, 2016b) and *Brain Computations: What and How* (Rolls, 2021b) to relate much more closely to the different cortical regions of the human brain, which is a key step in the biologically plausible approach to understanding brain computation developed in this book.

We can then ask whether the biologically plausible networks described in these books (Rolls, 2016b, 2021b, 2023a) are sufficient to account for brain computation.

A pattern association network (Section B.2) is excellent for recalling a stimulus or event with which a stimulus has been associated. A simple example is an association between a previously neutral visual stimulus, such as the sight of an object, with the taste of a food reward, to produce an expected reward value representation, that can be used to guide goal-directed actions to obtain the taste reward outcome. This type of learning is key in emotional learning (Chapter 11). This type of pattern association is also fundamental to how the backprojection pathways from the hippocampus to the neocortex in the brain are used to recall episodic memories to the neocortex (Section 9.3.8), and also to how backprojection pathways are used to implement top-down attention (Section 2.12).

An autoassociation network (Section B.3) performs *the* key type of cortical computation, and is implemented by the highly developed excitatory local recurrent collateral connections between nearby pyramidal cells in the neocortex (Section 1.14.5), or throughout the CA3 neurons of the hippocampus (Chapter 9). One key computational property is that the self-re-excitation of any one of many different sets of neurons with strong connections between them can maintain the firing of that set of neurons to implement short-term memory, and to provide a foundation for working memory and planning (Chapter 13). But this computational ability is useful not only for what we might think of as short-term memory functions, but for many other functions. An important example in sensory cortices is to maintain activity for sufficiently long, in the order of one to several seconds, for the statistics of the world to be able to guide the learning of representations that are useful because they capture the properties of stimuli that all can be produced by the same object or stimulus. A key example is the trace learning rule in VisNet to help learn invariant representations (Section 2.8). A key computational property that is provided here is that this is relatively unsupervised learning: there is no teacher for each output neuron, and no need to prespecify what categories should be formed, which is a limitation of brain computation that is used in typical supervised deep learning artificial neural networks. The point here is that the cortical recurrent collaterals can help to maintain neuronal activity in a population of neurons for sufficiently long to enable invariant representations to be formed based on the statistics of the input from the world. The same principle is useful in coordinate transforms learned by gain modulation (Section 3.5), and in the learning of global motion in the dorsal visual system (Section 3.3).

Another key property of autoassociation networks is that the whole of the representation, for example a whole memory, can be retrieved from any one part. This is key in the mechanisms of episodic memory (Chapter 9). It is emphasised that this is not a property of a pattern association network.

A key feature of pattern association and autoassociation networks in the brain is that they have a high capacity, which is in the order of the number of associatively modifiable synapses on any one neuron in a network with sparse representations (Sections B.2 and B.3). A typical

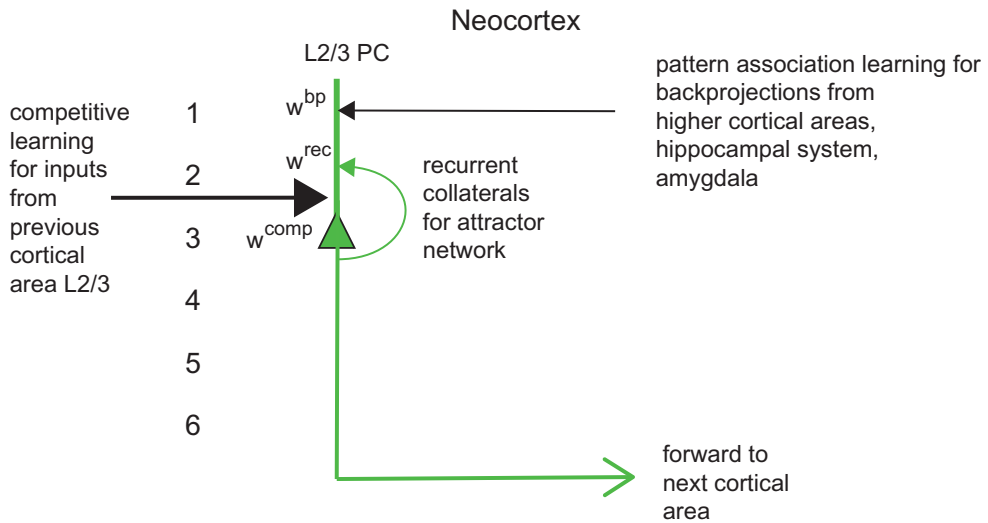

Fig. 19.1 The neocortical model that combines competitive learning using the forward inputs from the preceding cortical region, with associatively modifiable recurrent collateral synapses to form an autoassociation attractor network to maintain neuronal firing for short periods, and with pattern association learning to implement recall or top-down attention using cortico-cortical backprojections. L2/3 PC is a layer 2/3 pyramidal cell. The thick line above the pyramidal cell body is the dendrite, receiving inputs from the previous cortical area and operating by competitive learning using the synapses w^{comp} ; from the recurrent collaterals that operate as an attractor network using synapses w^{rec} ; and back-projections from higher cortical areas for memory recall and top-down attention that operate by pattern association learning using the synapses w^{bp} . 1-6 : the layers of the neocortex. (Reprinted from Rolls (2021) The connections of neocortical pyramidal cells can implement the learning of new categories, attractor memory, and top-down recall and attention. Brain Structure and Function 226: 2523-2536. © Springer.)

cortical neuron might have approximately 10,000 associatively modifiable synapses, so the storage capacity of a single local neocortical network which might be approximately 1–2 mm in diameter (and containing 100,000 neurons given the diluted connectivity that is a feature of the cortex) could store in the order of 10,000 memories, which is the size of a person’s typical working vocabulary. (And that may not be just a co-incidence.)

However a key property of the neocortex is that it learns new representations: it can categorise incoming stimuli for example as one type of object, or another. The key type of biologically plausible network for this type of learning is a competitive network (Section B.4). It can usefully allocate inputs that regularly occur together to form a category defined by their combination or conjunction. Competitive networks with sparse representations can learn to categorise inputs with a fairly high capacity. Moreover, competitive networks implement a type of unsupervised learning.

A very important property of competitive networks is that they can be combined with other synapses on the same neurons that implement short-term memory using attractor dynamics, and with another set of synaptic inputs that learn by pattern association to initiate memory recall later, or to implement top-down attention. This has been tested computationally: all three types of computation can be performed using these three types of computation by populations of such single neurons, and this is proposed to be *the* key feature of the design of the neocortex (Rolls, 2021c).

The architecture that was simulated to prove the operation of this computational combination is shown in Fig. 19.1 (Rolls, 2021c), and is a part of the neocortical architecture illustrated in Fig. 1.17. The computational model combines competitive learning using the forward inputs from the preceding cortical region, with associatively modifiable recurrent collateral synapses to form an autoassociation attractor network to maintain neuronal firing for short periods, and with pattern association learning to implement recall or top-down at-

tention using cortico-cortical backprojections. It was shown that during training, the forward inputs could be utilised for competitive learning, and at the same time the recurrent collateral connections could be trained to set up an attractor network between the set of neurons that had learned to recognise a pattern by competitive learning. Also during training, the top-down backprojections that were active could be associated with the pyramidal cells that responded to any one category. During the recall stage when there was no forward input from the preceding cortical stage, the top-down backprojection inputs could retrieve the correct set of pyramidal cells that had been active in association with the top-down recall cue, and the firing of the pyramidal cells could be maintained in short-term memory by the attractor synapses. The whole model was useful not only in showing that this could all be achieved in a single population of pyramidal cells with these three types of input, but also in showing suitable ranges for the strengths of the three types of synapse on each neocortical pyramidal cell (Rolls, 2021c).

Whether competitive networks are sufficiently powerful, when combined with pattern association and autoassociation properties on the same neurons, to account for the new categories that can be learned, typically in hierarchical networks, remains to be investigated. This is a key frontier for future research: if competitive networks, constructed with the addition of pattern and autoassociators in the neocortex, are not sufficiently powerful to account for the learning of new categories and the formation of semantic networks, then what alternatives are there? Potts attractor networks, which are combinations of attractor networks, may have high storage capacity (Song, Yao and Treves, 2014; Boboeva, Brasselet and Treves, 2018; Ryom, Stendardi, Ciaramelli and Treves, 2023), but it is not clear how useful new representations could be learned by them. So the area of how biologically plausible networks can learn new representations if competitive networks are not sufficiently powerful is of great interest for the future.

Another type of learning that is probably implemented in the brain is reinforcement learning using dopamine as a single reward prediction error signal (Schultz, 2016a,c, 2017). One of its main uses in the brain is for stimulus-response learning of rather fixed habits using the dopamine pathway that projects to the basal ganglia (Schultz, 2016c) (Chapter 16), and that is one of the relatively simple types of learning performed by the brain, and may even predate the neocortex in evolution.

Another type of learning may be some perceptron type of learning with a separate teacher for each neuron (Section B.11) in one part of the brain, the cerebellum, where the teacher may be the climbing fibre which forces a pyramidal cell to learn what is present on its parallel fibre inputs (Chapter 17). However, it is not clear how the teacher knows what to teach in that system.

Novelty detection is relatively easy to set up in neural networks, and is found in for example the orbitofrontal cortex (Rolls, Browning, Inoue and Hernadi, 2005a). The opposite, familiarity detection, which might help to represent one's friends, one's belongings, and one's territory, appears to be represented in the perirhinal cortex (Hölscher, Rolls and Xiang, 2003), and again can be easily learned in neural networks (Rolls, Franco and Stringer, 2005b).

The approach taken in this book and in my previous books (Rolls, 2016b, 2021b) may thus not be a 'a grand unifying theory' (Manohar, 2022) of how the brain works. But it is a pioneering approach to how biologically plausible computation may be performed in very many parts of our brains to implement very many of the wonderful things that our brains can do. It is an open issue at present about whether different principles are needed, and if so, how they are implemented in biologically plausible networks in our brains.

This book is intended to pioneer a foundation for future developments, by setting out

what we know about what computations are performed in many different brain regions, how biologically plausible networks could perform the computations in many brain regions, and leaves open the question of whether the computations that are performed might need some more powerful but biologically plausible algorithms than those described here.

This book is also pioneering in that it goes beyond purely theoretical studies of neural networks, and approaches instead what particular networks may be implemented in different brain regions, and how these networks or modules are interconnected to enable processes such as episodic memory, invariant visual object recognition, and emotion to be implemented in the primate including human brain.

A feature of this book is that it highlights many of the fundamental conceptual and empirical discoveries that have been made to help understand cortical function and computation, as seeing what the fundamental discoveries were, and how they were made, is didactically important to help foster future fundamental advances.

19.8 Brain-Inspired Intelligence

One of the aims of this book is to provide for neuroscientists a computational approach to brain function. This is I believe very important, for it takes us beyond metaphors and analogies and word-level descriptions about how the brain works, to well-defined computational hypotheses that allow testing at many levels of explanation, and indeed for the relations between the levels to be understood, as set out in Section 19.6.

Another key aim is to set out for those interested in machine intelligence, what is computed in different brain systems, so that those who wish to learn from or emulate brain function know what each part computes. That is an essential prerequisite for advances to be made, which might not only try to emulate brain function, but to be inspired by it, with possible new ways of solving similar computational problems.

This book also sets out many current hypotheses about how the brain solves these computational problems, and this is likely to be an area in which many advances can be made. Indeed, advances in our understanding of how the brain computes are likely to be facilitated by very large-scale simulations of parts of the brain, to test whether the computational hypotheses scale up appropriately, as well as enabling the machine implementations to be on the same, or a larger, scale than in the real brain. This should thus provide for fruitful advances to be made in both directions, from understanding the brain to machine intelligence; and from large scale simulation on large computers of well formulated computational hypotheses about how the brain computes. But all of this rests on evidence on what is computed in different brain regions, and how it is computed.

Advances in this area are made possible by the way in which the brain is designed compared to a digital computer, as summarized in Section 19.3 and in *Cerebral Cortex: Principles of Operation* (Rolls, 2016b). Key aspects that help us to understand what and how it computes include the following.

Brain functions are considerably localized, due to the importance of minimizing the length of neural connections, and of the simplicity that this offers in the genetic specification of the brain used while it develops, which often relies on proximity rules (Rolls, 2016b). Another key aspect is that the information is transmitted from the basic computing elements, the neurons, by spike trains with one output for each neuron, so that we can listen in to what is being transmitted from one brain area to another, using the methods described in Appendix C.

Further, by making more advances in understanding how genes specify the architecture of the brain (Rolls and Stringer, 2000; Rolls, 2016b), it will be possible in future to use ge-

netic algorithms to design the architecture of brain-like computing devices, which will enable the development of new types of computational solution to problems. Indeed, we were enormously surprised by the solutions found by neural architectures built by genetic algorithms, which frequently found ways to ‘cheat’, to operate in ways that we had not expected, in order to succeed at the fitness function that we had set (Rolls and Stringer, 2000) (Section B.20). And this was when all that the genetic algorithm had to work with were the building blocks of how genes might specify differences between neural architectures, in contrast to being allowed to explore new specification rules.

It seems as if we have reasonable approaches now, since the start in about 1970, of an understanding of what is computed in many brain systems in the macaque brain, and much of that and the complementary information about the human brain is what has been described in this book. We also have at least the start to approaches about how different brain systems compute. The area of brain function about which we know computationally the least is how language, including syntax and also semantics, are implemented in the brain, and how they operate together. That is an area in which at the computational level our understanding is still very incomplete, and where major advances are needed.

19.9 Brain-Inspired Medicine

There are many applications showing how advances in understanding brain function and computation have led to advances relevant to medicine. Some are highlighted in the following sections. Some others include the use of deep brain stimulation for Parkinson’s disease (Little and Brown, 2020), the use of antiphase brain stimulation to cancel for example tremor, and the identification that there are two subtypes of Parkinson’s disease, based on an analysis of functional connectivity (Wang, Cheng, Rolls, Dai, Gong, Du, Zhang, Wang, Liu, Wang, Brown and Feng, 2020d).

19.9.1 Computational psychiatry and neurology

As shown in Chapter 18, a number of mental disorders can be understood at least partly in terms of stability of different brain systems. This may be understood in the broader context that stability of a cortical system with positive feedback between its computing elements, the neurons, is a difficult issue to manage. This is compounded by the hypothesis that natural selection may be operating on parameters that influence the stability of different brain systems, in order to search for advantages of different options in different environments or situations.

For example, one strategy might be to make the system very sensitive to non-reward, as this may be adaptive in a number of obvious ways; yet too much sensitivity might lead to depression. Having a smaller degree of sensitivity to non-reward might also be a useful strategy in some circumstances, for it would result in continued trying, even in the face of adversity. This could result in genetic variation in sensitivity to, for example, non-reward, being maintained in the population.

The computational accounts being developed for a number of mental disorders have implications for medical treatment. For example, in depression approaches might be tried of ways to reduce the activity or connectivity of the non-reward lateral orbitofrontal cortex, and to increase the sensitivity or connectivity of the reward-related medial orbitofrontal cortex. In this context, it is interesting that modern antidepressant drugs (e.g SSRIs) do reduce the connectivity of the lateral orbitofrontal cortex back down towards levels in controls; but do not restore the reduced connectivity of the reward-related medial orbitofrontal cortex in depression. That sets a new target for the development of further treatments for depression aimed

to facilitate the operation of the reward-related medial orbitofrontal cortex, and the evidence described in Chapter 18 suggests that ketamine may act on the medial orbitofrontal cortex. If the latter turns out to be the case, that opens up possibilities for combined drug treatments that together correct the lateral and the medial orbitofrontal cortex. Similarly, the understanding of brain mechanisms of emotion described in this book suggests that a key brain system in emotion is the orbitofrontal cortex; and that points the way to possible brain stimulation of the orbitofrontal cortex as a new brain area to explore for the possible relief of treatment resistant depression.

However, the computational approach is helpful in another way in understanding and potentially treating some mental disorders, and these treatments might be at the purely behavioral level. For example, the modern computational approach to understanding possible causes of depression indicates that non-reward inputs in which no action is possible might lead to feelings of sadness and depression (Fig. 11.20). In this situation, advice at the behavioral level might be to avoid as much as is reasonable stimuli that are associated with non-reward. In the case of the loss of a loved one, this might lead for example to attempts to divert the mind to other more rewarding thoughts, and divert activities from being constantly focussed on the loss. These types of approach and many others to depression are described further in my book *The Brain, Emotion, and Depression* (Rolls, 2018a, 2022a).

A similar point can be made about attention deficit hyperactivity disorder (ADHD). We have found that the functional connectivity of the visual thalamic nucleus, the lateral geniculate, with early visual cortical areas is higher in ADHD than in controls (Rolls et al., 2021b). An implication is that this may make such individuals more easily distracted and dominated by visual stimuli in the environment, and indeed we have shown that people with ADHD do display very much more screen use (i.e. use of mobile phones, computers, computer games, television, etc) (Yang et al., 2022). There are implications from this neurocomputational approach for treatment at the purely behavioral level, for by understanding this sensitivity of some parts of the brain, advice might include limiting screen use to a reasonable level, and providing a quiet atmosphere for work without environmental distractions. There are opposite differences in schizophrenia, with decreased connectivity of thalamic with visual cortex connectivity (as well as overconnectivity of backprojections from areas concerned with the self and internal thoughts such as the precuneus), as described in Section 18.3 and by Rolls et al. (2021b), and that may also have implications for treatment.

In addition, understanding with computational methods the connectivity of the brain can help to identify subtypes of a disorder. For example, subtypes of depression have been found with and without anxiety as a comorbid condition (Drysdale et al., 2017), and this may be helpful for treatment, as it may be that the subgroups with anxiety are particularly helped by Transcranial Magnetic Stimulation of the lateral orbitofrontal cortex (Feffer, Fettes, Giacobbe, Daskalakis, Blumberger and Downar, 2018).

19.9.2 Reward systems in the brain, and their application to understanding food intake control and obesity

What is computed in reward systems in the brain, and how it is computed, are described in Chapters 4–7, 11, 12, and 16. In this Section, we consider some applications of this understanding.

Different individuals have different sensitivities to rewards, non-reward, etc, and indeed this provides a basis for understanding personality, and motivation (Rolls, 2014a, 2023b). This has application to a number of areas in medicine, of which one is obesity.

Understanding the mechanisms that control appetite is becoming an increasingly important issue, given the increasing incidence of obesity. Obesity affects approximately one third

of adults in the United States (with an additional one third falling into the overweight category). In the UK, there has been a three-fold increase since 1980 to a figure of 20% defined by a Body Mass Index > 30 , and there is a realization that it is associated with major health risks (with 1000 deaths each week in the UK attributable to obesity). It is important to understand and thereby be able to minimize and treat obesity because many diseases are associated with a body weight that is much above normal. These diseases include hypertension, cardiovascular disease, hypercholesterolaemia, and gall bladder disease; and in addition obesity is associated with some deficits in reproductive function (e.g. ovulatory failure), and with an excess mortality from certain types of cancer (Guyenet and Schwartz, 2012; Myers et al., 2021).

There are many factors that can cause or contribute to obesity in humans (Rolls, 2007g, 2011f, 2012f, 2016g; Myers et al., 2021; Farooqi, 2022). Rapid progress is being made in understanding many of these factors at present with the aim of leading to better ways to minimize and treat obesity. Some of these factors are related to reward systems in the brain (Rolls, 2012f, 2014a, 2016g, 2023f; Rolls et al., 2023g), as described next (see also Section 4.2.10).

The way in which the sensory factors produced by the taste, smell, texture and sight of food interact in the brain with satiety signals (such as gastric distension and satiety-related hormones) to determine the pleasantness and palatability of food, and therefore whether and how much food will be eaten, is described in Chapters 4, 5 and 11. The concept is that convergence of sensory inputs produced by the taste, smell, texture and sight of food occurs in the orbitofrontal cortex to build a representation of food flavor. The orbitofrontal cortex is where the pleasantness and palatability of food are represented, as shown by the discoveries that these representations of food value are only activated if appetite is present and the food is chosen, and correlate with the subjective pleasantness of the food flavor. The orbitofrontal cortex representation of whether food is pleasant (which takes into account any satiety signals present) then drives brain areas such as the striatum and cingulate cortex that then lead to eating behavior.

The fundamental concept this leads to about some of the major causes of obesity is that, over the last 30 years, sensory stimulation produced by the taste, smell, texture and appearance of food, as well as its availability, have increased dramatically, yet the satiety signals produced by stomach distension, satiety hormones etc. summarized in Rolls (2014a) have remained essentially unchanged (see Rolls (2014a) and Rolls (2016g)). The consequence is that the effect on the brain's control system for appetite is to lead to a net average increase in the reward value and palatability of food which over-rides the satiety signals, and contributes to the tendency to be overstimulated by food and to overeat (Rolls, 2014a, 2007g, 2011f, 2012f, 2016g, 2023f; Rolls et al., 2023g).

In this scenario, it is important to understand much better the rules used by the brain to produce the representation of the pleasantness of food and how the system is modulated by eating and satiety. This understanding, and how the sensory factors can be designed and controlled so as not to override satiety signals, are important research areas in the understanding, prevention, and treatment of obesity. Advances in understanding the receptors that encode the taste, olfactory, fat texture (Rolls, 2011e; Rolls et al., 2018b; Rolls, 2020c) and other properties of food, and the processing in the brain of these properties (Rolls, 2014a, 2007g, 2011f, 2012f, 2016g, 2020c, 2023f), are also important in providing the potential to produce highly palatable food that is at the same time nutritious and healthy.

An important aspect of this hypothesis is that different humans may have reward systems that are especially strongly driven by the sensory and cognitive factors that make food highly palatable. In a test of this, we showed that activation to the sight and flavor of chocolate in the orbitofrontal and pregenual cingulate cortex were much higher in chocolate cravers than

non-cravers (Rolls and McCabe, 2007). In more detail, the sight of chocolate produced more activation in chocolate cravers than non-cravers in the medial orbitofrontal cortex and ventral striatum. For cravers vs non-cravers, a combination of a picture of chocolate with chocolate in the mouth produced a greater effect than the sum of the components (i.e. supralinearity) in the medial orbitofrontal cortex and pregenual cingulate cortex. Furthermore, the pleasantness ratings of the chocolate and chocolate-related stimuli had higher positive correlations with the fMRI signals in the pregenual cingulate cortex and medial orbitofrontal cortex in the cravers than in the non-cravers. Thus there are differences between cravers and non-cravers in their responses to the reward components of a craved food in the orbitofrontal and pregenual cingulate cortex and a region to which they project the ventral striatum that is implicated in addiction (Rolls, 2019e), and in some of these regions the differences are related to the subjective pleasantness rating value of the craved food (Rolls and McCabe, 2007). It was of interest that there were no differences between the cravers and the non-cravers in the activations in the taste insula to the chocolate, so that the differences found were in the tuning of the reward system and not of the purely sensory system (Rolls and McCabe, 2007). Individual differences in brain responses to images of food have also been described by Beaver et al. (2006).

The concept that individual differences in responsiveness to food reward are reflected in brain activations in regions related to the control food intake (Rolls, 2014a, 2007g, 2011f, 2012f, 2016g) may provide a way for understanding and helping to control food intake. In this context, we should remember that individual differences in the reward systems are to be expected given that variation in these systems is an important part of the process of evolution by natural selection. Research in this area with the aim of understanding the relation between the activation of different brain systems by food, and obesity, is developing (Volkow et al., 2013, 2017).

A factor in obesity is food palatability, which with modern methods of food production can now be greater than would have been the case during the evolution of our feeding control systems. These brain systems evolved so that internal signals from for example gastric distension and glucose utilization could act to decrease the pleasantness of the sensations produced by feeding sufficiently by the end of a meal to stop further eating. However, the greater palatability of modern food may mean that this balance is altered, so that there is a tendency for the greater palatability of food to be insufficiently decreased by a standard amount of food eaten, so that extra food is eaten in a meal (Rolls, 2014a, 2012f, 2016g, 2023f).

Sensory-specific satiety is the decrease in the appetite for a particular food as it is eaten in a meal, without a decrease in the appetite for different foods, as shown above in Section 4.2.5 and Chapters 5 and 11 (Rolls, 2014a, 2016g, 2019e). It is an important factor influencing how much of each food is eaten in a meal, and its evolutionary significance may be to encourage eating of a range of different foods, and thus obtaining a range of nutrients. As a result of sensory-specific satiety, if a wide variety of foods is available, overeating in a meal can occur. Given that it is now possible to make available a very wide range of food flavors, textures, and appearances, and that such foods are readily available, this variety effect may be a factor in promoting excess food intake (Rolls, 2016g).

Another factor that could contribute to obesity is fixed meal times, in that the normal control of food intake by alterations in inter-meal interval is not readily available in humans, and food may be eaten at a meal-time even if hunger is not present (Rolls, 2014a, 2016g). Even more than this, because of the high and easy availability of food (in the home and workplace) and stimulation by advertising, there is a tendency to start eating again when satiety signals after a previous meal have decreased only a little, and the consequence is that the system again becomes overloaded.

Making food salient, for example by placing it on display, may increase food selection

particularly in the obese (Schachter, 1971; Rodin, 1976; Cornell et al., 1989), and portion size is a factor, with more being eaten if a large portion of food is presented (Rolls, 2012a), though whether this is a factor that can lead to obesity and not just alter test meal size is not yet clear. The driving effects of visual and other stimuli, including the effects of advertising, on the brain systems that are activated by food reward may be different in different individuals, and may contribute to obesity.

19.9.3 Multiple Routes to Action

Section 11.3.9 describes evidence that there are multiple routes to action, some of which are unconscious (Rolls, 2020a). The gene-specified reward value route to action may perform actions in the interests of the genes. The rational route may perform actions in the interests of the individual. Thus the goals for these routes may be different, and the route that causally accounts of the action performed may be subject to selection by noise-related attractor decision-making networks. This makes human decision-making particularly interesting. Further, although sometimes the reason given by the rational system for an action may be correct, in cases when the rational system initiated the action, on other occasions it may be producing a confabulated account of why an action was performed, if the action was performed by the gene-specified reward-related system. This has broad implications for understanding human behavior (Rolls, 2012e, 2023b), including human economic decision-making (Rolls, 2019d).

19.10 Primates including humans have a different systems-level organisation of many brain systems compared to rodents

Primates including humans have a different systems-level organisation of many brain systems compared to rodents. This is evident for at least the following systems, where rodents refers in particular to neuroscience investigations in rats and mice. This makes rodents in many cases not a good model for systems-level analysis of the computations performed in many primate (including human) brain systems. The focus of this book is therefore on primates including humans, with complementary evidence frequently provided by neurophysiological discoveries in primates, that are important for understanding the computations being performed, and that are closely related to corresponding processing in humans as shown by neuroimaging investigations and the effects of brain damage in humans. The interest here is to understand the human brain in health and disease, including understanding and a foundation that is relevant to treatment in humans.

19.10.1 The visual system

For primate **vision**, the fovea is associated with object recognition for what is at the fovea, and uses a highly developed ventral processing stream to compute transform-invariant representations of objects (Chapter 2). Associated with this foveate vision, primates have a highly developed dorsal visual system to enable fixation of objects, faces, parts of scenes etc (Chapter 3), and computes many coordinate transforms (Chapters 3 and 10). Part of the way that invariant object recognition is solved in the primate and human visual system is by having a high resolution fovea, and performing invariant object recognition for what is at the fovea, and then moving the eyes to fixate on another part of a scene, and perform invariant object recognition for what is then at the fovea. In contrast rodents do not have a fovea but instead

have vision with a field of view of 180–270°, do not have highly developed ventral and dorsal visual systems with visual areas in macaques that correspond to areas in humans, and so provide a poor model of primate including human vision. And of course the face identity and face expression systems, important in the primate and human visual system (Chapter 2), are not present in rodents. The very different visual systems of primates and rodents in turn appear to have profound implications on what is represented in the hippocampus, which in primates and humans can be about where an object is seen in a location in a spatial scene (Rolls, 2023c; Rolls and Wirth, 2018), whereas in rodents the emphasis is on the place where the individual is located (O’Keefe and Speakman, 1987; O’Keefe, 1979; O’Keefe and Krupic, 2021).

The differences between the rodent and primate visual system is highlighted by the report that when rodents locomote, the firing of neurons in the primary visual cortex is highly disturbed (Diamanti, Reddy, Schroder, Muzzu, Harris, Saleem and Carandini, 2021), whereas in primates the inferior temporal visual cortex has neuronal responses to visual stimuli that are independent of and not influenced by actions being made to obtain them including reaching to touch a computer screen (Rolls et al., 1977, 2003a). Similarly, visual responses to viewed spatial locations in macaques are not influenced by any locomotion being performed (Rolls et al., 1997a; Georges-François et al., 1999). This provides evidence that the rodent visual system operates far less specifically in terms of its encoding of visual stimuli than in primates, and indicates very poor cortical selectivity in visual cortical regions of rodents.

19.10.2 The taste system

For the **taste** system (Chapter 4), the rodent taste system is organised very differently to the primate taste system in two major ways. First in rodents there are connections from the nucleus of the solitary tract, and then to a taste area not present in primates the pontine taste area, which then sends information subcortically to regions such as the amygdala and hypothalamus (Rolls, 2016c, 2015d; Rolls and Scott, 2003; Scott and Small, 2009; Small and Scott, 2009; Rolls, 2019e). In contrast, in primates the taste system projects from the nucleus of the solitary tract to the thalamus and thence to the insular primary taste cortex. The insular taste cortex then projects into the orbitofrontal cortex (Chapter 4 and Fig. 4.1). Second, in rodents there is evidence that reward value, as assessed by the effects on neuronal responses to taste of feeding to satiety, is present even in the periphery, in for example the nucleus of the solitary tract, with the evidence reviewed by Rolls (2016c) and Rolls (2019e). In contrast, in primates including humans taste and flavor reward are represented in the orbitofrontal cortex (as shown by the effects of devaluation produced by feeding to satiety), but not at earlier stages of processing including the primary taste cortex in the anterior insula (Rolls, 2015d, 2016c, 2019e) (Chapter 4). The implication is that taste, and the closely related olfactory and visual processing that contribute to food reward value and expected value, are much more difficult to understand in rodents than in primates, partly because there is less segregation of ‘what’ (identity and intensity) from reward / hedonic processing in rodents.

It has been proposed that this great change in the systems-level computational design of the taste system in evolution from rodents to primates is related to the importance of cortical processing for all sensory systems in primates to the object level, so that multimodal representations can be formed about objects independently of whether they are currently rewarding (Rolls, 2019e, 2016b). Part of the value of this reward-independent representation of objects in primates including humans is that the neurons still respond to the object and can learn about the object, for example the location of food, even when the object may not be rewarding. (In rodents, the taste information is broadcast to many subcortical structures from the rodent pontine taste area, so that there is not the more powerful computational

design of primates in which multimodal object representations are built before reward-related processing.) Building such multimodal representations in primates, including to the level of semantic descriptions in humans, is much more stable if there are separate representations in each cortical processing system of ‘what’ object is present, independently of its current reward value.

This evolutionary argument applies also to processing in the olfactory system, and the visual system (Rolls, 2019e, 2016b). Moreover, this evolutionary evidence points to the particular importance of the orbitofrontal cortex and amygdala in primates including humans, as they are the first stages of processing at which reward value, and hence emotion, can be represented (Chapter 11).

19.10.3 The olfactory system

For the **olfactory** system (Chapter 5) there are great differences too in rodents in terms of processing of the reward value of odors. In humans, activity in the pyriform cortex appears to be related to ‘what’ stimulus is present (its identity), and its intensity, and not to its reward value, in that activations in the human pyriform cortex are linearly related to the intensity rating of odorants, and not to their pleasantness (Grabenhorst, Rolls, Margot, da Silva and Velazco, 2007); in that paying attention to the intensity vs the pleasantness of an odor increases activations in the pyriform cortex (Rolls, Grabenhorst, Margot, da Silva and Velazco, 2008b); and in that activations in the pyriform (primary olfactory) cortex were not decreased by odor devaluation by satiety (Gottfried, 2015). In contrast, in rodents, reducing reward value by feeding to satiety or by administering leptin reduces the neural activity even in the olfactory bulb (Pager, Giachetti, Holley and LeMagen, 1972; Sun, Tang, Wu, Xu, Zhang, Cao, Zhou, Yu and Li, 2019a). The same points can be made as for taste about the different computations of reward value performed in different parts of the rodent vs primate olfactory system. With the highly developed human orbitofrontal cortex, there is a hedonic map of odor in the medial vs lateral orbitofrontal cortex (see Fig. 5.5 and Rolls et al. (2003c)), and nothing like this is known in rodents. And of course top-down modulation of reward value for olfaction and taste, very evident in humans even from the word level (Chapters 4 and 5), has no correspondent in rodents, yet is probably very important in what makes foods and many other rewards become acceptable in humans (including the effects of advertising). Further, the emphasis on the olfactory system in rodents may bias rodents to spatial representations of the place where they are located, as evident in rodent hippocampal place cells. This is in contrast with the importance of spatial view in primates because of the emphasis in primates on visual processing of representations of viewed spatial locations ‘out there’, as evident in the responses of primate hippocampal spatial view cells (Chapter 9).

19.10.4 The somatosensory system

For the **somatosensory** system, the representations in the higher cortical parts of the system in the parietal cortex become closely linked to vision, with neurons specialized for reaching towards and then grasping with the correct grip an object being looked at in peripersonal space (Chapters 6 and 10). Nothing similar is present in rodents. An interesting computational feature of this in primates is that the coordinates of where to reach in peripersonal space can be communicated in a sense though the world, for the place to reach is the place currently being visually fixated.

The differences between the primate somatosensory cortex and the rodent somatosensory cortex are enormous. For example, rodents and macaques have for a primary somatosensory cortex area 3b, but macaques have in addition three additional anterior parietal fields includ-

ing area 1 which processes cutaneous input, area 3a which processes proprioceptive input, and area 2 which integrates cutaneous and proprioceptive inputs (O'Connor, Krubitzer and Bensaïa, 2021). In addition, humans have a great development of the somatosensory hierarchy in the inferior parietal cortex leading to region PF (Fig. 10.1, Chapters 6 and 10) (Rolls et al., 2023f), with little similar in rodents (O'Connor et al., 2021).

19.10.5 The auditory system

For the **auditory** system, the human auditory association cortex in the superior temporal gyrus becomes heavily involved in language processing and especially auditory comprehension of speech, as described in Chapters 7, 8 and 14 (Rolls et al., 2023h). Part of this specialisation involves major connections with the inferior frontal gyrus (Broca's area, involved in speech production).

19.10.6 The hippocampal system, memory, and navigation

The differences for the visual system have major effects on the **hippocampal system**, in which in primates parts of distant visual scenes are represented by spatial view cells that enable objects, rewards, and goals at different locations in a scene to be remembered (Rolls, 2021f), whereas in rodents the emphasis is on place cell representations for where the rodent is located (O'Keefe, 1990; Burgess and O'Keefe, 1996; Hartley, Lever, Burgess and O'Keefe, 2014; O'Keefe and Krupic, 2021) (Chapter 9). This in turn has major effects on navigation, which in primates including humans can be performed relatively easily using visual cells such as spatial view cells that respond to landmarks in scenes (Chapter 10, and Section 9.3.15.5) (Rolls, 2021f, 2023c). Navigation using a topological map of the type believed to be implemented by place cells in rodents is much more complicated, because of the need to constantly make conversions between allocentric spatial 'cognitive' maps, and egocentric, action-based movement systems (Chapter 10). The difference of the primate brain may also lead to differences in the recall of information about episodic events from the hippocampus to the neocortex for use in the neocortex. In primates and humans, with the highly developed temporal lobe, semantic representations can be built using the information recalled from the hippocampus, as described in Chapters 9, 8 and 14. Very little about this is known in rodents, and these temporal lobe neocortical areas are much less developed in rodents.

As described in Section 9.3.15.1, humans normally navigate to a viewed object or reward in a scene such as a building, and non-human primates might locomote to particular locations in the viewed environment with local cues where there are sources of food, water, shelter and a place to sleep etc. In these cases, environmental visual features identify each location, and spatial view cells are ideal for this type of navigation. What is often studied in rodents as a model of navigation without any local cues as in the Morris water maze (Morris, Garrud, Rawlins and O'Keefe, 1982) may not be at all commonly how humans and other primates navigate. Spatial view cells provide the mechanism often used for navigation in humans and other primates which is typically towards visible landmarks such as a building, the top of a hill, etc (Rolls, 2021f, 2023d). Navigation may thus be performed in primates including humans (Rolls, 2021f, 2023a,d) in very different ways to those utilised in rodents, in which local place-associated cues sensed with the vibrissae or olfactory system define places, and idiothetic navigation between such places often in the dark may be important (McNaughton, Barnes, Gerrard, Gothard, Jung, Knierim, Kudrimoti, Qin, Skaggs, Suster and Weaver, 1996; Moser, Rowland and Moser, 2015; Moser, Moser and McNaughton, 2017). Moreover, because of the limited visual acuity of rodents illustrated in Fig. 9.12 in Section 9.2.5, navigation in rodents is unlikely to be towards small objects or rewards located at distant locations

in visual scenes, whereas this is typical of navigation in primates including humans implemented using spatial view cells (Rolls, 2023d). Thus navigational strategies, and how they are implemented in the brain, may be very different in primates including humans to those in rodents.

19.10.7 The orbitofrontal cortex and amygdala

The organisation of the **orbitofrontal cortex and amygdala, and reward value systems** is also very different in primates including humans vs rodents (Chapter 11). One difference is that the orbitofrontal cortex is relatively little developed in rodents, yet is one of the major brain areas involved in emotion and motivation in primates including humans (Rolls, 2014a, 2019e). Indeed, it has been argued that the granular prefrontal cortex is a primate innovation (Passingham, 2021), and the implication of the argument is that any areas that might be termed orbitofrontal cortex in rats (Schoenbaum et al., 2009) are homologous only to the agranular parts of the primate orbitofrontal cortex (shaded mid grey in Fig. 11.3), that is to areas 13a, 14c, and the agranular insular areas labelled Ia in Fig. 11.3 (Wise, 2008; Passingham and Wise, 2012). It follows from that argument that for most areas of the orbitofrontal and medial prefrontal cortex in humans and macaques (those shaded light grey in Fig. 11.3), special consideration must be given to research in macaques and humans (Rolls, 2014a, 2017b). As shown in Fig. 11.3, there may be no cortical area in rodents that is homologous to most of the primate including human orbitofrontal cortex (Preuss, 1995; Wise, 2008; Passingham and Wise, 2012; Passingham, 2021).

A second difference is that reward value in primates including humans is represented in the orbitofrontal cortex, and to some extent in the amygdala, but not at earlier cortical areas (Chapter 11 and Fig. 11.1). As shown above, and in more detail in Chapter 8 of Rolls (2019e), reward value is represented early on in sensory processing in rodents, so that any distinction between object identity and object value is much less clear in rodents. An underlying evolutionary advantage for the primate design may be that the great development of the neocortex which enables for example invariant visual object recognition to be performed means that once formed, it is useful to interface this to other modalities to form multimodal object including semantic representations, and this benefits from having ‘what’ representations in every sensory modality, untrammelled by possible confusion by current reward value. This makes the system not only very different in rodents, but also much more difficult to analyze.

A third key difference is that the primate orbitofrontal cortex has neurons that reverse in one trial in a rule-based system, allowing very rapid updating of reward value representations based on feedback from the environment (Thorpe et al., 1983; Rolls et al., 2020e), and this is likely to have great advantage in social behavior (Chapter 11). I have discussed this with those who work with rodents, and none so far believes that rodents can perform this one-trial rule-based reversal, and indeed evidence that they do not is described in Chapter 11 (e.g. Hervig, Fiddian, Piilgaard, Bozic, Blanco-Pozo, Knudsen, Olesen, Alsio and Robbins (2020)).

A fourth key difference is that in association with the importance of face and voice expression and identity for emotional signals and social behavior in primates including humans, there are highly developed analysis systems for these signals in the temporal cortex (Chapter 2), which in turn projects to the orbitofrontal cortex which is involved in the social and emotional behavior produced by these stimuli (Chapter 11).

A fifth key difference is that the representations in the primate including human orbitofrontal cortex are of the reward value of stimuli, with very little representation of behavioral responses or actions (Chapter 11). In contrast, it has been suggested that in rodents the orbitofrontal cortex provides a cognitive map of state space that could describe its role in value-based decision-making (Wilson, Takahashi, Schoenbaum and Niv, 2014b; Sharpe, Stalnaker,

Schuck, Killcross, Schoenbaum and Niv, 2019). (A state-space representation as described in this context is a mathematical model of a physical system as a set of input, output and state variables related by differential equations or difference equations. State variables are variables whose values evolve through time in a way that depends on the values they have at any given time and also depends on the externally imposed values of input variables. Output variables' values depend on the values of the state variables.) According to this view, the orbitofrontal cortex represents previous stimuli, responses and actions, and other sensory features that occur in association with outcomes in a multidimensional array, and thus supports reinforcement learning implemented elsewhere in the brain. That suggestion is based on findings in rodents (Wilson et al., 2014b). That suggestion does not fit the primate, including human, findings on the orbitofrontal cortex. These findings, described in Chapter 11 and by Rolls (2019e), show that the primate orbitofrontal cortex contains representations of stimulus reward value, and is involved in learning and rapidly updating these reward value representations, but does not have major representations of actions (Thorpe, Rolls and Maddison, 1983; Rolls, 2019f; Padoa-Schioppa and Assad, 2006; Rolls, 2014a; Grattan and Glimcher, 2014; Rolls, 2019e). In another example, although neuronal systems involved in rewarded behavior are present in the mouse orbitofrontal cortex, behavioral responses are also represented (Kuwabara et al., 2020), and not primarily stimulus reward value as in primates. Thus the computations being performed in the rodent orbitofrontal cortex (Izquierdo, 2017; Rolls, 2019e) appear to be different in kind from those in the primate orbitofrontal cortex. Further, the functions of different parts of the rodent orbitofrontal cortex are poorly understood (Izquierdo, 2017; Barreiros et al., 2021).

A sixth key brain difference is that in rodents the amygdala is relatively important in emotion (LeDoux, 2000; LeDoux and Pine, 2016), but the amygdala appears to be overshadowed by the great development of the orbitofrontal cortex in humans, damage to which produces much greater changes in emotional behavior and subjective emotions than does damage to the human amygdala (Chapter 11) (Rolls, 2019e; Rolls et al., 2023b,h). Indeed the rodent and human amygdala appear to share similar functions in producing autonomic and behavioral responses such as freezing, but the human amygdala appears to be little involved in reported, declarative, experienced, emotion, with instead the human orbitofrontal cortex being involved in these major properties of emotion (Rolls et al., 2023h,b; Rolls, 2023b) (Section 11.4).

19.10.8 The cingulate cortex

The **cingulate cortex** in rodents also appears to be different to that in primates. In primates the anterior and mid-cingulate cortex are implicated in action-outcome learning, using information from the orbitofrontal cortex about reward outcomes, and information about actions from the parietal cortex via the posterior cingulate cortex (Rolls (2019c) and Chapter 12). In contrast, in rodents the state space proposals for the rodent 'orbitofrontal cortex' hold that the rodent 'orbitofrontal cortex' is involved in action-outcome learning (Wilson, Takahashi, Schoenbaum and Niv, 2014b; Sharpe, Stalnaker, Schuck, Killcross, Schoenbaum and Niv, 2019). Further, correspondences between the human and macaque anterior cingulate cortex are clear, but what the correspondences are to what is found in 'prelimbic' and related regions in rodents are very unclear, and there may be no clear correspondences (Klein-Flugge, Bongioanni and Rushworth, 2022a).

A further difference is that the rodent is believed not to have an equivalent to the primate posterior cingulate cortex areas 23 and 31 (Vogt, 2009; Rolls, 2019c; Rolls et al., 2023i), yet these regions are important in human episodic memory (Rolls et al., 2023i). Indeed, in humans the posterior cingulate cortex has greater functional connectivity with other cort-

ical regions in females than in males, and this can be related to evidence for better episodic memory in females in humans (Zhang et al., 2023b).

19.10.9 The motor system

The differences in the visual system of primates are also associated with differences in the **motor system**, for there are major specializations in primate parietal, premotor, and motor areas association for grasping and manipulating visually fixated objects and tools, and the precision grip (Chapter 15).

19.10.10 Language

Of course the organisation of brain systems for **language** (Chapters 14 and 8) is very different in humans. However, it is of interest that some parts of the system such as the inferior frontal gyrus and its connections with the anterior temporal cortex that are relevant to language can be identified as systems in non-human primates that will develop into language systems in evolution (Chapter 14).

The focus in this book on brain computations in primates including humans is because a key aim is to understand the human brain and human behavior in health and disease, and most of the systems-level organisation in rodents appears to be very different, and the rodent provides a poor model for the systems-level organisation of the human brain or the non-human primate brain.

Appendix 1 Introduction to linear algebra for neural networks

In this Appendix I review some simple elements of linear algebra relevant to understanding neural networks. This will provide a useful basis for a quantitative understanding of how neural networks operate (see Appendix B).

A.1 Vectors

A vector is an ordered set of numbers. An example of a vector is the set of numbers

$$\begin{bmatrix} 7 \\ 4 \end{bmatrix}$$

If we denote the j th element of this vector as w_j , then $w_1 = 7$, and $w_2 = 4$. We can denote the whole vector by \mathbf{w} . This notation is very economical. If the vector has 10,000 elements, then we can still refer to it in mathematical operations as \mathbf{w} . \mathbf{w} might refer to the vector of 10,000 synaptic weights on the dendrites of a neuron. Another example of a vector is the set of firing rates of the axons that make synapses onto a dendrite, as shown in Fig. 1.2. The firing rate x of each axon forming the input vector can be indexed by j , and is denoted by x_j . The vector would be denoted by \mathbf{x} .

Certain mathematical operations can be performed with vectors. We start with the operation which is fundamental to simple models of neural networks, the inner product or dot product of two vectors.

A.1.1 The inner or dot product of two vectors

The operation of computing the activation h of a neuron from the firing rate on its input axons multiplied by the corresponding synaptic weight can be expressed as:

$$h = \sum_j x_j w_j \tag{A.1}$$

where \sum_j indicates that the sum is over the C input axons to each neuron, indexed by j . Denoting the firing rate vector as \mathbf{x} and the synaptic weight vector as \mathbf{w} , we can write

$$h = \mathbf{x} \cdot \mathbf{w} \tag{A.2}$$

Fig. A.1 Illustration of a vector in a two-dimensional space. The basis for the space is made up of the x axis in the $[1,0]$ direction, and the y axis in the $[0,1]$ direction. (The first element of each vector is then the x value, and the second the y value. The values of x and y for different points, marked by a dot, in the space are shown. The origins of the axes are at point $0,0$.) The $[1,1]$ vector projects in the $[1,1]$ (or 45°) direction to the point $1,1$, with length 1.414 .

If the weight vector is

$$\mathbf{w} = \begin{bmatrix} 9 \\ 5 \\ 2 \end{bmatrix}$$

and the firing rate input vector is

$$\mathbf{x} = \begin{bmatrix} 3 \\ 6 \\ 7 \end{bmatrix}$$

then we can write

$$\mathbf{x} \cdot \mathbf{w} = (3 \cdot 9) + (6 \cdot 5) + (7 \cdot 2) = 71 \quad . \quad (\text{A.3})$$

Thus in the inner or dot product, we multiply the corresponding terms, and then sum the result. As this is the simple mathematical operation that is used to compute the activation h in the most simplified abstraction of a neuron (see Chapter 1), we see that it is indeed the fundamental operation underlying many types of neural network. We will shortly see that some of the properties of neuronal networks can be understood in terms of the properties of the dot product. We next review a number of basic aspects of vectors and inner products between vectors.

There is a simple geometrical interpretation of vectors, at least in low-dimensional spaces. If we define, for example, x and y axes at right angles to each other in a two-dimensional space, then any two-component vector can be thought of as having a direction and length in that space that can be defined by the values of the two elements of the vector. If the first element is taken to correspond to x and the second to y , then the x axis lies in the direction $[1,0]$ in the space, and the y axis in the direction $[0,1]$, as shown in Fig. A.1. The line to point $[1,1]$ in the space then lies at 45° to both axes, as shown in Fig. A.1.

A.1.2 The length of a vector

Consider taking the inner product of a vector

$$\mathbf{w} = \begin{bmatrix} 4 \\ 3 \end{bmatrix}$$

with itself. Then

$$\|\mathbf{w}\| = \sqrt{\mathbf{w} \cdot \mathbf{w}} = \sqrt{4^2 + 3^2} = 5. \quad (\text{A.4})$$

This is the length of the vector. We can represent this operation in the two-dimensional graph shown in Fig. A.1. In this case, the coordinates where vector \mathbf{w} ends in the space are [1,1]. The length of the vector (from [0,0]) to [1,1] is obtained by Pythagoras' theorem. Pythagoras' theorem states that the length of the vector \mathbf{w} is equal to the square root of the sum of the squares of the two sides. Thus we define the length of the vector \mathbf{w} as

$$\|\mathbf{w}\| = \sqrt{\mathbf{w} \cdot \mathbf{w}} \quad (\text{A.5})$$

In the [1,1] case, this value is $\sqrt{2} = 1.414$.

A.1.3 Normalizing the length of a vector

We can scale a vector in such a way that its length is equal to 1 by dividing it by its length. If we form the dot product of two normalized vectors, its maximum value will be 1, and its minimum value -1 .

A.1.4 The angle between two vectors: the normalized dot product

The angle between two vectors \mathbf{x} and \mathbf{w} is defined in terms of the inner product as follows:

$$\cos \theta = \frac{\mathbf{x} \cdot \mathbf{w}}{\|\mathbf{x}\| \|\mathbf{w}\|} \quad (\text{A.6})$$

For example, the angle between two vectors

$$\mathbf{x} = \begin{bmatrix} 0 \\ 1 \end{bmatrix} \quad \text{and} \quad \mathbf{w} = \begin{bmatrix} 1 \\ 1 \end{bmatrix}$$

where the length of vector \mathbf{x} is $\sqrt{0.0 + 1.1} = 1$ and of vector \mathbf{w} is $\sqrt{1.1 + 1.1} = \sqrt{2}$ is

$$\cos \theta = \frac{(0.1) + (1.1)}{1 \cdot \sqrt{2}} = 0.707. \quad (\text{A.7})$$

Thus $\theta = \cos^{-1}(0.707) = 45^\circ$.

We can give a simple geometrical interpretation of this as shown in Fig. A.1. However, Equation A.6 is much easier to use in a high-dimensional space!

The dot product reflects the similarity between two vectors. Once the length of the vectors is fixed, the higher their dot product, the more similar are the two vectors. By normalizing the dot product, that is by dividing by the lengths of each vector as shown in Equation A.6, we obtain a value that varies from -1 to $+1$. This normalized dot product is then just the cosine of the angle between the vectors, and is a very useful measure of the similarity between any two vectors, because it always lies in the range -1 to $+1$. It is closely related to the (Pearson

product–moment) correlation coefficient between any two vectors, as we see if we write the equation in terms of its components

$$\cos \theta = \frac{\sum_j x_j w_j}{(\sum_j x_j^2)^{1/2} (\sum_j w_j^2)^{1/2}} \quad (\text{A.8})$$

which is just the formula for the correlation coefficient between two sets of numbers with zero mean (or with the mean value removed by subtracting the mean of the components of each vector from each component of that vector).

Now consider two vectors that have a dot product of zero, that is where $\cos \theta = 0$ or the angle between the vectors is 90° . Such vectors are described as orthogonal (literally at right angles) to each other. If our two orthogonal vectors were \mathbf{x} and \mathbf{w} , then the activation of the neuron, measured by the dot product of these two vectors, would be zero. If our two orthogonal vectors each had a mean of zero, their correlation would also be zero: the two vectors can then be described as unrelated or independent.

If, instead, the two vectors had zero angle between them, that is if $\cos \theta = 1$, then the dot product would be maximal (given the vectors' lengths), the normalized dot product would be 1, and the two vectors would be described as identical to each other apart from their length. Note that in this case their correlation would also be 1, even if the two vectors did not have zero mean components.

For intermediate similarities of the two vectors, the degree of similarity would be expressed by the relative magnitude of the dot product, or by the normalized dot product of the two vectors, which is just the cosine of the angle between them. These measures are closely related to the correlation between two vectors.

Thus we can think of the simple operation performed by neurons as measuring the similarity between their current input vector and their synaptic weight vector. Their activation, h , is this dot product. It is because of this simple operation that neurons can generalize to similar inputs; can still produce useful outputs if some of their inputs or synaptic weights are damaged or missing, that is they can show graceful degradation or fault tolerance; and can be thought of as learning to point their weight vectors towards input patterns, which is very useful in enabling neurons to categorize their inputs in competitive networks (see Section B.4).

A.1.5 The outer product of two vectors

Let us take a row vector having as components the firing rates of a set of output neurons in a pattern associator or competitive network, which we might denote as \mathbf{y} , with components y_i and the index i running from 1 to the number N of output neurons. \mathbf{y} is then a shorthand for writing down each component, e.g. $[7,2,5,2,\dots]$, to indicate that the firing rate of neuron 1 is 7, etc. To avoid confusion, we continue in the following to denote the firing rate of input neuron j as x_j . Now recall (see Chapter 1 and Section B.2) how the synaptic weights are formed in a pattern associator using a Hebb rule as follows:

$$\delta w_{ij} = \alpha y_i x_j \quad (\text{A.9})$$

where δw_{ij} is the change of the synaptic weight w_{ij} which results from the simultaneous (or conjunctive) presence of presynaptic firing x_j and postsynaptic firing or activation y_i , and α is a learning rate constant which specifies how much the synapses alter on any one pairing. In a more compact vector notation, this expression would be

$$\delta \mathbf{w}_i = \alpha \mathbf{y}_i \mathbf{x}' \quad (\text{A.10})$$

where the firing rates on the axons form a column vector with the values, for example, as follows²³:

$$\mathbf{x}' = \begin{bmatrix} 2 \\ 0 \\ 3 \\ \dots \end{bmatrix}$$

The weights are then updated by a change proportional (the α factor) to the following matrix (Table A.1):

Table A.1 Multiplication of a row vector [7 2 5] by a column vector to form the external or tensor product, representing for example the changes to a matrix of synaptic weights \mathbf{W}

	[7	2	5]
[2]	14	4	10
[0]	0	0	0
[3]	21	6	15
.....

This multiplication of the two vectors is called the outer, or tensor, product, and forms a matrix, in this case of (alterations to) synaptic weights. Thus we see that the operation of altering synaptic weights in a network can be thought of as forming a matrix of weight changes, which can then be used to alter the existing matrix of synaptic weights.

A.1.6 Linear and non-linear systems

The operations with which we have been concerned in this Appendix so far are linear operations. We should note that if two matrices operate linearly, we can form their product by matrix multiplication, and then replace the two matrices with the single matrix that is their product. We can thus effectively replace two synaptic matrices in a linear multilayer neural network with one synaptic matrix, the product of the two matrices. For this reason, multilayer neural networks if linear cannot achieve more than can be achieved in a single-layer linear network. It is only in non-linear networks that more can be achieved, in terms of mapping input vectors through the synaptic weight matrices, to produce particular mappings to output vectors. Much of the power of many networks in the brain comes from the fact that they are multilayer non-linear networks (in that the computing elements in each network, the neurons, have non-linear properties such as thresholds, and saturation at high levels of output). Because the matrix by matrix multiplication operations of linear algebra cannot be applied directly to the operation of neural networks in the brain, we turn instead back to other aspects of linear algebra, which can help us to understand which classes of pattern can be successfully learned by different types of neural network.

²³The prime after the \mathbf{x} is used here to remind us that this vector is a column vector, which can be thought of as a transformed row vector, and the prime indicates the transformed vector. We do not use the prime for most of this book in order to keep the notation uncluttered.

A.1.7 Linear combinations of vectors, linear independence, and linear separability

We can multiply a vector by a scalar (a single value, e.g. 2) thus:

$$2 \cdot \begin{bmatrix} 4 \\ 1 \\ 3 \end{bmatrix} = \begin{bmatrix} 8 \\ 2 \\ 6 \end{bmatrix}$$

We can add two vectors thus:

$$\begin{bmatrix} 4 \\ 1 \\ 3 \end{bmatrix} + \begin{bmatrix} 2 \\ 7 \\ 2 \end{bmatrix} = \begin{bmatrix} 6 \\ 8 \\ 5 \end{bmatrix}$$

The sum of the two vectors is an example of a linear combination of vectors, which is in general a weighted sum of several vectors, component by component. Thus, the linear combination of vectors $\mathbf{v}_1, \mathbf{v}_2, \dots$ to form a vector \mathbf{v}_s is expressed by the sum

$$\mathbf{v}_s = c_1 \mathbf{v}_1 + c_2 \mathbf{v}_2 + \dots \quad (\text{A.11})$$

where c_1 and c_2 are scalars.

By adding vectors in this way, we can produce any vector in the space spanned by a set of vectors as a linear combination of vectors in the set. If in a set of n vectors at least one can be written as a linear combination of the others, then the vectors are described as **linearly dependent**. If in a set of n vectors none can be written as a linear combination of the others, then the vectors are described as **linearly independent**. A linearly independent set of vectors has the properties that any vector in the space spanned by the set can be written in only one way as a linear combination of the set, and the space has dimension $d = n$. In contrast, a vector in a space spanned by a linearly dependent set can be written in an infinite number of equivalent ways, and the dimension d of the space is less than n .

Consider a set of linearly dependent vectors and the d -dimensional space they span. Two subsets of this set are described as **linearly separable** if the vectors of one subset (that is, their endpoints) can be separated from those of the other by a hyperplane, that is a subspace of dimension $d - 1$. *Subsets formed from a set of linearly independent vectors are always linearly separable.* For example, the four vectors:

$$\begin{bmatrix} 0 \\ 0 \end{bmatrix} \quad \begin{bmatrix} 0 \\ 1 \end{bmatrix} \quad \begin{bmatrix} 1 \\ 0 \end{bmatrix} \quad \begin{bmatrix} 1 \\ 1 \end{bmatrix}$$

are linearly dependent, because the fourth can be formed by a linear combination of the second and third (and also because the first, being the null vector, can be formed by multiplying any other vector by zero, a specific linear combination). In fact, $n = 4$ and $d = 2$. If we split this set into subset A including the first and fourth vector, and subset B including the second and third, the two subsets are not linearly separable, because there is no way to draw a line (which is the subspace of dimension $d - 1 = 1$) to separate the two subsets A and B. We will encounter this set of vectors in Appendix B, and this is the geometrical interpretation of why a one-layer, one-output neuron network cannot separate these patterns. Such a network

(a simple perceptron) is equivalent to its (single) weight vector, and in turn the weight vector defines a set of parallel $d - 1$ dimensional hyperplanes. (Here $d = 2$, so a hyperplane is simply a line, any line perpendicular to the weight vector.) No line can be found that separates the first and fourth vector from the second and third, whatever the weight vector the line is perpendicular to, and hence no perceptron exists that performs the required classification (see Section A.2.1). To separate such patterns, a multilayer network with non-linear neurons is needed (see Appendix B).

Any set of linearly independent vectors comprise the basis of the space they span, and they are called basis vectors. All possible vectors in the space spanned by these vectors can be formed as linear combinations of these vectors. If the vectors of the basis are in addition mutually orthogonal, the basis is an orthogonal basis, and it is, further, an orthonormal basis if the vectors are chosen to be of unit length. Given any space of vectors with a preassigned meaning to each of their components (for example the space of patterns of activation, in which each component is the activation of a particular unit), the most natural, canonical choice for a basis is the set of vectors in which each vector has one component, in turn, with value 1, and all the others with value 0. For example, in the $d = 2$ space considered earlier, the natural choice is to take as basis vectors

$$\begin{bmatrix} 1 \\ 0 \end{bmatrix}$$

and

$$\begin{bmatrix} 0 \\ 1 \end{bmatrix}$$

from which all vectors in the space can be created. This can be seen from Fig. A.1. (A vector in the $[-1, -1]$ direction would have the opposite direction of the vector shown in Fig. A.1.)

If we had three vectors that were all in the same plane in a three-dimensional (x, y, z) space, then the space they spanned would be less than three-dimensional. For example, the three vectors

$$\begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix} \quad \begin{bmatrix} 0 \\ 1 \\ 0 \end{bmatrix} \quad \begin{bmatrix} -1 \\ -1 \\ 0 \end{bmatrix}$$

all lie in the same z plane, and span only a two-dimensional space. (All points in the space could be shown in the plane of the paper in Fig. A.1.)

A.2 Application to understanding simple neural networks

The operation of simple one-layer networks can be understood in terms of these concepts.

A.2.1 Capability and limitations of single-layer networks: linear separability and capacity

Single-layer perceptrons perform pattern classification, and can be trained by an associative (Hebb) learning rule or by an error-correction (delta) rule (see Appendix B). That is, each neuron classifies the input patterns it receives into classes determined by the teacher. Single-layer perceptrons are thus supervised networks, with a separate teacher for each output neuron. The classification is most clearly understood if the output neurons are binary, or are strongly non-linear, but the network will still try to obtain an optimal mapping with linear or near-linear output neurons.

When each neuron operates as a binary classifier, we can consider how many input patterns p can be classified by each neuron, and the classes of pattern that can be correctly classified. The result is that the maximum number of patterns that can be correctly classified by a neuron with C inputs is

$$p_{\max} = 2^C \quad (\text{A.12})$$

when the inputs have random continuous-valued inputs, but the patterns must be linearly separable (see Hertz et al. (1991)). More generally, a network with a single binary unit can implement a classification between two subspaces of a space of possible input patterns provided that the p actual patterns given as examples of the correct classification are linearly separable.

The linear separability requirement can be made clear by considering a geometric interpretation of the logical AND problem, which is linearly separable, and the XOR (exclusive OR) problem, which is not linearly separable. The truth tables for the AND and XOR functions are shown in Table A.2 (there are two inputs, x_1 and x_2 , and one output neuron):

Table A.2 Truth table for AND and XOR functions performed by a single output neuron with two inputs. 1 = active or firing; 0 = inactive.

Inputs		Output	
x_1	x_2	AND	XOR
0	0	0	0
1	0	0	1
0	1	0	1
1	1	1	0

For the AND function, we can plot the mapping required in a 2D graph as shown in Fig. A.2. A line can be drawn to separate the input coordinates for which 0 is required as the output from those for which 1 is required as the output. The problem is thus linearly separable. A neuron with two inputs can set its weights to values which draw this line through this space, and such a one-layer network can thus solve the AND function.

For the XOR function, we can plot the mapping required in a 2D graph as shown in Fig. A.3. No straight line can be drawn to separate the input coordinates for which 0 is required as the output from those for which 1 is required as the output. The problem is thus not linearly separable. For a one-layer network, no set of weights can be found that will perform the XOR, or any other non-linearly separable function.

Although the inability of one-layer networks with binary neurons to solve non-linearly separable problems is a limitation, it is not in practice a major limitation on the processing that can be performed in a neural network for a number of reasons. First, if the inputs can take continuous values, then if the patterns are drawn from a random distribution, the one-layer

Fig. A.2 Left: the AND function shown in a 2D space. Input values for the two neurons are shown along the two axes of the space. The outputs required are plotted at the coordinates where the inputs intersect, and the values of the output required are shown as an open circle for 0, and a filled circle for 1. The AND function is linearly separable, in that a line can be drawn in the space which separates the coordinates for which 0 output is required from those from which a 1 output is required. W shows the direction of the weight vector. Right: a one-layer neural network can set its two weights w_1 and w_2 to values which allow the output neuron to be activated only if both inputs are present. In this diagram, w_0 is used to set a threshold for the neuron, and is connected to an input with value 1. The neuron thus fires only if the threshold of 1.5 is exceeded, which happens only if both inputs to the neuron are 1.

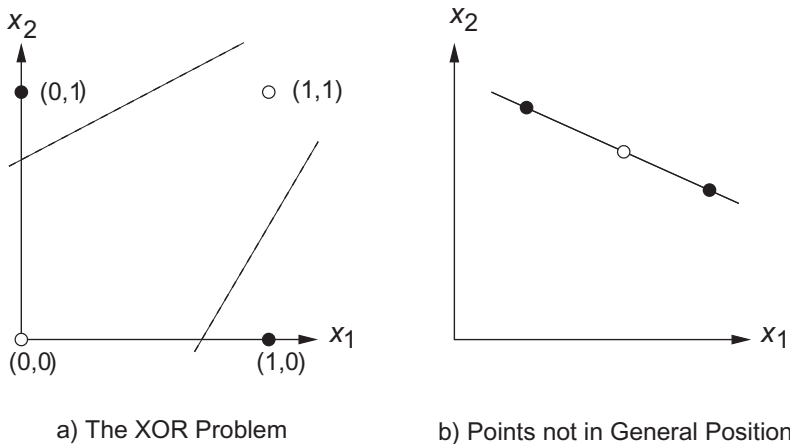

Fig. A.3 The XOR function shown in a 2D space. Input values for the two neurons are shown along the two axes of the space. The outputs required are plotted at the coordinates where the inputs intersect, and the values of the output required are shown as an open circle for 0, and a filled circle for 1. The XOR function is not linearly separable, in that a line cannot be drawn in the space to separate the coordinates for those from which a 0 output is required from those from which a 1 output is required. A one-layer neural network cannot set its two weights to values which allow the output neuron to be activated appropriately for the XOR function.

network can map up to 2^C of them. Second, as described for pattern associators, and for one-layer error-correcting perceptrons (see Appendix B), these networks could be preceded by an expansion recoding network such as a competitive network with more output than input neurons. This effectively provides a two-layer network for solving the problem, and multilayer networks are in general capable of solving arbitrary mapping problems. Ways in which such multilayer networks might be trained are discussed in Chapter 2 and Appendix B.

More generally, a binary output unit provides by its operation a hyperplane (the hyperplane orthogonal to its synaptic weight vector as shown in Fig. A.2) that divides the input space in two. The input space is of dimension C , if C is the number of input axons or con-

nections. A one-layer network with a number n of binary output units is equivalent to n hyperplanes, that could potentially divide the input space into as many as 2^n regions, each corresponding to input patterns leading to a different output. However the number p of *arbitrary* examples of the correct classification (each example consisting of an input pattern and its required correct output) that the network may be able to implement is well below 2^n , and in fact depends on C not on n . This is because for p too large it will be impossible to position the n weight vectors such that all examples of input vectors for which the first output unit is required to be ‘on’ fall on one side of the hyperplane associated with the first weight vector, all those for which it is required to be ‘off’ fall on the other side, and simultaneously the same holds with respect to the second output unit (a different dichotomy), the third, and so on. The limit on p , which can be thought of also as the number of independent associations implemented by the network, when this is viewed as a heteroassociator (i.e. pattern associator) with binary outputs, can be calculated with the Gardner method (Gardner, 1987, 1988) and depends on the statistics of the patterns. For input patterns that are also binary, random and with equal probability for each of the two states on every unit, the limit is $p_c = 2C$ (see further Appendix B, and Rolls and Treves (1998) Appendix A3).

A.2.2 Non-linear networks: neurons with non-linear activation functions

These concepts also help one to understand further the limitation of linear systems, and the power of non-linear systems. Consider the dot product operation by which the neuronal activation h is computed:

$$h = \sum_j x_j w_j. \quad (\text{A.13})$$

If the output firing is just a linear function of the activation, any input pattern will produce a non-zero output unless it happens to be exactly orthogonal to the weight vector. For positive-only firing rates and synaptic weights, being orthogonal means taking non-zero values only on non-corresponding components. Since with distributed representations the non-zero components of different input firing vectors will in general be overlapping (i.e. some corresponding components in both firing rate vectors will be on, that is the vectors will overlap), this will result effectively in interference between any two different patterns that for example have to be associated to different outputs. Thus a basic limitation of linear networks is that they can perform pattern association perfectly only if the input patterns \mathbf{x} are orthogonal; and for positive-only patterns that represent actual firing rates only if the different firing rate vectors are non-overlapping. Further, linear networks cannot of course perform any classification, just because they act linearly. (Classification implies producing output states that are clearly defined as being in one class, and not in other classes.) For example, in a linear network, if a pattern is presented that is intermediate between two patterns \mathbf{v}_1 and \mathbf{v}_2 , such as $c_1 \mathbf{v}_1 + c_2 \mathbf{v}_2$, then the output pattern will be a linear combination of the outputs produced by \mathbf{v}_1 and \mathbf{v}_2 (e.g. $c_1 \mathbf{o}_1 + c_2 \mathbf{o}_2$), rather than being classified into \mathbf{o}_1 or \mathbf{o}_2 . In contrast, with non-linear neurons, the patterns need not be orthogonal, only linearly separable, for a one-layer network to be able to correctly classify the patterns (provided that a sufficiently powerful learning rule is used – see Appendix B).

The networks just described, and most of those described in this book, are trained with a local learning rule, in which the pre- and post-synaptic terms needed to alter the synaptic weights are available locally in the synapses, in terms for example of the release of transmitter from the presynaptic terminal, and the depolarization of the postsynaptic neuron. This

type of network is considered because this is a biologically plausible constraint (see Section 19.4). It is much less biologically plausible to use an algorithm such as multilayer error backpropagation which calculates the correction to the value of a synapse that is needed taking into account the values of the errors of the neurons at later stages of the system and the strengths of all the synapses to these neurons (see Section B.12). This use of a local learning rule is a major difference of the networks described in this book, which is directed at neurally plausible computation, from connectionist and artificial neural networks, which typically assume non-local learning rules and which therefore operate very differently from real neural networks in the brain (see Section B.12, McLeod, Plunkett and Rolls (1998), and Lillicrap et al. (2020)).

A.2.3 Non-linear networks: neurons with non-linear activations

Most of the networks described in this book calculate the activation h of each neuron as the linear product of the input firing weighted by the synaptic weight vector (see Equation A.13). This corresponds in a real neuron to receiving currents from each of its synapses which sum to produce depolarization of the neuronal cell body and the spike initiation region which is located very close to the cell body. This is a reasonable reflection of what does happen in many neurons, especially those with large dendrites such as pyramidal cells (Koch, 1999). This calculation of the activation h by a linear summation not only approximates to what happens in many real neurons, but is also a useful simplification which makes tractable the analysis of many classes of network that utilize such neurons. These analyses provide insight into the operation of networks of neurons, even if the linear summation assumption is not perfectly realized. Having computed the activation linearly, the neurons do of course for essentially all the networks described in this book, then utilize a non-linear activation function, which, as described above, provides the networks with much of their interesting computational power. Given that the activation functions of the neurons are non-linear, some non-linearity in the summation expressed in Equation A.13 may in practice be lumped into the non-linearity in the activation function.

However, another class of neuron that is implemented in some networks in the brain utilizes non-linearity in the calculation of the activation h of the neuron, which reflects a local product of two inputs to a neuron. This could arise for example if one synapse makes a presynaptic contact with another synapse which in turn connects to the dendrite, or if two synapses are close together on a thin dendrite. In such situations, the current injected into the neuron could reflect the conjoint firing of the two classes of input (Koch, 1999). The dendrite as a whole could then sum all such products into the cell body, leading to the description **Sigma-Pi**. This could be expressed by equation A.14

$$h = \sum_j \sum_k w_{jk} x_j x_k^c \quad (\text{A.14})$$

where x_j is the firing rate of input cell j , x_k^c is the firing rate of input cell k of class c , and w_{jk} is the connection strength. Such Sigma-Pi neurons were utilized in the model described in Section B.5.5 of how idiotic inputs could update a continuous attractor network. Another possible application is to learning invariant representations in neural networks. For example, the x^c input in equation A.14 could be a signal that varies with the shift required to compute translation invariance, effectively mapping the appropriate set of x_j inputs through to the output neurons depending on the shift required (Mel, Ruderman and Archie, 1998; Mel and Fiser, 2000; Olshausen, Anderson and Van Essen, 1993, 1995).

To train such a Sigma-Pi network requires that combinations of the two presynaptic inputs to a neuron be learned onto a neuron, using for example associativity with the post-synaptic term y , as exemplified in Equation A.15

$$\delta w_{jk} = \alpha y x_j x_k^c. \quad (\text{A.15})$$

This learning principle is exemplified in the model described in Section B.5.5 of how idiotic inputs could update a continuous attractor network to perform path integration.

Sigma-Pi networks are clearly very powerful, but require rather specialized anatomical and biophysical arrangements (see Koch (1999) and Mel et al. (2017)), and hence we do not use them unless they become very necessary in models of neural network operations in the brain. We have shown that in at least some applications such as path integration, it is possible to replace a Sigma-Pi network with a competitive network followed by a pattern association network (Stringer and Rolls, 2006).

Appendix 2 Neuronal network models

B.1 Introduction

Formal models of neural networks are needed in order to provide a basis for understanding the processing and memory functions performed by real neuronal networks in the brain. The formal models included in this Appendix all describe fundamental types of network found in different brain regions, and the computations they perform. Each of the types of network described can be thought of as providing one of the fundamental building blocks that the brain uses. Often these building blocks are combined within a brain area to perform a particular computation.

The aim of this Appendix is to describe a set of fundamental networks used by the brain, including the parts of the brain involved in memory, attention, decision-making, and the building of perceptual representations. As each type of network is introduced, we will point briefly to parts of the brain in which each network is found. Understanding these models provides a basis for understanding the theories of how different types of brain computations are performed. The descriptions of these networks are kept relatively concise in this Appendix. More detailed descriptions of some of the quantitative aspects of storage in pattern associators and autoassociators are provided in the Appendices of Rolls and Treves (1998) *Neural Networks and Brain Function*. Another book that provides a clear and quantitative introduction to some of these networks is Hertz, Krogh and Palmer (1991) *Introduction to the Theory of Neural Computation*, and other useful sources include Dayan and Abbott (2001), Gerstner et al. (2014) (who focus on neuronal dynamics), Amit (1989) (for attractor networks), Koch (1999) (for a biophysical approach), Wilson (1999) (on spiking networks), and Rolls (2016b).

Some of the background to the operation of the types of neuronal network described here, including a brief review of the evidence on neuronal structure and function, and on synaptic plasticity and the rules by which synaptic strength is modified, much based on studies with long-term potentiation, is provided in Chapter 1.

The network models on which we focus in this Appendix utilize a local learning rule, that is a rule for synaptic modification, in which the signals needed to alter the synaptic strength are present in the pre- and post-synaptic neurons. We focus on these networks because use of a local learning rule is biologically plausible. We discuss the issue of biological plausibility of the networks described, and show how they differ from less biologically plausible networks such as multilayer backpropagation of error networks, in Section 19.4.

B.2 Pattern association memory

A fundamental operation of most nervous systems is to learn to associate a first stimulus with a second that occurs at about the same time, and to retrieve the second stimulus when the first is presented. The first stimulus might be the sight of food, and the second stimulus the taste of food. After the association has been learned, the sight of food would enable its taste to be retrieved. In classical conditioning, the taste of food might elicit an unconditioned response of salivation, and if the sight of the food is paired with its taste, then the sight of that food would

Fig. B.1 A pattern association memory. An unconditioned stimulus has activity or firing rate e_i for the i th neuron, and produces firing y_i of the i th neuron. An unconditioned stimulus may be treated as a vector, across the set of neurons indexed by i , of activity \mathbf{e} . The firing rate response can also be thought of as a vector of firing \mathbf{y} . The conditioned stimuli have activity or firing rate x_j for the j th axon, which can also be treated as a vector \mathbf{x} .

by learning come to produce salivation. Pattern associators are thus used where the outputs of the visual system interface to learning systems in the orbitofrontal cortex and amygdala that learn associations between the sight of objects and their taste or touch in stimulus–reinforcer association learning (see Chapter 11). Pattern association is also used throughout the cerebral (neo)cortical areas, as it is the architecture that describes the backprojection connections from one cortical area to the preceding cortical area (see Chapters 1, 9 and 13). Pattern association thus contributes to implementing top-down influences in attention, including the effects of attention from higher to lower cortical areas, and thus between the visual object and spatial processing streams (Rolls and Deco, 2002) (see Chapter 13); the effects of mood on memory and visual information processing (Rolls and Stringer, 2001b); the recall of visual memories; and the operation of short-term memory systems (see Section 13.6.1).

B.2.1 Architecture and operation

The essential elements necessary for pattern association, forming what could be called a prototypical pattern associator network, are shown in Fig. B.1. What we have called the second or unconditioned stimulus pattern is applied through unmodifiable synapses generating an input to each neuron, which, being external with respect to the synaptic matrix we focus on, we can call the external input e_i for the i th neuron. [We can also treat this as a vector, \mathbf{e} , as indicated in the legend to Fig. B.1. Vectors and simple operations performed with them are summarized in Appendix A. This unconditioned stimulus is dominant in producing or forcing the firing of the output neurons (y_i for the i th neuron, or the vector \mathbf{y})]. At the same time, the first or conditioned stimulus pattern consisting of the set of firings on the horizontally running input axons in Fig. B.1 (x_j for the j th axon) (or equivalently the vector \mathbf{x}) is applied through modifiable synapses w_{ij} to the dendrites of the output neurons. The synapses are modifiable in such a way that if there is presynaptic firing on an input axon x_j paired during learning with postsynaptic activity on neuron i , then the strength or weight w_{ij} between that axon and

the dendrite increases. This simple learning rule is often called the Hebb rule, after Donald Hebb who in 1949 formulated the hypothesis that if the firing of one neuron was regularly associated with another, then the strength of the synapse or synapses between the neurons should increase²⁴. After learning, presenting the pattern \mathbf{x} on the input axons will activate the dendrite through the strengthened synapses. If the cue or conditioned stimulus pattern is the same as that learned, the postsynaptic neurons will be activated, even in the absence of the external or unconditioned input, as each of the firing axons produces through a strengthened synapse some activation of the postsynaptic element, the dendrite. The total activation h_i of each postsynaptic neuron i is then the sum of such individual activations. In this way, the ‘correct’ output neurons, that is those activated during learning, can end up being the ones most strongly activated, and the second or unconditioned stimulus can be effectively recalled. The recall is best when only strong activation of the postsynaptic neuron produces firing, that is if there is a threshold for firing, just like real neurons. The advantages of this are evident when many associations are stored in the memory, as will soon be shown.

Next we introduce a more precise description of the above by writing down explicit mathematical rules for the operation of the simple network model of Fig. B.1, which will help us to understand how pattern association memories in general operate. (In this description we introduce simple vector operations, and, for those who are not familiar with these, refer the reader to Appendix A.) We have denoted above a conditioned stimulus input pattern as \mathbf{x} . Each of the axons has a firing rate, and if we count or index through the axons using the subscript j , the firing rate of the first axon is x_1 , of the second x_2 , of the j th x_j , etc. The whole set of axons forms a vector, which is just an ordered (1, 2, 3, etc.) set of elements. The firing rate of each axon x_j is one element of the firing rate vector \mathbf{x} . Similarly, using i as the index, we can denote the firing rate of any output neuron as y_i , and the firing rate output vector as \mathbf{y} . With this terminology, we can then identify any synapse onto neuron i from neuron j as w_{ij} (see Fig. B.1). In this book, the first index, i , always refers to the receiving neuron (and thus signifies a dendrite), while the second index, j , refers to the sending neuron (and thus signifies a conditioned stimulus input axon in Fig. B.1). We can now specify the learning and retrieval operations as follows:

B.2.1.1 Learning

The firing rate of every output neuron is forced to a value determined by the unconditioned (or external or forcing stimulus) input e_i . In our simple model this means that for any one neuron i ,

$$y_i = f(e_i) \quad (\text{B.1})$$

which indicates that the firing rate is a function of the dendritic activation, taken in this case to reduce essentially to that resulting from the external forcing input (see Fig. B.1). The function f is called the activation function (see Fig. 1.3), and its precise form is irrelevant, at least during this learning phase. For example, the function at its simplest could be taken to be linear, so that the firing rate would be just proportional to the activation.

The Hebb rule can then be written as follows:

$$\delta w_{ij} = \alpha y_i x_j \quad (\text{B.2})$$

²⁴In fact, the terms in which Hebb put the hypothesis were a little different from an association memory, in that he stated that if one neuron regularly comes to elicit firing in another, then the strength of the synapses should increase. He had in mind the building of what he called cell assemblies. In a pattern associator, the conditioned stimulus need not produce before learning any significant activation of the output neurons. The connection strengths must simply increase if there is associated pre- and postsynaptic firing when, in pattern association, most of the postsynaptic firing is being produced by a different input.

where δw_{ij} is the change of the synaptic weight w_{ij} that results from the simultaneous (or conjunctive) presence of presynaptic firing x_j and postsynaptic firing or activation y_i , and α is a learning rate constant that specifies how much the synapses alter on any one pairing.

The Hebb rule is expressed in this multiplicative form to reflect the idea that both presynaptic and postsynaptic activity must be present for the synapses to increase in strength. The multiplicative form also reflects the idea that strong pre- and postsynaptic firing will produce a larger change of synaptic weight than smaller firing rates. It is also assumed for now that before any learning takes place, the synaptic strengths are small in relation to the changes that can be produced during Hebbian learning. We will see that this assumption can be relaxed later when a modified Hebb rule is introduced that can lead to a reduction in synaptic strength under some conditions.

B.2.1.2 Recall

When the conditioned stimulus is present on the input axons, the total activation h_i of a neuron i is the sum of all the activations produced through each strengthened synapse w_{ij} by each active neuron x_j . We can express this as

$$h_i = \sum_{j=1}^C x_j w_{ij} \quad (\text{B.3})$$

where $\sum_{j=1}^C$ indicates that the sum is over the C input axons (or connections) indexed by j to each neuron.

The multiplicative form here indicates that activation should be produced by an axon only if it is firing, and only if it is connected to the dendrite by a strengthened synapse. It also indicates that the strength of the activation reflects how fast the axon x_j is firing, and how strong the synapse w_{ij} is. The sum of all such activations expresses the idea that summation (of synaptic currents in real neurons) occurs along the length of the dendrite, to produce activation at the cell body, where the activation h_i is converted into firing y_i . This conversion can be expressed as

$$y_i = f(h_i) \quad (\text{B.4})$$

where the function f is again the activation function. The form of the function now becomes more important. Real neurons have thresholds, with firing occurring only if the activation is above the threshold. A threshold linear activation function is shown in Fig. 1.3b on page 8. This has been useful in formal analysis of the properties of neural networks. Neurons also have firing rates that become saturated at a maximum rate, and we could express this as the sigmoid activation function shown in Fig. 1.3c. Yet another simple activation function, used in some models of neural networks, is the binary threshold function (Fig. 1.3d), which indicates that if the activation is below threshold, there is no firing, and that if the activation is above threshold, the neuron fires maximally. Whatever the exact shape of the activation function, some non-linearity is an advantage, for it enables small activations produced by interfering memories to be minimized, and it can enable neurons to perform logical operations, such as to fire or respond only if two or more sets of inputs are present simultaneously.

B.2.2 A simple model

An example of these learning and recall operations is provided in a simple form as follows. The neurons will have simple firing rates, which can be 0 to represent no activity, and 1 to indicate high firing. They are thus binary neurons, which can assume one of two firing rates. If

we have a pattern associator with six input axons and four output neurons, we could represent the network before learning, with the same layout as in Fig. B.1, as shown in Fig. B.2:

Fig. B.2 Pattern association: before synaptic modification. The unconditioned stimulus (UCS) firing rates are shown as 1 if high and 0 if low as a row vector being applied to force firing of the four output neurons. The six conditioned stimulus (CS) firing rates are shown as a column vector being applied to the vertical dendrites of the output neurons which have initial synaptic weights of 0.

where x or the conditioned stimulus (CS) is 101010, and y or the firing produced by the unconditioned stimulus (UCS) is 1100. (The arrows indicate the flow of signals.) The synaptic weights are initially all 0.

After pairing the CS with the UCS during one learning trial, some of the synaptic weights will be incremented according to Equation B.2, so that after learning this pair the synaptic weights will become as shown in Fig. B.3:

Fig. B.3 Pattern association: after synaptic modification. The synapses where there is conjunctive pre- and post-synaptic activity have been strengthened to value 1.

We can represent what happens during recall, when, for example, we present the CS that has been learned, as shown in Fig. B.4:

CS				
1 →	1	1	0	0
0 →	0	0	0	0
1 →	1	1	0	0
0 →	0	0	0	0
1 →	1	1	0	0
0 →	0	0	0	0
	↓	↓	↓	↓
	3	3	0	0
	1	1	0	0
	Activation h_i			
	Firing y_i			

Fig. B.4 Pattern association: recall. The activation h_i of each neuron i is converted with a threshold of 2 to the binary firing rate y_i (1 for high, and 0 for low).

The activation of the four output neurons is 3300, and if we set the threshold of each output neuron to 2, then the output firing is 1100 (where the binary firing rate is 0 if below threshold, and 1 if above). The pattern associator has thus achieved recall of the pattern 1100, which is correct.

We can now illustrate how a number of different associations can be stored in such a pattern associator, and retrieved correctly. Let us associate a new CS pattern 110001 with the UCS 0101 in the same pattern associator. The weights will become as shown next in Fig. B.5 after learning:

	U	C	S	
	0	1	0	1
	↓	↓	↓	↓
CS				
1 →	1	2	0	1
1 →	0	1	0	1
0 →	1	1	0	0
0 →	0	0	0	0
0 →	1	1	0	0
1 →	0	1	0	1

Fig. B.5 Pattern association: synaptic weights after learning a second pattern association.

If we now present the second CS, the retrieval is as shown in Fig. B.6:

Fig. B.6 Pattern association: recall with the second CS.

The binary output firings were again produced with the threshold set to 2. Recall is perfect.

This illustration shows the value of some threshold non-linearity in the activation function of the neurons. In this case, the activations did reflect some small cross-talk or interference from the previous pattern association of CS1 with UCS1, but this was removed by the threshold operation, to clean up the recall firing. The example also shows that when further associations are learned by a pattern associator trained with the Hebb rule, Equation B.2, some synapses will reflect increments above a synaptic strength of 1. It is left as an exercise to the reader to verify that recall is still perfect to CS1, the vector 101010. (The activation vector \mathbf{h} is 3401, and the output firing vector \mathbf{y} with the same threshold of 2 is 1100, which is perfect recall.)

B.2.3 The vector interpretation

The way in which recall is produced, Equation B.3, consists for each output neuron i of multiplying each input firing rate x_j by the corresponding synaptic weight w_{ij} and summing the products to obtain the activation h_i . Now we can consider the firing rates x_j where j varies from 1 to N' , the number of axons, to be a vector. (A vector is simply an ordered set of numbers – see Appendix A.) Let us call this vector \mathbf{x} . Similarly, on a neuron i , the synaptic weights can be treated as a vector, \mathbf{w}_i . (The subscript i here indicates that this is the weight vector on the i th neuron.) The operation we have just described to obtain the activation of an output neuron can now be seen to be a simple multiplication operation of two vectors to produce a single output value (called a scalar output). This is the inner product or dot product of two vectors, and can be written

$$h_i = \mathbf{x} \cdot \mathbf{w}_i. \tag{B.5}$$

The inner product of two vectors indicates how similar they are. If two vectors have corresponding elements the same, then the dot product will be maximal. If the two vectors are similar but not identical, then the dot product will be high. If the two vectors are completely different, the dot product will be 0, and the vectors are described as orthogonal. (The term orthogonal means at right angles, and arises from the geometric interpretation of vectors, which is summarized in Appendix A.) Thus the dot product provides a direct measure of how similar two vectors are.

It can now be seen that a fundamental operation many neurons perform is effectively to compute how similar an input pattern vector \mathbf{x} is to their stored weight vector \mathbf{w}_i . The similarity measure they compute, the dot product, is a very good measure of similarity, and indeed, the standard (Pearson product–moment) correlation coefficient used in statistics is the same as a normalized dot product with the mean subtracted from each vector, as shown in Appendix A. (The normalization used in the correlation coefficient results in the coefficient varying always between $+1$ and -1 , whereas the actual scalar value of a dot product clearly depends on the length of the vectors from which it is calculated.)

With these concepts, we can now see that during learning, a pattern associator adds to its weight vector a vector $\delta\mathbf{w}_i$ that has the same pattern as the input pattern \mathbf{x} , if the postsynaptic neuron i is strongly activated. Indeed, we can express Equation B.2 in vector form as

$$\delta\mathbf{w}_i = \alpha y_i \mathbf{x}. \quad (\text{B.6})$$

We can now see that what is recalled by the neuron depends on the similarity of the recall cue vector \mathbf{x}_r to the originally learned vector \mathbf{x} . The fact that during recall the output of each neuron reflects the similarity (as measured by the dot product) of the input pattern \mathbf{x}_r to each of the patterns used originally as \mathbf{x} inputs (conditioned stimuli in Fig. B.1) provides a simple way to appreciate many of the interesting and biologically useful properties of pattern associators, as described next.

B.2.4 Properties

B.2.4.1 Generalization

During recall, pattern associators generalize, and produce appropriate outputs if a recall cue vector \mathbf{x}_r is similar to a vector that has been learned already. This occurs because the recall operation involves computing the dot (inner) product of the input pattern vector \mathbf{x}_r with the synaptic weight vector \mathbf{w}_i , so that the firing produced, y_i , reflects the similarity of the current input to the previously learned input pattern \mathbf{x} . (Generalization will occur to input cue or conditioned stimulus patterns \mathbf{x}_r that are incomplete versions of an original conditioned stimulus \mathbf{x} , although the term completion is usually applied to the autoassociation networks described in Section B.3.)

This is an extremely important property of pattern associators, for input stimuli during recall will rarely be absolutely identical to what has been learned previously, and automatic generalization to similar stimuli is extremely useful, and has great adaptive value in biological systems.

Generalization can be illustrated with the simple binary pattern associator considered above. (Those who have appreciated the vector description just given might wish to skip this illustration.) Instead of the second CS, pattern vector 110001, we will use the similar recall cue 110100, as shown in Fig. B.7:

CS				
1 →	1	2	0	1
1 →	0	1	0	1
0 →	1	1	0	0
1 →	0	0	0	0
0 →	1	1	0	0
0 →	0	1	0	1
	↓	↓	↓	↓
	1	3	0	2
	0	1	0	1
			2	Activation h_i
			1	Firing y_i

Fig. B.7 Pattern association: generalization using an input vector similar to the second CS.

It is seen that the output firing rate vector, 0101, is exactly what should be recalled to CS2 (and not to CS1), so correct generalization has occurred. Although this is a small network trained with few examples, the same properties hold for large networks with large numbers of stored patterns, as described more quantitatively in Section B.2.7.1 on capacity below and in Appendix A3 of Rolls and Treves (1998).

B.2.4.2 Graceful degradation or fault tolerance

If the synaptic weight vector w_i (or the weight matrix, which we can call \mathbf{W}) has synapses missing (e.g. during development), or loses synapses, then the activation h_i or \mathbf{h} is still reasonable, because h_i is the dot product (correlation) of \mathbf{x} with w_i . The result, especially after passing through the activation function, can frequently be perfect recall. The same property arises if for example one or some of the conditioned stimulus (CS) input axons are lost or damaged. This is a very important property of associative memories, and is not a property of conventional computer memories, which produce incorrect data if even only 1 storage location (for 1 bit or binary digit of data) of their memory is damaged or cannot be accessed. This property of graceful degradation is of great adaptive value for biological systems.

We can illustrate this with a simple example. If we damage two of the synapses in Fig. B.6 to produce the synaptic matrix shown in Fig. B.8 (where x indicates a damaged synapse which has no effect, but was previously 1), and now present the second CS, the retrieval is as follows:

CS				
1 →	1	2	0	1
1 →	0	1	0	x
0 →	1	1	0	0
0 →	0	0	0	0
0 →	1	x	0	0
1 →	0	1	0	1
	↓	↓	↓	↓
	1	4	0	2
	0	1	0	1
			2	Activation h_i
			1	Firing y_i

Fig. B.8 Pattern association: graceful degradation when some synapses are damaged (x).

The binary output firings were again produced with the threshold set to 2. The recalled vector, 0101, is perfect. This illustration again shows the value of some threshold non-linearity in the activation function of the neurons. It is left as an exercise to the reader to verify that recall is still perfect to CS1, the vector 101010. (The output activation vector \mathbf{h} is 3301, and the output firing vector \mathbf{y} with the same threshold of 2 is 1100, which is perfect recall.)

B.2.4.3 The importance of distributed representations for pattern associators

A distributed representation is one in which the firing or activity of all the elements in the vector is used to encode a particular stimulus. For example, in a conditioned stimulus vector CS1 that has the value 101010, we need to know the state of all the elements to know which stimulus is being represented. Another stimulus, CS2, is represented by the vector 110001. We can represent many different events or stimuli with such overlapping sets of elements, and because in general any one element cannot be used to identify the stimulus, but instead the information about which stimulus is present is distributed over the population of elements or neurons, this is called a distributed representation (see Section 1.7). If, for binary neurons, half the neurons are in one state (e.g. 0), and the other half are in the other state (e.g. 1), then the representation is described as fully distributed. The CS representations above are thus fully distributed. If only a smaller proportion of the neurons is active to represent a stimulus, as in the vector 100001, then this is a sparse representation. For binary representations, we can quantify the sparseness by the proportion of neurons in the active (1) state.

In contrast, a local representation is one in which all the information that a particular stimulus or event has occurred is provided by the activity of one of the neurons, or elements in the vector. One stimulus might be represented by the vector 100000, another stimulus by the vector 010000, and a third stimulus by the vector 001000. The activity of neuron or element 1 would indicate that stimulus 1 was present, and of neuron 2, that stimulus 2 was present. The representation is local in that if a particular neuron is active, we know that the stimulus represented by that neuron is present. In neurophysiology, if such cells were present, they might be called ‘grandmother cells’ (cf. Barlow (1972), (1995); see Chapter 1 and Appendix C), in that one neuron might represent a stimulus in the environment as complex and specific as one’s grandmother. Where the activity of a number of cells must be taken into account in order to represent a stimulus (such as an individual taste), then the representation is sometimes described as using ensemble encoding.

The properties just described for associative memories, generalization, and graceful degradation are only implemented if the representation of the CS or \mathbf{x} vector is distributed. This occurs because the recall operation involves computing the dot (inner) product of the input pattern vector \mathbf{x}_r with the synaptic weight vector \mathbf{w}_i . This allows the activation h_i to reflect the similarity of the current input pattern to a previously learned input pattern \mathbf{x} only if several or many elements of the \mathbf{x} and \mathbf{x}_r vectors are in the active state to represent a pattern. If local encoding were used, e.g. 100000, then if the first element of the vector (which might be the firing of axon 1, i.e. x_1 , or the strength of synapse $i1$, w_{i1}) is lost, the resulting vector is not similar to any other CS vector, and the activation is 0. In the case of local encoding, the important properties of associative memories, generalization and graceful degradation do not thus emerge. Graceful degradation and generalization are dependent on distributed representations, for then the dot product can reflect similarity even when some elements of the vectors involved are altered. If we think of the correlation between Y and X in a graph, then this correlation is affected only a little if a few X, Y pairs of data are lost (see Appendix A).

B.2.5 Prototype extraction, extraction of central tendency, and noise reduction

If a set of similar conditioned stimulus vectors \mathbf{x} are paired with the same unconditioned stimulus e_i , the weight vector \mathbf{w}_i becomes (or points towards) the sum (or with scaling, the average) of the set of similar vectors \mathbf{x} . This follows from the operation of the Hebb rule in Equation B.2. When tested at recall, the output of the memory is then best to the average input pattern vector denoted $\langle \mathbf{x} \rangle$. If the average is thought of as a prototype, then even though the prototype vector $\langle \mathbf{x} \rangle$ itself may never have been seen, the best output of the neuron or network is to the prototype. This produces ‘extraction of the prototype’ or ‘central tendency’. The same phenomenon is a feature of human memory performance (see McClelland and Rumelhart (1986) Chapter 17), and this simple process with distributed representations in a neural network accounts for the psychological phenomenon.

If the different exemplars of the vector \mathbf{x} are thought of as noisy versions of the true input pattern vector $\langle \mathbf{x} \rangle$ (with incorrect values for some of the elements), then the pattern associator has performed ‘noise reduction’, in that the output produced by any one of these vectors will represent the output produced by the true, noiseless, average vector $\langle \mathbf{x} \rangle$.

B.2.6 Speed

Recall is very fast in a real neuronal network, because the conditioned stimulus input firings x_j ($j = 1, C$ axons) can be applied simultaneously to the synapses w_{ij} , and the activation h_i can be accumulated in one or two time constants of the dendrite (e.g. 10–20 ms). Whenever the threshold of the cell is exceeded, it fires. Thus, in effectively one step, which takes the brain no more than 10–20 ms, all the output neurons of the pattern associator can be firing with rates that reflect the input firing of every axon. This is very different from a conventional digital computer, in which computing h_i in Equation B.3 would involve C multiplication and addition operations occurring one after another, or $2C$ time steps.

The brain performs parallel computation in at least two senses in even a pattern associator. One is that for a single neuron, the separate contributions of the firing rate x_j of each axon j multiplied by the synaptic weight w_{ij} are computed in parallel and added in the same timestep. The second is that this can be performed in parallel for all neurons $i = 1, N$ in the network, where there are N output neurons in the network. It is these types of parallel and time-continuous (see Section B.6) processing that enable these classes of neuronal network in the brain to operate so fast, in effectively so few steps.

Learning is also fast (‘one-shot’) in pattern associators, in that a single pairing of the conditioned stimulus \mathbf{x} and the unconditioned stimulus (UCS) e which produces the unconditioned output firing \mathbf{y} enables the association to be learned. There is no need to repeat the pairing in order to discover over many trials the appropriate mapping. This is extremely important for biological systems, in which a single co-occurrence of two events may lead to learning that could have life-saving consequences. (For example, the pairing of a visual stimulus with a potentially life-threatening aversive event may enable that event to be avoided in future.) Although repeated pairing with small variations of the vectors is used to obtain the useful properties of prototype extraction, extraction of central tendency, and noise reduction, the essential properties of generalization and graceful degradation are obtained with just one pairing. The actual time scales of the learning in the brain are indicated by studies of associative synaptic modification using long-term potentiation paradigms (LTP, see Section 1.6). Co-occurrence or near simultaneity of the CS and UCS is required for periods of as little as 100 ms, with expression of the synaptic modification being present within typically a few seconds.

Fig. B.9 (b) In vertebrate pattern association learning, the unconditioned stimulus (UCS) may be made available at all the conditioned stimulus (CS) terminals onto the output neuron because the dendrite of the postsynaptic neuron is electrically short, so that the effect of the UCS spreads for long distances along the dendrite. (a) In contrast, in at least some invertebrate association learning systems, the unconditioned stimulus or teaching input makes a synapse onto the presynaptic terminal carrying the conditioned stimulus.

B.2.7 Local learning rule

The simplest learning rule used in pattern association neural networks, a version of the Hebb rule, is, as shown in Equation B.2 above,

$$\delta w_{ij} = \alpha y_i x_j.$$

This is a local learning rule in that the information required to specify the change in synaptic weight is available locally at the synapse, as it is dependent only on the presynaptic firing rate x_j available at the synaptic terminal, and the postsynaptic activation or firing y_i available on the dendrite of the neuron receiving the synapse (see Fig. B.9b). This makes the learning rule biologically plausible, in that the information about how to change the synaptic weight does not have to be carried from a distant source, where it is computed, to every synapse. Such a non-local learning rule would not be biologically plausible, in that there are no appropriate connections known in most parts of the brain to bring in the synaptic training or teacher signal to every synapse.

Evidence that a learning rule with the general form of Equation B.2 is implemented in at least some parts of the brain comes from studies of long-term potentiation, described in Section 1.6. Long-term potentiation (LTP) has the synaptic specificity defined by Equation B.2, in that only synapses from active afferents, not those from inactive afferents, become strengthened. Synaptic specificity is important for a pattern associator, and most other types of neuronal network, to operate correctly. The number of independently modifiable synapses on each neuron is a primary factor in determining how many different memory patterns can be stored in associative memories (see Sections B.2.7.1 and B.3.3.7).

Another useful property of real neurons in relation to Equation B.2 is that the postsynaptic term, y_i , is available on much of the dendrite of a cell, because the electrotonic length of the dendrite is short. In addition, active propagation of spiking activity from the cell body along the dendrite may help to provide a uniform postsynaptic term for the learning. Thus if a neuron is strongly activated with a high value for y_i , then any active synapse onto the cell will be capable of being modified. This enables the cell to learn an association between the pattern of activity on all its axons and its postsynaptic activation, which is stored as an addition to its weight vector \mathbf{w}_i . Then later on, at recall, the output can be produced as a vector dot product operation between the input pattern vector \mathbf{x} and the weight vector \mathbf{w}_i , so that the output of

the cell can reflect the correlation between the current input vector and what has previously been learned by the cell.

It is interesting that at least many invertebrate neuronal systems may operate very differently from those described here, as described by Rolls and Treves (1998) (see Fig. B.9a). If there were 5,000 conditioned stimulus inputs to a neuron, the implication is that every one would need to have a presynaptic terminal conveying the same UCS to each presynaptic terminal, which is hardly plausible. The implication is that at least some invertebrate neural systems operate very differently to those in vertebrates and, in such systems, the useful properties that arise from using distributed CS representations such as generalization would not arise in the same simple way as a property of the network.

B.2.7.1 Capacity

The question of the storage capacity of a pattern associator is considered in detail in Appendix A3 of Rolls and Treves (1998). It is pointed out there that, for this type of associative network, the number of memories that it can hold simultaneously in storage has to be analyzed together with the retrieval quality of each output representation, and then only for a given quality of the representation provided in the input. This is in contrast to autoassociative nets (Section B.3), in which a critical number of stored memories exists (as a function of various parameters of the network), beyond which attempting to store additional memories results in it becoming impossible to retrieve essentially anything. With a pattern associator, instead, one will always retrieve something, but this something will be very small (in information or correlation terms) if too many associations are simultaneously in storage and/or if too little is provided as input.

The conjoint quality–capacity input analysis can be carried out, for any specific instance of a pattern associator, by using formal mathematical models and established analytical procedures (see e.g. Treves (1995), Rolls and Treves (1998), Treves (1990) and Rolls and Treves (1990)). This, however, has to be done case by case. It is anyway useful to develop some intuition for how a pattern associator operates, by considering what its capacity would be in certain well-defined simplified cases.

Linear associative neuronal networks These networks are made up of units with a linear activation function, which appears to make them unsuitable to represent real neurons with their positive-only firing rates. However, even purely linear units have been considered as provisionally relevant models of real neurons, by assuming that the latter operate sometimes in the linear regime of their transfer function. (This implies a high level of spontaneous activity, and may be closer to conditions observed early on in sensory systems rather than in areas more specifically involved in memory.) As usual, the connections are trained by a Hebb (or similar) associative learning rule. The capacity of these networks can be defined as the total number of associations that can be learned independently of each other, given that the linear nature of these systems prevents anything more than a linear transform of the inputs. This implies that if input pattern C can be written as the weighted sum of input patterns A and B , the output to C will be just the same weighted sum of the outputs to A and B . If there are N' input axons, then there can be only at most N' mutually independent input patterns (i.e. none able to be written as a weighted sum of the others), and therefore the capacity of linear networks, defined above, is just N' , or equal to the number of inputs to each neuron. In general, a random set of less than N' vectors (the CS input pattern vectors) will tend to be mutually independent but not mutually orthogonal (at 90 deg to each other) (see Appendix A). If they are not orthogonal (the normal situation), then the dot product of them is not 0, and the output pattern activated by one of the input vectors will be partially activated by other input pattern vectors, in accordance with how similar they are (see Equations B.5 and B.6).

This amounts to interference, which is therefore the more serious the less orthogonal, on the whole, is the set of input vectors.

Since input patterns are made of elements with positive values, if a simple Hebbian learning rule like the one of Equation B.2 is used (in which the input pattern enters directly with no subtraction term), the output resulting from the application of a stored input vector will be the sum of contributions from all other input vectors that have a non-zero dot product with it (see Appendix A), and interference will be disastrous. The only situation in which this would not occur is when different input patterns activate completely different input lines, but this is clearly an uninteresting circumstance for networks operating with distributed representations. A solution to this issue is to use a modified learning rule of the following form:

$$\delta w_{ij} = \alpha y_i (x_j - x) \quad (\text{B.7})$$

where x is a constant, approximately equal to the average value of x_j . This learning rule includes (in proportion to y_i) increasing the synaptic weight if $(x_j - x) > 0$ (long-term potentiation), and decreasing the synaptic weight if $(x_j - x) < 0$ (heterosynaptic long-term depression). It is useful for x to be roughly the average activity of an input axon x_j across patterns, because then the dot product between the various patterns stored on the weights and the input vector will tend to cancel out with the subtractive term, except for the pattern equal to (or correlated with) the input vector itself. Then up to N' input vectors can still be learned by the network, with only minor interference (provided of course that they are mutually independent, as they will in general tend to be).

Table B.1 Effects of pre- and post-synaptic activity on synaptic modification

		Post-synaptic activation	
		0	high
Presynaptic firing	0	No change	Heterosynaptic LTD
	high	Homosynaptic LTD	LTP

This modified learning rule can also be described in terms of a contingency table (Table B.1) showing the synaptic strength modifications produced by different types of learning rule, where LTP indicates an increase in synaptic strength (called long-term potentiation in neurophysiology), and LTD indicates a decrease in synaptic strength (called long-term depression in neurophysiology). Heterosynaptic long-term depression is so-called because it is the decrease in synaptic strength that occurs to a synapse that is other than that through which the postsynaptic cell is being activated. This heterosynaptic long-term depression is the type of change of synaptic strength that is required (in addition to LTP) for effective subtraction of the average presynaptic firing rate, in order, as it were, to make the CS vectors appear more orthogonal to the pattern associator. The rule is sometimes called the Singer–Stent rule, after work by Singer (1987) and Stent (1973), and was discovered in the brain by Levy (Levy, 1985; Levy and Desmond, 1985) (see also Brown, Kairiss and Keenan (1990b)). Homosynaptic long-term depression is so-called because it is the decrease in synaptic strength that occurs to a synapse which is (the same as that which is) active. For it to occur, the postsynaptic neuron must simultaneously be inactive, or have only low activity. (This rule is sometimes called the BCM rule after the paper of Bienenstock, Cooper and Munro (1982); see Rolls and

Deco (2002), Chapter 7).

Associative neuronal networks with non-linear neurons With non-linear neurons, that is with at least a threshold in the activation function so that the output firing y_i is 0 when the activation h_i is below the threshold, the capacity can be measured in terms of the number of different clusters of output pattern vectors that the network produces. This is because the non-linearities now present (one per output neuron) result in some clustering of the outputs produced by all possible (conditioned stimulus) input patterns \mathbf{x} . Input patterns that are similar to a stored input vector can produce, due to the non-linearities, output patterns even closer to the stored output; and vice versa, sufficiently dissimilar inputs can be assigned to different output clusters thereby increasing their mutual dissimilarity. As with the linear counterpart, in order to remove the correlation that would otherwise occur between the patterns because the elements can take only positive values, it is useful to use a modified Hebb rule of the form shown in Equation B.7.

With fully distributed output patterns, the number p of associations that leads to different clusters is of order C , the number of input lines (axons) per output neuron (that is, of order N' for a fully connected network), as shown in Appendix A3 of Rolls and Treves (1998). If sparse patterns are used in the output, or alternatively if the learning rule includes a non-linear postsynaptic factor that is effectively equivalent to using sparse output patterns, the coefficient of proportionality between p and C can be much higher than one, that is, many more patterns can be stored than inputs onto each output neuron (see Appendix A3 of Rolls and Treves (1998)). Indeed, the number of different patterns or prototypes p that can be stored can be derived for example in the case of binary units (Gardner, 1988) to be

$$p \approx C / [a_o \log(1/a_o)] \quad (\text{B.8})$$

where a_o is the sparseness of the output firing pattern \mathbf{y} produced by the unconditioned stimulus. p can in this situation be much larger than C (see Appendix A3 of Rolls and Treves (1998), Rolls and Treves (1990) and Treves (1990)). This is an important result for encoding in pattern associators, for it means that provided that the activation functions are non-linear (which is the case with real neurons), there is a very great advantage to using sparse encoding, for then many more than C pattern associations can be stored. Sparse representations may well be present in brain regions involved in associative memory for this reason (see Appendix C).

The non-linearity inherent in the NMDA receptor-based Hebbian plasticity present in the brain may help to make the stored patterns more sparse than the input patterns, and this may be especially beneficial in increasing the storage capacity of associative networks in the brain by allowing participation in the storage of especially those relatively few neurons with high firing rates in the exponential firing rate distributions typical of neurons in sensory systems (see Appendix C).

Dilution of the connectivity in pattern association networks can help to maximize capacity by reducing the probability of more than one synapse between an input and output neuron (Rolls, 2015a).

B.2.7.2 Interference

Interference occurs in linear pattern associators if two vectors are not orthogonal, and is simply dependent on the angle between the originally learned vector and the recall cue or CS vector (see Appendix A), for the activation of the output neuron depends simply on the dot product of the recall vector and the synaptic weight vector (equation B.5). Also in non-linear pattern associators (the interesting case for all practical purposes), interference may occur if two CS patterns are not orthogonal, though the effect can be controlled with sparse encoding

Input <i>A</i>	1		0		1
Input <i>B</i>	0		1		1
Required Output	1		1		0

Fig. B.10 A non-linearly separable mapping.

of the UCS patterns, effectively by setting high thresholds for the firing of output units. In other words, the CS vectors need not be strictly orthogonal, but if they are too similar, some interference will still be likely to occur.

The fact that interference is a property of neural network pattern associator memories is of interest, for interference is a major property of human memory. Indeed, the fact that interference is a property of human memory and of neural network association memories is entirely consistent with the hypothesis that human memory is stored in associative memories of the type described here, or at least that network associative memories of the type described represent a useful exemplar of the class of parallel distributed storage network used in human memory.

It may also be suggested that one reason that interference is tolerated in biological memory is that it is associated with the ability to generalize between stimuli, which is an invaluable feature of biological network associative memories, in that it allows the memory to cope with stimuli that will almost never be identical on different occasions, and in that it allows useful analogies that have survival value to be made.

B.2.7.3 Expansion recoding

If patterns are too similar to be stored in associative memories, then one solution that the brain seems to use repeatedly is to expand the encoding to a form in which the different stimulus patterns are less correlated, that is, more orthogonal, before they are presented as CS stimuli to a pattern associator. The problem can be highlighted by a non-linearly separable mapping (which captures part of the eXclusive OR (XOR) problem), in which the mapping that is desired is as shown in Fig. B.10. The neuron has two inputs, *A* and *B*.

This is a mapping of patterns that is impossible for a one-layer network, because the patterns are not linearly separable²⁵. A solution is to remap the two input lines *A* and *B* to three input lines 1–3, that is to use expansion recoding, as shown in Fig. B.11. This can be performed by a competitive network (see Section B.4). The synaptic weights on the dendrite of the output neuron could then learn the following values using a simple Hebb rule, Equation B.2, and the problem could be solved as in Fig. B.12. The whole network would look like that shown in Fig. B.11.

Competitive networks could help with this type of recoding, and could provide very useful preprocessing for a pattern associator in the brain (Rolls and Treves, 1998; Rolls, 2016b). It is possible that the lateral nucleus of the amygdala performs this function, for it receives inputs from the temporal cortical visual areas, and may preprocess them before they become the inputs to associative networks at the next stage of amygdala processing (Rolls, 2016b, 2014a). The granule cells of the cerebellum may operate similarly (Chapter 17).

²⁵See Appendix A. There is no set of synaptic weights in a one-layer net that could solve the problem shown in Fig. B.10. Two classes of patterns are not linearly separable if no hyperplane can be positioned in their *N*-dimensional space so as to separate them (see Appendix A). The XOR problem has the additional constraint that $A = 0, B = 0$ must be mapped to Output = 0.

Fig. B.11 Expansion recoding. A competitive network followed by a pattern associator that can enable patterns that are not linearly separable to be learned correctly.

B.2.8 Implications of different types of coding for storage in pattern associators

Throughout this section, we have made statements about how the properties of pattern associators – such as the number of patterns that can be stored, and whether generalization and graceful degradation occur – depend on the type of encoding of the patterns to be associated. (The types of encoding considered, local, sparse distributed, and fully distributed, are described above.) We draw together these points in Table B.2.

Table B.2 Coding in associative memories*

	Local	Sparse distributed	Fully distributed
Generalization, completion, graceful degradation	No	Yes	Yes
Number of patterns that can be stored	N (large)	of order $C/[a_o \log(1/a_o)]$ (can be larger)	of order C (usually smaller than N)
Amount of information in each pattern (values if binary)	Minimal ($\log(N)$ bits)	Intermediate ($Na_o \log(1/a_o)$ bits)	Large (N bits)

* N refers here to the number of output units, and C to the average number of inputs to each output unit. a_o is the sparseness of output patterns, or roughly the proportion of output units activated by a UCS pattern. Note: logs are to the base 2.

The amount of information that can be stored in each pattern in a pattern associator is considered in Appendix A3 of Rolls and Treves (1998). That Appendix has been made available at <https://www.oxcns.org>, and contains a quantitative approach to the capacity of pattern association networks that has not been published elsewhere.

In conclusion, the architecture and properties of pattern association networks make them very appropriate for stimulus–reinforcer association learning. Their high capacity enables them to learn the reinforcement associations for very large numbers of different stimuli.

B.3 Autoassociation or attractor memory

Autoassociative memories, or attractor neural networks, store memories, each one of which is represented by a pattern of neural activity. The memories are stored in the recurrent synaptic connections between the neurons of the network, for example in the recurrent collateral connections between cortical pyramidal cells. Autoassociative networks can then recall the appropriate memory from the network when provided with a fragment of one of the memories. This is called completion. Many different memories can be stored in the network and retrieved correctly. A feature of this type of memory is that it is content addressable; that is, the information in the memory can be accessed if just the contents of the memory (or a part of the contents of the memory) are used. This is in contrast to a conventional computer, in which the address of what is to be accessed must be supplied, and used to access the contents of the memory. Content addressability is an important simplifying feature of this type of memory, which makes it suitable for use in biological systems. The issue of content addressability will be amplified below.

An autoassociation memory can be used as a short-term memory, in which iterative processing round the recurrent collateral connection loop keeps a representation active by continuing neuronal firing. The short-term memory reflected in continuing neuronal firing for several hundred milliseconds after a visual stimulus is removed which is present in visual cortical areas such as the inferior temporal visual cortex (see Chapter 2) is probably implemented in this way. This short-term memory is one possible mechanism that contributes to the implementation of the trace memory learning rule which can help to implement invariant object recognition as described in Chapter 2. Autoassociation memories also appear to be used in a short-term memory role in the prefrontal cortex. In particular, the temporal visual cortical areas have connections to the ventrolateral prefrontal cortex which help to implement the short-term memory for visual stimuli (in for example delayed match to sample tasks, and visual search tasks, as described in Section 13.6.1). In an analogous way the parietal cortex has connections to the dorsolateral prefrontal cortex for the short-term memory of spatial responses (see Section 13.6.1). These short-term memories provide a mechanism that enables attention to be maintained through backprojections from prefrontal cortex areas to the temporal and parietal areas that send connections to the prefrontal cortex, as described in Chapter 13. Autoassociation networks implemented by the recurrent collateral synapses between cortical pyramidal cells also provide a mechanism for constraint satisfaction and also noise reduction whereby the firing of neighbouring neurons can be taken into account in enabling the network to settle into a state that reflects all the details of the inputs activating the population of connected neurons, as well as the effects of what has been set up during developmental plasticity as well as later experience. Attractor networks are also effectively implemented by virtue of the forward and backward connections between cortical areas (see Sections 9.3.8 and 13.6.1). An autoassociation network with rapid synaptic plasticity can learn each memory in one trial. Because of its ‘one-shot’ rapid learning, and ability to complete, this type of network is well suited for episodic memory storage, in which each past episode must be stored and recalled later from a fragment, and kept separate from other episodic memories (see Chapter 9).

B.3.1 Architecture and operation

The prototypical architecture of an autoassociation memory is shown in Fig. B.13. The external input e_i is applied to each neuron i by unmodifiable synapses. This produces firing y_i of each neuron, or a vector of firing on the output neurons y . Each output neuron i is connected by a recurrent collateral connection to the other neurons in the network, via mod-

Fig. B.13 The architecture of an autoassociative neural network.

ifiable connection weights w_{ij} . This architecture effectively enables the output firing vector \mathbf{y} to be associated during learning with itself. Later on, during recall, presentation of part of the external input will force some of the output neurons to fire, but through the recurrent collateral axons and the modified synapses, other neurons in \mathbf{y} can be brought into activity. This process can be repeated a number of times, and recall of a complete pattern may be perfect. Effectively, a pattern can be recalled or recognized because of associations formed between its parts. This of course requires distributed representations.

Next we introduce a more precise and detailed description of the above, and describe the properties of these networks. Ways to analyze formally the operation of these networks are introduced in Appendix A4 of Rolls and Treves (1998) and by Amit (1989).

B.3.1.1 Learning

The firing of every output neuron i is forced to a value y_i determined by the external input e_i . Then a Hebb-like associative local learning rule is applied to the recurrent synapses in the network:

$$\delta w_{ij} = \alpha y_i y_j. \quad (\text{B.9})$$

It is notable that in a fully connected network, this will result in a symmetric matrix of synaptic weights, that is the strength of the connection from neuron 1 to neuron 2 will be the same as the strength of the connection from neuron 2 to neuron 1 (both implemented via recurrent collateral synapses).

It is a factor that is sometimes overlooked that there must be a mechanism for ensuring that during learning y_i does approximate e_i , and must not be influenced much by activity in the recurrent collateral connections, otherwise the new external pattern \mathbf{e} will not be stored in the network, but instead something will be stored that is influenced by the previously stored memories. It is thought that in some parts of the brain, such as the hippocampus, there are processes that help the external connections to dominate the firing during learning (see Chapter 9, Treves and Rolls (1992) and Rolls and Treves (1998)).

B.3.1.2 Recall

During recall, the external input e_i is applied, and produces output firing, operating through the non-linear activation function described below. The firing is fed back by the recurrent collateral axons shown in Fig. B.13 to produce activation of each output neuron through the modified synapses on each output neuron. The activation h_i produced by the recurrent

collateral effect on the i th neuron is, in the standard way, the sum of the activations produced in proportion to the firing rate of each axon y_j operating through each modified synapse w_{ij} , that is,

$$h_i = \sum_j y_j w_{ij} \quad (\text{B.10})$$

where \sum_j indicates that the sum is over the C input axons to each neuron, indexed by j .

The output firing y_i is a function of the activation produced by the recurrent collateral effect (internal recall) and by the external input (e_i):

$$y_i = f(h_i + e_i) \quad (\text{B.11})$$

The activation function should be non-linear, and may be for example binary threshold, linear threshold, sigmoid, etc. (see Fig. 1.3). The threshold at which the activation function operates is set in part by the effect of the inhibitory neurons in the network (not shown in Fig. B.13). The connectivity is that the pyramidal cells have collateral axons that excite the inhibitory interneurons, which in turn connect back to the population of pyramidal cells to inhibit them by a mixture of shunting (divisive) and subtractive inhibition using GABA (gamma-aminobutyric acid) terminals, as described in Section B.6. There are many fewer inhibitory neurons than excitatory neurons (in the order of 5–10%, see Table 1.8) and of connections to and from inhibitory neurons (see Table 1.8), and partly for this reason the inhibitory neurons are considered to perform generic functions such as threshold setting, rather than to store patterns by modifying their synapses. Similar inhibitory processes are assumed for the other networks described in this Appendix. The non-linear activation function can minimize interference between the pattern being recalled and other patterns stored in the network, and can also be used to ensure that what is a positive feedback system remains stable. The network can be allowed to repeat this recurrent collateral loop a number of times. Each time the loop operates, the output firing becomes more like the originally stored pattern, and this progressive recall is usually complete within 5–15 iterations.

B.3.2 Introduction to the analysis of the operation of autoassociation networks

With complete connectivity in the synaptic matrix, and the use of a Hebb rule, the matrix of synaptic weights formed during learning is symmetric. The learning algorithm is fast, ‘one-shot’, in that a single presentation of an input pattern is all that is needed to store that pattern.

During recall, a part of one of the originally learned stimuli can be presented as an external input. The resulting firing is allowed to iterate repeatedly round the recurrent collateral system, gradually on each iteration recalling more and more of the originally learned pattern. Completion thus occurs. If a pattern is presented during recall that is similar but not identical to any of the previously learned patterns, then the network settles into a stable recall state in which the firing corresponds to that of the previously learned pattern. The network can thus generalize in its recall to the most similar previously learned pattern. The activation function of the neurons should be non-linear, since a purely linear system would not produce any categorization of the input patterns it receives, and therefore would not be able to effect anything more than a trivial (i.e. linear) form of completion and generalization.

Recall can be thought of in the following way, relating it to what occurs in pattern associators. The external input \mathbf{e} is applied, produces firing \mathbf{y} , which is applied as a recall cue on the recurrent collaterals as \mathbf{y}^T . (The notation \mathbf{y}^T signifies the transpose of \mathbf{y} , which is implemented by the application of the firing of the neurons \mathbf{y} back via the recurrent collateral axons as the next set of inputs to the neurons.) The activity on the recurrent collaterals is then

multiplied by the synaptic weight vector stored during learning on each neuron to produce the new activation h_i which reflects the similarity between \mathbf{y}^T and one of the stored patterns. Partial recall has thus occurred as a result of the recurrent collateral effect. The activations h_i after thresholding (which helps to remove interference from other memories stored in the network, or noise in the recall cue) result in firing y_i , or a vector of all neurons \mathbf{y} , which is already more like one of the stored patterns than, at the first iteration, the firing resulting from the recall cue alone, $\mathbf{y} = f(\mathbf{e})$. This process is repeated a number of times to produce progressive recall of one of the stored patterns.

Autoassociation networks operate by effectively storing associations between the elements of a pattern. Each element of the pattern vector to be stored is simply the firing of a neuron. What is stored in an autoassociation memory is a set of pattern vectors. The network operates to recall one of the patterns from a fragment of it. Thus, although this network implements recall or recognition of a pattern, it does so by an association learning mechanism, in which associations between the different parts of each pattern are learned. These memories have sometimes been called autocorrelation memories (Kohonen, 1977), because they learn correlations between the activity of neurons in the network, in the sense that each pattern learned is defined by a set of simultaneously active neurons. Effectively each pattern is associated by learning with itself. This learning is implemented by an associative (Hebb-like) learning rule.

The system formally resembles spin glass systems of magnets analyzed quantitatively in statistical mechanics. This has led to the analysis of (recurrent) autoassociative networks as dynamical systems made up of many interacting elements, in which the interactions are such as to produce a large variety of basins of attraction of the dynamics. Each basin of attraction corresponds to one of the originally learned patterns, and once the network is within a basin it keeps iterating until a recall state is reached that is the learned pattern itself or a pattern closely similar to it. (Interference effects may prevent an exact identity between the recall state and a learned pattern.) This type of system is contrasted with other, simpler, systems of magnets (e.g. ferromagnets), in which the interactions are such as to produce only a limited number of related basins, since the magnets tend to be, for example, all aligned with each other. The states reached within each basin of attraction are called attractor states, and the analogy between autoassociator neural networks and physical systems with multiple attractors was drawn by Hopfield (1982) in a very influential paper. He was able to show that the recall state can be thought of as the local minimum in an energy landscape, where the energy would be defined as

$$E = -\frac{1}{2} \sum_{i,j} w_{ij} (y_i - \langle y \rangle)(y_j - \langle y \rangle). \quad (\text{B.12})$$

This Equation can be understood in the following way. If two neurons are both firing above their mean rate (denoted by $\langle y \rangle$), and are connected by a weight with a positive value, then the firing of these two neurons is consistent with each other, and they mutually support each other, so that they contribute to the system's tendency to remain stable. If across the whole network such mutual support is generally provided, then no further change will take place, and the system will indeed remain stable. If, on the other hand, either of our pair of neurons was not firing, or if the connecting weight had a negative value, the neurons would not support each other, and indeed the tendency would be for the neurons to try to alter ('flip' in the case of binary units) the state of the other. This would be repeated across the whole network until a situation in which most mutual support, and least 'frustration', was reached. What makes it possible to define an energy function and for these points to hold is that the matrix is symmetric (see Hopfield (1982), Hertz, Krogh and Palmer (1991), Amit (1989)).

Physicists have generally analyzed a system in which the input pattern is presented and then immediately removed, so that the network then ‘falls’ without further assistance (in what is referred to as the unclamped condition) towards the minimum of its basin of attraction. A more biologically realistic system is one in which the external input is left on contributing to the recall during the fall into the recall state. In this clamped condition, recall is usually faster, and more reliable, so that more memories may be usefully recalled from the network. The approach using methods developed in theoretical physics has led to rapid advances in the understanding of autoassociative networks, and its basic elements are described in Appendix A4 of Rolls and Treves (1998), and by Hertz, Krogh and Palmer (1991) and Amit (1989).

B.3.3 Properties

The internal recall in autoassociation networks involves multiplication of the firing vector of neuronal activity by the vector of synaptic weights on each neuron. This inner product vector multiplication allows the similarity of the firing vector to previously stored firing vectors to be provided by the output (as effectively a correlation), if the patterns learned are distributed. As a result of this type of ‘correlation computation’ performed if the patterns are distributed, many important properties of these networks arise, including pattern completion (because part of a pattern is correlated with the whole pattern), and graceful degradation (because a damaged synaptic weight vector is still correlated with the original synaptic weight vector). Some of these properties are described next.

B.3.3.1 Completion

Perhaps the most important and useful property of these memories is that they complete an incomplete input vector, allowing recall of a whole memory from a small fraction of it. The memory recalled in response to a fragment is that stored in the memory that is closest in pattern similarity (as measured by the dot product, or correlation). Because the recall is iterative and progressive, the recall can be perfect.

This property and the associative property of pattern associator neural networks are very similar to the properties of human memory. This property may be used when we recall a part of a recent memory of a past episode from a part of that episode. The way in which this could be implemented in the hippocampus is described in Chapter 9.

B.3.3.2 Generalization

The network generalizes in that an input vector similar to one of the stored vectors will lead to recall of the originally stored vector, provided that distributed encoding is used. The principle by which this occurs is similar to that described for a pattern associator.

B.3.3.3 Graceful degradation or fault tolerance

If the synaptic weight vector \mathbf{w}_i on each neuron (or the weight matrix) has synapses missing (e.g. during development), or loses synapses (e.g. with brain damage or ageing), then the activation h_i (or vector of activations \mathbf{h}) is still reasonable, because h_i is the dot product (correlation) of \mathbf{y}^T with \mathbf{w}_i . The same argument applies if whole input axons are lost. If an output neuron is lost, then the network cannot itself compensate for this, but the next network in the brain is likely to be able to generalize or complete if its input vector has some elements missing, as would be the case if some output neurons of the autoassociation network were damaged.

B.3.3.4 Prototype extraction, extraction of central tendency, and noise reduction

These arise when a set of similar input pattern vectors $\{e\}$ (which induce firing of the output neurons $\{y\}$) are learned by the network. The weight vectors w_i (or strictly w_i^T) become (or point towards) the average $\langle y \rangle$ of that set of similar vectors. This produces ‘extraction of the prototype’ or ‘extraction of the central tendency’, and ‘noise reduction’. This process can result in better recognition or recall of the prototype than of any of the exemplars, even though the prototype may never itself have been presented. The general principle by which the effect occurs is similar to that by which it occurs in pattern associators. It of course only occurs if each pattern uses a distributed representation.

Related to outputs of the visual system to long-term memory systems (see Chapter 9), there has been intense debate about whether when human memories are stored, a prototype of what is to be remembered is stored, or whether all the instances or the exemplars are each stored separately so that they can be individually recalled (McClelland and Rumelhart (1986), Chapter 17, p. 172). Evidence favouring the prototype view is that if a number of different examples of an object are shown, then humans may report more confidently that they have seen the prototype before than any of the different exemplars, even though the prototype has never been shown (Posner and Keele, 1968; Rosch, 1975). Evidence favouring the view that exemplars are stored is that in categorization and perceptual identification tasks the responses made are often sensitive to the congruity between particular training stimuli and particular test stimuli (Brooks, 1978; Medin and Schaffer, 1978; Jacoby, 1983a,b; Whittlesea, 1983). It is of great interest that both types of phenomena can arise naturally out of distributed information storage in a neuronal network such as an autoassociator. This can be illustrated by the storage in an autoassociation memory of sets of stimuli that are all somewhat different examples of the same pattern. These can be generated, for example, by randomly altering each of the input vectors from the input stimulus. After many such randomly altered exemplars have been learned by the network, recall can be tested, and it is found that the network responds best to the original (prototype) input vector, with which it has never been presented. The reason for this is that the autocorrelation components that build up in the synaptic matrix with repeated presentations of the exemplars represent the average correlation between the different elements of the vector, and this is highest for the prototype. This effect also gives the storage some noise immunity, in that variations in the input that are random noise average out, while the signal that is constant builds up with repeated learning.

B.3.3.5 Speed

The recall operation is fast on each neuron on a single iteration, because the pattern y^T on the axons can be applied simultaneously to the synapses w_i , and the activation h_i can be accumulated in one or two time constants of the dendrite (e.g. 10–20 ms). If a simple implementation of an autoassociation net such as that described by Hopfield (1982) is simulated on a computer, then 5–15 iterations are typically necessary for completion of an incomplete input cue e . This might be taken to correspond to 50–200 ms in the brain, rather too slow for any one local network in the brain to function. However, it has been shown that if the neurons are treated not as McCulloch–Pitts neurons which are simply ‘updated’ at each iteration, or cycle of timesteps (and assume the active state if the threshold is exceeded), but instead are analyzed and modelled as ‘integrate-and-fire’ neurons in real continuous time, then the network can effectively ‘relax’ into its recall state very rapidly, in one or two time constants of the synapses (see Section B.6 and Treves (1993), Battaglia and Treves (1998a) and Appendix A5 of Rolls and Treves (1998)). This corresponds to perhaps 20 ms in the brain.

One factor in this rapid dynamics of autoassociative networks with brain-like ‘integrate-and-fire’ membrane and synaptic properties is that with some spontaneous activity, some of the neurons in the network are close to threshold already before the recall cue is applied, and hence some of the neurons are very quickly pushed by the recall cue into firing, so that information starts to be exchanged very rapidly (within 1–2 ms of brain time) through the modified synapses by the neurons in the network. The progressive exchange of information starting early on within what would otherwise be thought of as an iteration period (of perhaps 20 ms, corresponding to a neuronal firing rate of 50 spikes/s) is the mechanism accounting for rapid recall in an autoassociative neuronal network made biologically realistic in this way. Further analysis of the fast dynamics of these networks if they are implemented in a biologically plausible way with ‘integrate-and-fire’ neurons is provided in Section B.6, in Appendix A5 of Rolls and Treves (1998), and by Treves (1993). *The general approach applies to other networks with recurrent connections, not just autoassociators, and the fact that such networks can operate much faster than it would seem from simple models that follow discrete time dynamics is probably a major factor in enabling these networks to provide some of the building blocks of brain function.*

Learning is fast, ‘one-shot’, in that a single presentation of an input pattern \mathbf{e} (producing \mathbf{y}) enables the association between the activation of the dendrites (the post-synaptic term h_i) and the firing of the recurrent collateral axons \mathbf{y}^T , to be learned. Repeated presentation with small variations of a pattern vector is used to obtain the properties of prototype extraction, extraction of central tendency, and noise reduction, because these arise from the averaging process produced by storing very similar patterns in the network.

B.3.3.6 Local learning rule

The simplest learning used in autoassociation neural networks, a version of the Hebb rule, is (as in equation B.9)

$$\delta w_{ij} = \alpha y_i y_j.$$

The rule is a local learning rule in that the information required to specify the change in synaptic weight is available locally at the synapse, as it is dependent only on the presynaptic firing rate y_j available at the synaptic terminal, and the postsynaptic activation or firing y_i available on the dendrite of the neuron receiving the synapse. This makes the learning rule biologically plausible, in that the information about how to change the synaptic weight does not have to be carried to every synapse from a distant source where it is computed. As with pattern associators, since firing rates are positive quantities, a potentially interfering correlation is induced between different pattern vectors. This can be removed by subtracting the mean of the presynaptic activity from each presynaptic term, using a type of long-term depression. This can be specified as

$$\delta w_{ij} = \alpha y_i (y_j - z) \tag{B.13}$$

where α is a learning rate constant. This learning rule includes (in proportion to y_i) increasing the synaptic weight if $(y_j - z) > 0$ (long-term potentiation), and decreasing the synaptic weight if $(y_j - z) < 0$ (heterosynaptic long-term depression). This procedure works optimally if z is the average activity $\langle y_j \rangle$ of an axon across patterns.

Evidence that a learning rule with the general form of Equation B.9 is implemented in at least some parts of the brain comes from studies of long-term potentiation, described in Section 1.6. One of the important potential functions of heterosynaptic long-term depression is its ability to allow in effect the average of the presynaptic activity to be subtracted from the presynaptic firing rate (see Appendix A3 of Rolls and Treves (1998), and Rolls and Treves (1990)).

Autoassociation networks can be trained with the error-correction or delta learning rule described in Section B.11. Although a delta rule is less biologically plausible than a Hebb-like rule, a delta rule can help to store separately patterns that are very similar (see McClelland and Rumelhart (1989) and Hertz, Krogh and Palmer (1991)).

B.3.3.7 Capacity

One measure of storage capacity is to consider how many orthogonal patterns could be stored, as with pattern associators. If the patterns are orthogonal, there will be no interference between them, and the maximum number p of patterns that can be stored will be the same as the number N of output neurons in a fully connected network. Although in practice the patterns that have to be stored will hardly be orthogonal, this is not a purely academic speculation, since it was shown how one can construct a synaptic matrix that effectively orthogonalizes any set of (linearly independent) patterns (Kohonen, 1977, 1989; Personnaz, Guyon and Dreyfus, 1985; Kanter and Sompolinsky, 1987). However, this matrix cannot be learned with a local, one-shot learning rule, and therefore its interest for autoassociators in the brain is limited. The more general case of random non-orthogonal patterns, and of Hebbian learning rules, is considered next. However, it is important to reduce the correlations between patterns to be stored in an autoassociation network to not limit the capacity (Marr, 1971; Kohonen, 1977, 1989; Kohonen et al., 1981; Sompolinsky, 1987; Rolls and Treves, 1998; Boboeva et al., 2018; Rolls, 2023d; Ryom et al., 2023), and in the brain mechanisms to perform pattern separation are frequently present (Rolls, 2016f), including granule cells, as shown in many places in this book.

With non-linear neurons used in the network, the capacity can be measured in terms of the number of input patterns \mathbf{y} (produced by the external input \mathbf{e} , see Fig. B.13) that can be stored in the network and recalled later whenever the network settles within each stored pattern's basin of attraction. The first quantitative analysis of storage capacity (Amit, Gutfreund and Sompolinsky, 1987) considered a fully connected Hopfield (1982) autoassociator model, in which units are binary elements with an equal probability of being 'on' or 'off' in each pattern, and the number C of inputs per unit is the same as the number N of output units. (Actually it is equal to $N - 1$, since a unit is taken not to connect to itself.) Learning is taken to occur by clamping the desired patterns on the network and using a modified Hebb rule, in which the mean of the presynaptic and postsynaptic firings is subtracted from the firing on any one learning trial (this amounts to a covariance learning rule, and is described more fully in Appendix A4 of Rolls and Treves (1998)). With such fully distributed random patterns, the number of patterns that can be learned is (for C large) $p \approx 0.14C = 0.14N$, hence well below what could be achieved with orthogonal patterns or with an 'orthogonalizing' synaptic matrix. Many variations of this 'standard' autoassociator model have been analyzed subsequently.

Treves and Rolls (1991) have extended this analysis to autoassociation networks that are much more biologically relevant in the following ways. First, some or many connections between the recurrent collaterals and the dendrites are missing (this is referred to as diluted connectivity, and results in a non-symmetric synaptic connection matrix in which w_{ij} does not equal w_{ji} , one of the original assumptions made in order to introduce the energy formalism in the Hopfield model). Second, the neurons need not be restricted to binary threshold neurons, but can have a threshold linear activation function (see Fig. 1.3). This enables the neurons to assume real continuously variable firing rates, which are what is found in the brain (Rolls and Tovee, 1995b; Treves, Panzeri, Rolls, Booth and Wakeman, 1999). Third, the representation need not be fully distributed (with half the neurons 'on', and half 'off'), but instead can have a small proportion of the neurons firing above the spontaneous rate, which is what is found in parts of the brain such as the hippocampus that are involved in memory (see Treves and Rolls

(1994), and Chapter 6 of Rolls and Treves (1998)). Such a representation is defined as being sparse, and the sparseness a of the representation can be measured, by extending the binary notion of the proportion of neurons that are firing, as

$$a = \frac{\left(\sum_{i=1}^N y_i/N\right)^2}{\sum_{i=1}^N y_i^2/N} \quad (\text{B.14})$$

where y_i is the firing rate of the i th neuron in the set of N neurons. Treves and Rolls (1991) have shown that such a network does operate efficiently as an autoassociative network, and can store (and recall correctly) a number of different patterns p as follows

$$p \approx \frac{C^{\text{RC}}}{a \ln\left(\frac{1}{a}\right)} k \quad (\text{B.15})$$

where C^{RC} is the number of synapses on the dendrites of each neuron devoted to the recurrent collaterals from other neurons in the network, and k is a factor that depends weakly on the detailed structure of the rate distribution, on the connectivity pattern, etc., but is roughly in the order of 0.2–0.3.

The main factors that determine the maximum number of memories that can be stored in an autoassociative network are thus the number of connections on each neuron devoted to the recurrent collaterals, and the sparseness of the representation. For example, for $C^{\text{RC}} = 12,000$ and $a = 0.02$, p is calculated to be approximately 36,000. This storage capacity can be realized, with little interference between patterns, if the learning rule includes some form of heterosynaptic long-term depression that counterbalances the effects of associative long-term potentiation (Treves and Rolls (1991); see Appendix A4 of Rolls and Treves (1998)). It should be noted that the number of neurons N (which is greater than C^{RC} , the number of recurrent collateral inputs received by any neuron in the network from the other neurons in the network) is not a parameter that influences the number of different memories that can be stored in the network. The implication of this is that increasing the number of neurons (without increasing the number of connections per neuron) does not increase the number of different patterns that can be stored (see Rolls and Treves (1998) Appendix A4), although it may enable simpler encoding of the firing patterns, for example more orthogonal encoding, to be used. This latter point may account in part for why there are generally in the brain more neurons in a recurrent network than there are connections per neuron (see e.g. Chapter 9).

The non-linearity inherent in the NMDA receptor-based Hebbian plasticity present in the brain may help to make the stored patterns more sparse than the input patterns, and this may be especially beneficial in increasing the storage capacity of associative networks in the brain by allowing participation in the storage of especially those relatively few neurons with high firing rates in the exponential firing rate distributions typical of neurons in sensory systems (see Sections B.4.9.3 and C.3.1).

B.3.3.8 Context

The environmental context in which learning occurs can be a very important factor that affects retrieval in humans and other animals. Placing the subject back into the same context in which the original learning occurred can greatly facilitate retrieval.

Context effects arise naturally in association networks if some of the activity in the network reflects the context in which the learning occurs. Retrieval is then better when that context is present, for the activity contributed by the context becomes part of the retrieval

cue for the memory, increasing the correlation of the current state with what was stored. (A strategy for retrieval arises simply from this property. The strategy is to keep trying to recall as many fragments of the original memory situation, including the context, as possible, as this will provide a better cue for complete retrieval of the memory than just a single fragment.)

The effects that mood has on memory including visual memory retrieval may be accounted for by backprojections from brain regions such as the amygdala and orbitofrontal cortex in which the current mood, providing a context, is represented, to brain regions involved in memory such as the perirhinal cortex, and in visual representations such as the inferior temporal visual cortex (see Rolls and Stringer (2001b)). The very well-known effects of context in the human memory literature could arise in the simple way just described. An implication of the explanation is that context effects will be especially important at late stages of memory or information processing systems in the brain, for there information from a wide range of modalities will be mixed, and some of that information could reflect the context in which the learning takes place. One part of the brain where such effects may be strong is the hippocampus, which is implicated in the memory of recent episodes, and which receives inputs derived from most of the cortical information processing streams, including those involved in space (see Chapter 9).

B.3.3.9 Mixture states

If an autoassociation memory is trained on pattern vectors \mathbf{A} , \mathbf{B} , and $\mathbf{A} + \mathbf{B}$ (i.e. \mathbf{A} and \mathbf{B} are both included in the joint vector $\mathbf{A} + \mathbf{B}$; that is if the vectors are not linearly independent), then the autoassociation memory will have difficulty in learning and recalling these three memories as separate, because completion from either \mathbf{A} or \mathbf{B} to $\mathbf{A} + \mathbf{B}$ tends to occur during recall. (The ability to separate such patterns is referred to as configurational learning in the animal learning literature, see e.g. Sutherland and Rudy (1991).) This problem can be minimized by re-representing \mathbf{A} , \mathbf{B} , and $\mathbf{A} + \mathbf{B}$ in such a way that they are different vectors before they are presented to the autoassociation memory. This can be performed by recoding the input vectors to minimize overlap using, for example, a competitive network, and possibly involving expansion recoding, as described for pattern associators (see Section B.2, Fig. B.11). It is suggested that this is a function of the dentate granule cells in the hippocampus, which precede the CA3 recurrent collateral network (Treves and Rolls, 1992, 1994; Rolls, 2018b) (see Chapter 9).

B.3.3.10 Memory for sequences

One of the first extensions of the standard autoassociator paradigm that has been explored in the literature is the capability to store and retrieve not just individual patterns, but whole sequences of patterns. Hopfield (1982), suggested that this could be achieved by adding to the standard connection weights, which associate a pattern with itself, a new, asymmetric component, which associates a pattern with the next one in the sequence. In practice this scheme does not work very well, unless the new component is made to operate on a slower time scale than the purely autoassociative component (Kleinfeld, 1986; Sompolinsky and Kanter, 1986). With two different time scales, the autoassociative component can stabilize a pattern for a while, before the heteroassociative component moves the network, as it were, into the next pattern. The heteroassociative retrieval cue for the next pattern in the sequence is just the previous pattern in the sequence. A particular type of ‘slower’ operation occurs if the asymmetric component acts after a delay τ . In this case, the network sweeps through the sequence, staying for a time of order τ in each pattern.

One can see how the necessary ingredient for the storage of sequences is only a minor departure from purely Hebbian learning: in fact, the (symmetric) autoassociative component of the weights can be taken to reflect the Hebbian learning of strictly simultaneous conjunctions

of pre- and post-synaptic activity, whereas the (asymmetric) heteroassociative component can be implemented by Hebbian learning of each conjunction of postsynaptic activity with pre-synaptic activity shifted a time τ in the past. Both components can then be seen as resulting from a generalized Hebbian rule, which increases the weight whenever postsynaptic activity is paired with presynaptic activity occurring within a given time range, which may extend from a few hundred milliseconds in the past up to include strictly simultaneous activity. This is similar to a trace rule (see Chapter 2), which itself matches very well the observed conditions for induction of long-term potentiation, and appears entirely plausible. The learning rule necessary for learning sequences, though, is more complex than a simple trace rule in that the time-shifted conjunctions of activity that are encoded in the weights must in retrieval produce activations that are time-shifted as well (otherwise one falls back into the Hopfield (1982) proposal, which does not quite work). The synaptic weights should therefore keep separate ‘traces’ of what was simultaneous and what was time-shifted during the original experience, and this is not very plausible.

Levy and colleagues (Levy, Wu and Baxter, 1995; Wu, Baxter and Levy, 1996) have investigated these issues further, and the temporal asymmetry that may be present in LTP (see Section 1.6) has been suggested as a mechanism that might provide some of the temporal properties that are necessary for the brain to store and recall sequences (Minai and Levy, 1993; Abbott and Blum, 1996; Markram, Pikus, Gupta and Tsodyks, 1998; Abbott and Nelson, 2000). A problem with this suggestion is that, given that the temporal dynamics of attractor networks are inherently very fast when the networks have continuous dynamics (see Section B.6), and that the temporal asymmetry in LTP may be in the order of only milliseconds to a few tens of milliseconds (see Section 1.6), the recall of the sequences would be very fast, perhaps 10–20 ms per step of the sequence, with every step of a 10-step sequence effectively retrieved and gone in a quick-fire session of 100–200 ms.

Rolls and Stringer (see Rolls and Kesner (2006b)) have suggested that the over-rapid replay of a sequence of memories stored in an autoassociation network such as CA3 if it included asymmetric synaptic weights to encode a sequence could be controlled by the physical inputs from the environment. If a sequence of places 1, 2, and 3 had been learned by the use of an asymmetric trace learning rule implemented in the CA3 network, then the firing initiated by place 1 would reflect (by the learned association) a small component of place 2 (which might be used to guide navigation to place 2, and which might be separated out from place 1 better by the competitive network action in CA1), but would not move fully away from representing place 1 until the animal moved away from place 1, because of the clamping effect on the CA3 firing of the external input representing place 1 to the recurrent network. In this way, the physical constraints of movements between the different places in the environment would control the speed of readout from the sequence memory. In the network of Rolls and Stringer (see Rolls and Kesner (2006b)), CA3 might, by the continuing firing implemented by autoassociation, allow one item to be held in short-term memory until the next item arrives for heteroassociation. This would enable long time gaps within the sequence during training to be bridged.

Another way in which a delay could be inserted in a recurrent collateral path in the brain is by inserting another cortical area in the recurrent path. This could fit in with the cortico-cortical backprojection connections described in Fig. 9.2 with return projections to the entorhinal cortex, which might then send information back into the hippocampus, which would introduce some conduction delay (Panzeri, Rolls, Battaglia and Lavis, 2001). Another possibility is that the connections between the deep and the superficial layers of the entorhinal cortex help to close a loop from entorhinal cortex through hippocampal circuitry and back to the entorhinal cortex (van Haeften et al., 2003). Another suggestion is that the CA3 system holds by continuing firing a memory for event 1, which can then be associated with event 2

at the CA3 to CA1 synapses if event 2 activates CA1 neurons by the direct entorhinal input (Levy, 1989).

Another proposal is that sequence memory can be implemented by using synaptic adaptation to effectively encode the order of the items in a sequence (Deco and Rolls, 2005c) (see Section B.10). Whenever the attractor system is quenched into inactivity, the next member of the sequence emerges out of the spontaneous activity, because the least recently activated member of the sequence has the least synaptic or neuronal adaptation. This could be implemented in recurrent networks such as the CA3 or the prefrontal cortex.

For the recall of which item occurred most recently in short-term memory, the sequence type of memory would be possible, but difficult because once a sequence has been recalled, a system has to “manipulate” the items, picking out which is later (or earlier) in the sequence. A simpler possibility is to use a short term form of long term potentiation (LTP) which decays, and, then the latest of two items can be picked out because when it is seen again, the neuronal response is larger than to the earlier items (Rolls and Deco, 2002; Renart et al., 2001). This type of memory does not explicitly encode sequences, but instead reflects just how recently an item occurred. This could be implemented at any synapses in the system (e.g. in CA3 or CA1), and does not require recurrent collateral connectivity.

Using a single attractor network to store sequences does thus not turn out to be very efficient. One solution that the brain uses instead to implement sequence memory are associations made to hippocampal time cells, as described in Section 9.3.4 (Rolls and Mills, 2019) together with the neural network computations that may produce time cells.

B.3.4 Diluted connectivity and the storage capacity of attractor networks

Rolls (2012b) investigated how diluted connectivity can increase the storage capacity of attractor networks, by reducing the probability that there will be more than one synaptic connection between any pair of neurons, which would distort the landscape of the basins of attraction.

B.3.4.1 The autoassociative or attractor network architecture being studied

The architecture and functional properties of autoassociative or attractor networks are described in detail by Hertz et al. (1991), by Amit (1989), and earlier in Section B.3. Here it is assumed that the memory patterns are stored in the autoassociative network by an associative (or Hebbian) learning process in an architecture of the type shown in Fig. B.13 as follows. The firing of every output neuron i is forced to a value y_i determined by the external input e_i . Then a Hebb-like associative local learning rule is applied to the recurrent synapses in the network:

$$\delta w_{ij} = \alpha y_i y_j. \quad (\text{B.16})$$

where α is a learning rate constant, and y_j is the presynaptic firing rate.

During recall, the external input e_i is applied, and produces output firing, operating through the non-linear activation function described below. The firing is fed back by the recurrent collateral axons shown in Fig. B.13 to produce activation of each output neuron through the modified synapses on each output neuron. The activation h_i produced by the recurrent collateral effect on the i th neuron is the sum of the activations produced in proportion to the firing rate of each axon y_j operating through each modified synapse w_{ij} , that is,

$$h_i = \sum_j^C y_j w_{ij} \quad (\text{B.17})$$

where \sum_j^C indicates that the sum is over the C input axons to each neuron, indexed by j .

The output firing y_i is a function of the activation produced by the recurrent collateral effect (internal recall) and by the external input (e_i):

$$y_i = f(h_i + e_i). \quad (\text{B.18})$$

The activation function should be non-linear, and may be for example binary threshold, linear threshold, sigmoid, etc. (Hopfield, 1982; Hertz et al., 1991; Rolls, 2016b) (Fig. 1.3 and Section B.3).

B.3.4.2 The storage capacity of attractor networks with diluted connectivity

With non-linear neurons used in the network, the capacity can be measured in terms of the number of input memory patterns \mathbf{y} (each a firing rate vector comprised by the firing rate of each neuron forming a vector of firing rates across the population of neurons) produced by the external input \mathbf{e} , see Fig. B.13), that can be stored in the network and recalled later, even from a fragment of the stored memory pattern, whenever the network settles within each stored pattern's basin of attraction. The accuracy of the recall of each memory pattern can be measured by the correlation between the recalled firing rate vector and the stored firing rate vector. The first quantitative analysis of storage capacity, measured by the number of memory patterns that can be stored and later recalled correctly, considered a fully connected Hopfield (1982) autoassociator model, in which neurons are binary elements with an equal probability of being 'on' or 'off' in each pattern, and the number C of inputs per neuron is the same as the number N of output units (Amit, Gutfreund and Sompolinsky, 1987). (Actually it is equal to $N - 1$, since a neuron is taken not to connect to itself.) Learning is taken to occur by clamping the desired patterns on the network and using a modified Hebb rule, in which the mean of the presynaptic and postsynaptic firings is subtracted from the firing on any one learning trial (this amounts to a covariance learning rule, and is described more fully in Appendix A4 of Rolls and Treves (1998), and is shown in Equation B.21). With such fully distributed binary random patterns, the number of patterns that can be learned is (for C large) $p \approx 0.14C = 0.14N$, hence well below what could be achieved with orthogonal patterns or with an 'orthogonalizing' synaptic matrix (Hopfield, 1982; Amit et al., 1987). Many variations of this 'standard' autoassociator model have been analyzed subsequently (Amit, 1989; Hertz et al., 1991; Rolls and Treves, 1998).

This analysis has been extended to autoassociation networks that are much more biologically relevant in the following ways (Treves, 1990, 1991b; Treves and Rolls, 1991; Rolls, Treves, Foster and Perez-Vicente, 1997c; Rolls and Treves, 1998; Rolls, 2016b). First, some or many connections between the recurrent collaterals and the dendrites are missing (this is referred to as diluted connectivity, and results in a non-symmetric synaptic connection matrix in which w_{ij} does not equal w_{ji} , one of the original assumptions made in order to introduce the energy formalism in the Hopfield (1982) model). Second, the neurons need not be restricted to binary threshold neurons, but can have a threshold linear activation function (see Fig. 1.3). This enables the neurons to assume real continuously graded firing rates to different stimuli (Treves, 1990; Treves and Rolls, 1991), which are what is found in the brain (Rolls and Tovee, 1995b; Treves, Panzeri, Rolls, Booth and Wakeman, 1999; Rolls, 2016b; Rolls and Treves, 2011). Third, the representation need not be fully distributed (with half the neurons 'on', and half 'off'), but instead can have a small proportion of the neurons firing above the spontaneous rate (Treves and Rolls, 1991), which is what is found in parts of the brain such as the hippocampus that are involved in memory (Rolls, 2016b) (Appendix C). Such a representation is defined as being sparse, and the sparseness a of the representation can be measured, by extending the binary notion of the proportion of neurons that are firing, as

$$a = \left(\sum_{i=1}^N y_i / N \right)^2 / \sum_{i=1}^N y_i^2 / N \quad (\text{B.19})$$

where y_i is the firing rate of the i th neuron in the set of N neurons. Treves and Rolls (1991) have shown that such a network does operate efficiently as an autoassociative network, and can store (and recall correctly) a number of different patterns p as follows

$$p \approx \frac{C^{\text{RC}}}{a \ln(\frac{1}{a})} k \quad (\text{B.20})$$

where C^{RC} is the number of synapses on the dendrites of each neuron devoted to the recurrent collaterals from other neurons in the network, and k is a factor that depends weakly on the detailed structure of the rate distribution, on the connectivity pattern, etc., but is roughly in the order of 0.2–0.3.

The main factors that determine the maximum number of memories that can be stored in an autoassociative network are thus the number of connections on each neuron devoted to the recurrent collaterals, and the sparseness of the representation (Treves, 1991b; Treves and Rolls, 1991; Rolls and Treves, 1998; Rolls, 2016b) (Section B.3). For example, for $C^{\text{RC}} = 12,000$ and $a = 0.02$, p is calculated to be approximately 36,000. This storage capacity can be realized, with little interference between patterns, if the learning rule includes some form of heterosynaptic long-term depression that counterbalances the effects of associative long-term potentiation (Treves and Rolls (1991); see Appendix A4 of Rolls and Treves (1998)). It should be noted that the number of neurons N (which is greater than C^{RC} , the number of recurrent collateral inputs received by any neuron in the network from the other neurons in the network) is not a parameter that influences the number of different memories that can be stored in the network. The implication of this is that increasing the number of neurons (without increasing the number of connections per neuron) does not increase the number of different patterns that can be stored (see Rolls and Treves (1998) Appendix A4), although it may enable simpler encoding of the firing patterns, for example more orthogonal encoding, to be used. *This latter point may account in part for why there are generally in the cerebral cortex more neurons in a recurrent network than there are connections per neuron (Rolls, 2016b), which is an important principle of cortical function.* In addition, the random stochastic fluctuations (or ‘noise’ (Rolls and Deco, 2010)) related to the finite number of spiking neurons is smaller with diluted compared to fully connected networks when the number of connections C per neuron and hence the storage capacity is equated (Rolls and Webb, 2012).

B.3.4.3 The network simulated

The network can be described under four headings which correspond to the four stages in which the simulation of the network operates. The formal specification of the operation of the network is the same as that of the network analyzed by Treves (1990) (see also Treves (1991b)) and simulated by Rolls, Treves, Foster and Perez-Vicente (1997c), except where indicated. First, the patterns that the net is to be trained on are binary, that is, a fraction of the neurons, which defines the sparseness a , are 1, and the remainder are 0. Second, the weights are set according to a Hebbian covariance rule. Third, the weight matrix is ablated, that is a proportion of its elements are probabilistically set to zero, to achieve an effective dilution of recurrent connectivity. In other tests, in addition, some of the synaptic weights are multiplied by 2, 3 etc as defined by a Poisson distribution to investigate the effects of multiple synaptic connections between some of the neurons. Fourth, the net undergoes testing with incomplete persistent external cues until the state has settled into retrieval or otherwise.

Pattern generation

Random binary patterns with a sparseness a of 0.1 were used.

The sparseness of the retrieved patterns was measured, to ensure that the network was operating in such a way that the sparseness of the retrieved patterns was close to that of the stored patterns. In these simulations, in contrast to earlier simulations (Rolls, Treves, Foster and Perez-Vicente, 1997c), the sparseness was set by altering the threshold T_{thr} for the activation of a neuron to produce firing in such a way that the sparseness reached a value of $a=0.1$. This has the advantage that it can be implemented by an automatic algorithm, and ensures that the sparseness of the retrieved pattern is close to the value desired of a .

Learning

The learning mechanism is a form of Hebbian covariance synaptic modification, a one-step application of a simple rule which takes account of simple pairwise covariance relationships within each pattern. The exact rule is as follows. Note that the form of the covariance rule is commutative with respect to units i and j , therefore forcing a fully connected net with such a rule to have symmetric weights.

$$w_{ij} = \frac{1}{Na^2} \sum_{\mu=1}^p (y_i^\mu - a)(y_j^\mu - a) \quad (\text{B.21})$$

where w_{ij} is the weight between units i and j . y_i^μ represents the firing rate of unit i within pattern μ . This is a simple covariance rule, and a represents the mean activity in the neuronal network.

Connectivity

Networks with asymmetrical dilution of the connectivity were investigated. The dilution applied is described below where the effects of different types of dilution, and of some probability of multiple synapses between pairs of neurons, are analyzed. The total number of neurons is N , each neuron receives exactly C inputs, the dilution is C/N , and $p = \alpha C$ is the number of patterns stored in the net. The critical loading of the net, when it fails to operate as a memory, is denoted as α_c .

Testing recall by the net

During recall, the activity of each neuron in the network was asynchronously updated according to a rule which, by analogy with the theoretical analysis, considered a local field h_i at each unit i consisting of an internal field and external field, as follows:

$$h_i = \sum_{j(\neq i)} w_{ij} y_j + \sum_{\mu} s^\mu \frac{e_i^\mu}{a} \quad (\text{B.22})$$

where y_j represents the output of neuron j , and s^μ represents the relative strength of pattern μ , see below.

The external field (the last term in the above Equation with e_i^μ the firing rate of the external input to neuron i produced by the pattern μ) is equivalent to the clamping, persistent external cue, which is believed to be provided by for example the direct perforant path afferents into CA3 from entorhinal cortex (Treves and Rolls, 1992). The ratio between the average number of perforant path synapses per CA3 cell and that of the recurrent collaterals is in this model allowed to determine their relative influence on the firing of CA3 cells. Anatomical evidence available from the rat suggests that the ratio of the external input (the retrieval cue) to the internal recall provided by the recurrent collaterals should be in the order of 0.25 (see Treves

and Rolls (1992)), and s^μ was set to produce this ratio (for example when the retrieval cue had a correlation of 0.5 with the originally learned pattern).

The internal field (the first term in the above Equation) is equivalent to the recurrent activation provided by the recurrent collaterals in CA3. This is implemented through a standard autoassociation update rule involving weighted inputs from each of the other units. As explained above, this is qualified by the connectivity enforced through zero weights.

The activation function of the neurons is a threshold linear function of the local field h_i , with a gain factor g described by Treves (1990) set to 0.5, and with the threshold T_{thr} adjusted after each iteration in the recall to produce a retrieval sparseness that was close to 0.1 (which was the sparseness of the stored patterns), as described above.

$$y = \begin{cases} g(h - T_{\text{thr}}), & h > T_{\text{thr}} \\ 0 & , h < T_{\text{thr}} \end{cases}$$

The recall of the net was measured by the correlation of the retrieved pattern with that stored, when incomplete retrieval cues were used. The performance of the network was also measured by the information retrievable from the network in bits per synapse about the set of stored patterns, as follows

$$I = \frac{\alpha}{\log 2} \sum_{k=0}^m \sum_{l=0}^n c_k^l \log \frac{c_k^l}{c_k c^l} \quad (\text{B.23})$$

with Treves (1990) and Rolls (2016b) providing further details. Briefly, for each element of the retrieved network state and the corresponding stored pattern, the firing was first discretized into bins, and then the expression above was evaluated. In the above, c_k is the probability that the pattern element is in the k th bin of m bins, c^l is the probability that the retrieved element is in the l th bin of n bins, and c_k^l is the probability that the retrieved element is in the l th bin, and the pattern element is in the k th bin. In the implementation of this calculation, due to practical limitations, both the patterns and network states were binned into 15 bins. Note that the factor α means that the result is in bits per synapse, which is proportional to the total information stored in, and retrievable from, the whole network.

Parameters

The network functioned with a set of parameters chosen to be biologically relevant. Where the parameters are not in correspondence with measurable quantities, they were optimized to the values required for the theory to apply (Treves, 1990). This subsection details some of these parameters, and the reason for their choice.

The total number of neurons in the net was set to 1000 for the results reported.

The gain parameter, equivalent to the gradient of the linear threshold function producing the output of each unit from its incoming local field, was tested at a number of different values, and found to be optimal in the region of $g = 0.5$ for binary neurons. The actual value of g used was 0.5 for the binary patterns.

The loading α was expressed as the ratio p/C , where p is the number of patterns stored, and C is the number of connections per neuron. The loading was varied between 0.1 and 1.2 to investigate the maximum value of the storage capacity α_c , in terms of patterns, as well as to investigate the effect of over-loading. The number of patterns was varied from 40 to 480. The net was allowed to iterate for a maximum of 30 epochs.

B.3.4.4 The effects of diluted connectivity on the storage capacity of attractor networks

First a model of how the connections may be set up between neurons is formulated. The initial value of the synaptic weights is 0. This is only the prescription for whether a neuron i will receive a synaptic connection from neuron j . Let us assume that some genetic factors set the number of connections to be received by a neuron of class A from class B to be a constant C (Rolls and Stringer, 2000), the number of neurons in the network to be N , and the average connection probability to be p , so that $C = pN$. Previous analyses (Treves and Rolls, 1991; Treves, 1991b; Rolls and Treves, 1998) have assumed that when diluted connectivity is present there are exactly C connections onto each neuron i , that $C < N$, that the connections between pairs of neurons need not be reciprocal and symmetrical, and that there is at most 1 connection from neuron i to neuron j and vice versa. It is this last condition that is relaxed in this investigation (Rolls, 2012b), to examine the consequence of different scenarios that might arise according to different prescriptions for determining whether there is a synaptic connection between any two neurons in the network. Three prescriptions are considered.

Full connectivity

With full connectivity, there is one and only one synapse in a given direction between neurons i and j , and all neurons are reciprocally connected with equal weights in the two directions. This situation arises in a fully connected autoassociation network trained with an associative (Hebbian) synaptic modification rule, which produces a symmetric synaptic weight matrix (Section B.3).

Although this is the system favoured for formal analysis (Hopfield, 1982; Amit, 1989), I suggest that this would be extremely difficult for real biological systems to set up. There would have to be a biological system that would have to detect whether among something in the order of say 10,000 synapses being received by neuron i , there was more than one from neuron j . This is rejected as being implausible. There would also have to be a mechanism for ensuring that every neuron in the set of N neurons had at least 1 connection to every other neuron in the set of N neurons. This is rejected as being implausible. There would also need to be a way for genes to specify that a particular set of N neurons specified a particular network. This is rejected as being implausible. Thus it is argued that fully connected networks are unlikely to be found in the brain if they are set up by a simple mechanism such as a neuron making synapses at random with nearby neurons, which is consistent with the evidence (Hill, Wang, Riachi, Schürmann and Markram, 2012). Thus this genetically simple mechanism to prescribe connections for neurons to make would not lead to a fully connected network.

Connectivity with on average one synapse in a given direction between neurons j and i

Let us assume that among a population of N neurons, a biological process forms connections at random to any one neuron i from the other neurons j until the average number of connections to any neuron i from any one neuron j is 1. In this situation, some neurons i will receive more than one connection from neuron j , and some will receive 0 connections from neuron j . In fact, the number of connections received by neuron i from neuron j will follow approximately a Poisson distribution with mean $(\lambda) = 1$. Given that all neurons are trained using an associative synaptic modification rule of the form shown in Equation B.16, this will mean that some neuron pairs will have a synaptic strength that is twice, three times, etc. the strength of the connections between the neurons with one synapse between them. It is suggested, and tested next, that the consequences of this are that the energy landscape is considerably distorted. Hopfield (1982) was able to show that in a fully connected network trained associatively the recall state can be thought of as the local minimum in an energy

Table B.3 The probability of different numbers of connections X between neurons for different values of λ , the average number of connections between neurons in the network, based on a Poisson distribution. The column labelled $C(N = 1000)$ shows the numbers of synaptic connections to a neuron i multiplied by X in prescribing a network with $N=1000$ neurons with $\lambda=1$.

X	$\lambda=1$	$C(N = 1000)$	$\lambda=0.1$	$\lambda=0.04$
0	0.3679	368	0.9048	0.9608
1	0.3679	368	0.0905	0.0384
2	0.1839	184	0.0045	0.0008
3	0.0613	61	0.0002	0.0000
4	0.0153	15	0.0000	0.0000
5	0.0031	3	0.0000	0.0000
6	0.0005	0.5	0.0000	0.0000

landscape, where the energy would be defined as

$$E = -\frac{1}{2} \sum_{i,j} w_{ij} (y_i - \langle y \rangle) (y_j - \langle y \rangle). \quad (\text{B.24})$$

This Equation can be understood in the following way. If two neurons are both firing above their mean rate (denoted by $\langle y \rangle$), and are connected by a weight with a positive value, then the firing of these two neurons is consistent with each other, and they mutually support each other, so that they contribute to the system's tendency to remain stable. If across the whole network such mutual support is generally provided, then no further change will take place, and the system will indeed remain stable. If, on the other hand, either of our pair of neurons was not firing, or if the connecting weight had a negative value, the neurons would not support each other, and indeed the tendency would be for the neurons to try to alter ('flip' in the case of binary units) the state of the other. This would be repeated across the whole network until a situation in which most mutual support, and least 'frustration', was reached. What makes it possible to define an energy function and for these points to hold is that the matrix is symmetric (see Hopfield (1982), Hertz, Krogh and Palmer (1991), Amit (1989)).

It is shown next by simulations that if connectivity of the type defined in this section is present, with some pairs of neurons having several connections between them, then the energy landscape is distorted in such a way that there are deep energy minima in some parts of the energy landscape, and this reduces the capacity of the network, that is, its ability to store $0.14 N$ binary patterns with sparseness $a=0.5$ (Hopfield, 1982), or a larger number of patterns with more sparse representations as shown in Equations B.20 and B.15 (Treves and Rolls, 1991).

Simulations were run with the attractor network described in Section B.3.4.3 and by Rolls, Treves, Foster and Perez-Vicente (1997c) with 1000 neurons (Rolls, 2012b). The sparseness of the randomly chosen binary patterns was 0.1. The connectivity was set to have a mean number of connections between any pair of neurons, λ , equal to 1.0 with a Poisson distribution, resulting in the number of connections between pairs of neurons shown in Table B.3. The algorithm for setting the number of connections was to select an output neuron i , and then set it to have exactly the number of inputs from each of the other neurons in the network (chosen in a random sequence to prevent connections from a neuron already chosen) shown in Table B.3. This resulted in an asymmetric connection matrix with each neuron i having exactly the number of 0, single, double, etc synaptic connections to other neurons in the network shown in Table B.3. In practice, the algorithm was applied after training by multiplying the synaptic weights by the values shown in Table B.3. The resulting synaptic connectivity matrix thus reflected what would be produced by any one neuron having a mean number of connections with other neurons set according to a Poisson distribution with the mean number

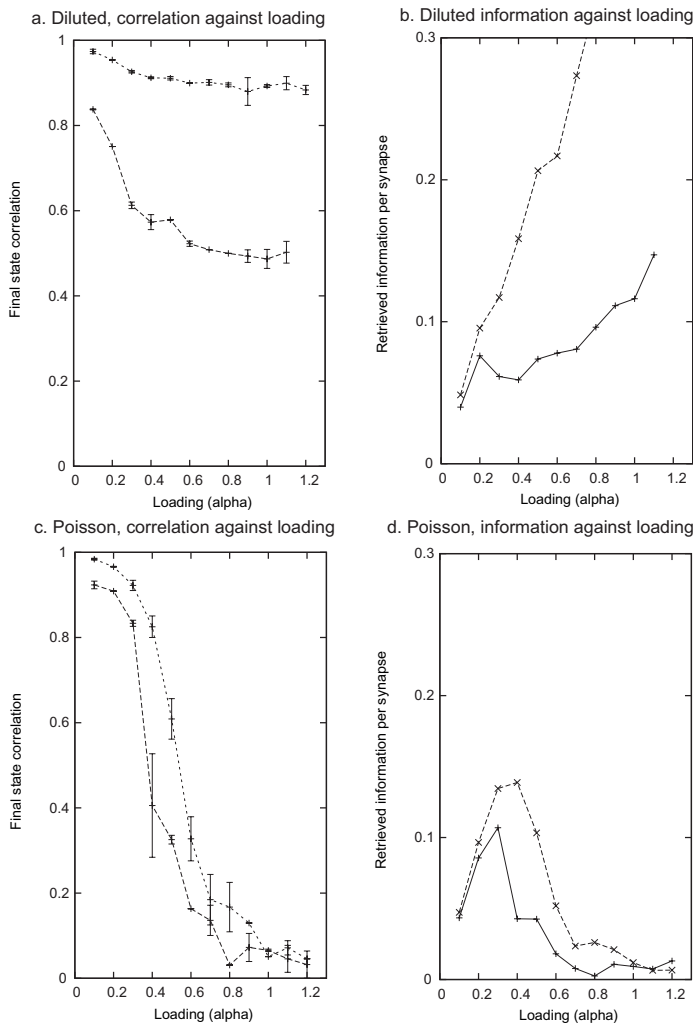

Fig. B.14 (a, b). The performance of the attractor network with diluted connectivity only with $\lambda=1$ for the average number of connections received by each output neuron. In this case, there were 368 weights of zero, and the remainder were multiplied by 1. (c, d). The performance of the attractor network with the numbers of connections between neurons specified by the full Poisson distribution shown in Table B.3 diluted connectivity only with $\lambda=1$ for the average number of connections received by each output neuron. In this case, there were 368 weights of zero, and 368 were multiplied by 1, 184 by 2, 61 by 3, etc. (a,c). The correlation of the final state of the network after recall with the stored pattern, as a function of loading $\alpha = p/C$. The two lines in each graph correspond to two retrieval cue levels: the lower line is for a cue correlated 0.5–0.55 with the original stored pattern, and the upper line is for a cue correlation of 0.9–0.95. The error bars represent the standard deviations. (b,d). The information retrieved in bits per synapse after recall with the stored pattern, as a function of loading $\alpha = p/C$. (From Edmund T. Rolls (2012) *Advantages of dilution in the connectivity of attractor networks in the brain. Biologically Inspired Cognitive Architectures 1: 44–54.* Copyright © Elsevier B.V.)

of connections between any pair of neurons, λ , equal to 1. In some cases a pair of neurons would have no synaptic connections, and in other cases 1, 2, 3 etc synaptic connections as shown by the probabilities and numbers for a network of 1000 neurons shown in Table B.3.

Fig. B.14a,b shows the results of applying just the degree of dilution of the synaptic weights indicated in Table B.3 as the baseline control condition, without any double, triple etc synapses. In this case, there were 368 weights of zero out of the starting number of $C=1000$, and the remainder were multiplied by 1. The correlation of the final state of the network after recall with the stored pattern, as a function of loading $\alpha = p/C$, is shown in Fig. B.14a. The

two lines in each graph correspond to two retrieval cue levels: the lower line is for a retrieval cue correlated 0.5–0.55 with the original stored pattern, and the upper line is for a retrieval cue correlation of 0.9–0.95. The information retrieved in bits per synapse after recall with the stored pattern, as a function of loading $\alpha = p/C$ is shown in Fig. B.14b. (In this Figure, the loading value α shown on the abscissa refers to the fully connected case with $C=1000$ connections per neuron, and should be multiplied by 1.58 given that with the dilution there are in fact $C=638$ connections per neuron, as shown in Table B.3.) The results in Fig. B.14a,b show good performance up to high loading levels when only dilution of the connectivity is present, and there are no multiple synapses between neuron pairs present.

These results emphasize that with diluted connectivity, and asymmetric connections between pairs of neurons, the attractor network still displays its predicted memory capacity, and ability to complete memories from incomplete patterns (Treves and Rolls, 1991; Treves, 1991b; Bovier and Gayraud, 1992; Perez Castillo and Skantzos, 2004; Rolls et al., 1997c; Rolls and Treves, 1998).

Fig. B.14c,d shows the results of applying the identical degree of dilution of the synaptic weights to that used in Fig. B.14a,b, but now with the number of double, triple etc weight synapses indicated in Table B.3 column 3. At low levels of loading $\alpha \leq 0.4$ the performance is as good as or better than the control baseline dilution-only simulation shown in Fig. B.14a,b, but at higher loading levels the performance drops off very greatly (Fig. B.14c,d). Fig. B.14a,b shows that α_c , the critical loading capacity of the network beyond which the memory fails and little information can be retrieved from it, is approximately 0.4. With just diluted connectivity, without multiple synaptic connections, the critical capacity α_c was higher than 1.2, as shown in Fig. B.14a,b.

It is therefore concluded (Rolls, 2012b) that prescription 2 (section B.3.4.4) for setting the connectivity is seriously flawed, as it reduces the capacity of the attractor network, i.e. the number of patterns that it can store per synapse onto each neuron (Treves and Rolls, 1991; Rolls, 2016b), because of the multiple synapses found between a proportion of the neurons. The interpretation of the loss of capacity with some multiple synapses present is that this distorts the energy landscape by producing irregular deep and broad areas which attract patterns that are some distance away, so that it is not possible to have a large number of approximately equal-size basins of attraction in the energy landscape. The interpretation of the somewhat better performance at low loading with some multiple synapses present is that if there are few basins present, but they are deep and large due to the multiple synapses, then patterns some distance away can be drawn into a nearby attractor, which, given large spacing between the attractor basins, is likely to be the correct attractor basin.

I further hypothesize that double synapses would distort the patterns being stored if they are graded (for example having an exponential distribution of firing rates across the population of neurons for any one stimulus), which is typical of neural representations (Treves, 1990; Rolls, 2016b; Rolls and Treves, 2011; Rolls et al., 1997c; Franco et al., 2007; Rolls and Treves, 2011) (Appendix C). It is possible that the graded firing rate representation could no longer be accurately stored: the graded representation would be distorted by the extra firing of neurons with double connections. Simulations of the type described by Rolls, Treves, Foster and Perez-Vicente (1997c) could be performed to check whether this becomes an issue, depending on the number of double, triple etc synapses between some neuron pairs.

Diluted connectivity with $C < N$

Let us assume that among a population of N neurons, a biological process forms connections at random between any pair of neurons, so that in the resulting network there are C incoming connections to any of N neurons, with $C < N$. Assuming symmetry, this implies that the number L_{ij} of the connections from any neuron j to any neuron i follows a Binomial

distribution $\text{Bin}\left(C, \frac{1}{N-1}\right)$:

$$\begin{aligned} \text{Prob}\{L_{ij} = k\} &= \frac{C!}{k!(C-k)!} \left(\frac{1}{N-1}\right)^k \left(1 - \frac{1}{N-1}\right)^{C-k} \\ &= \frac{C(C-1)\dots(C-k+1)}{1 \cdot 2 \cdot \dots \cdot k} (N-1)^{C-k} \end{aligned} \quad (\text{B.25})$$

where k is between 0 and C . When $C = \lambda N$ and $N \rightarrow \infty$, this distribution is well approximated by the Poisson distribution with mean λ .

For example, let us assume a diluted connectivity with the average number of connections per neuron $\lambda=0.1$. We set up connections with the same general prescription as in prescription 2 (Section B.3.4.4). However, if $\lambda = 0.1$, the probability that any two neurons will have two connections between them is 0.0045, as shown in Table B.3. (In a network with $N=1000$ neurons, there would be 91 single connections onto each neuron, and only 5 double connections onto each neuron, with no triple connections.) This is a much smaller probability. Additional simulations of the type illustrated in Fig. B.14 were performed with $\lambda = 0.1$. The results showed that having this small proportion of double strength synapses in the network produced very little reduction in the correlation of the retrieved patterns with those stored, or in the capacity of the attractor network to store many patterns using the type of analysis shown in Fig. B.14c,d. The number of patterns that can be stored is still of order C (Treves and Rolls, 1991), with the constant k in Equation B.20 little affected by this small number of multiple connections between pairs of neurons.

This scenario applies in the real brain. For example, an estimate for the dilution C/N in the neocortex might be 0.1. (For the neocortex, assuming 10,000 recurrent collaterals per pyramidal cell, that the density of pyramidal cells is 30,000 / mm³ (Rolls, 2016b), that the radius of the recurrent collaterals is 1 mm, and that we are dealing with the superficial (or deep) layers of the cortex with a depth of approximately 1 mm, the dilution between the superficial (or deep) pyramidal cells would be approximately 0.1.)

A similar but somewhat more diluted scenario applies in the hippocampus. In the rat hippocampus, there are $N = 300,000$ CA3 neurons, and each neuron receives $C = 12,000$ synapses (see Fig. 9.23) (Rolls, 1990b; Treves and Rolls, 1992). (It is assumed that each CA3 neuron correspondingly makes 12,000 recurrent collateral synapses.) The dilution of this network C/N thus equals 0.04. In a network with $N=1000$ neurons and $\lambda=0.04$, there would be 38 single synapses onto each neuron, and only 1 double synapse, as is evident from Table B.3. This low number of double synapses, with no triple etc synapses, has little effect on the operation of the network, as shown by further simulations of the type illustrated in Fig. B.14 (Rolls, 2012b). It is proposed that this network operates as an autoassociation or attractor network, and is key to how the hippocampus operates to store episodic memories (Rolls, 1996d, 2016b, 2010b) (see Chapter 2 of Rolls (2016b)), and here the number of different memories that can be stored in the network is at a premium, and is provided for by this level of dilution of the connectivity which ensures few multiple synapses between any pair of neurons.

B.3.4.5 Synthesis of the effects of diluted connectivity in attractor networks

The results of the simulations (Rolls, 2012b) therefore support the proposal made by Rolls (2012b) that the reason why networks in the neocortex and hippocampal cortex have diluted connectivity is that the diluted connectivity ensures that the energy landscape and thereby the memory capacity is not disturbed by multiple connections between pairs of neurons, with the network still operating correctly in the diluted regime where C/N is in the range 0.1–0.01 (Treves, 1991b; Rolls et al., 1997c; Rolls and Treves, 1998; Rolls, 2016b). The somewhat

greater dilution of connectivity (with fewer multiple synapses) in the hippocampal CA3 network (0.04) than the estimate of its value in the neocortex (0.1) may be related to the great importance of achieving a high memory capacity with good retrieval of all stored patterns in the hippocampus where this may be useful for episodic memory, for which memory capacity in a single network is important (Rolls, 2016b, 2010b) (Chapter 9).

In both these types of cortex, there is evidence that the excitatory interconnections between neurons are associatively modifiable, and that the system supports attractor dynamics that enable memories to be stored (Section B.3). One of the points made here is that with a local associative rule, the presynaptic and the postsynaptic activity at a given synapse to determine the strength of that connection between a pair of neurons, which is a widely held assumption (Rolls and Treves, 1998; Rolls, 2016b), then consequences of the type described here on memory capacity would ensue. A difference between these cortical structures is that the CA3 network is a single network allowing any representation to be associated with any other representation, providing an implementation of episodic memory (Rolls, 2016b, 2010b; Kesner and Rolls, 2015). In contrast, the neocortex has local connectivity with a radius of approximately 2 mm, and this enables the whole of the cerebral cortex to have many separate attractor networks, each storing a large number of memories (O’Kane and Treves, 1992; Rolls, 2016b).

Another potential advantage of diluted connectivity in which the number of neurons N is greater than C^{RC} , the number of recurrent collateral inputs received by any neuron in the network from the other neurons in the network, is that this may enable simpler encoding of the firing patterns, for example more orthogonal encoding, to be used. For example, much of the information available from the firing rates of a population of neurons about which stimulus was presented can be read by a decoding procedure as simple as a dot product, which is what neurons compute using their synaptic weight vector, and which is very biologically plausible (Rolls, 2016b; Rolls and Treves, 2011) (Appendix C).

Another advantage of diluted recurrent collateral connectivity is that it can increase the storage capacity α_c of autoassociation (attractor) networks, that is the number of patterns that can be stored per recurrent collateral synapse (Treves and Rolls, 1991). (This useful effect applies provided that representations are not too sparse, because when the sparseness is very low, $a \ll 0.01$, the performance becomes similar to that of a fully connected network (see Treves and Rolls (1991) Fig. 5a; and Rolls and Treves (1998) Fig. A4.2.)

Another advantage of diluted connectivity (for the same number of connections per neuron) is that this increases the stability and accuracy of the network as there is less spiking-related noise producing stochastic fluctuations in the diluted network (which has more neurons in it), with little cost in increased decision times (Rolls and Webb, 2012).

Very diluted connectivity in feedforward networks (for example, competitive networks) can also play a role in pattern separation, by encouraging different output neurons to respond to different, random, combinations of the inputs because each neuron is connected to a different combination of inputs (Rolls, 2016b,f). This finds application in the brain in for example the dentate granule cell mossy fibre to CA3 connections which are very dilute but strong. The architecture helps grid cell representations to be transformed into place or spatial view representations (Treves and Rolls, 1992; Rolls, Stringer and Elliot, 2006c; Rolls and Kesner, 2006b; Rolls, 2016b, 2010b).

In summary, Rolls (2012b) proposed that the reason why networks in the neocortex and hippocampal cortex have diluted connectivity in the recurrent collateral connections is that the diluted connectivity ensures that the energy landscape and thereby the memory capacity is not disturbed by multiple connections between pairs of neurons, with the network still operating correctly in the diluted regime where C/N is in the range 0.1–0.01 (Treves, 1991b; Rolls et al., 1997c; Rolls and Treves, 1998; Rolls, 2016b). It was shown that having a proportion

of multiple connections between neurons in an attractor network trained by an associative rule produces a major reduction in $\alpha_c = p/C$, the memory capacity of the network beyond which adding further memories drastically impairs the ability of the network to retrieve any memories. That important reason for dilution in the connectivity of cortical networks, which helps them to be specified by relatively few and simple genetic rules consistent with a limited number of genes in the whole genome in the order of 25,000 compared to the number of synapses which is in the order of 10^{15} (Rolls and Stringer, 2000; Rolls, 2016b), is accompanied by other advantages of the dilution of cortical connectivity elucidated by Rolls (2012b).

B.3.5 Use of autoassociation networks in the brain

Because of its ‘one-shot’ rapid learning, and ability to complete, this type of network is well suited for episodic memory storage, in which each episode must be stored and recalled later from a fragment, and kept separate from other episodic memories. It does not take a long time (the ‘many epochs’ of backpropagation networks) to train this network, because it does not have to ‘discover the structure’ of a problem. Instead, it stores information in the form in which it is presented to the memory, without altering the representation. An autoassociation network may be used for this function in the CA3 region of the hippocampus (see Chapter 9, and Rolls and Treves (1998) Chapter 6).

An autoassociation memory can also be used as a short-term memory, in which iterative processing round the recurrent collateral loop keeps a representation active until another input cue is received. This may be used to implement many types of short-term memory in the brain (see Section 13.6.1). For example, it may be used in the perirhinal cortex and adjacent temporal lobe cortex to implement short-term visual object memory (Miyashita and Chang, 1988; Amit, 1995; Hirabayashi, Takeuchi, Tamura and Miyashita, 2013); in the dorsolateral prefrontal cortex to implement a short-term memory for spatial responses (Goldman-Rakic, 1996); and in the prefrontal cortex to implement a short-term memory for where eye movements should be made in space (see Section 13.6.1 and Rolls (2016b)). Such an autoassociation memory in the temporal lobe visual cortical areas may be used to implement the firing that continues for often 300 ms after a very brief (16 ms) presentation of a visual stimulus (Rolls and Tovee, 1994) (see e.g. Fig. C.19), and may be one way in which a short memory trace is implemented to facilitate invariant learning about visual stimuli (see Chapter 2). In all these cases, the short-term memory may be implemented by the recurrent excitatory collaterals that connect nearby pyramidal cells in the cerebral cortex. The connectivity in this system, that is the probability that a neuron synapses on a nearby neuron, may be in the region of 10% (Braitenberg and Schüz, 1991; Abeles, 1991; Rolls, 2016b).

The recurrent connections between nearby neocortical pyramidal cells may also be important in defining the response properties of cortical cells, which may be triggered by external inputs (from for example the thalamus or a preceding cortical area), but may be considerably dependent on the synaptic connections received from nearby cortical pyramidal cells.

The cortico-cortical backprojection connectivity described in Chapters 1, and 9 can be interpreted as a system that allows the forward-projecting neurons in one cortical area to be linked autoassociatively with the backprojecting neurons in the next cortical area (see Chapter 9). This would be implemented by associative synaptic modification in for example the backprojections. This particular architecture may be especially important in constraint satisfaction (as well as recall), that is it may allow the networks in the two cortical areas to settle into a mutually consistent state. This would effectively enable information in higher cortical areas, which would include information from more divergent sources, to influence the response properties of neurons in earlier cortical processing stages. This is an important function in cortical information processing of interacting associative networks.

For semantic memory, different cortical regions may specialize in different attributes of a semantic memory, e.g. an individual with attributes such as the sight of the face, the sound of the voice, the location where they work, etc. Semantic memories could be formed by coupling many such attractor networks together, in what are described as Potts attractor networks (Treves, 2005; Kropff and Treves, 2005; Boboeva, Brasselet and Treves, 2018; Ryom, Stendardi, Ciaramelli and Treves, 2023). An interesting issue arises though that if similar features (e.g. the sounds of the voices of several of the individuals are similar) are present in such compositional memories in the semantic representations of different individual items, this effectively increases the correlations between the items in the whole memory, and this can reduce somewhat the total memory capacity that might be expected (Ryom, Stendardi, Ciaramelli and Treves, 2023). Given that the formation of semantic memories is facilitated by the recall of episodic memory from the hippocampus (Section 9.2.8.5), it is proposed that an important contribution of the hippocampus to semantic memories is that pattern separation performed by the hippocampal system including the dentate granule cells (Rolls, 2016f), helps to reduce the correlations between the different semantic memories formed by hippocampus to neocortical recall. How semantic representations are stored using coupled attractor networks is a topic of current interest.

B.4 Competitive networks, including self-organizing maps

B.4.1 Function

Competitive neural networks learn to categorize input pattern vectors. Each category of inputs activates a different output neuron (or set of output neurons – see below). The categories formed are based on similarities between the input vectors. Similar, that is correlated, input vectors activate the same output neuron. In that the learning is based on similarities in the input space, and there is no external teacher that forces classification, this is an unsupervised network. The term categorization is used to refer to the process of placing vectors into categories based on their similarity. The term classification is used to refer to the process of placing outputs in particular classes as instructed or taught by a teacher. Examples of classifiers are pattern associators, one-layer delta-rule perceptrons, and multilayer perceptrons taught by error backpropagation (see Sections B.2, B.3, B.11 and B.12). In supervised networks there is usually a teacher for each output neuron.

The categorization produced by competitive nets is of great potential importance in perceptual systems including the whole of the visual cortical processing hierarchies, as described in Chapter 2. Each category formed reflects a set or cluster of active inputs x_j that occur together. This cluster of coactive inputs can be thought of as a feature, and the competitive network can be described as building feature analyzers, where a feature can now be defined as a correlated set of inputs. During learning, a competitive network gradually discovers these features in the input space, and the process of finding these features without a teacher is referred to as self-organization.

Another important use of competitive networks is to remove redundancy from the input space, by allocating output neurons to reflect a set of inputs that co-occur.

Another important aspect of competitive networks is that they separate patterns that are somewhat correlated in the input space, to produce outputs for the different patterns that are less correlated with each other, and may indeed easily be made orthogonal to each other. This has been referred to as orthogonalization.

Fig. B.15 The architecture of a competitive network.

Another important function of competitive networks is that partly by removing redundancy from the input information space, they can produce sparse output vectors, without losing information. We may refer to this as sparsification.

B.4.2 Architecture and algorithm

B.4.2.1 Architecture

The basic architecture of a competitive network is shown in Fig. B.15. It is a one-layer network with a set of inputs that make modifiable excitatory synapses w_{ij} with the output neurons. The output cells compete with each other (for example by mutual inhibition) in such a way that the most strongly activated neuron or neurons win the competition, and are left firing strongly. The synaptic weights, w_{ij} , are initialized to random values before learning starts. If some of the synapses are missing, that is if there is randomly diluted connectivity, that is not a problem for such networks, and can even help them (see below).

In the brain, the inputs arrive through axons, which make synapses with the dendrites of the output or principal cells of the network. The principal cells are typically pyramidal cells in the cerebral cortex. In the brain, the principal cells are typically excitatory, and mutual inhibition between them is implemented by inhibitory interneurons, which receive excitatory inputs from the principal cells. The inhibitory interneurons then send their axons to make synapses with the pyramidal cells, typically using GABA (gamma-aminobutyric acid) as the inhibitory transmitter.

B.4.2.2 Algorithm

1. Apply an input vector \mathbf{x} and calculate the activation h_i of each neuron

$$h_i = \sum_j x_j w_{ij} \quad (\text{B.26})$$

where the sum is over the C input axons, indexed by j . (It is useful to normalize the length of each input vector \mathbf{x} . In the brain, a scaling effect is likely to be achieved both by feedforward inhibition, and by feedback inhibition among the set of input cells (in a preceding network) that give rise to the axons conveying \mathbf{x} .)

The output firing y_i^1 is a function of the activation of the neuron

$$y_i^1 = f(h_i). \quad (\text{B.27})$$

The function f can be linear, sigmoid, monotonically increasing, etc. (see Fig. 1.3).

2. Allow competitive interaction between the output neurons by a mechanism such as lateral or mutual inhibition (possibly with self-excitation), to produce a contrast-enhanced version of the firing rate vector

$$y_i = g(y_i^1). \quad (\text{B.28})$$

Function g is typically a non-linear operation, and in its most extreme form may be a winner-take-all function, in which after the competition one neuron may be ‘on’, and the others ‘off’. Algorithms that produce softer competition without a single winner to produce a distributed representation are described in Section B.4.9.4 below. Grossberg (2021) has described suitable mathematical formulations.

3. Apply an associative Hebb-like learning rule

$$\delta w_{ij} = \alpha y_i x_j. \quad (\text{B.29})$$

4. Normalize the length of the synaptic weight vector on each dendrite to prevent the same few neurons always winning the competition:

$$\sum_j (w_{ij})^2 = 1. \quad (\text{B.30})$$

(A less efficient alternative is to scale the sum of the weights to a constant, e.g. 1.0.)

5. Repeat steps 1–4 for each different input stimulus \mathbf{x} , in random sequence, a number of times.

B.4.3 Properties

B.4.3.1 Feature discovery by self-organization

Each neuron in a competitive network becomes activated by a set of consistently coactive, that is correlated, input axons, and gradually learns to respond to that cluster of coactive inputs. We can think of competitive networks as discovering features in the input space, where features can now be defined by a set of consistently coactive inputs. Competitive networks thus show how feature analyzers can be built, with no external teacher. The feature analyzers respond to correlations in the input space, and the learning occurs by self-organization in the competitive network. Competitive networks are therefore well suited to the analysis of sensory inputs. Ways in which they may form fundamental building blocks of sensory systems are described in Chapter 2.

The operation of competitive networks can be visualized with the help of Fig. B.16. The input patterns are represented as dots on the surface of a sphere. (The patterns are on the surface of a sphere because the patterns are normalized to the same length.) The directions of the weight vectors of the three neurons are represented by ‘ \times ’s. The effect of learning is to move the weight vector of each of the neurons to point towards the centre of one of the clusters of inputs. If the neurons are winner-take-all, the result of the learning is that although there are correlations between the input stimuli, the outputs of the three neurons are orthogonal. In this sense, orthogonalization is performed. At the same time, given that each of the patterns within a cluster produces the same output, the correlations between the patterns within a cluster become higher. In a winner-take-all network, the within-pattern correlation becomes 1, and the patterns within a cluster have been placed within the same category.

B.4.3.2 Removal of redundancy

In that competitive networks recode sets of correlated inputs to one or a few output neurons, then redundancy in the input representation is removed. Identifying and removing redundancy

Fig. B.16 Competitive learning. The dots represent the directions of the input vectors, and the 'x's the weights for each of three output neurons. (a) Before learning. (b) After learning. (After Rumelhart, D.E. and Zipser, D. (1985) Feature discovery by competitive learning. *Cognitive Science* 9: 75–112.)

in sensory inputs is an important part of processing in sensory systems (cf. Barlow (1989)), in part because a compressed representation is more manageable as an output of sensory systems. The reason for this is that neurons in the receiving systems, for example pattern associators in the orbitofrontal cortex or autoassociation networks in the hippocampus, can then operate with the limited numbers of inputs that each neuron can receive. For example, although the information that a particular face is being viewed is present in the 10^6 fibres in the optic nerve, the information is unusable by associative networks in this form, and is compressed through the visual system until the information about which of many hundreds of faces is present can be represented by less than 100 neurons in the temporal cortical visual areas (Rolls, Treves and Tovee, 1997b; Abbott, Rolls and Tovee, 1996). (Redundancy can be defined as the difference between the maximum information content of the input data stream (or channel capacity) and its actual content; see Appendix C.)

The recoding of input pattern vectors into a more compressed representation that can be conveyed by a much reduced number of output neurons of a competitive network is referred to in engineering as vector quantization. With a winner-take-all competitive network, each output neuron points to or stands for one of or a cluster of the input vectors, and it is more efficient to transmit the states of the few output neurons than the states of all the input elements. (It is more efficient in the sense that the information transmission rate required, that is the capacity of the channel, can be much smaller.) Vector quantization is of course possible when the input representation contains redundancy.

B.4.3.3 Orthogonalization and categorization

Figure B.16 shows visually how competitive networks reduce the correlation between different clusters of patterns, by allocating them to different output neurons. This is described as orthogonalization. It is a process that is very usefully applied to signals before they are used as inputs to associative networks (pattern associators and autoassociators) trained with Hebbian rules (see Sections B.2 and B.3), because it reduces the interference between patterns stored in these memories. The opposite effect in competitive networks, of bringing closer together very similar input patterns, is referred to as categorization.

These two processes are also illustrated in Fig. B.17, which shows that in a competitive network, very similar input patterns (with correlations higher in this case than approximately 0.8) produce more similar outputs (close to 1.0), whereas the correlations between pairs of input patterns that are smaller than approximately 0.7 become much smaller in the output representation. (This simulation used soft competition between neurons with graded firing rates.)

Further analyses of the operation of competitive networks, and how diluted connectivity

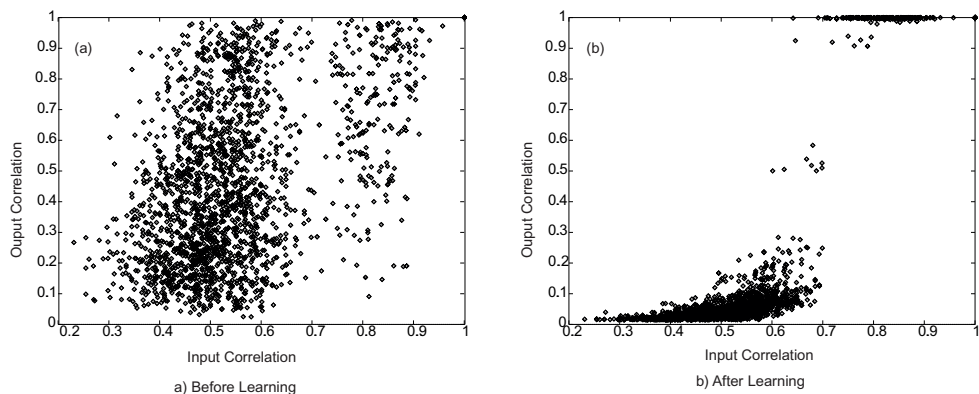

Fig. B.17 Orthogonalization and categorization in a competitive network: (a) before learning; (b) after learning. The correlations between pairs of output vectors (abscissa) are plotted against the correlations of the corresponding pairs of input vectors that generated the output pair, for all possible pairs in the input set. The competitive net learned for 16 cycles. One cycle consisted of presenting the complete input set of stimuli in a renewing random sequence. The correlation measure shown is the cosine of the angle between two vectors (i.e. the normalized dot product). The network used had 64 input axons to each of 8 output neurons. The net was trained with 64 stimuli, made from 8 initial random binary vectors with each bit having a probability of 0.5 of being 1, from each of which 8 noisy exemplars were made by randomly altering 10 % of the 64 elements. Soft competition was used between the output neurons. (A normalized exponential activation function described in Section B.4.9.4 was used to implement the soft competition.) The sparseness α of the input patterns thus averaged 0.5; and the sparseness α of the output firing vector after learning was close to 0.17 (i.e. after learning, primarily one neuron was active for each input pattern; before learning, the average sparseness of the output patterns produced by each of the inputs was 0.39).

can help the operation of competitive networks, are provided elsewhere (Rolls, 2016f) (see also Section 7.4 of Rolls (2016b)). Dilution in the connectivity of competitive networks can help to break the symmetry, so that some neurons are likely to be allocated to some patterns, and other neurons to other patterns (because of the particular set of input connections of each neuron), and this can help to stabilize a competitive network, by making it difficult for neurons to drift during further learning if the input patterns drift (Rolls, 2016f,b). In such a system, multiple connections from some input neurons to an output neuron might even be advantageous, for the reasons just given. This emphasizes the point that multiple connections between neurons are found in some parts of the cortex, including for example thalamo-cortical inputs and cortico-cortical forward projections, where a strong selective drive to some neurons may be important (Rolls, 2016b).

B.4.3.4 Sparsification

Competitive networks can produce more sparse representations than those that they receive, depending on the degree of competition. With the greatest competition, winner-take-all, only one output neuron remains active, and the representation is at its most sparse. This effect can be understood further using Figs. B.16 and B.17. This sparsification is useful to apply to representations before input patterns are applied to associative networks, because sparse representations allow many different pattern associations or memories to be stored in these networks (see Sections B.2 and B.3).

B.4.3.5 Capacity

In a competitive net with N output neurons and a simple winner-take-all rule for the competition, it is possible to learn up to N output categories, in that each output neuron may be allocated a category. When the competition acts in a less rudimentary way, the number of categories that can be learned becomes a complex function of various factors, including the number of modifiable connections per cell and the degree of dilution, or incompleteness, of the connections. Such a function has not yet been described analytically in general, but an

Fig. B.18 Separation of linearly dependent patterns by a competitive network. The network was trained on patterns 10, 01, and 11, applied on the inputs x_1 and x_2 . After learning, the network allocated output neuron 1 to pattern 10, neuron 2 to pattern 01, and neuron 3 to pattern 11. The weights in the network produced during the learning are shown. Each input pattern was normalized to unit length, and thus for pattern 11, $x_1=0.7$ and $x_2=0.7$, as shown. Because the weight vectors were also normalized to unit length, $w_{31}=0.7$ and $w_{32}=0.7$.

upper bound on it can be deduced for the particular case in which the learning is fast, and can be achieved effectively in one shot, or one presentation of each pattern. In that case, the number of categories that can be learned (by the self-organizing process) will at most be equal to the number of associations that can be formed by the corresponding pattern associators, a process that occurs with the additional help of the driving inputs, which effectively determine the categorization in the pattern associator.

Separate constraints on the capacity result if the output vectors are required to be strictly orthogonal. Then, if the output firing rates can assume only positive values, the maximum number p of categories arises, obviously, in the case when only one output neuron is firing for any stimulus, so that up to N categories are formed. If ensemble encoding of output neurons is used (soft competition), again under the orthogonality requirement, then the number of output categories that can be learned will be reduced according to the degree of ensemble encoding. The p categories in the ensemble-encoded case reflect the fact that the between-cluster correlations in the output space are lower than those in the input space. The advantages of ensemble encoding are that dendrites are more evenly allocated to patterns (see Section B.4.9.5), and that correlations between different input stimuli can be reflected in correlations between the corresponding output vectors, so that later networks in the system can generalize usefully. This latter property is of crucial importance, and is utilized for example when an input pattern is presented that has not been learned by the network. The relative similarity of the input pattern to previously learned patterns is indicated by the relative activation of the members of an ensemble of output neurons. This makes the number of different representations that can be reflected in the output of competitive networks with ensemble encoding much higher than with winner-take-all representations, even though with soft competition all these representations cannot strictly be learned.

B.4.3.6 Separation of non-linearly separable patterns

A competitive network can not only separate (e.g. by activating different output neurons) pattern vectors that overlap in almost all elements, but can also help with the separation of vectors that are not linearly separable. An example is that three patterns **A**, **B**, and **A+B** will lead to three different output neurons being activated (see Fig. B.18). For this to occur, the length of the synaptic weight vectors must be normalized (to for example unit length), so that they lie on the surface of a sphere or hypersphere (see Fig. B.16). (If the weight vectors of each neuron are scaled to the same sum, then the weight vectors do not lie on the surface of a hypersphere, and the ability of the network to separate patterns is reduced.)

The property of pattern separation makes a competitive network placed before an auto-association (or pattern association) network very valuable, for it enables the autoassociator to store the three patterns separately, and to recall **A+B** separately from **A** and **B**. This is referred to as the configuration learning problem in animal learning theory (Sutherland and Rudy, 1991). Placing a competitive network before a pattern associator will enable a linearly inseparable problem to be solved. For example, three different output neurons of a two-input competitive network could respond to the patterns 01, 10, and 11, and a pattern associator can learn different outputs for neurons 1–3, which are orthogonal to each other (see Fig. B.11). This is an example of expansion recoding (cf. Marr (1969), who used a different algorithm to obtain the expansion). The sparsification that can be produced by the competitive network can also be advantageous in preparing patterns for presentation to a pattern associator or autoassociator, because the sparsification can increase the number of memories that can be associated or stored.

B.4.3.7 Stability

These networks are generally stable if the input statistics are stable. If the input statistics keep varying, then the competitive network will keep following the input statistics. If this is a problem, then a critical period in which the input statistics are learned, followed by stabilization, may be useful. This appears to be a solution used in developing sensory systems, which have critical periods beyond which further changes become more difficult. An alternative approach taken by Carpenter and Grossberg in their ‘Adaptive Resonance Theory’ (Carpenter, 1997; Grossberg, 2021) is to allow the network to learn only if it does not already have categorizers for a pattern (see Hertz, Krogh and Palmer (1991), p. 228).

Diluted connectivity can help stability, by making neurons tend to find inputs to categorize in only certain parts of the input space, and then making it difficult for the neuron to wander randomly throughout the space later (Rolls, 2016f,b).

B.4.3.8 Frequency of presentation

If some stimuli are presented more frequently than others, then there will be a tendency for the weight vectors to move more rapidly towards frequently presented stimuli, and more neurons may become allocated to the frequently presented stimuli. If winner-take-all competition is used, the result is that the neurons will tend to become allocated during the learning process to the more frequently presented patterns. If soft competition is used, the tendency of neurons to move from patterns that are infrequently or never presented can be reduced by making the competition fairly strong, so that only a few neurons show any learning when each pattern is presented. Provided that the competition is moderately strong (see Section B.4.9.4), the result is that more neurons are allocated to frequently presented patterns, but one or some neurons are allocated to infrequently presented patterns. These points can all be easily demonstrated in simulations.

In an interesting development, it has been shown that if objects consisting of groups of features are presented during training always with another object present, then separate representations of each object can be formed provided that each object is presented many times, but on each occasion is paired with a different object (Stringer and Rolls, 2008; Stringer, Rolls and Tromans, 2007b). This is related to the fact that in this scenario the frequency of co-occurrence of features within the same object is greater than that of features between different objects (see Section 2.8.6.2).

B.4.3.9 Comparison to principal component analysis (PCA) and cluster analysis

Although competitive networks find clusters of features in the input space, they do not perform hierarchical cluster analysis as typically performed in statistics. In hierarchical cluster analysis, input vectors are joined starting with the most correlated pair, and the level of the joining of vectors is indicated. Competitive nets produce different outputs (i.e. activate different output neurons) for each cluster of vectors (i.e. perform vector quantization), but do not compute the level in the hierarchy, unless the network is redesigned (see Hertz, Krogh and Palmer (1991)).

The feature discovery can also be compared to principal component analysis (PCA). (In PCA, the first principal component of a multidimensional space points in the direction of the vector that accounts for most of the variance, and subsequent principal components account for successively less of the variance, and are mutually orthogonal.) In competitive learning with a winner-take-all algorithm, the outputs are mutually orthogonal, but are not in an ordered series according to the amount of variance accounted for, unless the training algorithm is modified. The modification amounts to allowing each of the neurons in a winner-take-all network to learn one at a time, in sequence. The first neuron learns the first principal component. (Neurons trained with a modified Hebb rule learn to maximize the variance of their outputs – see Hertz, Krogh and Palmer (1991).) The second neuron is then allowed to learn, and because its output is orthogonal to the first, it learns the second principal component. This process is repeated. Details are given by Hertz, Krogh and Palmer (1991), but as this is not a biologically plausible process, it is not considered in detail here.

I note that simple competitive learning is very helpful biologically, because it can separate patterns, but that a full ordered set of principal components as computed by PCA would probably not be very useful in biologically plausible networks. The point here is that biological neuronal networks may operate well if the variance in the input representation is distributed across many input neurons, whereas principal component analysis would tend to result in most of the variance being allocated to a few neurons, and the variance being unevenly distributed across the neurons.

B.4.4 Utility of competitive networks in information processing by the brain

B.4.4.1 Feature analysis and preprocessing

Neurons that respond to correlated combinations of their inputs can be described as feature analyzers. Neurons that act as feature analyzers perform useful preprocessing in many sensory systems (see e.g. Chapter 8 of Rolls and Treves (1998) and Rolls (2021b)). The power of competitive networks in multistage hierarchical processing to build combinations of what is found at earlier stages, and thus effectively to build higher-order representations, is also described in Chapter 2 of this book. An interesting development is that competitive networks can learn about individual objects even when multiple objects are presented simultaneously, provided that each object is presented several times more frequently than it is paired with any other individual object (Stringer and Rolls, 2008) (see Section 2.8.6.2). This property arises because learning in competitive networks is primarily about forming representations of objects defined by a high correlation of coactive features in the input space (Stringer and Rolls, 2008; Rolls, 2021d).

B.4.4.2 Removal of redundancy

The removal of redundancy by competition is thought to be a key aspect of how sensory systems, including the ventral cortical visual system, operate. Competitive networks can also be thought of as performing dimension reduction, in that a set of correlated inputs may be responded to as one category or dimension by a competitive network. The concept of redundancy removal can be linked to the point that individual neurons trained with a modified Hebb rule point their weight vector in the direction of the vector that accounts for most of the variance in the input, that is (acting individually) they find the first principal component of the input space (see Section B.4.3.9 and Hertz, Krogh and Palmer (1991)). Although networks with anti-Hebbian synapses between the principal cells (in which the anti-Hebbian learning forces neurons with initially correlated activity to effectively inhibit each other) (Földiák, 1991), and networks that perform Independent Component Analysis (Bell and Sejnowski, 1995), could in principle remove redundancy more effectively, it is not clear that they are implemented biologically. In contrast, competitive networks are more biologically plausible, and illustrate redundancy reduction. The more general use of an unsupervised competitive preprocessor is discussed below (see Fig. B.25).

B.4.4.3 Orthogonalization

The orthogonalization performed by competitive networks is very useful for preparing signals for presentation to pattern associators and autoassociators, for this re-representation decreases interference between the patterns stored in such networks. Indeed, this can be essential if patterns are overlapping and not linearly independent, e.g. 01, 10, and 11. If three such binary patterns were presented to an autoassociative network, it would not form separate representations of them, because either of the patterns 01 or 10 would result by completion in recall of the 11 pattern. A competitive network allows a separate neuron to be allocated to each of the three patterns, and this set of orthogonal representations can be learned by associative networks (see Fig. B.18).

B.4.4.4 Sparsification

The sparsification performed by competitive networks is very useful for preparing signals for presentation to pattern associators and autoassociators, for this re-representation increases the number of patterns that can be associated or stored in such networks (see Sections B.2 and B.3).

B.4.4.5 Brain systems in which competitive networks may be used for orthogonalization and sparsification

One system is the hippocampus, in which the dentate granule cells are believed to operate as a competitive network in order to prepare signals for presentation to the CA3 autoassociative network (see Chapter 9). In this case, the operation is enhanced by expansion recoding, in that (in the rat) there are approximately three times as many dentate granule cells as there are cells in the preceding stage, the entorhinal cortex. This expansion recoding will itself tend to reduce correlations between patterns (cf. Marr (1970), and Marr (1969)).

Also in the hippocampus, the CA1 neurons are thought to act as a competitive network that recodes the separate representations of each of the parts of an episode that must be separately represented in CA3, into a form more suitable for the recall using pattern association performed by the backprojections from the hippocampus to the cerebral cortex (see Chapter 9 and Rolls and Treves (1998) Chapter 6).

The granule cells of the cerebellum may perform a similar function, but in this case the principle may be that each of the very large number of granule cells receives a very small

Fig. B.19 Competitive net receiving a normal forward set of inputs **A**, but also another set of inputs **B** that can be used to influence the categories formed in response to **A** inputs. The inputs **B** might be backprojection inputs.

random subset of inputs, so that the outputs of the granule cells are decorrelated with respect to the inputs (Marr (1969); see Chapter 17).

B.4.5 Guidance of competitive learning

Although competitive networks are primarily unsupervised networks, it is possible to influence the categories found by supplying a second input, as follows (Rolls, 1989a). Consider a competitive network as shown in Fig. B.19 with the normal set of inputs **A** to be categorized, and with an additional set of inputs **B** from a different source. Both sets of inputs work in the normal way for a competitive network, with random initial weights, competition between the output neurons, and a Hebb-like synaptic modification rule that normalizes the lengths of the synaptic weight vectors onto each neuron. The idea then is to use the **B** inputs to influence the categories formed by the **A** input vectors. The influence of the **B** vectors works best if they are orthogonal to each other. Consider any two **A** vectors. If they occur together with the same **B** vector, then the categories produced by the **A** vectors will be more similar than they would be without the influence of the **B** vectors. The categories will be pulled closer together if soft competition is used, or will be more likely to activate the same neuron if winner-take-all competition is used. Conversely, if any two **A** vectors are paired with two different, preferably orthogonal, **B** vectors, then the categories formed by the **A** vectors will be drawn further apart than they would be without the **B** vectors. The differences in categorization remain present after the learning when just the **A** inputs are used.

This guiding function of one of the inputs is one way in which the consequences of sensory stimuli could be fed back to a sensory system to influence the categories formed when the **A** inputs are presented. This could be one function of backprojections in the cerebral cortex (Rolls, 1989c,a) (Chapter 9). In this case, the **A** inputs of Fig. B.19 would be the forward inputs from a preceding cortical area, and the **B** inputs backprojecting axons from the next cortical area, or from a structure such as the amygdala or hippocampus. If two **A** vectors were both associated with positive reinforcement that was fed back as the same **B** vector from another part of the brain, then the two **A** vectors would be brought closer together in the representational space provided by the output of the neurons. If one of the **A** vectors was associated with positive reinforcement, and the other with negative reinforcement, then the output representations of the two **A** vectors would be further apart. This is one way in which external signals could influence in a mild way the categories formed in sensory systems.

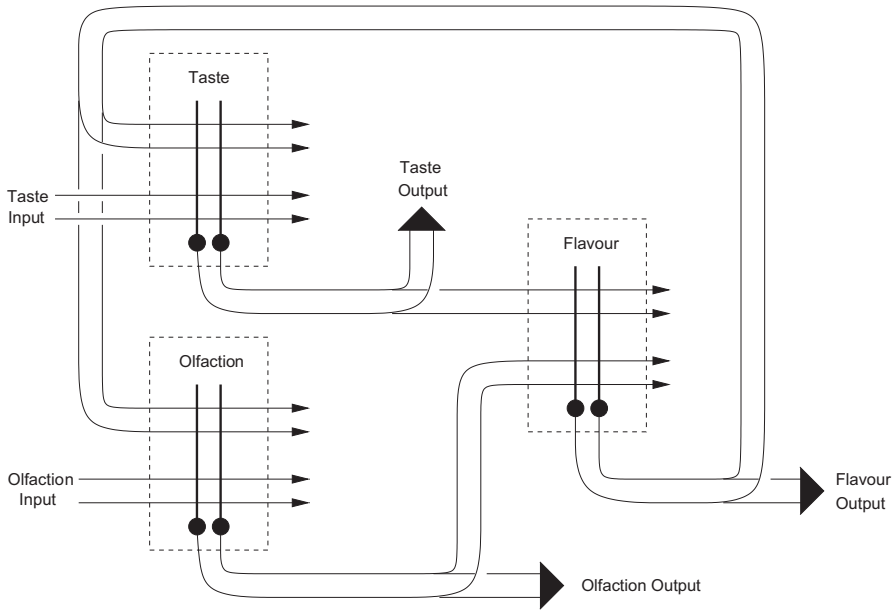

Fig. B.20 A two-layer set of competitive nets in which feedback from layer 2 can influence the categories formed in layer 1. Layer 2 could be a higher cortical visual area with convergence from earlier cortical visual areas (see Chapter 2). In the example, taste and olfactory inputs are received by separate competitive nets in layer 1, and converge into a single competitive net in layer 2. The categories formed in layer 2 (which may be described as representing 'flavor') may be dominated by the relatively orthogonal set of a few tastes that are received by the net. When these layer 2 categories are fed back to layer 1, they may produce in layer 1 categories in, for example, the olfactory network that reflect to some extent the flavor categories of layer 2, and are different from the categories that would otherwise be formed to a large set of rather correlated olfactory inputs. A similar principle may operate in any multilayer hierarchical cortical processing system, such as the ventral visual system, in that the categories that can be formed only at later stages of processing may help earlier stages to form categories relevant to what can be identified at later stages.

Another is that if any **B** vector only occurred for important sensory **A** inputs (as shown by the immediate consequences of receiving those sensory inputs), then the **A** inputs would simply be more likely to have any representation formed than otherwise, due to strong activation of neurons only when combined **A** and **B** inputs are present.

A similar architecture could be used to provide mild guidance for one sensory system (e.g. olfaction) by another (e.g. taste), as shown in Fig. B.20. (Another example of where this architecture could be used is convergence in the visual system at the next cortical stage of processing, with guiding feedback to influence the categories formed in the different regions of the preceding cortical area, as illustrated in Chapter 9.) The idea is that the taste inputs would be more orthogonal to each other than the olfactory inputs, and that the taste inputs would influence the categories formed in the olfactory input categorizer in layer 1, by feedback from a convergent net in layer 2. The difference from the previous architecture is that we now have a two-layer net, with unimodal or separate networks in layer 1, each feeding forward to a single competitive network in layer 2. The categories formed in layer 2 reflect the co-occurrence of a particular taste with particular odors (which together form flavor in layer 2). Layer 2 then provides feedback connections to both the networks in layer 1. It can be shown in such a network that the categories formed in, for example, the olfactory net in layer 1 are influenced by the tastes with which the odors are paired. The feedback signal is built only in layer 2, after there has been convergence between the different modalities. This architecture captures some of the properties of sensory systems, in which there are unimodal processing cortical areas followed by multimodal cortical areas. The multimodal cortical areas can build representations that represent the unimodal inputs that tend to co-occur, and the

higher level representations may in turn, by the highly developed cortico-cortical backprojections, be able to influence sensory categorization in earlier cortical processing areas (Rolls, 1989a).

Another such example might be the effect by which the phonemes heard are influenced by the visual inputs produced by seeing mouth movements (cf. McGurk and MacDonald (1976)). This could be implemented by auditory inputs coming together in the cortex in the superior temporal sulcus onto neurons activated by the sight of the lips moving (recorded during experiments of Baylis, Rolls and Leonard (1987), and Hasselmo, Rolls, Baylis and Nalwa (1989b)), using Hebbian learning with co-active inputs. Backprojections from such multimodal areas to the early auditory cortical areas could then influence the responses of auditory cortex neurons to auditory inputs (see Section B.9 and Fig. B.41, and cf. Calvert et al. (1997)).

A similar principle may operate in any multilayer hierarchical cortical processing system, such as the ventral visual system, in that the categories that can be formed only at later stages of processing may help earlier stages to form categories relevant to what can be identified at the later stages as a result of the operation of backprojections (Rolls, 1989a). The idea that the statistical correlation between the inputs received by neighbouring processing streams can be used to guide unsupervised learning within each stream has also been developed by Becker and Hinton (1992) and others (see Phillips, Kay and Smyth (1995)). The networks considered by these authors self-organize under the influence of collateral connections, such as may be implemented by cortico-cortical connections between parallel processing systems in the brain. They use learning rules that, although somewhat complex, are still local in nature, and tend to optimize specific objective functions. The locality of the learning rule, and the simulations performed so far, raise some hope that, once the operation of these types of networks is better understood, they might achieve similar computational capabilities to backpropagation networks (see Section B.12) while retaining biological plausibility.

B.4.6 Topographic map formation

A simple modification to the competitive networks described so far enables them to develop topological maps. In such maps, the closeness in the map reflects the similarity (correlation) between the features in the inputs. The modification that allows such maps to self-organize is to add short-range excitation and long-range inhibition between the neurons. The function to be implemented has a spatial profile that is described as having a Mexican hat shape (see Fig. B.21). The effect of this connectivity between neurons, which need not be modifiable, is to encourage neurons that are close together to respond to similar features in the input space, and to encourage neurons that are far apart to respond to different features in the input space. When these response tendencies are present during learning, the feature analyzers that are built by modifying the synapses from the input onto the activated neurons tend to be similar if they are close together, and different if far apart. This is illustrated in Figs. B.22 and B.23. Feature maps built in this way were described by von der Malsburg (1973) and Willshaw and von der Malsburg (1976). It should be noted that the learning rule needed is simply the modified Hebb rule described above for competitive networks, and is thus local and biologically plausible. (For computational convenience, the algorithm that Kohonen (Kohonen, 1982, 1989, 1995) has mainly used does not use Mexican hat connectivity between the neurons, but instead arranges that when the weights to a winning neuron are updated, so to a smaller extent are those of its neighbours – see further Hertz, Krogh and Palmer (1991).)

A very common characteristic of connectivity in the brain, found for example throughout the neocortex, consists of short-range excitatory connections between neurons, with inhibition mediated via inhibitory interneurons. The density of the excitatory connectivity even

Fig. B.21 Mexican hat lateral spatial interaction profile.

falls gradually as a function of distance from a neuron, extending typically a distance in the order of 1 mm from the neuron (Braitenberg and Schüz, 1991), contributing to a spatial function quite like that of a Mexican hat. (Longer-range inhibitory influences would form the negative part of the spatial response profile.) This supports the idea that topological maps, though in some cases probably seeded by chemoaffinity, could develop in the brain with the assistance of the processes just described. It is noted that some cortico-cortical connections even within an area may be longer, skipping past some intermediate neurons, and then making connections after some distance with a further group of neurons. Such longer-range connections are found for example between different columns with similar orientation selectivity in the primary visual cortex. The longer range connections may play a part in stabilizing maps, and again in the exchange of information between neurons performing related computations, in this case about features with the same orientations.

If a low-dimensional space, for example the orientation sensitivity of cortical neurons in the primary visual cortex (which is essentially one-dimensional, the dimension being angle), is mapped to a two-dimensional space such as the surface of the cortex, then the resulting map can have long spatial runs where the value along the dimension (in this case orientation tuning) alters gradually, and continuously. Such self-organization can account for many aspects of the mapping of orientation tuning, and of ocular dominance columns, in V1 (Miller, 1994; Harris, Ermentrout and Small, 1997). If a high-dimensional information space is mapped to the two-dimensional cortex, then there will be only short runs of groups of neurons with similar feature responsiveness, and then the map must fracture, with a different type of feature mapped for a short distance after the discontinuity. This is exactly what Rolls suggests is the type of topology found in the anterior inferior temporal visual cortex, with the individual groupings representing what can be self-organized by competitive networks combined with a trace rule as described in Section 2.8. Here, visual stimuli are not represented with reference to their position on the retina, because here the neurons are relatively translation invariant. Instead, when recording here, small clumps of neurons with similar responses may be encountered close together, and then one moves into a group of neurons with quite different feature selectivity (personal observations). This topology will arise naturally, given the anatomical connectivity of the cortex with its short-range excitatory connections, because there are very many different objects in the world and different types of features that describe objects, with no special continuity between the different combinations of features possible.

Rolls' hypothesis contrasts with the view of Tanaka (1996), who has claimed that the

Fig. B.22 Kohonen feature mapping from a two-dimensional L-shaped region to a linear array of 50 units. Each unit has 2 inputs. The input patterns are the X,Y coordinates of points within the L-shape shown. In the diagrams, each point shows the position of a weight vector. Lines connect adjacent units in the 1 D (linear) array of 50 neurons. The weights were initialized to random values within the unit square (a). During feature mapping training, the weights evolved through stages (b) and (c) to (d). By stage (d) the weights have formed so that the positions in the original input space are mapped to a 1 D vector in which adjacent points in the input space activate neighbouring units in the linear array of output units. (Reproduced from Hertz, J.A., Krogh, A. and Palmer, R.G. (1991) *Introduction to the Theory of Neural Computation*. Addison-Wesley: Wokingham, UK. Fig. 9.13.)

inferior temporal cortex provides an alphabet of visual features arranged in discrete modules. The type of mapping found in higher cortical visual areas as proposed by Rolls implies that topological self-organization is an important way in which maps in the brain are formed, for it seems most unlikely that the locations in the map of different types of object seen in an environment could be specified genetically (Rolls and Stringer, 2000). Consistent with this, Tsao, Freiwald, Tootell and Livingstone (2006) described with macaque fMRI ‘anterior face patches’ at A15 to A22. A15 might correspond to where we have analyzed face-selective neurons (it might translate to 3 mm posterior to our sphenoid reference, see Section 2.4), and at this level there are separate regions specialized for face identity in areas TEa and TE_m on the ventral lip of the superior temporal sulcus and the adjacent gyrus, and for face expression and movement in the cortex deep in the superior temporal sulcus (Hasselmo, Rolls and Baylis, 1989a; Baylis, Rolls and Leonard, 1987; Rolls, 2007e). The ‘middle face patch’ of Tsao, Freiwald, Tootell and Livingstone (2006) was at A6, which is probably part of the posterior inferior temporal cortex, and, again consistent with self-organizing map principles, has a high concentration of face-selective neurons within the patch.

The biological utility of developing such topology-preserving feature maps may be that if the computation requires neurons with similar types of response to exchange information more than neurons involved in different computations (which is more than reasonable), then the total length of the connections between the neurons is minimized if the neurons that need to exchange information are close together (cf. Cowey (1979), Durbin and Mitchison (1990)). Examples of this include the separation of color constancy processing in V4 from global motion processing in MT as follows (see Chapter 3 of Rolls and Deco (2002)). In V4, to compute color constancy, an estimate of the illuminating wavelengths can be obtained by summing the outputs of the pyramidal cells in the inhibitory interneurons over several degrees of visual space, and subtracting this from the excitatory central ON color-tuned region of the receptive field by (subtractive) feedback inhibition. This enables the cells to discount the illuminating

Fig. B.23 Example of a one-dimensional topological map that self-organized from inputs in a low-dimensional space. The network has 64 neurons (vertical elements in the diagram) and 64 inputs per neuron (horizontal elements in the diagram). The four different diagrams represent the net tested with different input patterns. The input patterns X are displayed at the left of each diagram, with white representing firing and black not firing for each of the 64 inputs. The central square of each diagram represents the synaptic weights of the neurons, with white representing a strong weight. The row vector below each weight matrix represents the activations of the 64 output neurons, and the bottom row vector the output firing Y . The network was trained with a set of 8 binary input patterns, each of which overlapped in 8 of its 16 'on' elements with the next pattern. The diagram shows that as one moves through correlations in the input space (top left to top right to bottom left to bottom right), so the output neurons activated move steadily across the output array of neurons. Closely correlated inputs are represented close together in the output array of neurons. The way in which this occurs can be seen by inspection of the weight matrix. The network architecture was the same as for a competitive net, except that the activations were converted linearly into output firings, and then each neuron excited its neighbours and inhibited neurons further away. This lateral inhibition was implemented for the simulation by a spatial filter operating on the output firings with the following filter weights (cf. Fig. B.21): 5, 5, 5, 5, 5, 5, 5, 5, 10, 10, 10, 10, 10, 10, 10, 10, 5, 5, 5, 5, 5, 5, 5, 5 which operated on the 64-element firing rate vector.

wavelength, and thus compute color constancy. For this computation, no inputs from motion-selective cells (which in the dorsal stream are color insensitive) are needed. In MT, to compute global motion (e.g. the motion produced by the average flow of local motion elements, exemplified for example by falling snow), the computation can be performed by averaging in the larger (several degrees) receptive fields of MT the local motion inputs received by neurons in earlier cortical areas (V1 and V2) with small receptive fields (see Chapter 3 of Rolls and Deco (2002) and Rolls and Stringer (2006a)). For this computation, no input from color cells is useful. Having separate areas (V4 and MT) for these different computations minimizes the wiring lengths, for having intermingled color and motion cells in a single cortical area would increase the average connection length between the neurons that need to be connected for the computations being performed. Minimizing the total connection length between neurons in the brain is very important in order to keep the size of the brain relatively small.

Placing close to each other neurons that need to exchange information, or that need to receive information from the same source, or that need to project towards the same destination, may also help to minimize the complexity of the rules required to specify cortical (and indeed brain) connectivity (Rolls and Stringer, 2000). For example, in the case of V4 and MT, the connectivity rules can be simpler (e.g. connect to neurons in the vicinity, rather than look for

color-, or motion-marked cells, and connect only to the cells with the correct genetically specified label specifying that the cell is either part of motion or of color processing). Further, the V4 and MT example shows that how the neurons are connected can be specified quite simply, but of course it needs to be specified to be different for different computations. Specifying a general rule for the classes of neurons in a given area also provides a useful simplification to the genetic rules needed to specify the functional architecture of a given cortical area (Rolls and Stringer, 2000). In our V4 and MT example, the genetic rules would need to specify the rules separately for different populations of inhibitory interneurons if the computations performed by V4 and MT were performed with intermixed neurons in a single brain area. Together, these two principles, of minimization of wiring length, and allowing simple genetic specification of wiring rules, may underlie the separation of cortical visual information processing into different (e.g. ventral and dorsal) processing streams. The same two principles operating within each brain processing stream may underlie (taken together with the need for hierarchical processing to enable the computations to be biologically plausible in terms of the number of connections per neuron, and the need for local learning rules, see Section 19.4) much of the overall architecture of visual cortical processing, and of information processing and its modular architecture throughout the cortex more generally.

The rules of information exchange just described could also tend to produce more gross topography in cortical regions. For example, neurons that respond to animate objects may have certain visual feature requirements in common, and may need to exchange information about these features. Other neurons that respond to inanimate objects might have somewhat different visual feature requirements for their inputs, and might need to exchange information strongly. (For example, selection of whether an object is a chisel or a screwdriver may require competition by mutual (lateral) inhibition to produce the contrast enhancement necessary to result in unambiguous neuronal responses.) The rules just described would account for neurons with responsiveness to inanimate and animate objects tending to be grouped in separate parts of a cortical map or representation, and thus separately susceptible to brain damage (see e.g. Farah (1990), Farah (2000)).

B.4.7 Invariance learning by competitive networks

In conventional competitive learning, the weight vector of a neuron can be thought of as moving towards the centre of a cluster of similar overlapping input stimuli (Rumelhart and Zipser, 1985; Hertz, Krogh and Palmer, 1991; Rolls and Treves, 1998; Rolls and Deco, 2002; Perry, Rolls and Stringer, 2006; Rolls, 2016b). The weight vector points towards the centre of the set of stimuli in the category. The different training stimuli that are placed into the same category (i.e. activate the same neuron) are typically overlapping in that the pattern vectors are correlated with each other. Figure B.24a illustrates this.

For the formation of invariant representations, there are multiple occurrences of the object at different positions in the space. The object at each position represents a different transform (whether in position, size, view etc.) of the object. The different transforms may be uncorrelated with each other, as would be the case for example with an object translated so far in the space that there would be no active afferents in common between the two transforms. Yet we need these two orthogonal patterns to be mapped to the same output. It may be a very elongated part of the input space that has to be mapped to the same output in invariance learning. These concepts are illustrated in Fig. B.24b.

Objects in the world have temporal and spatial continuity. That is, the statistics of the world are such that we tend to look at one object for some time, during which it may be transforming continuously from one view to another. The temporal continuity property is used in trace rule invariance training, in which a short-term memory in the associative learning rule

Fig. B.24 (a) Conventional competitive learning. A cluster of overlapping input patterns is categorized as being similar, and this is implemented by a weight vector of an output neuron pointing towards the centre of the cluster. Three clusters are shown, and each cluster might after training have a weight vector pointing towards it. (b) Invariant representation learning. The different transforms of an object may span an elongated region of the space, and the transforms at the far ends of the space may have no overlap (correlation), yet the network must learn to categorize them as similar. The different transforms of two different objects are represented.

normally used to train competitive networks is used to help build representations that reflect the continuity in time that characterizes the different transforms of each object, as described in Chapter 2. The transforms of an object also show spatial continuity, and this can also be used in invariance training in what is termed continuous spatial transform learning, described in Section 2.8.11.

In conventional competitive learning the overall weight vector points to the prototypical representation of the object. The only sense in which after normal competitive training (without translations etc) the network generalizes is with respect to the dot product similarity of any input vector compared to the central vector from the training set that the network learns. Continuous spatial transformation learning works by providing a set of training vectors that overlap, and between them cover the whole space over which an invariant transform of the object must be learned. Indeed, it is important for continuous spatial transformation learning that the different exemplars of an object are sufficiently close that the similarity of adjacent training exemplars is sufficient to ensure that the same postsynaptic neuron learns to bridge the continuous space spanned by the whole set of training exemplars of a given object (Stringer, Perry, Rolls and Proske, 2006; Perry, Rolls and Stringer, 2006; Rolls, 2021d). This will enable the postsynaptic neuron to span a very elongated space of the different transforms of an object, as described in Section 2.8.11.

B.4.8 Radial Basis Function networks

As noted above, a competitive network can act as a useful preprocessor for other networks. In the neural examples above, competitive networks were useful preprocessors for associative networks. Competitive networks are also used as preprocessors in artificial neural networks, for example in hybrid two-layer networks such as that illustrated in Fig. B.25. The competitive network is advantageous in this hybrid scheme, because as an unsupervised network, it can relatively quickly (with a few presentations of each stimulus) discover the main features in the input space, and code for them. This leaves the second layer of the network to act as a supervised network (taught for example by the delta rule, see Section B.11), which learns to map the features found by the first layer into the output required. This learning scheme is very much faster than that of a (two-layer) backpropagation network, which learns very

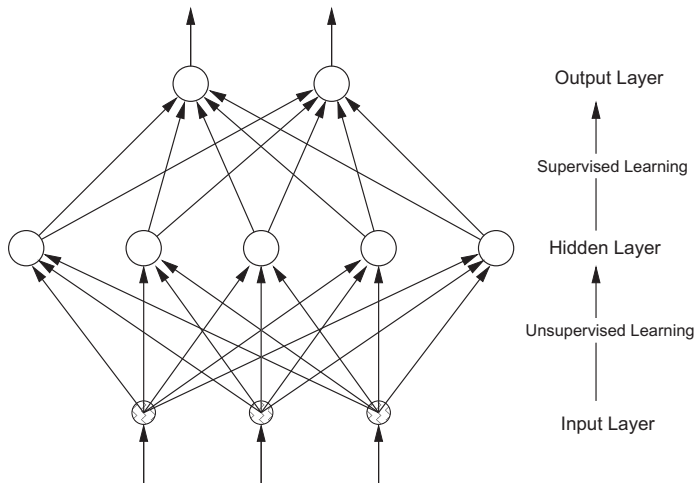

Fig. B.25 A hybrid network, in which for example unsupervised learning rapidly builds relatively orthogonal representations based on input differences, and this is followed by a one-layer supervised network (taught for example by the delta rule) that learns to classify the inputs based on the categorizations formed in the hidden/intermediate layer.

slowly because it takes it a long time to perform the credit assignment to build useful feature analyzers in layer one (the hidden layer) (see Section B.12).

The general scheme shown in Fig. B.25 is used in radial basis function (RBF) neural networks. The main difference from what has been described is that in an RBF network, the hidden neurons do not use a winner-take-all function (as in some competitive networks), but instead use a normalized activation function in which the measure of distance from a weight vector of the neural input is (instead of the dot product $\mathbf{x} \cdot \mathbf{w}_i$ used for most of the networks described in this book), a Gaussian measure of distance:

$$y_i = \frac{\exp[-(\mathbf{x} - \mathbf{w}_i)^2 / 2\sigma_i^2]}{\sum_k \exp[-(\mathbf{x} - \mathbf{w}_k)^2 / 2\sigma_k^2]}. \quad (\text{B.31})$$

The effect is that the response y_i of neuron i is a maximum if the input stimulus vector \mathbf{x} is centred at \mathbf{w}_i , the weight vector of neuron i (this is the upper term in Equation B.31). The magnitude is normalized by dividing by the sum of the activations of all the k neurons in the network. If the input vector \mathbf{x} is not at the centre of the receptive field of the neuron, then the response is decreased according to how far the input vector is from the weight vector \mathbf{w}_i of the neuron, with the weighting decreasing as a Gaussian function with a standard deviation of σ . The idea is like that implemented with soft competition, in that the relative response of different neurons provides an indication of where the input pattern is in relation to the weight vectors of the different neurons. The rapidity with which the response falls off in a Gaussian radial basis function neuron is set by σ_i , which is adjusted so that for any given input pattern vector, a number of RBF neurons are activated. The positions in which the RBF neurons are located (i.e. the directions of their weight vectors, \mathbf{w}) are determined usually by unsupervised learning, e.g. the vector quantization that is produced by the normal competitive learning algorithm. The first layer of an RBF network is not different in principle from a network with soft competition, and it is not clear how biologically a Gaussian activation function would be implemented, so the treatment is not developed further here (see Hertz, Krogh and Palmer (1991), Poggio and Girosi (1990a), and Poggio and Girosi (1990b) for further details).

B.4.9 Further details of the algorithms used in competitive networks

B.4.9.1 Normalization of the inputs

Normalization is useful because in step 1 of the training algorithm described in Section B.4.2.2, the neuronal activations, formed by the inner product of the pattern and the normalized weight vector on each neuron, are scaled in such a way that they have a maximum value of 1.0. This helps different input patterns to be equally effective in the learning process. A way in which this normalization could be achieved by a layer of input neurons is given by Grossberg (1976a, 2021). In the brain, a number of factors may contribute to normalization of the inputs. One factor is that a set of input axons to a neuron will come from another network in which the firing is controlled by inhibitory feedback, and if the numbers of axons involved is large (hundreds or thousands), then the inputs will be in a reasonable range. Second, there is increasing evidence that the different classes of input to a neuron may activate different types of inhibitory interneuron (e.g. Buhl, Halasy and Somogyi (1994)), which terminate on separate parts of the dendrite, usually close to the site of termination of the corresponding excitatory afferents. This may allow separate feedforward inhibition for the different classes of input. In addition, the feedback inhibitory interneurons also have characteristic termination sites, often on or close to the cell body, where they may be particularly effective in controlling firing of the neuron by shunting (divisive) inhibition, rather than by scaling a class of input (see Section B.6).

B.4.9.2 Normalization of the length of the synaptic weight vector on each dendrite

This is necessary to ensure that one or a few neurons do not always win the competition. (If the weights on one neuron were increased by simple Hebbian learning, and there was no normalization of the weights on the neuron, then it would tend to respond strongly in the future to patterns with some overlap with patterns to which that neuron has previously learned, and gradually that neuron would capture a large number of patterns.) A biologically plausible way to achieve this weight adjustment is to use a modified Hebb rule:

$$\delta w_{ij} = \alpha y_i (x_j - w_{ij}) \quad (\text{B.32})$$

where α is a constant, and x_j and w_{ij} are in appropriate units. In vector notation,

$$\delta \mathbf{w}_i = \alpha y_i (\mathbf{x} - \mathbf{w}_i) \quad (\text{B.33})$$

where \mathbf{w}_i is the synaptic weight vector on neuron i . This implements a Hebb rule that increases synaptic strength according to conjunctive pre- and post-synaptic activity, and also allows the strength of each synapse to decrease in proportion to the firing rate of the postsynaptic neuron (as well as in proportion to the existing synaptic strength). This results in a decrease in synaptic strength for synapses from weakly active presynaptic neurons onto strongly active postsynaptic neurons. Such a modification in synaptic strength is termed heterosynaptic long-term depression in the neurophysiological literature, referring to the fact that the synapses that weaken are other than those that activate the neuron.

This is an important computational use of heterosynaptic long-term depression (LTD). In that the amount of decrease of the synaptic strength depends on how strong the synapse is already, the rule is compatible with what is frequently reported in studies of LTD (see Section 1.6). This rule can maintain the sums of the synaptic weights on each dendrite to be very similar without any need for explicit normalization of the synaptic strengths, and is useful in competitive nets. This rule was used by Willshaw and von der Malsburg (1976). As is made clear with the vector notation above, the modified Hebb rule moves the direction of

the weight vector w_i towards the current input pattern vector x in proportion to the difference between these two vectors and the firing rate y_i of neuron i .

If explicit weight (vector length) normalization is needed, the appropriate form of the modified Hebb rule is:

$$\delta w_{ij} = \alpha y_i (x_j - y_i w_{ij}). \quad (\text{B.34})$$

This rule, formulated by Oja (1982), makes weight decay proportional to y_i^2 , normalizes the synaptic weight vector (see Hertz, Krogh and Palmer (1991)), is still a local learning rule, and is known as the Oja rule.

B.4.9.3 Non-linearity in the learning rule

Non-linearity in the learning rule can assist competition (Rolls, 1990b, 1996d). For example, in the brain, long-term potentiation typically occurs only when strong activation of a neuron has produced sufficient depolarization for the voltage-dependent NMDA receptors to become unblocked, allowing Ca^{2+} to enter the cell (see Section 1.6). This means that synaptic modification occurs only on neurons that are strongly activated, effectively assisting competition to select few winners. The learning rule can be written:

$$\delta w_{ij} = \alpha m_i x_j \quad (\text{B.35})$$

where m_i is a (e.g. threshold) non-linear function of the post-synaptic firing y_i which mimics the operation of the NMDA receptors in learning. (It is noted that in associative networks the same process may result in the stored pattern being more sparse than the input pattern, and that this may be beneficial, especially given the exponential firing rate distribution of neurons, in helping to maximize the number of patterns stored in associative networks (see Sections B.2, B.3, and C.3.1).

B.4.9.4 Competition

In a simulation of a competitive network, a single winner can be selected by searching for the neuron with the maximum activation. If graded competition is required, this can be achieved by an activation function that increases greater than linearly. In some of the networks we have simulated (Rolls, 1990b, 1989a; Wallis and Rolls, 1997), raising the activation to a fixed power, typically in the range 2–5, and then rescaling the outputs to a fixed maximum (e.g. 1) is simple to implement. In a real neuronal network, winner-take-all competition can be implemented using mutual (lateral) inhibition between the neurons with non-linear activation functions, and self-excitation of each neuron (see e.g. Grossberg (1976a), Grossberg (1988), Hertz, Krogh and Palmer (1991), and Grossberg (2021)).

Another method to implement soft competition in simulations is to use the normalized exponential or ‘softmax’ activation function for the neurons (Bridle (1990); see Bishop (1995)):

$$y = \exp(h) / \sum_i \exp(h_i). \quad (\text{B.36})$$

This function specifies that the firing rate of each neuron is an exponential function of the activation, scaled by the whole vector of activations h_i , $i = 1, N$. The exponential function (in increasing supralinearly) implements soft competition, in that after the competition the faster firing neurons are firing relatively much faster than the slower firing neurons. In fact, the strength of the competition can be adjusted by using a ‘temperature’ T greater than 0 as follows:

$$y = \exp(h/T) / \sum_i \exp(h_i/T). \quad (\text{B.37})$$

Very low temperatures increase the competition, until with $T \rightarrow 0$, the competition becomes ‘winner-take-all’. At high temperatures, the competition becomes very soft. (When using

the function in simulations, it may be advisable to prescale the firing rates to for example the range 0–1, both to prevent machine overflow, and to set the temperature to operate on a constant range of firing rates, as increasing the range of the inputs has an effect similar to decreasing T .)

The softmax function has the property that activations in the range $-\infty$ to $+\infty$ are mapped into the range 0 to 1.0, and the sum of the firing rates is 1.0. This facilitates interpretation of the firing rates under certain conditions as probabilities, for example that the competitive network firing rate of each neuron reflects the probability that the input vector is within the category or cluster signified by that output neuron (see Bishop (1995)).

B.4.9.5 Soft competition

The use of graded (continuous valued) output neurons in a competitive network, and soft competition rather than winner-take-all competition, has the value that the competitive net generalizes more continuously to an input vector that lies between input vectors that it has learned. Also, with soft competition, neurons with only a small amount of activation by any of the patterns being used will nevertheless learn a little, and move gradually towards the patterns that are being presented. The result is that with soft competition, the output neurons all tend to become allocated to one of the input patterns or one of the clusters of input patterns.

B.4.9.6 Untrained neurons

In competitive networks, especially with winner-take-all or finely tuned neurons, it is possible that some neurons remain unallocated to patterns. This may be useful, in case patterns in the unused part of the space occur in future. Alternatively, unallocated neurons can be made to move towards the parts of the space where patterns are occurring by allowing such losers in the competition to learn a little. Another mechanism is to subtract a bias term μ_i from y_i , and to use a ‘conscience’ mechanism that raises μ_i if a neuron wins frequently, and lowers μ_i if it wins infrequently (Grossberg, 1976b; Bienenstock, Cooper and Munro, 1982; De Sieno, 1988).

B.4.9.7 Large competitive nets: further aspects

If a large neuronal network is considered, with the number of synapses on each neuron in the region of 10,000, as occurs on large pyramidal cells in some parts of the brain, then there is a potential disadvantage in using neurons with synaptic weights that can take on only positive values. This difficulty arises in the following way. Consider a set of positive normalized input firing rates and synaptic weight vectors (in which each element of the vector can take on any value between 0.0 and 1.0). Such vectors of random values will on average be more highly aligned with the direction of the central vector (1,1,1,...,1) than with any other vector. An example can be given for the particular case of vectors evenly distributed on the positive ‘quadrant’ of a high-dimensional hypersphere: the average overlap (i.e. normalized dot product) between two binary random vectors with half the elements on and thus a sparseness of 0.5 (e.g. a random pattern vector and a random dendritic weight vector) will be approximately 0.5, while the average overlap between a random vector and the central vector will be approximately 0.707. A consequence of this will be that if a neuron begins to learn towards several input pattern vectors it will get drawn towards the average of these input patterns which will be closer to the 1,1,1,...,1 direction than to any one of the patterns. As a dendritic weight vector moves towards the central vector, it will become more closely aligned with more and more input patterns so that it is more rapidly drawn towards the central vector. The end result is that in large nets of this type, many of the dendritic weight vectors will point towards the central vector. This effect is not seen so much in small systems, since the fluctuations in the magnitude of the overlaps are sufficiently large that in most cases a dendritic weight vector

will have an input pattern very close to it and thus will not learn towards the centre. In large systems, the fluctuations in the overlaps between random vectors become smaller by a factor of $\frac{1}{\sqrt{N}}$ so that the dendrites will not be particularly close to any of the input patterns.

One solution to this problem is to allow the elements of the synaptic weight vectors to take negative as well as positive values. This could be implemented in the brain by feedforward inhibition. A set of vectors taken with random values will then have a reduced mean correlation between any pair, and the competitive net will be able to categorize them effectively. A system with synaptic weights that can be negative as well as positive is not physiologically plausible, but we can instead imagine a system with weights lying on a hypersphere in the positive quadrant of space but with additional inhibition that results in the cumulative effects of some input lines being effectively negative. This can be achieved in a network by using positive input vectors, positive synaptic weight vectors, and thresholding the output neurons at their mean activation. A large competitive network of this general nature does categorize well, and has been described more fully elsewhere (Bennett, 1990). In a large network with inhibitory feedback neurons, and principal cells with thresholds, the network could achieve at least in part an approximation to this type of thresholding useful in large competitive networks.

A second way in which nets with positive-only values of the elements could operate is by making the input vectors sparse and initializing the weight vectors to be sparse, or to have a reduced contact probability. (A measure a of neuronal population sparseness is defined (as before) in Equation B.38:

$$a = \frac{\left(\sum_{i=1}^N y_i/N\right)^2}{\sum_{i=1}^N y_i^2/N} \quad (\text{B.38})$$

where y_i is the firing rate of the i th neuron in the set of N neurons.) For relatively small net sizes simulated ($N = 100$) with patterns with a sparseness a of, for example, 0.1 or 0.2, learning onto the average vector can be avoided. However, as the net size increases, the sparseness required does become very low. In large nets, a greatly reduced contact probability between neurons (many synapses kept identically zero, i.e. diluted connectivity) would prevent learning of the average vector, thus allowing categorization to occur (Rolls, 2016f,b). Reduced contact probability will, however, prevent complete alignment of synapses with patterns, so that the performance of the network will be affected.

B.5 Continuous attractor networks

B.5.1 Introduction

Single-cell recording studies have shown that some neurons represent the current position along a continuous physical dimension or space even when no inputs are available, for example in darkness (see Chapter 9). Examples include neurons that represent the positions of the eyes (i.e. eye direction with respect to the head), the place where the animal is looking in space, head direction, and the place where the animal is located. In particular, examples of such classes of cells include head direction cells in rats (Ranck, 1985; Taube, Muller and Ranck, 1990a; Taube, Goodridge, Golob, Dudchenko and Stackman, 1996; Muller, Ranck and Taube, 1996) and primates (Robertson, Rolls, Georges-François and Panzeri, 1999), which respond maximally when the animal's head is facing in a particular preferred direction; place cells in rats (O'Keefe and Dostrovsky, 1971; McNaughton, Barnes and O'Keefe, 1983;

Fig. B.26 The architecture of a continuous attractor neural network (CANN).

O’Keefe, 1984; Muller, Kubie, Bostock, Taube and Quirk, 1991; Markus, Qin, Leonard, Skaggs, McNaughton and Barnes, 1995) that fire maximally when the animal is in a particular location; and spatial view cells in primates that respond when the monkey is looking towards a particular location in space (Rolls, Robertson and Georges-François, 1997a; Georges-François, Rolls and Robertson, 1999; Robertson, Rolls and Georges-François, 1998; Rolls, 2023c). In the parietal cortex there are many spatial representations, in several different coordinate frames (see Chapters 3 and 10, and Andersen, Batista, Snyder, Buneo and Cohen (2000)), and they have some capability to remain active during memory periods when the stimulus is no longer present. Even more than this, the dorsolateral prefrontal cortex networks to which the parietal networks project have the capability to maintain spatial representations active for many seconds or minutes during short-term memory tasks, when the stimulus is no longer present (see Section 13.6.1). In this section, we describe how such networks representing continuous physical space could operate. The locations of such spatial networks in the brain are the parietal areas, the prefrontal areas that implement short-term spatial memory and receive from the parietal cortex (see Section 13.6.1), and the hippocampal system which combines information about objects from the inferior temporal visual cortex with spatial information (see Chapter 9).

A class of network that can maintain the firing of its neurons to represent any location along a continuous physical dimension such as spatial position, head direction, etc. is a ‘Continuous Attractor’ neural network (CANN). It uses excitatory recurrent collateral connections between the neurons to reflect the distance between the neurons in the state space of the animal (e.g. head direction space). These networks can maintain the bubble of neural activity constant for long periods wherever it is started to represent the current state (head direction, position, etc) of the animal, and are likely to be involved in many aspects of spatial processing and memory, including spatial vision. Global inhibition is used to keep the number of neurons in a bubble or packet of actively firing neurons relatively constant, and to help to ensure that there is only one activity packet. Continuous attractor networks can be thought of as very similar to autoassociation or discrete attractor networks (described in Section B.3), and have the same architecture, as illustrated in Fig. B.26. The main difference is that the patterns stored in a CANN are continuous patterns, with each neuron having broadly tuned firing which decreases with for example a Gaussian function as the distance from the optimal firing location of the cell is varied, and with different neurons having tuning that overlaps throughout the space. Such tuning is illustrated in Fig. 9.30. For comparison, the autoassociation networks described in Section B.3 have discrete (separate) patterns (each pattern implemented by the

firing of a particular subset of the neurons), with no continuous distribution of the patterns throughout the space (see Fig. 9.30). A consequent difference is that the CANN can maintain its firing at any location in the trained continuous space, whereas a discrete attractor or autoassociation network moves its population of active neurons towards one of the previously learned attractor states, and thus implements the recall of a particular previously learned pattern from an incomplete or noisy (distorted) version of one of the previously learned patterns. The energy landscape of a discrete attractor network (see Equation B.12) has separate energy minima, each one of which corresponds to a learned pattern, whereas the energy landscape of a continuous attractor network is flat, so that the activity packet remains stable with continuous firing wherever it is started in the state space. (The state space refers to the set of possible spatial states of the animal in its environment, e.g. the set of possible head directions.)

In Section B.5.2, we first describe the operation and properties of continuous attractor networks, which have been studied by for example Amari (1977), Zhang (1996), and Taylor (1999), and then, following Stringer, Trappenberg, Rolls and De Araujo (2002b), address four key issues about the biological application of continuous attractor network models.

One key issue in such continuous attractor neural networks is how the synaptic strengths between the neurons in the continuous attractor network could be learned in biological systems (Section B.5.3).

A second key issue in such continuous attractor neural networks is how the bubble of neuronal firing representing one location in the continuous state space should be updated based on non-visual cues to represent a new location in state space (Section B.5.5). This is essentially the problem of path integration: how a system that represents a memory of where the agent is in physical space could be updated based on idiothetic (self-motion) cues such as vestibular cues (which might represent a head velocity signal), or proprioceptive cues (which might update a representation of place based on movements being made in the space, during for example walking in the dark).

A third key issue is how stability in the bubble of activity representing the current location can be maintained without much drift in darkness, when it is operating as a memory system (Section B.5.6).

A fourth key issue is considered in Section B.5.8 in which we describe networks that store both continuous patterns and discrete patterns (see Fig. 9.30), which can be used to store for example the location in (continuous, physical) space where an object (a discrete item) is present.

B.5.2 The generic model of a continuous attractor network

The generic model of a continuous attractor is as follows. (The model is described in the context of head direction cells, which represent the head direction of rats (Taube et al., 1996; Muller et al., 1996) and macaques (Robertson, Rolls, Georges-François and Panzeri, 1999), and can be reset by visual inputs after gradual drift in darkness.) The model is a recurrent attractor network with global inhibition. It is different from a Hopfield attractor network primarily in that there are no discrete attractors formed by associative learning of discrete patterns. Instead there is a set of neurons that are connected to each other by synaptic weights w_{ij} that are a simple function, for example Gaussian, of the distance between the states of the agent in the physical world (e.g. head directions) represented by the neurons. Neurons that represent similar states (locations in the state space) of the agent in the physical world have strong synaptic connections, which can be set up by an associative learning rule, as described in Section B.5.3. The network updates its firing rates by the following ‘leaky-integrator’ dynamical Equations. The continuously changing activation h_i^{HD} of each head direction cell i is governed by the Equation

$$\tau \frac{dh_i^{\text{HD}}(t)}{dt} = -h_i^{\text{HD}}(t) + \frac{\phi_0}{C^{\text{HD}}} \sum_j (w_{ij} - w^{\text{inh}}) r_j^{\text{HD}}(t) + I_i^V, \quad (\text{B.39})$$

where r_j^{HD} is the firing rate of head direction cell j , w_{ij} is the excitatory (positive) synaptic weight from head direction cell j to cell i , w^{inh} is a global constant describing the effect of inhibitory interneurons, and τ is the time constant of the system²⁶. The term $-h_i^{\text{HD}}(t)$ indicates the amount by which the activation decays (in the leaky integrator neuron) at time t . (The network is updated in a typical simulation at much smaller timesteps than the time constant of the system, τ .) The next term in Equation B.39 is the input from other neurons in the network r_j^{HD} weighted by the recurrent collateral synaptic connections w_{ij} (scaled by a constant ϕ_0 and C^{HD} which is the number of synaptic connections received by each head direction cell from other head direction cells in the continuous attractor). The term I_i^V represents a visual input to head direction cell i . Each term I_i^V is set to have a Gaussian response profile in most continuous attractor networks, and this sets the firing of the cells in the continuous attractor to have Gaussian response profiles as a function of where the agent is located in the state space (see e.g. Fig. 9.30 on page 385), but the Gaussian assumption is not crucial. (It is known that the firing rates of head direction cells in both rats (Taube, Goodridge, Golob, Dudchenko and Stackman, 1996; Muller, Ranck and Taube, 1996) and macaques (Robertson, Rolls, Georges-François and Panzeri, 1999) are approximately Gaussian.) When the agent is operating without visual input, in memory mode, then the term I_i^V is set to zero. The firing rate r_i^{HD} of cell i is determined from the activation h_i^{HD} and the sigmoid function

$$r_i^{\text{HD}}(t) = \frac{1}{1 + e^{-2\beta(h_i^{\text{HD}}(t) - \alpha)}}, \quad (\text{B.40})$$

where α and β are the sigmoid threshold and slope, respectively.

B.5.3 Learning the synaptic strengths between the neurons that implement a continuous attractor network

So far we have said that the neurons in the continuous attractor network are connected to each other by synaptic weights w_{ij} that are a simple function, for example Gaussian, of the distance between the states of the agent in the physical world (e.g. head directions, spatial views etc) represented by the neurons. In many simulations, the weights are set by formula to have weights with these appropriate Gaussian values. However, Stringer, Trappenberg, Rolls and De Araujo (2002b) showed how the appropriate weights could be set up by learning. They started with the fact that since the neurons have broad tuning that may be Gaussian in shape, nearby neurons in the state space will have overlapping spatial fields, and will thus be co-active to a degree that depends on the distance between them. They postulated that therefore the synaptic weights could be set up by associative learning based on the co-activity of the neurons produced by external stimuli as the animal moved in the state space. For example, head direction cells are forced to fire during learning by visual cues in the environment that produce Gaussian firing as a function of head direction from an optimal head direction for each cell. The learning rule is simply that the weights w_{ij} from head direction cell j with firing rate r_j^{HD} to head direction cell i with firing rate r_i^{HD} are updated according to an associative (Hebb) rule

$$\delta w_{ij} = k r_i^{\text{HD}} r_j^{\text{HD}} \quad (\text{B.41})$$

²⁶Note that for this section, we use r rather than y to refer to the firing rates of the neurons in the network, remembering that, because this is a recurrently connected network (see Fig. B.13), the output from a neuron y_i might be the input x_j to another neuron.

Fig. B.27 Training the weights in a continuous attractor network with an associative rule (equation B.41). Left: the trained recurrent synaptic weights from head direction cell 50 to the other head direction cells in the network arranged in head direction space (solid curve). The dashed line shows a Gaussian curve fitted to the weights shown in the solid curve. The dash-dot curve shows the recurrent synaptic weights trained with rule Equation (B.41), but with a non-linearity introduced that mimics the properties of NMDA receptors by allowing the synapses to modify only after strong postsynaptic firing is present. Right: the stable firing rate profiles forming an activity packet in the continuous attractor network during the testing phase when the training (visual) inputs are no longer present. The firing rates are shown after the network has been initially stimulated by visual input to initialize an activity packet, and then allowed to settle to a stable activity profile without visual input. The three graphs show the firing rates for low, intermediate and high values of the lateral inhibition parameter w^{inh} . For both left and right plots, the 100 head direction cells are arranged according to where they fire maximally in the head direction space of the agent when visual cues are available. (After Stringer, S.M., Trappenberg, T.P., Rolls, E.T. and De Araujo, I.E.T. (2002) Self-organizing continuous attractor networks and path integration: One-dimensional models of head direction cells. *Network: Computation in Neural Systems* 13: 217–242. © Informa Ltd.)

where δw_{ij} is the change of synaptic weight and k is the learning rate constant. During the learning phase, the firing rate r_i^{HD} of each head direction cell i might be the following Gaussian function of the displacement of the head from the optimal firing direction of the cell

$$r_i^{\text{HD}} = e^{-s_{\text{HD}}^2/2\sigma_{\text{HD}}^2}, \quad (\text{B.42})$$

where s_{HD} is the difference between the actual head direction x (in degrees) of the agent and the optimal head direction x_i for head direction cell i , and σ_{HD} is the standard deviation.

Stringer, Trappenberg, Rolls and De Araujo (2002b) showed that after training at all head directions, the synaptic connections develop strengths that are an almost Gaussian function of the distance between the cells in head direction space, as shown in Fig. B.27 (left). Interestingly if a non-linearity is introduced into the learning rule that mimics the properties of NMDA receptors by allowing the synapses to modify only after strong postsynaptic firing is present, then the synaptic strengths are still close to a Gaussian function of the distance between the connected cells in head direction space (see Fig. B.27, left). They showed that after training, the continuous attractor network can support stable activity packets in the absence of visual inputs (see Fig. B.27, right) provided that global inhibition is used to prevent all the neurons becoming activated. (The exact stability conditions for such networks have been analyzed by Amari (1977)). Thus Stringer, Trappenberg, Rolls and De Araujo (2002b) demonstrated biologically plausible mechanisms for training the synaptic weights in a continuous attractor using a biologically plausible local learning rule.

Stringer, Trappenberg, Rolls and De Araujo (2002b) went on to show that if there was a short term memory trace built into the operation of the learning rule, then this could help to produce smooth weights in the continuous attractor if only incomplete training was available, that is if the weights were trained at only a few locations. The same rule can take advantage in training the synaptic weights of the temporal probability distributions of firing when they

happen to reflect spatial proximity. For example, for head direction cells the agent will necessarily move through similar head directions before reaching quite different head directions, and so the temporal proximity with which the cells fire can be used to set up the appropriate synaptic weights. This new proposal for training continuous attractor networks can also help to produce broadly tuned spatial cells even if the driving (e.g. visual) input (I_i^V in Equation B.39) during training produces rather narrowly tuned neuronal responses. The learning rule with such temporal properties is a memory trace learning rule that strengthens synaptic connections between neurons, based on the temporal probability distribution of the firing. There are many versions of such rules (Rolls and Milward, 2000; Rolls and Stringer, 2001a), which are described more fully in Chapter 2, but a simple one that works adequately is

$$\delta w_{ij} = k \bar{r}_i^{\text{HD}} \bar{r}_j^{\text{HD}} \quad (\text{B.43})$$

where δw_{ij} is the change of synaptic weight, and \bar{r}^{HD} is a local temporal average or trace value of the firing rate of a head direction cell given by

$$\bar{r}^{\text{HD}}(t + \delta t) = (1 - \eta) r^{\text{HD}}(t + \delta t) + \eta \bar{r}^{\text{HD}}(t) \quad (\text{B.44})$$

where η is a parameter set in the interval [0,1] which determines the contribution of the current firing and the previous trace. For $\eta = 0$ the trace rule (B.43) becomes the standard Hebb rule (B.41), while for $\eta > 0$ learning rule (B.43) operates to associate together patterns of activity that occur close together in time. The rule might allow temporal associations to influence the synaptic weights that are learned over times in the order of 1 s. The memory trace required for operation of this rule might be no more complicated than the continuing firing that is an inherent property of attractor networks, but it could also be implemented by a number of biophysical mechanisms, discussed in Chapter 2. Finally, we note that some long-term depression (LTD) in the learning rule could help to maintain the weights of different neurons equally potent (see Section B.4.9.2 and Equation B.32), and could compensate for irregularity during training in which the agent might be trained much more in some than other locations in the space (see Stringer, Trappenberg, Rolls and De Araujo (2002b)).

B.5.4 The capacity of a continuous attractor network: multiple charts and packets

The capacity of a continuous attractor network can be approached on the following bases. First, as there are no discrete attractor states, but instead a continuous physical space is being represented, some concept of spatial resolution must be brought to bear, that is the number of different positions in the space that can be represented. Second, the number of connections per neuron in the continuous attractor will directly influence the number of different spatial positions (locations in the state space) that can be represented. Third, the sparseness of the representation can be thought of as influencing the number of different spatial locations (in the continuous state space) that can be represented, in a way analogous to that described for discrete attractor networks in Equation B.14 (Battaglia and Treves, 1998b). That is, if the tuning of the neurons is very broad, then fewer locations in the state space may be represented. Fourth, and very interestingly, if representations of different continuous state spaces, for example maps or charts of different environments, are stored in the same network, there may be little cost of adding extra maps or charts. The reason for this is that the large part of the interference between the different memories stored in such a network arises from the correlations between the different positions in any one map, which are typically relatively high because quite broad tuning of individual cells is common. In contrast, there are in general low correlations between the representations of places in different maps or charts, and

therefore many different maps can be simultaneously stored in a continuous attractor network (Battaglia and Treves, 1998b).

For a similar reason, it is even possible to have the activity packets that operate in different spaces simultaneously active in a single continuous attractor network of neurons, and to move independently of each other in their respective spaces or charts (Stringer, Rolls and Trappenberg, 2004).

B.5.5 Continuous attractor models: path integration

So far, we have considered how spatial representations could be stored in continuous attractor networks, and how the activity can be maintained at any location in the state space in a form of short-term memory when the external (e.g. visual) input is removed. However, many networks with spatial representations in the brain can be updated by internal, self-motion (i.e. idiothetic), cues even when there is no external (e.g. visual) input. Examples are head direction cells in the presubiculum of rats and macaques, place cells in the rat hippocampus, and spatial view cells in the primate hippocampus (see Chapter 9). The major question arises about how such idiothetic inputs could drive the activity packet in a continuous attractor network and, in particular, how such a system could be set up biologically by self-organizing learning.

One approach to simulating the movement of an activity packet produced by idiothetic cues (which is a form of path integration whereby the current location is calculated from recent movements) is to employ a look-up table that stores (taking head direction cells as an example), for every possible head direction and head rotational velocity input generated by the vestibular system, the corresponding new head direction (Samsonovich and McNaughton, 1997). Another approach involves modulating the strengths of the recurrent synaptic weights in the continuous attractor on one but not the other side of a currently represented position, so that the stable position of the packet of activity, which requires symmetric connections in different directions from each node, is lost, and the packet moves in the direction of the temporarily increased weights, although no possible biological implementation was proposed of how the appropriate dynamic synaptic weight changes might be achieved (Zhang, 1996). Another mechanism (for head direction cells) (Skaggs, Knierim, Kudrimoti and McNaughton, 1995) relies on a set of cells, termed (head) rotation cells, which are co-activated by head direction cells and vestibular cells and drive the activity of the attractor network by anatomically distinct connections for clockwise and counter-clockwise rotation cells, in what is effectively a look-up table. However, no proposal had been made about how this could be achieved by a biologically plausible learning process for most approaches to path integration in continuous attractor networks, which relied heavily on rather artificial pre-set synaptic connectivities.

In that context Stringer, Trappenberg, Rolls and De Araujo (2002b) introduced a proposal with more biological plausibility about how the synaptic connections from idiothetic inputs to a continuous attractor network can be learned by a self-organizing learning process. The essence of the hypothesis is described with Fig. B.28. The continuous attractor synaptic weights w^{RC} are set up under the influence of the external visual inputs I^{V} as described in Section B.5.3. At the same time, the idiothetic synaptic weights w^{ID} (in which the ID refers to the fact that they are in this case produced by idiothetic inputs, produced by cells that fire to represent the velocity of clockwise and anticlockwise head rotation), are set up by associating the change of head direction cell firing that has just occurred (detected by a trace memory mechanism described below) with the current firing of the head rotation cells r^{ID} . For example, when the trace memory mechanism incorporated into the idiothetic synapses w^{ID} detects that the head direction cell firing is at a given location (indicated by the firing r^{HD}) and is moving clockwise (produced by the altering visual inputs I^{V}), and there is

Fig. B.28 General network architecture for a one-dimensional continuous attractor model of head direction cells which can be updated by idiothetic inputs produced by head rotation cell firing r^{ID} . The head direction cell firing is r^{HD} , the continuous attractor synaptic weights are w^{RC} , the idiothetic synaptic weights are w^{ID} , and the external visual input is I^V . (After Stringer, S.M., Trappenberg, T.P., Rolls, E.T. and De Araujo, I.E.T. (2002) Self-organizing continuous attractor networks and path integration: One-dimensional models of head direction cells. *Network: Computation in Neural Systems* 13: 217–242. © Informa Ltd.)

simultaneous clockwise head rotation cell firing, the synapses w^{ID} learn the association, so that when that rotation cell firing occurs later without visual input, it takes the current head direction firing in the continuous attractor into account, and moves the location of the head direction attractor in the appropriate direction.

For the learning to operate, the idiothetic synapses onto head direction cell i with firing r_i^{HD} need two inputs: the memory traced term from other head direction cells \bar{r}_j^{HD} (given by Equation B.44), and the head rotation cell input with firing r_k^{ID} ; and the learning rule can be written

$$\delta w_{ijk}^{ID} = \tilde{k} r_i^{HD} \bar{r}_j^{HD} r_k^{ID}, \quad (\text{B.45})$$

where \tilde{k} is the learning rate associated with this type of synaptic connection. The head rotation cell firing (r_k^{ID}) could be as simple as one set of cells that fire for clockwise head rotation (for which k might be 1), and a second set of cells that fire for anticlockwise head rotation (for which k might be 2).

After learning, the firing of the head direction cells would be updated in the dark (when $I_i^V = 0$) by idiothetic head rotation cell firing r_k^{ID} as follows

$$\begin{aligned} \tau \frac{dh_i^{HD}(t)}{dt} &= -h_i^{HD}(t) + \frac{\phi_0}{C^{HD}} \sum_j (w_{ij} - w^{inh}) r_j^{HD}(t) + I_i^V \\ &+ \phi_1 \left(\frac{1}{C^{HD \times ID}} \sum_{j,k} w_{ijk}^{ID} r_j^{HD} r_k^{ID} \right). \end{aligned} \quad (\text{B.46})$$

Equation B.46 is similar to Equation B.39, except for the last term, which introduces the effects of the idiothetic synaptic weights w_{ijk}^{ID} , which effectively specify that the current firing of head direction cell i , r_i^{HD} , must be updated by the previously learned combination of the

particular head rotation now occurring indicated by r_k^{ID} , and the current head direction indicated by the firings of the other head direction cells r_j^{HD} indexed through j^{27} . This makes it clear that the idiothetic synapses operate using combinations of inputs, in this case of two inputs. Neurons that sum the effects of such local products are termed Sigma-Pi neurons (see Section A.2.3). Although such synapses are more complicated than the two-term synapses used throughout the rest of this book, such three-term synapses appear to be useful to solve the computational problem of updating representations based on idiothetic inputs in the way described. Synapses that operate according to Sigma-Pi rules might be implemented in the brain by a number of mechanisms described by Koch (1999) (Section 21.1.1), Jonas and Kaczmarek (1999), and Stringer, Trappenberg, Rolls and De Araujo (2002b), including having two inputs close together on a thin dendrite, so that local synaptic interactions would be emphasized.

Simulations demonstrating the operation of this self-organizing learning to produce movement of the location being represented in a continuous attractor network were described by Stringer, Trappenberg, Rolls and De Araujo (2002b), and one example of the operation is shown in Fig. B.29. They also showed that, after training with just one value of the head rotation cell firing, the network showed the desirable property of moving the head direction being represented in the continuous attractor by an amount that was proportional to the value of the head rotation cell firing. Stringer, Trappenberg, Rolls and De Araujo (2002b) also describe a related model of the idiothetic cell update of the location represented in a continuous attractor, in which the rotation cell firing directly modulates in a multiplicative way the strength of the recurrent connections in the continuous attractor in such a way that clockwise rotation cells modulate the strength of the synaptic connections in the clockwise direction in the continuous attractor, and vice versa.

It should be emphasized that although the cells are organized in Fig. B.29 according to the spatial position being represented, there is no need for cells in continuous attractors that represent nearby locations in the state space to be close together, as the distance in the state space between any two neurons is represented by the strength of the connection between them, not by where the neurons are physically located. This enables continuous attractor networks to represent spaces with arbitrary topologies, as the topology is represented in the connection strengths (Stringer, Trappenberg, Rolls and De Araujo, 2002b; Stringer, Rolls, Trappenberg and De Araujo, 2002a; Stringer, Rolls and Trappenberg, 2005; Stringer and Rolls, 2002). Indeed, it is this that enables many different charts each with its own topology to be represented in a single continuous attractor network (Battaglia and Treves, 1998b).

In the network described so far, self-organization occurs, but one set of synapses is Sigma-Pi. We have gone on to show that the Sigma-Pi synapses are not necessary, and can be replaced by a competitive network that learns to respond to combinations of the spatial position and the idiothetic velocity, as illustrated in Fig. B.30 (Stringer and Rolls, 2006).

B.5.6 Stabilization of the activity packet within the continuous attractor network when the agent is stationary

With irregular learning conditions (in which identical training with high precision of every node cannot be guaranteed), the recurrent synaptic weights between nodes in the continuous attractor will not be of the perfectly regular and symmetric form normally required in a continuous attractor neural network. This can lead to drift of the activity packet within the

²⁷The term $\phi_1/C^{\text{HD} \times \text{ID}}$ is a scaling factor that reflects the number $C^{\text{HD} \times \text{ID}}$ of inputs to these synapses, and enables the overall magnitude of the idiothetic input to each head direction cell to remain approximately the same as the number of idiothetic connections received by each head direction cell is varied.

Fig. B.29 Idiothetic update of the location represented in a continuous attractor network. The firing rate of the cells with optima at different head directions (organized according to head direction on the ordinate) is shown by the blackness of the plot, as a function of time. The activity packet was initialized to a head direction of 75 degrees, and the packet was allowed to settle without visual input. For timestep=0 to 100 there was no rotation cell input, and the activity packet in the continuous attractor remained stable at 75 degrees. For timestep=100 to 300 the clockwise rotation cells were active with a firing rate of 0.15 to represent a moderate angular velocity, and the activity packet moved clockwise. For timestep=300 to 400 there was no rotation cell firing, and the activity packet immediately stopped, and remained still. For timestep=400 to 500 the anti-clockwise rotation cells had a high firing rate of 0.3 to represent a high velocity, and the activity packet moved anticlockwise with a greater velocity. For timestep=500 to 600 there was no rotation cell firing, and the activity packet immediately stopped. (After Stringer, S.M., Trappenberg, T.P., Rolls, E.T. and De Araujo, I.E.T. (2002) Self-organizing continuous attractor networks and path integration: One-dimensional models of head direction cells. *Network: Computation in Neural Systems* 13: 217–242. © Informa Ltd.)

continuous attractor network of e.g. head direction cells when no visual cues are present, even when the agent is not moving. This drift is a common property of the short-term memories of spatial position implemented in the brain, which emphasizes the computational problems that can arise in continuous attractor networks if the weights between nodes are not balanced in different directions in the space being represented. An approach to stabilizing the activity packet when it should not be drifting in real nervous systems, which does help to minimize the drift that can occur, is now described.

The activity packet may be stabilized within a continuous attractor network, when the agent is stationary and the network is operating in memory mode without an external stabilizing input, by enhancing the firing of those cells that are already firing. In biological systems this might be achieved through mechanisms for short-term synaptic enhancement (Koch, 1999). Another way is to take advantage of the non-linearity of the activation function of neurons with NMDA receptors, which only contribute to neuronal firing once the neuron is sufficiently depolarized (Wang, 1999). The effect is to enhance the firing of neurons that are already reasonably well activated. The effect has been utilized in a model of a network with recurrent excitatory synapses that can maintain active an arbitrary set of neurons that are initially sufficiently strongly activated by an external stimulus (see Lisman, Fellous and Wang (1998), and, for a discussion on whether these networks could be used to implement short-term memories, see Kesner and Rolls (2001)).

We have incorporated this non-linearity into a model of a head direction continuous attractor network by adjusting the sigmoid threshold α_i (see Equation B.40) for each head direction cell i as follows (Stringer, Trappenberg, Rolls and De Araujo, 2002b). If the head

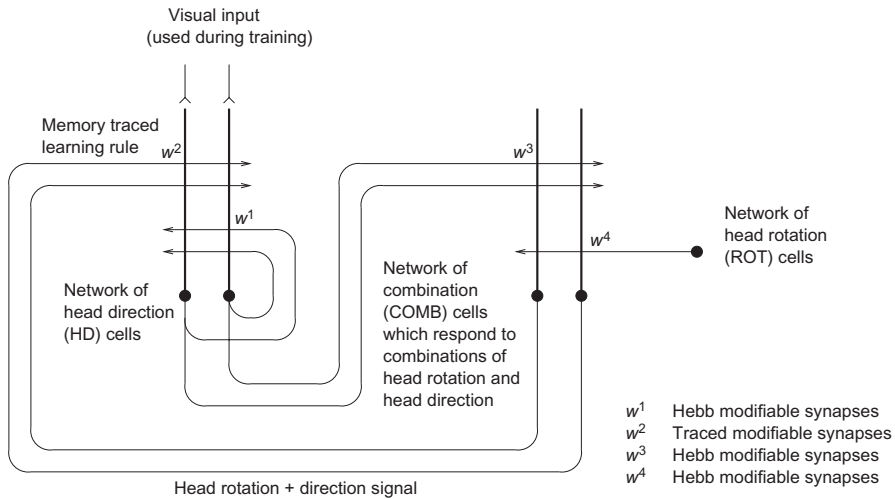

Fig. B.30 Network architecture for a two-layer self-organizing neural network model of the head direction system. The network architecture contains a layer of head direction (HD) cells representing the head direction of the agent, a layer of combination (COMB) cells representing a combination of head direction and rotational velocity, and a layer of rotation (ROT) cells which become active when the agent rotates. There are four types of synaptic connection in the network, which operate as follows. The w^1_{ij} synapses are Hebb-modifiable recurrent connections between head direction cells. These connections help to support stable packets of activity within this continuous attractor layer of head direction cells in the absence of visual input. The combination cells receive inputs from the head direction cells through the Hebb-modifiable w^3_{ij} synapses, and inputs from the rotation cells through the Hebb-modifiable w^4_{ij} synapses. These synaptic inputs encourage combination cells by competitive learning to respond to particular combinations of head direction and rotational velocity. In particular, the combination cells only become significantly active when the agent is rotating. The head direction cells receive inputs from the combination cells through the w^2_{ij} synapses. The w^2_{ij} synapses are trained using a 'trace' learning rule, which incorporates a temporal trace of recent combination cell activity. This rule introduces an asymmetry into the w^2_{ij} weights, which plays an important role in shifting the activity packet through the layer of head direction cells during path integration in the dark. (After Stringer, S.M. and Rolls, E. T. (2006) Self-organizing path integration using a linked continuous attractor and competitive network: path integration of head direction. Network: Computation in Neural Systems 17: 419–445. © Informa Ltd.)

direction cell firing rate r_i^{HD} is lower than a threshold value, γ , then the sigmoid threshold α_i is set to a relatively high value α^{high} . Otherwise, if the head direction cell firing rate r_i^{HD} is greater than or equal to the threshold value, γ , then the sigmoid threshold α_i is set to a relatively low value α^{low} . It was shown that this procedure has the effect of enhancing the current position of the activity packet within the continuous attractor network, and so prevents the activity packet drifting erratically due to the noise in the recurrent synaptic weights produced for example by irregular learning. An advantage of using the non-linearity in the activation function of a neuron (produced for example by the operation of NMDA receptors) is that this tends to enable packets of activity to be kept active without drift even when the packet is not in one of the energy minima that can result from irregular learning (or from diluted connectivity in the continuous attractor as described below). Thus use of this non-linearity increases the number of locations in the continuous physical state space at which a stable activity packet can be maintained (Stringer, Trappenberg, Rolls and De Araujo, 2002b).

The same process might help to stabilize the activity packet against drift caused by the probabilistic spiking of neurons in the network (cf. Section 11.5.1).

B.5.7 Continuous attractor networks in two or more dimensions

Some types of spatial representation used by the brain are of spaces that exist in two or more dimensions. Examples are the two- (or three-) dimensional space representing where one is looking at in a spatial scene. Another is the two- (or three-) dimensional space represent-

ing where one is located. It is possible to extend continuous attractor networks to operate in higher dimensional spaces than the one-dimensional spaces considered so far (Taylor, 1999; Stringer, Rolls, Trappenberg and De Araujo, 2002a). Indeed, it is also possible to extend the analyses of how idiothetic inputs could be used to update two-dimensional state spaces, such as the locations represented by place cells in rats (Stringer, Rolls, Trappenberg and De Araujo, 2002a) and the location at which one is looking represented by primate spatial view cells (Stringer, Rolls and Trappenberg, 2005; Stringer and Rolls, 2002). Interestingly, the number of terms in the synapses implementing idiothetic update do not need to increase beyond three (as in Sigma-Pi synapses) even when higher dimensional state spaces are being considered (Stringer, Rolls, Trappenberg and De Araujo, 2002a). Also interestingly, a continuous attractor network can in fact represent the properties of very high dimensional spaces, because the properties of the spaces are captured by the connections between the neurons of the continuous attractor, and these connections are of course, as in the world of discrete attractor networks, capable of representing high dimensional spaces (Stringer, Rolls, Trappenberg and De Araujo, 2002a). With these approaches, continuous attractor networks have been developed of the two-dimensional representation of rat hippocampal place cells with idiothetic update by movements in the environment (Stringer, Rolls, Trappenberg and De Araujo, 2002a), and of primate hippocampal spatial view cells with idiothetic update by eye and head movements (Stringer, Rolls and Trappenberg, 2005; Rolls and Stringer, 2005; Stringer and Rolls, 2002). Continuous attractor models with some similar properties have also been applied to understanding motor control, for example the generation of a continuous movement in space (Stringer and Rolls, 2007; Stringer, Rolls and Taylor, 2007a).

B.5.8 Mixed continuous and discrete attractor networks

It has now been shown that attractor networks can store both continuous patterns and discrete patterns, and can thus be used to store for example the location in (continuous, physical) space where an object (a discrete item) is present (see Fig. 9.30 and Rolls, Stringer and Trappenberg (2002)). In this network, when events are stored that have both discrete (object) and continuous (spatial) aspects, then the whole place can be retrieved later by the object, and the object can be retrieved by using the place as a retrieval cue. Such networks are likely to be present in parts of the brain that receive and combine inputs both from systems that contain representations of continuous (physical) space, and from brain systems that contain representations of discrete objects, such as the inferior temporal visual cortex. One such brain system is the hippocampus, which appears to combine and store such representations in a mixed attractor network in the CA3 region, which thus is able to implement episodic memories which typically have a spatial component, for example where an item such as a key is located (see Chapter 9). This network thus shows that in brain regions where the spatial and object processing streams are brought together, then a single network can represent and learn associations between both types of input. Indeed, in brain regions such as the hippocampal system, it is essential that the spatial and object processing streams are brought together in a single network, for it is only when both types of information are in the same network that spatial information can be retrieved from object information, and vice versa, which is a fundamental property of episodic memory (see Chapter 9). It may also be the case that in the prefrontal cortex, attractor networks can store both spatial and discrete (e.g. object-based) types of information in short-term memory (see Section 13.6.1).

B.6 Network dynamics: the integrate-and-fire approach

The concept that attractor (autoassociation) networks can operate very rapidly if implemented with neurons that operate dynamically in continuous time was introduced in Section B.3.3.5. The result described was that the principal factor affecting the speed of retrieval is the time constant of the synapses between the neurons that form the attractor ((Treves, 1993; Rolls and Treves, 1998; Battaglia and Treves, 1998a; Panzeri, Rolls, Battaglia and Lavis, 2001). This was shown analytically by Treves (1993), and described by Rolls and Treves (1998) Appendix 5. We now describe in more detail the approaches that produce these results, and the actual results found on the speed of processing.

The networks described so far in this chapter, and analyzed in Appendices 3 and 4 of Rolls and Treves (1998), were described in terms of the steady-state activation of networks of neuron-like units. Those may be referred to as ‘static’ properties, in the sense that they do not involve the time dimension. In order to address ‘dynamical’ questions, the time dimension has to be reintroduced into the formal models used, and the adequacy of the models themselves has to be reconsidered in view of the specific properties to be discussed.

Consider for example a real network whose operation has been described by an auto-associative formal model that acquires, with learning, a given attractor structure. How does the state of the network approach, in real time during a retrieval operation, one of those attractors? How long does it take? How does the amount of information that can be read off the network’s activity evolve with time? Also, which of the potential steady states is indeed a stable state that can be reached asymptotically by the net? How is the stability of different states modulated by external agents? These are examples of dynamical properties, which to be studied require the use of models endowed with some dynamics.

B.6.1 From discrete to continuous time

Already at the level of simple models in which each unit is described by an input–output relation, one may introduce equally simple ‘dynamical’ rules, in order both to fully specify the model, and to simulate it on computers. These rules are generally formulated in terms of ‘updatings’: time is considered to be discrete, a succession of time steps, and at each time step the output of one or more of the units is set, or updated, to the value corresponding to its input variable. The input variable may reflect the outputs of other units in the net as updated at the previous time step or, if delays are considered, the outputs as they were at a prescribed number of time steps in the past. If all units in the net are updated together, the dynamics is referred to as parallel; if instead only one unit is updated at each time step, the dynamics is sequential. (One main difference between the Hopfield (1982) model of an autoassociator and a similar model considered earlier by Little (1974) is that the latter was based on parallel rather than sequential dynamics.) Many intermediate possibilities obviously exist, involving the updating of groups of units at a time. The order in which sequential updatings are performed may for instance be chosen at random at the beginning and then left the same in successive cycles across all units in the net; or it may be chosen anew at each cycle; yet a third alternative is to select at each time step a unit, at random, with the possibility that a particular unit may be selected several times before some of the other ones are ever updated. The updating may also be made probabilistic, with the output being set to its new value only with a certain probability, and otherwise remaining at the current value.

Variants of these dynamical rules have been used for decades in the analysis and computer simulation of physical systems in statistical mechanics (and field theory). They can reproduce in simple but effective ways the stochastic nature of transitions among discrete quantum states, and they have been subsequently considered appropriate also in the simula-

tion of neural network models in which units have outputs that take discrete values, implying that a change from one value to another can only occur in a sudden jump. To some extent, different rules are equivalent, in that they lead, in the evolution of the activity of the net along successive steps and cycles, to the same set of possible steady states. For example, it is easy to realize that when no delays are introduced, states that are stable under parallel updating are also stable under sequential updating. The reverse is not necessarily true, but on the other hand states that are stable when updating one unit at a time are stable irrespective of the updating order. Therefore, static properties, which can be deduced from an analysis of stable states, are to some extent robust against differences in the details of the dynamics assigned to the model. (This is a reason for using these dynamical rules in the study of the thermodynamics of physical systems.) Such rules, however, bear no relation to the actual dynamical processes by which the activity of real neurons evolves in time, and are therefore inadequate for the discussion of dynamical issues in neural networks.

A first step towards realism in the dynamics is the substitution of discrete time with continuous time. This somewhat parallels the substitution of the discrete output variables of the most rudimentary models with continuous variables representing firing rates. Although continuous output variables may evolve also in discrete time, and as far as static properties are concerned differences are minimal, with the move from discrete to continuous outputs the main *raison d'être* for a dynamics in terms of sudden updates ceases to exist, since continuous variables can change continuously in continuous time. A paradox arises immediately, however, if a continuous time dynamics is assigned to firing rates. The paradox is that firing rates, although in principle continuous if computed with a generic time-kernel, tend to vary in jumps as new spikes – essentially discrete events – come to be included in the kernel. To avoid this paradox, a continuous time dynamics can be assigned, instead, to instantaneous continuous variables such as membrane potentials. Hopfield (1984), among others, has introduced a model of an autoassociator in which the output variables represent membrane potentials and evolve continuously in time, and has suggested that under certain conditions the stable states attainable by such a network are essentially the same as for a network of binary units evolving in discrete time. If neurons in the central nervous system communicated with each other via the transmission of graded membrane potentials, as they do in some peripheral and invertebrate neural systems, this model could be an excellent starting point. The fact that, centrally, transmission is primarily via the emission of discrete spikes makes a model based on membrane potentials as output variables inadequate to correctly represent spiking dynamics.

B.6.2 Continuous dynamics with discontinuities

In principle, a solution would be to keep the membrane potential as the basic dynamical variable, evolving in continuous time, and to use as the output variable the spike emission times, as determined by the rapid variation in membrane potential corresponding to each spike. A point-like neuron can generate spikes by altering the membrane potential V according to continuous equations of the Hodgkin–Huxley type:

$$C \frac{dV}{dt} = g_0(V_{\text{rest}} - V) + g_{\text{Na}} m h^3 (V_{\text{Na}} - V) + g_{\text{K}} n^4 (V_{\text{K}} - V) + I \quad (\text{B.47})$$

$$\tau_m \frac{dm}{dt} = m_{\infty}(V) - m \quad (\text{B.48})$$

$$\tau_h \frac{dh}{dt} = h_{\infty}(V) - h \quad (\text{B.49})$$

$$\tau_n \frac{dn}{dt} = n_{\infty}(V) - n. \quad (\text{B.50})$$

The changes in the membrane potential, driven by the input current I , interact with the opening and closing of intrinsic conductances (here a sodium conductance, whose channels are gated by the ‘particles’ m and h , and a potassium conductance, whose channels are gated by n ; Hodgkin and Huxley (1952)). These equations provide an effective description, phenomenological but broadly based on physical principles, of the conductance changes underlying action potentials, and they are treated in any standard neurobiology text.

From the point of view of formal models of neural networks, this level of description is too complicated to be the basis for an analytic understanding of the operation of networks, and it must be simplified. The most widely used simplification is the so-called integrate-and-fire model (see for example MacGregor (1987) and Brunel and Wang (2001)), which is legitimized by the observation that (sodium) action potentials are typically brief and self-similar events. If, in particular, the only relevant variable associated with the spike is its time of emission (at the soma, or axon hillock), which essentially coincides with the time the potential V reaches a certain threshold level V_{thr} , then the conductance changes underlying the rest of the spike can be omitted from the description, and substituted with the ad hoc prescription that (i) a spike is emitted, with its effect on receiving units and on the unit itself; and (ii) after a brief time corresponding to the duration of the spike plus a refractory period, the membrane potential is reset and resumes its integration of the input current I . After a spike the membrane potential is taken to be reset to a value V_{reset} . This type of simplified dynamics of the membrane potentials is thus in continuous time with added discontinuities: continuous in between spikes, with discontinuities occurring at different times for each neuron in a population, every time a neuron emits a spike.

A leaky integrate-and-fire neuron can be modelled as follows (see also Section 11.5.1.2 and Fig. 11.34). The model describes the depolarization of the membrane potential V (which typically is dynamically changing as a result of the synaptic effects described below between approximately -70 and -50 mV) until threshold V_{thr} (typically -50 mV) is reached when a spike is emitted and the potential is reset to V_{reset} (typically -55 mV). The membrane time constant τ_m is set by the membrane capacitance C_m and the membrane leakage conductance g_m where $\tau_m = C_m/g_m$. V_L denotes the resting potential of the cell, typically -70 mV. Changes in the membrane potential are defined by the following equation

$$C_m \frac{dV(t)}{dt} = g_m (V_L - V(t)) + \sum_j g_j (V_{\text{AMPA}} - V(t)) + \sum_j g_j (V_{\text{GABA}} - V(t)). \quad (\text{B.51})$$

The first term on the right of the equation describes how the membrane potential decays back towards the resting potential of the cell depending on how far the cell potential V is from the resting potential V_L , and the membrane leak conductance g_m . The second term on the right represents the excitatory synaptic current that could be injected through AMPA receptors. This is a sum over all AMPA synapses indexed by j on the cell. At each synapse, the current is driven into the cell by the difference between the membrane potential V and the reversal potential V_{AMPA} of the channels opened by AMPA receptors, weighted by the synaptic conductance g_j . This synaptic conductance changes dynamically as a function of the time since a spike reached the synapse, as shown below. Due to their reversal potential V_{AMPA} of typically 0 mV, these currents will tend to depolarize the cell, that is to move the membrane potential towards the firing threshold. The third term on the right represents the inhibitory synaptic current that could be injected through GABA receptors. Due to their reversal potential V_{GABA} of typically -70 mV, these currents will tend to hyperpolarize the cell, that is to move the membrane potential away from the firing threshold. There may be other types of receptor on a cell, for example NMDA receptors, and these operate analogously though with interesting differences, as described in Section B.6.3.

Fig. B.31 Model behavior of an integrate-and-fire neuron: the membrane potential and adaptation-producing potassium conductance in response to a step of injected current. The spikes were added to the graph by hand, as they do not emerge from the simplified voltage equation. (From Treves, A. (1993) Mean-field analysis of neuronal spike dynamics. Network: Computation in Neural Systems 4: 259–284. Copyright © Taylor and Francis Ltd.)

The opening of each synaptic conductance g_j is driven by the arrival of spikes at the presynaptic terminal j , and its closing can often be described as a simple exponential process. A simplified equation for the dynamics of $g_j(t)$ is then

$$\frac{dg_j(t)}{dt} = -\frac{g_j(t)}{\tau} + \Delta g_j \sum_l \delta(t - \Delta t - t_l). \quad (\text{B.52})$$

According to the above equation, each synaptic conductance opens instantaneously by a fixed amount Δg_j a time Δt after the emission of the presynaptic spike at t_l . Δt summarizes delays (axonal, synaptic, and dendritic), and each opening superimposes linearly, without saturating, on previous openings. The value of τ in this equation will be different for AMPA receptors (typically 2–10 ms), NMDA receptors (typically 100 ms), and GABA receptors (typically 10 ms).

In order to model the phenomenon of adaptation in the firing rate, prominent especially with pyramidal cells, it is possible to include a time-varying intrinsic (potassium-like) conductance in the cell membrane (Brown, Gähwiler, Griffith and Halliwell, 1990a) (shown as g_K in equations B.53 and B.54). This can be done by specifying that this conductance, which if open tends to shunt the membrane and thus to prevent firing, opens by a fixed amount with the potential excursion associated with each spike, and then relaxes exponentially to its closed state. In this manner sustained firing driven by a constant input current occurs at lower rates after the first few spikes, in a way similar, if the relevant parameters are set appropriately, to the behavior observed in vitro of many pyramidal cells (for example, Lanthorn, Storm and Andersen (1984), Mason and Larkman (1990)).

Fig. B.32 Current-to-frequency transduction in a pyramidal cell modelled as an integrate-and-fire neuron. The top solid curve is the firing frequency in the absence of adaptation, $\Delta g_K = 0$. The dotted curves are the instantaneous frequencies computed as the inverse of the i th interspike interval (top to bottom, $i = 1, \dots, 6$). The bottom solid curve is the adapted firing curve ($i \rightarrow \infty$). With or without adaptation, the input–output transform is close to threshold–linear. (From Treves, A. (1993) Mean-field analysis of neuronal spike dynamics. Network: Computation in Neural Systems 4: 259–284. Copyright © Taylor and Francis Ltd.)

The equations for the dynamics of each neuron with adaptation are then

$$C_m \frac{dV(t)}{dt} = g_m(V_L - V(t)) + \sum_j g_j(V_{\text{AMPA}} - V(t)) + \sum_j g_j(V_{\text{GABA}} - V(t)) + g_K(t)(V_K - V(t)) \quad (\text{B.53})$$

and

$$\frac{dg_K(t)}{dt} = -\frac{g_K(t)}{\tau_K} + \sum_k \Delta g_K \delta(t - t_k) \quad (\text{B.54})$$

supplemented by the prescription that when at time $t = t_{k+1}$ the potential reaches the level V_{thr} , a spike is emitted, and hence included also in the sum of Equation B.54, and the potential resumes its evolution according to Equation B.53 from the reset level V_{reset} . The resulting behavior is exemplified in Fig. B.31, while Fig. B.32 shows the input–output transform (current to frequency transduction) operated by an integrate-and-fire unit of this type with firing rate adaptation. One should compare this with the transduction operated by real cells, as exemplified for example in Fig. 1.4.

It should be noted that synaptic conductance dynamics is not always included in integrate-and-fire models: sometimes it is substituted with current dynamics, which essentially amounts to neglecting non-linearities due to the appearance of the membrane potential in the driving force for synaptic action (see for example, Amit and Tsodyks (1991), Gerstner (1995)); and sometimes it is simplified altogether by assuming that the membrane potential undergoes small sudden jumps when it receives instantaneous pulses of synaptic current (see the review in Gerstner (1995)). The latter simplification is quite drastic and changes the character of the dynamics markedly; whereas the former can be a reasonable simplification in some circumstances, but it produces serious distortions in the description of inhibitory GABA_A currents, which, having an equilibrium (Cl^-) synaptic potential close to the operating range of the membrane potential, are quite sensitive to the instantaneous value of the membrane potential itself.

B.6.3 An integrate-and-fire implementation

In this subsection the mathematical equations that describe the spiking activity and synapse dynamics in some of the integrate-and-fire simulations performed by Rolls and Deco (Deco and Rolls, 2003; Deco, Rolls and Horwitz, 2004; Deco and Rolls, 2005d,c,b, 2006; Loh, Rolls and Deco, 2007a; Rolls, Loh and Deco, 2008c; Rolls, Grabenhorst and Deco, 2010b,c; Insabato, Pannunzi, Rolls and Deco, 2010; Deco, Rolls and Romo, 2010; Rolls and Deco, 2011b; Webb, Rolls, Deco and Feng, 2011; Rolls and Webb, 2012; Rolls, Webb and Deco, 2012; Martinez-Garcia, Rolls, Deco and Romo, 2011; Rolls, Dempere-Marco and Deco, 2013; Rolls and Deco, 2015a,b, 2016) are set out, in order to show in more detail how an integrate-and-fire simulation is implemented. The equations follow in general the formulation described by Brunel and Wang (2001), though each simulation describes its own architecture to be simulated and neurocomputational questions to be addressed, with additional dynamics introduced where described to implement synaptic facilitation and/or synaptic adaptation (Rolls, 2016b).

Each neuron is described by an integrate-and-fire model. The subthreshold membrane potential $V(t)$ of each neuron evolves according to the following equation:

$$C_m \frac{dV(t)}{dt} = -g_m(V(t) - V_L) - I_{\text{syn}}(t) \quad (\text{B.55})$$

where $I_{\text{syn}}(t)$ is the total synaptic current flow into the cell, V_L is the resting potential, C_m is the membrane capacitance, and g_m is the membrane conductance. When the membrane potential $V(t)$ reaches the threshold V_{thr} a spike is generated, and the membrane potential is reset to V_{reset} . The neuron is unable to spike during the first τ_{ref} which is the absolute refractory period.

The total synaptic current is given by the sum of glutamatergic excitatory components (NMDA and AMPA) and inhibitory components (GABA). The external excitatory contributions (ext) from outside the network are produced through AMPA receptors ($I_{\text{AMPA,ext}}$), while the excitatory recurrent synapses (rec) within the network act through AMPA and NMDA receptors ($I_{\text{AMPA,rec}}$ and $I_{\text{NMDA,rec}}$). The total synaptic current is therefore given by:

$$I_{\text{syn}}(t) = I_{\text{AMPA,ext}}(t) + I_{\text{AMPA,rec}}(t) + I_{\text{NMDA,rec}}(t) + I_{\text{GABA}}(t) \quad (\text{B.56})$$

where

$$I_{\text{AMPA,ext}}(t) = g_{\text{AMPA,ext}}(V(t) - V_E) \sum_{j=1}^{N_{\text{ext}}} s_j^{\text{AMPA,ext}}(t) \quad (\text{B.57})$$

$$I_{\text{AMPA,rec}}(t) = g_{\text{AMPA,rec}}(V(t) - V_E) \sum_{j=1}^{N_E} w_j s_j^{\text{AMPA,rec}}(t) \quad (\text{B.58})$$

$$I_{\text{NMDA,rec}}(t) = \frac{g_{\text{NMDA,rec}}(V(t) - V_E)}{(1 + [\text{Mg}^{++}] \exp(-0.062V(t)))/3.57)} \sum_{j=1}^{N_E} w_j s_j^{\text{NMDA,rec}}(t) \quad (\text{B.59})$$

$$I_{\text{GABA}}(t) = g_{\text{GABA}}(V(t) - V_I) \sum_{j=1}^{N_I} s_j^{\text{GABA}}(t) \quad (\text{B.60})$$

In the preceding equations the reversal potential of the excitatory synaptic currents $V_E = 0$ mV and of the inhibitory synaptic currents $V_I = -70$ mV. The different form for the NMDA receptor-activated channels implements the voltage-dependence of NMDA receptors. This voltage-dependency, and the long time constant of the NMDA receptors, are important in

the effects produced through NMDA receptors (Brunel and Wang, 2001; Wang, 1999). The synaptic strengths w_j are specified in the papers by Rolls and Deco cited above, and depend on the architecture being simulated. The fractions of open channels s are given by:

$$\frac{ds_j^{\text{AMPA,ext}}(t)}{dt} = -\frac{s_j^{\text{AMPA,ext}}(t)}{\tau_{\text{AMPA}}} + \sum_k \delta(t - t_j^k) \quad (\text{B.61})$$

$$\frac{ds_j^{\text{AMPA,rec}}(t)}{dt} = -\frac{s_j^{\text{AMPA,rec}}(t)}{\tau_{\text{AMPA}}} + \sum_k \delta(t - t_j^k) \quad (\text{B.62})$$

$$\frac{ds_j^{\text{NMDA,rec}}(t)}{dt} = -\frac{s_j^{\text{NMDA,rec}}(t)}{\tau_{\text{NMDA,decay}}} + \alpha x_j(t)(1 - s_j^{\text{NMDA,rec}}(t)) \quad (\text{B.63})$$

$$\frac{dx_j(t)}{dt} = -\frac{x_j(t)}{\tau_{\text{NMDA,rise}}} + \sum_k \delta(t - t_j^k) \quad (\text{B.64})$$

$$\frac{ds_j^{\text{GABA}}(t)}{dt} = -\frac{s_j^{\text{GABA}}(t)}{\tau_{\text{GABA}}} + \sum_k \delta(t - t_j^k) \quad (\text{B.65})$$

where the sums over k represent a sum over spikes emitted by presynaptic neuron j at time t_j^k . The value of $\alpha = 0.5 \text{ ms}^{-1}$.

Typical values of the conductances for pyramidal neurons are: $g_{\text{AMPA,ext}}=2.08$, $g_{\text{AMPA,rec}}=0.052$, $g_{\text{NMDA,rec}}=0.164$, and $g_{\text{GABA}}=0.67$ nS; and for interneurons: $g_{\text{AMPA,ext}}=1.62$, $g_{\text{AMPA,rec}}=0.0405$, $g_{\text{NMDA,rec}}=0.129$ and $g_{\text{GABA}}=0.49$ nS.

A full list of the values of the parameters used is given in Section B.8.3 and in each of the papers cited above in this Section B.6.3.

B.6.4 The speed of processing of one-layer attractor networks with integrate-and-fire neurons

Given that the analytic approach to the rapidity of the dynamics of attractor networks with integrate-and-fire dynamics (Treves, 1993; Rolls and Treves, 1998) applies mainly when the state is close to the attractor basin, it is of interest to check the performance of such networks by simulation when the completion of partial patterns that may be towards the edge of the attractor basin can be tested. Simmen, Rolls and Treves (1996a) and Treves, Rolls and Simmen (1997) made a start with this, and showed that retrieval could indeed be fast, within 1–2 time constants of the synapses. However, they found that they could not load the systems they simulated with many patterns, and the firing rates during the retrieval process tended to be unstable. The cause of this turned out to be that the inhibition they used to maintain the activity level during retrieval was subtractive, and it turns out that divisive (shunting) inhibition is much more effective in such networks, as described by Rolls and Treves (1998) in Appendix 5. Divisive inhibition is likely to be organized by inhibitory inputs that synapse close to the cell body (where the reversal potential is close to that of the channels opened by GABA receptors), in contrast to synapses on dendrites, where the different potentials result in opening of the same channels producing hyperpolarization (that is an effectively subtractive influence with respect to the depolarizing currents induced by excitatory (glutamate-releasing) terminals). Battaglia and Treves (1998a) therefore went on to study networks with neurons where the inhibitory neurons could be made to be divisive by having them synapse close to the cell body in neurons modelled with multiple (ten) dendritic compartments. The excitatory inputs terminated on the compartments more distant from the cell body in the model. They found

that with this divisive inhibition, the neuronal firing during retrieval was kept under much better control, and the number of patterns that could be successfully stored and retrieved was much higher. Some details of their simulation follow.

Battaglia and Treves (1998a) simulated a network of 800 excitatory and 200 inhibitory cells in its retrieval of one of a number of memory patterns stored in the synaptic weights representing the excitatory-to-excitatory recurrent connections. The memory patterns were assigned at random, drawing the value of each unit in each of the patterns from a binary distribution with sparseness 0.1, that is a probability of 1 in 10 for the unit to be active in the pattern. No baseline excitatory weight was included, but the modifiable weights were instead constrained to remain positive (by clipping at zero synaptic modifications that would make a synaptic weight negative), and a simple exponential decay of the weight with successive modifications was also applied, to prevent runaway synaptic modifications within a rudimentary model of forgetting. Both excitation on inhibitory units and inhibition were mediated by non-modifiable uniform synaptic weights, with values chosen so as to satisfy stability conditions of the type shown in Equations A5.13 of Rolls and Treves (1998). Both inhibitory and excitatory neurons were of the general integrate-and-fire type, but excitatory units had in addition an extended dendritic cable, and they received excitatory inputs only at the more distal end of the cable, and inhibitory inputs spread along the cable. In this way, inhibitory inputs reached the soma of excitatory cells with variable delays, and in any case earlier than synchronous excitatory inputs, and at the same time they could shunt the excitatory inputs, resulting in a largely multiplicative form of inhibition (Abbott, 1991). The uniform connectivity was not complete, but rather each type of unit could contact units of the other type with a probability of 0.5, and the same was true for inhibitory-to-inhibitory connections.

After 100 (simulated) ms of activity evoked by external inputs uncorrelated with any of the stored patterns, a cue was provided that consisted of the external input becoming correlated with one of the patterns, at various levels of correlation, for 300 ms. After that, external inputs were removed, but when retrieval operated successfully the activity of the units remained strongly correlated with the memory pattern, or even reached a higher level of correlation if a rather corrupted cue had been used, so that, if during the 300 ms the network had stabilized into a state rather distant from the memory pattern, it got much closer to it once the cue was removed. All correlations were quantified using information measures (see Appendix C)), in terms of mutual information between the firing rate pattern across units and the particular memory pattern being retrieved, or in terms of mutual information between the firing rate of one unit and the set of patterns, or, finally, in terms of mutual information between the decoded firing rates of a subpopulation of 10 excitatory cells and the set of memory patterns. The same algorithms were used to extract information measures as were used for example by Rolls, Treves, Tovee and Panzeri (1997d) with real neuronal data from inferior temporal cortex neurons (see further (Rolls and Treves, 2011)). The firing rates were measured over sliding windows of 30 ms, after checking that shorter windows produced noisier measures. The effect of using a relatively long window, 30 ms, for measuring rates is an apparent linear early rise in information values with time. Nevertheless, in the real system the activity of these cells is ‘read’ by other cells receiving inputs from them, and that in turn have their own membrane capacitance-determined characteristic time for integrating input activity, a time broadly in the order of 30 ms. Using such a time window for integrating firing rates did not therefore artificially slow down the read-out process.

It was shown that the time course of different information measures did not depend significantly on the firing rates prevailing during the retrieval state, nor on the resistance–capacitance-determined membrane time constants of the units. Figure B.33 shows that the rise in information after providing the cue at time = 100 ms followed a roughly exponential approach to its steady-state value, which continued until the steady state switched to a new

Fig. B.33 The speed of memory retrieval in an integrate-and-fire attractor network is very fast: in the order of 1.5 times the time constants of the recurrent collateral synapses. Time course of the transinformation about which memory pattern had been selected, as decoded from the firing rates of 10 randomly selected excitatory units. Excitatory conductances closed exponentially with time constants of 5, 10, 20 and 40 ms (curves from top to bottom). A cue of correlation 0.2 with the memory pattern was presented from 100 to 400 ms, uncorrelated external inputs with the same mean strength and sparseness as the cue were applied at earlier times, and no external inputs were applied at later times. (From Battaglia, F. and Treves, A. (1998) Stable and rapid recurrent processing in realistic autoassociative memories. *Neural Computation* 10: 431–450. © Massachusetts Institute of Technology.)

value when the retrieval cue was removed at time = 400 ms. The time constant of the approach to the first steady state was a linear function, as shown in Fig. B.33, of the time constant for excitatory conductances, as predicted by the analysis. (The proportionality factor in the Figure is 2.5, or a collective time constant 2.5 times longer than the synaptic time constant.) The approach to the second steady-state value was more rapid, and the early apparent linear rise prevented the detection of a consistent exponential mode. Therefore, it appears that the cue leads to the basin of attraction of the correct retrieval state by activating transient modes, whose time constant is set by that of excitatory conductances; once the network is in the correct basin, its subsequent reaching the ‘very bottom’ of the basin after the removal of the cue is not accompanied by any prominent transient mode (see further Battaglia and Treves (1998a)).

Overall, these simulations confirm that recurrent networks, in which excitation is mediated mainly by fast (AMPA, see Section 1.6) channels, can reach asynchronous steady firing states very rapidly, over a few tens of milliseconds, and the rapid approach to steady state is reflected in the relatively rapid rise of information quantities that measure the speed of the operation in functional terms. If the AMPA receptor time constant is 10 ms in the brain, the implication is that the attractor network would fall into its attractor basin in 15 ms.

An analysis based on integrate-and-fire model units thus indicates that recurrent dynamics can be so fast as to be practically indistinguishable from purely feedforward dynamics, in contradiction to what simple intuitive arguments would suggest. This makes it hazardous to draw conclusions on the underlying circuitry on the basis of the experimentally observed speed with which selective neuronal responses arise, as attempted by Thorpe and Imbert (1989). The results also show that networks that implement feedback processing can settle into a global retrieval state very rapidly, and that rapid processing is not just a feature of feedforward networks.

We return to the intuitive understanding of this rapid processing. The way in which networks with continuous dynamics (such as networks made of real neurons in the brain, and

networks modelled with integrate-and-fire neurons) can be conceptualized as settling so fast into their attractor states is that spontaneous activity in the network ensures that some neurons are close to their firing threshold when the retrieval cue is presented, so that the firing of these neurons is influenced within 1–2 ms by the retrieval cue. These neurons then influence other neurons within milliseconds (given the point that some other neurons will be close to threshold) through the modified recurrent collateral synapses that store the information. In this way, the neurons in networks with continuous dynamics can influence each other within a fraction of the synaptic time constant, and retrieval can be very rapid.

B.6.5 The speed of processing of a four-layer hierarchical network with integrate-and-fire attractor dynamics in each layer

Given that the visual system has a whole series of cortical areas organized predominantly hierarchically (e.g. V1 to V2 to V4 to inferior temporal cortex), the issue arises of whether the rapid information processing that can be performed for object recognition is predominantly feedforward, or whether there is sufficient time for feedback processing within each cortical area implemented by the local recurrent collaterals to contribute to the visual information processing being performed. Some of the constraints are as follows.

An analysis of response latencies indicates that there is sufficient time for only 10–20 ms per processing stage in the visual system. In the primate cortical ventral visual system the response latency difference between neurons in layer $4C\beta$ of V1 and inferior temporal cortical cells is approximately 60 ms (Bullier and Nowak, 1995; Nowak and Bullier, 1997; Schmolesky, Wang, Hanes, Thompson, Leutgeb, Schall and Leventhal, 1998). For example, the latency of the responses of neurons in V1 is approximately 30–40 ms (Celebrini, Thorpe, Trotter and Imbert, 1993), and in the temporal cortex visual areas approximately 80–110 ms (Baylis, Rolls and Leonard, 1987; Sugase, Yamane, Ueno and Kawano, 1999). Given that there are 4–6 stages of processing in the ventral visual system from V1 to the anterior inferior temporal cortex, the difference in latencies between each ventral cortical stage is on this basis approximately 10 ms (Rolls, 1992a; Oram and Perrett, 1994). Information theoretic analyses of the responses of single visual cortical cells in primates reveal that much of the information that can be extracted from neuronal spike trains is often found to be present in periods as short as 20–30 ms (Tovee, Rolls, Treves and Bellis, 1993; Tovee and Rolls, 1995; Heller, Hertz, Kjaer and Richmond, 1995; Rolls, Tovee and Panzeri, 1999b). Backward masking experiments indicate that each cortical area needs to fire for only 20–30 ms to pass information to the next stage (Rolls and Tovee, 1994; Rolls, Tovee, Purcell, Stewart and Azzopardi, 1994b; Kovacs, Vogels and Orban, 1995; Rolls, Tovee and Panzeri, 1999b; Rolls, 2003) (see Section C.3.4). Rapid serial visual presentation of image sequences shows that cells in the temporal visual cortex are still face selective when faces are presented at the rate of 14 ms/image (Keysers, Xiao, Foldiak and Perrett, 2001). Finally, event-related potential studies in humans provide strong evidence that the visual system is able to complete some analyses of complex scenes in less than 150 ms (Thorpe, Fize and Marlot, 1996).

To investigate whether feedback processing within each layer could contribute to information processing in such a multilayer system in times as short as 10–20 ms per layer, Panzeri, Rolls, Battaglia and Lavis (2001) simulated a four-layer network with attractor networks in each layer. The network architecture is shown schematically in Fig. B.34. All the neurons realized integrate-and-fire dynamics, and indeed the individual layers and neurons were implemented very similarly to the implementation used by Battaglia and Treves (1998a). In particular, the current flowing from each compartment of the multicompartment neurons to the external medium was expressed as:

Fig. B.34 Model for the speed of operation of a cortical hierarchical network with attractor dynamics at each stage. The structure of the excitatory connections in the network. There are feedforward (FF) connections between each layer and the next, and excitatory recurrent collaterals (RC) in each layer. Inhibitory connections are also present within each layer, but they are not shown in this Figure. (After Panzeri, S., Rolls, E. T., Battaglia, F. and Lavis, R. (2001) Speed of feedforward and recurrent processing in multilayer networks of integrate-and-fire neurons. *Network: Computation in Neural Systems* 12: 423–440. © Informa Ltd.)

$$I(t) = g_{\text{leak}}(V(t) - V^0) + \sum_j g_j(t)(V(t) - V_j), \quad (\text{B.66})$$

where g_{leak} is a constant passive leakage conductance, V^0 the membrane resting potential, $g_j(t)$ the value of the j th synapse conductance at time t , and V_j the reversal potential of the j th synapse. $V(t)$ is the potential in the compartment at time t . The most important parameter in the simulation, the AMPA inactivation time constant, was set to 10 ms. The recurrent collateral (RC) integration time constant of the membrane of excitatory cells was 20 ms long for the simulations presented. The synaptic conductances decayed exponentially in time, obeying the Equation

$$\frac{dg_j}{dt} = -\frac{g_j}{\tau_j} + \Delta g_j \sum_k \delta(t - \Delta t - t_k^j), \quad (\text{B.67})$$

where τ_j is the synaptic decay time constant, Δt is a delay term summarizing axonal and synaptic delays, and Δg_j is the amount that the conductance is increased when the pre-synaptic unit fires a spike. Δg_j thus represents the (unidirectional) coupling strength between the pre-synaptic and the post-synaptic cell. t_k^j is the time at which the pre-synaptic unit fires its k th spike.

An example of the rapid information processing of the system is shown in Fig. B.35, obtained under conditions in which the local recurrent collaterals can contribute to correct performance because the feedforward (FF) inputs from the previous stage are noisy. (The noise implemented in these simulations was some imperfection in the FF signals produced by some alterations to the FF synaptic weights.) Figure B.35 shows that, when the FF carry an incomplete signal, some information is still transmitted successfully in the ‘No RC’ condition (in which the recurrent collateral connections in each layer are switched off), and with a relatively short latency. However, the noise term in the FF synaptic strengths makes the retrieval fail more and more layer by layer. When in contrast the recurrent collaterals (RC) are present and operating after Hebbian training, the amount of information retrieved is now much higher, because the RC are able to correct a good part of the erroneous information injected into the neurons by the noisy FF synapses. In Layer 4, 66 ms after cue injection in Layer 1, the information in the Hebbian RC case is 0.2 bits higher than that provided by the FF connections in the ‘No RC’ condition. This shows that the RC are able to retrieve information in Layer 4 that is not available by any other purely FF mechanism after only roughly 50–55 ms from the time when Layer 1 responds. (This corresponds to 17–18 ms per layer.)

A direct comparison of the latency differences in layers 1–4 of the integrate-and-fire network simulated by Panzeri, Rolls, Battaglia and Lavis (2001) is shown in Fig. B.36. The

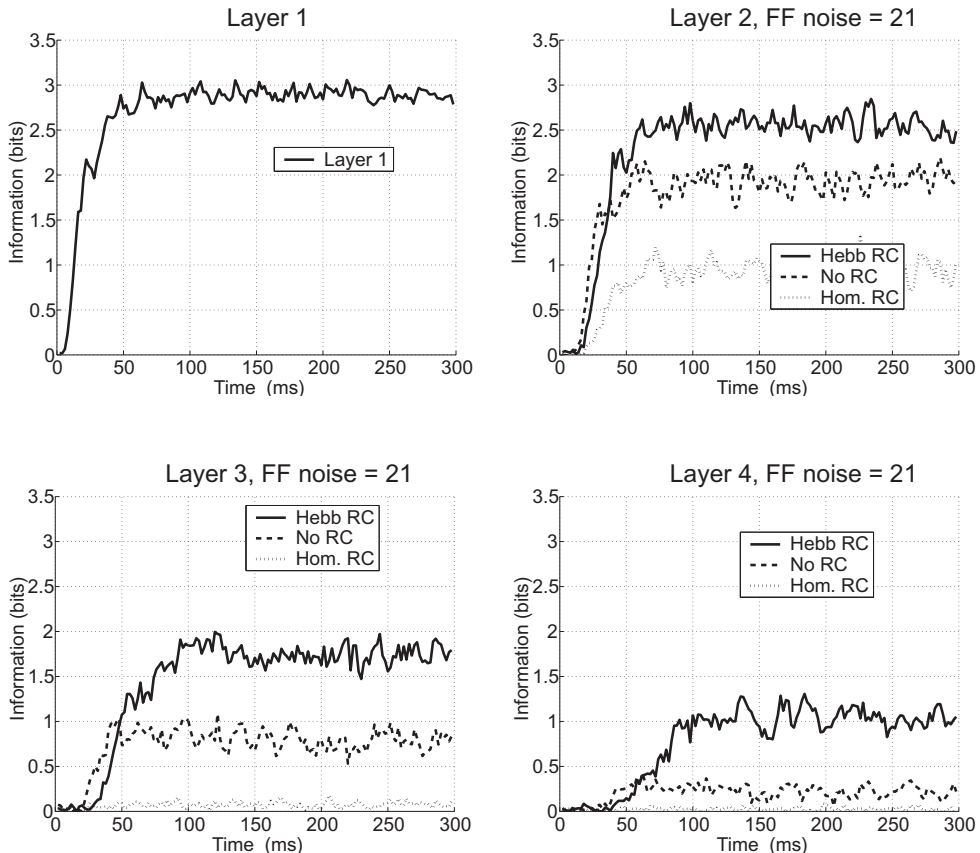

Fig. B.35 The speed of information processing in a 4-layer network with integrate-and-fire attractor dynamics at each stage requires only about 1.5 times the synaptic time constant for each stage or layer. The information time course of the average information carried by the responses of a population of 30 excitatory neurons in each layer. In the simulations considered here, there is noise in the feedforward (FF) synapses. Layer 1 was tested in just one condition. Layers 2–4 are tested in three different conditions: No RC (in which the recurrent collateral synaptic effects do not operate), Hebbian RC (in which the recurrent collaterals have been trained by an associative rule and can help pattern retrieval in each layer), and a control condition named Homogeneous RC (in which the recurrent collaterals could inject current into the neurons, but no useful information was provided by them because they were all set to the same strength). (After Panzeri, S., Rolls, E. T., Battaglia, F. and Lavis, R. (2001) Speed of feedforward and recurrent processing in multilayer networks of integrate-and-fire neurons. *Network: Computation in Neural Systems* 12: 423–440. © Informa Ltd.)

results are shown for the Hebbian condition illustrated in Fig. B.35, and separate curves are shown for each of the layers 1–4. The Figure shows that, with the time constant of the synapses set to 10 ms, the network can operate with full utilization of and benefit from recurrent processing within each layer in a time which enables the signal to propagate through the 4-layer system with a time course of approximately 17 ms per layer.

The overall results of Panzeri, Rolls, Battaglia and Lavis (2001) were as follows. Through the implementation of continuous dynamics, latency differences were found in information retrieval of only 5 ms per layer when local excitation was absent and processing was purely feedforward. However, information latency differences increased significantly when non-associative local excitation (simulating spontaneous firing or unrelated inputs present in the brain) was included. It was also found that local recurrent excitation through associatively modified synapses can contribute significantly to processing in as little as 15 ms per layer, including the feedforward and local feedback processing. Moreover, and in contrast to purely feed-forward processing, the contribution of local recurrent feedback was useful and approximately this rapid even when retrieval was made difficult by noise. These findings provide ev-

Fig. B.36 The speed of information processing in a 4-layer network with integrate-and-fire attractor dynamics at each stage requires only about 1.5 times the synaptic time constant for each stage or layer. The information time course of the average information carried by the responses of a population of 30 excitatory neurons in each layer. The results are shown for the Hebbian condition illustrated in Fig. B.35, and separate curves are shown for each of the layers 1–4. The Figure shows that, with the time constant of the synapses set to 10 ms, the network can operate with full utilization of and benefit from recurrent processing within each layer in a time in the order of 17 ms per layer. (After Panzeri, S., Rolls, E. T., Battaglia, F. and Lavis, R. (2001) Speed of feedforward and recurrent processing in multilayer networks of integrate-and-fire neurons. *Network: Computation in Neural Systems* 12: 423–440. © Informa Ltd.)

idence that cortical information processing can be very fast even when local recurrent circuits are critically involved. The time cost of this recurrent processing is minimal when compared with a feedforward system with spontaneous firing or unrelated inputs already present, and the performance is better than that of a purely feedforward system when noise is present.

It is concluded that local feedback loops within each cortical area can contribute to fast visual processing and cognition.

B.6.6 Spike response model

In this section, I describe another mathematical approach that models the activity of single spiking neurons. This model captures the principal effects of real neurons in a realistic way and is simple enough to permit analytical calculations (Gerstner, Ritz and Van Hemmen, 1993; Gerstner and Kistler, 2002; Gerstner, Kistler, Naud and Paninski, 2014). In contrast to some integrate-and-fire models (Tuckwell, 1988), which are essentially given by differential equations, the spike-response model is based on response kernels that describe the integrated effect of spike reception or emission on the membrane potential. In this model, spikes are generated by a threshold process (i.e. the firing time t' is given by the condition that the membrane potential reaches the firing threshold θ ; that is, $h(t') = \theta$). Figure B.37 (bottom) shows schematically the spike-generating mechanism.

The membrane potential is given by the integration of the input signal weighted by a kernel defined by the Equations

$$h(t') = h^{\text{refr}}(t') + h^{\text{syn}}(t') \tag{B.68}$$

$$h^{\text{refr}}(t') = \int_0^\infty \eta^{\text{refr}}(z) \delta(t' - z - t'_{\text{last}}) dz \tag{B.69}$$

$$h^{\text{syn}}(t') = \sum_j J_j \int_0^\infty \Lambda(z', t' - t'_{\text{last}}) s(t' - z') dz' . \tag{B.70}$$

The kernel $\eta^{\text{refr}}(z)$ is the refractory function. If we consider only absolute refractoriness, $\eta^{\text{refr}}(z)$ is given by:

$$\eta^{\text{refr}}(z) = \begin{cases} -\infty & \text{for } 0 < z \leq \tau^{\text{refr}} \\ 0 & \text{for } z \geq \tau^{\text{refr}} \end{cases} \tag{B.71}$$

where τ^{refr} is the absolute refractory time. The time t'_{last} corresponds to the last postsynaptic spike (i.e. the most recent firing of the particular neuron). The second response function is the synaptic kernel $\Lambda(z', t' - t'_{\text{last}})$. It describes the effect of an incoming spike on the membrane potential at the soma of the postsynaptic neuron, and it eventually includes also the dependence on the state of the receiving neuron through the difference $t' - t'_{\text{last}}$ (i.e. through the time that has passed since the last postsynaptic spike). The input spike train yields $s(t' - z') = \sum_i \delta(t' - z' - t_{ij})$, t_{ij} being the i th spike at presynaptic input j . In order to simplify the discussion and without losing generality, let us consider only a single synaptic input, and therefore we can remove the subindex j . In addition, we assume that the synaptic strength J is positive (i.e. excitatory). Integrating Equations B.69 and B.70, we obtain

$$h(t') = \eta^{\text{refr}}(t' - t'_{\text{last}}) + J \sum_i \Lambda(t' - t_i, t' - t'_{\text{last}}) \quad (\text{B.72})$$

Synaptic kernels are of the form

$$\Lambda(t' - t_i, t' - t'_{\text{last}}) = \text{H}(t' - t_i) \text{H}(t_i - t'_{\text{last}}) \Psi(t' - t_i) \quad (\text{B.73})$$

where $\text{H}(s)$ is the step (or Heaviside) function which vanishes for $s \leq 0$ and takes a value of 1 for $s > 0$. After firing, the membrane potential is reset according to the renewal hypothesis.

This spike-response model is not used in the models described in this book, but is presented to show alternative approaches to modelling the dynamics of network activity.

B.7 Network dynamics: introduction to the mean-field approach

Model neurons whose potential and conductances follow the integrate-and-fire equations in Section B.6 can be assembled together in a model network of any composition and architecture. It is convenient to imagine that units (neurons) are grouped into classes, such that the parameters quantifying the electrophysiological properties of the units are uniform, or nearly uniform, within each class, while the parameters assigned to synaptic connections are uniform or nearly uniform for all connections from a given presynaptic class to another given postsynaptic class. The parameters that have to be set in a model at this level of description are quite numerous, as listed in Tables B.4 and B.5.

In the limit in which the parameters are constant within each class or pair of classes, a mean-field treatment can be applied to analyze a model network, by summing equations that describe the dynamics of individual units to obtain a more limited number of equations that describe the dynamical behavior of groups of units (Frolov and Medvedev, 1986). The treatment is exact in the further limit in which very many units belong to each class, and is an approximation if each class includes just a few units. Suppose that N_C is the number of classes defined. Summing equations B.53 and B.54 across units of the same class results in N_C functional equations describing the evolution in time of the fraction of cells of a particular class that at a given instant have a given membrane potential. In other words, from a treatment in which the evolution of the variables associated with each unit is followed separately, one moves to a treatment based on density functions, in which the common behavior of units of the same class is followed together, keeping track solely of the portion of units at any given value of the membrane potential. Summing equation B.52 across connections with the same class of origin and destination results in $N_C \times N_C$ equations describing the dynamics of the overall summed conductance opened on the membrane of a cell of a particular class by all

Table B.4 Cellular parameters (chosen according to the class of each unit)

Δg_{α}	Conductance opened by one presynaptic spike
Δt_{α}	Delay of the connection

the cells of another given class. A more explicit derivation of mean-field equations is given by Treves (1993) and in Section B.8.

The system of mean-field equations can have many types of asymptotic solutions for long times, including chaotic, periodic, and stationary ones. The stationary solutions are stationary in the sense of the mean fields, but in fact correspond to the units of each class firing tonically at a certain rate. They are of particular interest as the dynamical equivalent of the steady states analyzed by using non-dynamical model networks. In fact, since the neuronal current-to-frequency transfer function resulting from the dynamical equations is rather similar to a threshold linear function (see Fig. B.32), and since each synaptic conductance is constant in time, the stationary solutions are essentially the same as the states described using model networks made up of threshold linear, non-dynamical units. Thus the dynamical formulation reduces to the simpler formulation in terms of steady-state rates when applied to asymptotic stationary solutions; but, among simple rate models, it is equivalent only to those that allow description of the continuous nature of neuronal output, and not to those, for example based on binary units, that do not reproduce this fundamental aspect. The advantages of the dynamical formulation are that (i) it enables one to describe the character and prevalence of other types of asymptotic solutions, and (ii) it enables one to understand how the network reaches, in time, the asymptotic behavior.

The development of this mean-field approach, and the foundations for its application to models of cortical visual processing and attention, are described in Section B.8.

B.8 Mean-field based neurodynamics

A model of brain functions requires the choice of an appropriate theoretical framework, which permits the investigation and simulation of large-scale biologically realistic neural networks. Starting from the mathematical models of biologically realistic single neurons (i.e. spiking neurons), one can derive models that describe the joint activity of pools (i.e. populations) of equivalent neurons. This kind of neurodynamical model at the neuronal assembly level is motivated by the experimental observation that cortical neurons of the same type that are near to each other tend to receive similar inputs. As described in the previous section, it is convenient

in this simplified approach to neural dynamics to consider all neurons of the same type in a small cortical volume as a computational unit of a neural network. This computational unit is called a neuronal pool or assembly. The mathematical description of the dynamical evolution of neuronal pool activity in multimodular networks, associated with different cortical areas, establishes the roots of the dynamical approach that are used in Chapter 13 and Section 11.5.1, and in Rolls and Deco (2002) Chapters 9–11. In this Section (B.8), we introduce the mathematical fundamentals utilized for a neurodynamical description of pool activity (see also Section B.8.2). Beginning at the microscopic level and using single spiking neurons to form the pools of a network, we derive the mathematical formulation of the neurodynamics of cell assemblies. Further, we introduce the basic architecture of neuronal pool networks that fulfil the basic mechanisms consistent with the biased competition hypothesis. Each of these networks corresponds to cortical areas that also communicate with each other. We describe therefore the dynamical interaction between different modules or networks, which will be the basis for the implementation of attentional top-down bias.

B.8.1 Population activity

We now introduce thoroughly the concept of a neuronal pool and the differential equations representing the neurodynamics of pool activity.

Starting from individual spiking neurons one can derive a differential equation that describes the dynamical evolution of the averaged activity of a pool of extensively many equivalent neurons. Several areas of the brain contain groups of neurons that are organized in populations of units with (somewhat) similar properties (though in practice the neurons convey independent information, as described in Appendix C). These groups for mean-field modelling purposes are usually called pools of neurons and are constituted by a large and similar population of identical spiking neurons that receive similar external inputs and are mutually coupled by synapses of similar strength. Assemblies of motor neurons (Kandel, Koester, Mack and Siegelbaum, 2021) and the columnar organization in the visual and somatosensory cortex (Hubel and Wiesel, 1962; Mountcastle, 1957) are examples of these pools. Each single cell in a pool can be described by a spiking model, e.g. the spike response model presented in Section B.6.6. Due to the fact that for large-scale cortical modelling, neuronal pools form a relevant computational unit, we adopt a population code. We take the activity level of each pool of neurons as the relevant dependent variable rather than the spiking activity of individual neurons. We therefore derive a dynamical model for the mean activity of a neural population. In a population of M neurons, the mean activity $A(t)$ is determined by the proportion of active neurons by counting the number of spikes $n_{\text{spikes}}(t, t + \Delta t)$ in a small time interval Δt and dividing by M and by Δt (Gerstner, 2000), i.e. formally

$$A(t) = \lim_{\Delta t \rightarrow 0} \frac{n_{\text{spikes}}(t, t + \Delta t)}{M \Delta t}. \quad (\text{B.74})$$

As indicated by Gerstner (2000), and as depicted in Fig. B.37, the concept of pool activity is quite different from the definition of the average firing rate of a single neuron. Contrary to the concept of temporal averaging over many spikes of a single cell, which requires that the input is slowly varying compared with the size of the temporal averaging window, a coding scheme based on pool activity allows rapid adaptation to real-world situations with quickly changing inputs. It is possible to derive dynamical equations for pool activity levels by utilizing the mean-field approximation (Wilson and Cowan, 1972; Abbott, 1991; Amit and Tsodyks, 1991). The mean-field approximation consists of replacing the temporally averaged

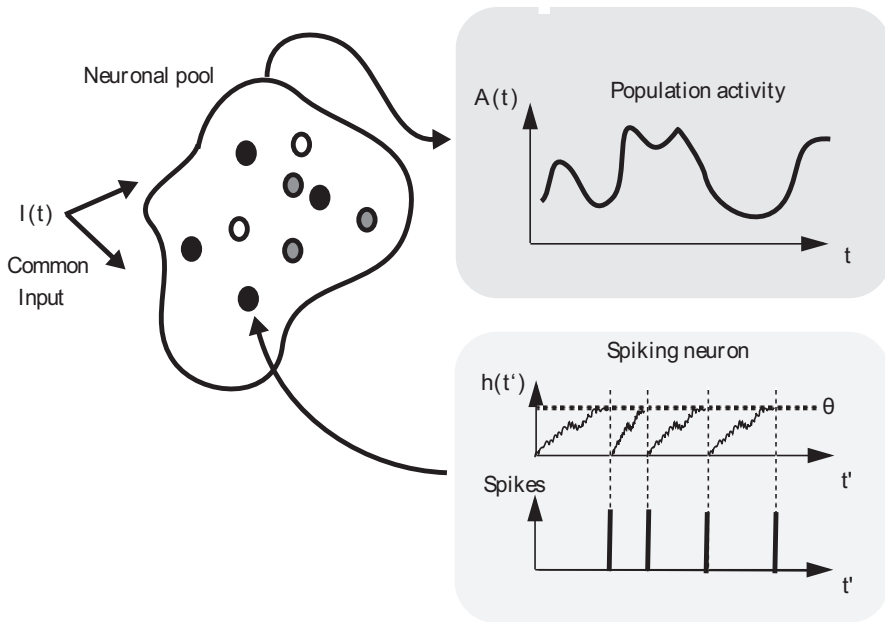

Fig. B.37 Population averaged rate of a neuronal pool of spiking neurons (top) and the action potential generating mechanism of single neurons (bottom). In a neuronal pool, the mean activity $A(t)$ is determined by the proportion of active neurons by counting the number of spikes in a small time interval Δt and dividing by the number of neurons in the pool and by Δt . Spikes are generated by a threshold process. The firing time t' is given by the condition that the membrane potential $h(t')$ reaches the firing threshold θ . The membrane potential $h(t')$ is given by the integration of the input signal weighted by a given kernel (see text for details). (From Rolls, E. T. and Deco, G. (2002) Computational Neuroscience of Vision. Oxford University Press: Oxford.)

discharge rate of a cell with an equivalent momentary activity of a neural population (ensemble average) that corresponds to the assumption of ergodicity. According to this approximation, we categorize each cell assembly by means of its activity $A(t)$. A pool of excitatory neurons without external input can be described by the dynamics of the pool activity given by

$$\tau \frac{\partial A(t)}{\partial t} = -A(t) + qF(A(t)) \tag{B.75}$$

where the first term on the right hand side is a decay term and the second term takes into account the excitatory stimulation between the neurons in the pool. In the previous equation, the non-linearity

$$F(x) = \frac{1}{T_r - \tau \log(1 - \frac{1}{\tau x})} \tag{B.76}$$

is the response function (transforming current into discharge rate) for a spiking neuron with deterministic input, membrane time constant τ , and absolute refractory time T_r . Equation B.75 was derived by Gerstner (2000) assuming adiabatic conditions. Gerstner (2000) has shown that the population activity in a homogeneous population of neurons can be described by an integral equation. A systematic reduction of the integral equation to a single differential equation of the form B.75 always supposes that the activity changes only slowly compared with the typical interval length. In other words, the mean-field approach described in the above equations and utilized in parts of Chapters 2 and 13, and Section 11.5.1 generates a dynamics that neglects fast, transient behavior. This means that we are assuming that rapid oscillations (and synchronization) do not play a computational role at least for the brain functions that we will consider. Rapid oscillations of neural activity could have a relevant functional role,

namely of dynamical cooperation between pools in the same or different brain areas. It is well known in the theory of dynamical systems that the synchronization of oscillators is a cooperative phenomenon. Cooperative mechanisms might complement the competitive mechanisms on which this computational cortical model is based.

An example of the application of the mean field approach, used in a model of decision-making (Deco and Rolls, 2006), is provided in Section B.8.2, with the parameters used provided in Section B.8.3. The mean-field analysis described is consistent with the integrate-and-fire spiking simulation described in Section B.6.3, that is, the same parameters used in the mean-field analysis can then be used in the integrate-and-fire simulations. Part of the value of the mean-field analysis is that it provides a way of determining the parameters that will lead to the specified steady state behavior (in the absence of noise), and these parameters can then be used in a well-defined system for the integrate-and-fire simulations to investigate the full dynamics of the system in the presence of the noise generated by the random spike timings of the neurons.

Ways in which noise can be introduced into the mean-field approach are described by Rolls and Deco (2010).

B.8.2 The mean-field approach used in a model of decision-making

The mean-field approximation used by Deco and Rolls (2006) was derived by Brunel and Wang (2001), assuming that the network of integrate-and-fire neurons is in a stationary state. This mean-field formulation includes synaptic dynamics for AMPA, NMDA and GABA activated ion channels (Brunel and Wang, 2001). In this formulation the potential of a neuron is calculated as:

$$\tau_x \frac{dV(t)}{dt} = -V(t) + \mu_x + \sigma_x \sqrt{\tau_x} \eta(t) \quad (\text{B.77})$$

where $V(t)$ is the membrane potential, x labels the populations, τ_x is the effective membrane time constant, μ_x is the mean value the membrane potential would have in the absence of spiking and fluctuations, σ_x measures the magnitude of the fluctuations, and η is a Gaussian process with absolute exponentially decaying correlation function with time constant τ_{AMPA} . The quantities μ_x and σ_x^2 are given by:

$$\mu_x = \frac{(T_{\text{ext}} \nu_{\text{ext}} + T_{\text{AMPA}} n_x^{\text{AMPA}} + \rho_1 n_x^{\text{NMDA}}) V_E + \rho_2 n_x^{\text{NMDA}} \langle V \rangle + T_I n_x^{\text{GABA}} V_I + V_L}{S_x} \quad (\text{B.78})$$

$$\sigma_x^2 = \frac{g_{\text{AMPA,ext}}^2 (\langle V \rangle - V_E)^2 N_{\text{ext}} \nu_{\text{ext}} \tau_{\text{AMPA}}^2 \tau_x}{g_m^2 \tau_m^2}. \quad (\text{B.79})$$

where ν_{ext} Hz is the external incoming spiking rate, $\tau_m = C_m/g_m$ with the values for the excitatory or inhibitory neurons depending on the population considered, and the other quantities are given by:

$$S_x = 1 + T_{\text{ext}}\nu_{\text{ext}} + T_{\text{AMPA}}n_x^{\text{AMPA}} + (\rho_1 + \rho_2)n_x^{\text{NMDA}} + T_1n_x^{\text{GABA}} \quad (\text{B.80})$$

$$\tau_x = \frac{C_m}{g_m S_x} \quad (\text{B.81})$$

$$n_x^{\text{AMPA}} = \sum_{j=1}^p r_j w_{jx}^{\text{AMPA}} \nu_j \quad (\text{B.82})$$

$$n_x^{\text{NMDA}} = \sum_{j=1}^p r_j w_{jx}^{\text{NMDA}} \psi(\nu_j) \quad (\text{B.83})$$

$$n_x^{\text{GABA}} = \sum_{j=1}^p r_j w_{jx}^{\text{GABA}} \nu_j \quad (\text{B.84})$$

$$\psi(\nu) = \frac{\nu\tau_{\text{NMDA}}}{1 + \nu\tau_{\text{NMDA}}} \left(1 + \frac{1}{1 + \nu\tau_{\text{NMDA}}} \sum_{n=1}^{\infty} \frac{(-\alpha\tau_{\text{NMDA,rise}})^n T_n(\nu)}{(n+1)!} \right) \quad (\text{B.85})$$

$$T_n(\nu) = \sum_{k=0}^n (-1)^k \binom{n}{k} \frac{\tau_{\text{NMDA,rise}}(1 + \nu\tau_{\text{NMDA}})}{\tau_{\text{NMDA,rise}}(1 + \nu\tau_{\text{NMDA}}) + k\tau_{\text{NMDA,decay}}} \quad (\text{B.86})$$

$$\tau_{\text{NMDA}} = \alpha\tau_{\text{NMDA,rise}}\tau_{\text{NMDA,decay}} \quad (\text{B.87})$$

$$T_{\text{ext}} = \frac{g_{\text{AMPA,ext}}\tau_{\text{AMPA}}}{g_m} \quad (\text{B.88})$$

$$T_{\text{AMPA}} = \frac{g_{\text{AMPA,rec}}N_{\text{E}}\tau_{\text{AMPA}}}{g_m} \quad (\text{B.89})$$

$$\rho_1 = \frac{g_{\text{NMDA}}N_{\text{E}}}{g_m J} \quad (\text{B.90})$$

$$\rho_2 = \beta \frac{g_{\text{NMDA}}N_{\text{E}}(\langle V_x \rangle - V_{\text{E}})(J-1)}{g_m J^2} \quad (\text{B.91})$$

$$J = 1 + \gamma \exp(-\beta\langle V_x \rangle) \quad (\text{B.92})$$

$$T_1 = \frac{g_{\text{GABA}}N_{\text{I}}\tau_{\text{GABA}}}{g_m} \quad (\text{B.93})$$

$$\langle V_x \rangle = \mu_x - (V_{\text{thr}} - V_{\text{reset}})\nu_x\tau_x, \quad (\text{B.94})$$

where p is the number of excitatory populations, r_x is the fraction of neurons in the excitatory population x , w_{jx} the weight of the connections from population x to population j , ν_x is the spiking rate of the population x , $\gamma = [\text{Mg}^{++}]/3.57$, $\beta = 0.062$ and the average membrane potential $\langle V_x \rangle$ has a value between -55 mV and -50 mV.

The spiking rate of a population as a function of the defined quantities is then given by:

$$\nu_x = \phi(\mu_x, \sigma_x), \quad (\text{B.95})$$

where

$$\phi(\mu_x, \sigma_x) = \left(\tau_{\text{tp}} + \tau_x \int_{\beta(\mu_x, \sigma_x)}^{\alpha(\mu_x, \sigma_x)} du \sqrt{\pi} \exp(u^2) [1 + \text{erf}(u)] \right)^{-1} \quad (\text{B.96})$$

$$\alpha(\mu_x, \sigma_x) = \frac{(V_{\text{thr}} - \mu_x)}{\sigma_x} \left(1 + 0.5 \frac{\tau_{\text{AMPA}}}{\tau_x} \right) + 1.03 \sqrt{\frac{\tau_{\text{AMPA}}}{\tau_x}} - 0.5 \frac{\tau_{\text{AMPA}}}{\tau_x} \quad (\text{B.97})$$

$$\beta(\mu_x, \sigma_x) = \frac{(V_{\text{reset}} - \mu_x)}{\sigma_x} \quad (\text{B.98})$$

with $\text{erf}(u)$ the error function and τ_{rp} the refractory period which is considered to be 2 ms for excitatory neurons and 1 ms for inhibitory neurons. To solve the equations defined by (B.95) for all x s we integrate numerically (B.94) and the differential Equation B.99, which has fixed point solutions corresponding to Equation B.95:

$$\tau_x \frac{d\nu_x}{dt} = -\nu_x + \phi(\mu_x, \sigma_x). \quad (\text{B.99})$$

The values of the parameters used in a mean-field analysis of decision-making are provided in Section B.8.3, with further details of the parameters in Chapter 11.5.1.

B.8.3 The model parameters used in the mean-field analyses of decision-making

The fixed parameters of the model are shown in Table B.6, and not only provide information about the values of the parameters used in the simulations, but also enable them to be compared to experimentally measured values.

Table B.6 Parameters used in the integrate-and-fire simulations

Fig. B.38 Basic computational module for biased competition: a competitive network with external top-down bias. Excitatory pools with activity A_i for the i th pool are connected with a common inhibitory pool with activity A^I in order to implement a competition mechanism. I_i^E is the external sensory input to the cells in pool i , and I_i^A attentional top-down bias, an external input coming from higher modules. The external top-down bias can shift the competition in favour of a specific pool or group of pools. This architecture is similar to that shown in Fig. B.19, but with competition between pools of similar neurons. (After Rolls, E. T. and Deco, G. (2002) *Computational Neuroscience of Vision*. Oxford University Press: Oxford.)

B.8.4 A basic computational module based on biased competition

We are interested in the neurodynamics of modules composed of several pools that implement a competitive mechanism²⁸. This can be achieved by connecting the pools of a given module with a common inhibitory pool, as is schematically shown in Fig. B.38.

In this way, the more pools of the module that are active, the more active the common inhibitory pool will be, and consequently, the more feedback inhibition will affect the pools in the module, such that only the most excited group of pools will survive the competition. On the other hand, external top-down bias could shift the competition in favour of a specific group of pools. This basic computational module implements therefore the biased competition hypothesis described in Chapter 13. Let us assume that there are m pools in a given module. The system of differential equations describing the dynamics of such a module is given by two differential equations, both of the type of equation B.75. The first differential equation describes the dynamics of the activity level of the excitatory pools (pyramidal neurons) and is mathematically expressed by

$$\tau \frac{\partial A_i(t)}{\partial t} = -A_i(t) + aF(A_i(t)) - bF(A^I(t)) + I_0 + I_i^E(t) + I_i^A(t) + \nu \quad ; \quad \text{for } i = 1, \dots, m \quad (\text{B.100})$$

and the second one describes the dynamics of the activity level of the common inhibitory pool for each feature dimension (stellate neurons)

$$\tau_p \frac{\partial A^I(t)}{\partial t} = -A^I(t) + c \sum_{i=1}^m F(A_i(t)) - dF(A^I(t)) \quad (\text{B.101})$$

where $A_i(t)$ is the activity for pool i , $A^I(t)$ is the activity in the inhibitory pool, I_0 is a diffuse spontaneous background input, $I^E(t)$ is the external sensory input to the cells in pool i , and ν is additive Gaussian noise. The attentional top-down bias $I_i^A(t)$ is defined as an external input coming from higher modules that is not explicitly modelled.

A qualitative description of the main fixed point attractors of the system of differential Equations B.100 and B.101 was provided by Usher and Niebur (1996). Basically, we will

²⁸These neurodynamics are used in Chapter 13.

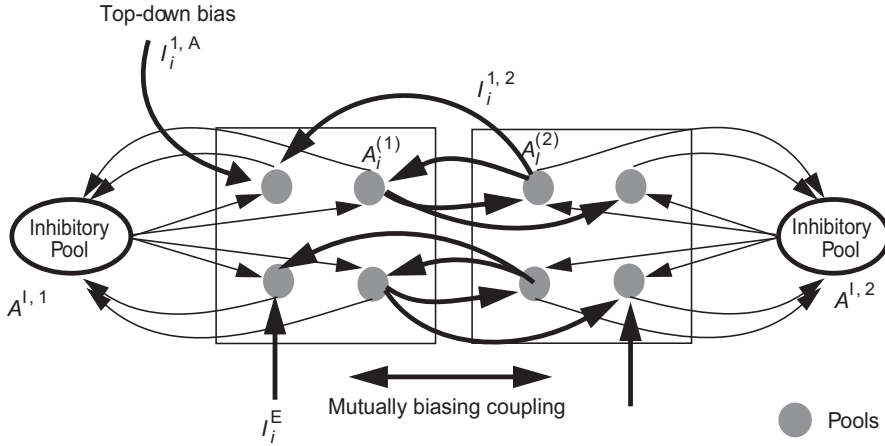

Fig. B.39 Two competitive networks mutually biased through intermodular connections. The activity $A_i^{(1)}$ of the i th excitatory pool in module 1 (on the left) and of the l th excitatory pool in module 2 (on the right) are connected by the mutually biasing coupling $I_i^{1,2}$. The architecture could implement top-down feedback originating from the interaction between brain areas that are explicitly modelled in the system. (Module 2 might be the higher module.) The external top-down bias $I_i^{1,A}$ corresponds to the coupling to pool i of module 1 from brain area A that is not explicitly modelled in the system. (After Rolls, E. T. and Deco, G. (2002) Computational Neuroscience of Vision. Oxford University Press: Oxford.)

be interested in the fixed points corresponding to zero activity and larger activation. The parameters will therefore be fixed such that the dynamics evolves to these attractors.

B.8.5 Multimodular neurodynamical architectures

In order to model complex psychophysically and neuropsychologically relevant brain functions such as visual search or object recognition (see e.g. Chapter 13 and Rolls and Deco (2002)), we must take into account the computational role of individual brain areas and their mutual interaction. The macroscopic phenomenological behavior will therefore be the result of the mutual interaction of several computational modules.

The dynamical coupling of different basic modules in a multimodular architecture can be described, in our neurodynamical framework, by allowing mutual interaction between pools belonging to different modules. Figure B.39 shows this idea schematically. The system of differential equations describing the global dynamics of such a multimodular system is given by a set of equations of the type of Equation B.75.

The excitatory pools belonging to a module obey the following equations:

$$\tau \frac{\partial A_i^{(j)}(t)}{\partial t} = -A_i^{(j)}(t) + aF(A_i^{(j)}(t)) - bF(A^{I,j}(t)) + I_i^{j,k} + I_0 + I_i^E(t) + I_i^A(t) + \nu \quad \text{for } i = 1, \dots, m \quad (\text{B.102})$$

and the corresponding inhibitory pools evolve according to

$$\tau_p \frac{\partial A^{I,j}(t)}{\partial t} = -A^{I,j}(t) + c \sum_{i=1}^m F(A_i^{(j)}(t)) - dF(A^{I,j}(t)). \quad (\text{B.103})$$

The mutual coupling $I_i^{j,k}$ between module (j) and (k) is given by

$$I_i^{j,k} = \sum_l W_{il} F(I_l^{(k)}(t)) \quad (\text{B.104})$$

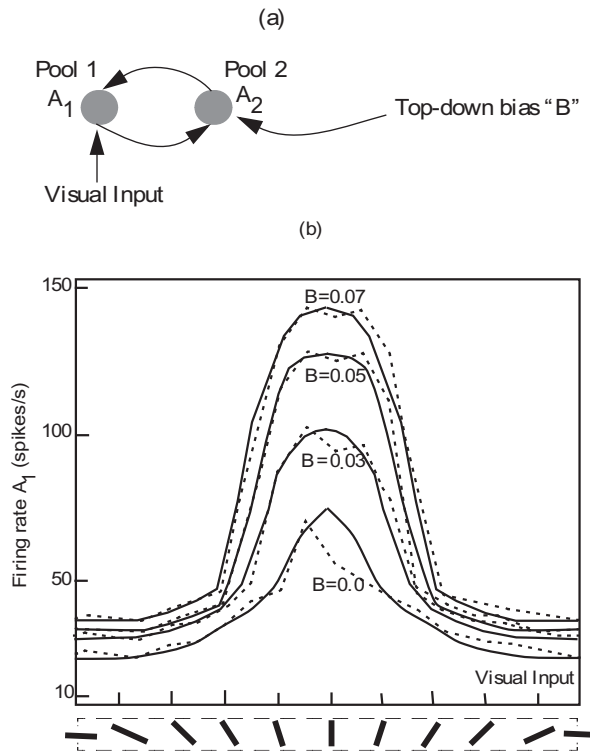

Fig. B.40 (a) The basic building block of the top-down attentional system utilizes non-specific competition between pools within the same module and specific mutual facilitation between pools in different modules. Excitatory neuronal pools within the same module compete with each other through one or more inhibitory neuronal pool(s) I_I with activity A^{I_I} . Excitatory pool 1 (with activity A_1) receives a bottom-up (visual) input I_1^V , and excitatory pool 2 receives a top-down ('attentional') bias input I_2^A . Excitatory neuronal pools in the two different modules can excite each other via mutually biased coupling. (b) The effect of altering the bias input B to pool 2 on the responses or activity of pool 1 to its orientation-tuned visual input (see text). (After Rolls, E. T. and Deco, G. (2002) *Computational Neuroscience of Vision*. Oxford University Press: Oxford.)

where W_{ij} is the synaptic coupling strength between the pool i of module (j) and pool l of module (k). This mutual coupling term can be interpreted as a top-down bias originating from the interaction between brain areas that is explicitly modelled in our system. On the other hand, the external top-down bias I_i^A corresponds to the coupling with brain areas A that are not explicitly modelled in our system.

Additionally, it is interesting to note that the top-down bias in this kind of architecture modulates the response of the pool activity in a multiplicative manner. Responses of neurons in parietal area 7a are modulated by combined eye and head movement, exhibiting a multiplicative gain modulation that modifies the amplitude of the neural responses to retinal input but does not change the preferred retinal location of a cell, nor in general the width of the receptive field (Brochic, Andersen, Snyder and Goodman, 1995). It has also been suggested that multiplicative gain modulation might play a role in translation invariant object representation (Salinas and Abbott, 1997). We use this multiplicative effect for formulating an architecture for attentional gain modulation, which can contribute to correct translation invariant object recognition in ways described in Chapter 13.

We show now that multiplicative-like responses can arise from the top-down biased mutual interaction between pools. Another alternative architecture that can also perform product operations on additive synaptic inputs was proposed by Salinas and Abbott (1996). Our basic architecture for showing this multiplicative effect is presented schematically in Fig. B.40a.

Two pools are mutually connected via fixed weights. The first pool or unit receives a bottom-up visual input I_1^V , modelled by the response of a vertically oriented complex cell. The second pool receives a top-down attentional bias $I_2^A = B$. The two pools are mutually coupled with unity weight. The equations describing the activities of the two pools are given by:

$$\tau \frac{\partial A_1(t)}{\partial t} = -A_1(t) + \alpha F(A_1(t)) + I_o + I_1^V + \nu \quad (\text{B.105})$$

$$\tau \frac{\partial A_2(t)}{\partial t} = -A_2(t) + \alpha F(A_2(t)) + I_o + I_2^A + \nu \quad (\text{B.106})$$

where A_1 and A_2 are the activities of pool 1 and pool 2 respectively, $\alpha = 0.95$ is the coefficient of recurrent self-excitation of the pool, ν is the noise input to the pool drawn from a normal distribution $N(\mu = 0, \sigma = 0.02)$, and $I_o = 0.025$ is a direct current biasing input to the pool.

Simulation of the above dynamical equations produces the results shown in Fig. B.40b. The orientation tuning curve of unit (or pool) 1 was modulated by a top-down bias B introduced to unit (pool) 2. The gain modulation was transmitted through the coupling from pool 2 to pool 1 after a few steps of evolution of the dynamical equations. Without the feedback from unit 2, unit 1 exhibits the orientation tuning curve shown as ($B = 0$). As B increased, the increase in pool 1's response to the vertical bar was significantly greater than the increase in its response to the horizontal bar. Therefore, the attentional gain modulation produced in pool 1 through the mutual coupling was not a simple additive effect, but had a strong multiplicative component. The net effect was that the width of the orientation tuning curve of the cell was roughly preserved under attentional modulation. This was due to the non-linearity in the activation function.

This finding is basically consistent with the effect of attention on the orientation tuning curves of neurons in V4 (McAdams and Maunsell, 1999).

Summarizing, the neurodynamics of the competitive mechanisms between neuronal pools, and their mutual gain modulation, are the two main ingredients used for a cortical architecture that models attention and different kinds of object search in a visual scene (see Chapter 13, and Rolls and Deco (2002) Chapters 9–11 which are available at <https://www.oxcns.org>).

B.9 Interacting attractor networks

It is prototypical of the cerebral neocortical areas that there are recurrent collateral connections between the neurons within an area or module, and forward connections to the next cortical area in the hierarchy, which in turn sends backprojections (see Section 9.3.8). This architecture, made explicit in Fig. 13.10, immediately suggests, given that the recurrent connections within a module, and the forward and backward connections, are likely to be associatively modifiable, that the operation incorporates at least to some extent, interactions between coupled attractor (autoassociation) networks. For these reasons, it is important to analyze the rules that govern the interactions between coupled attractor networks. This has been done using the formal type of model described in Section 13.6.2.2.

One boundary condition is when the coupling between the networks is so weak that there is effectively no interaction. This holds when the coupling parameter g between the networks is less than approximately 0.002, where the coupling parameter indicates the relative strength of the inter-modular to the intra-modular connections, and measures effectively the relative strengths of the currents injected into the neurons by the inter-modular relative to the intra-modular (recurrent collateral) connections (Renart, Parga and Rolls, 1999b). At the other

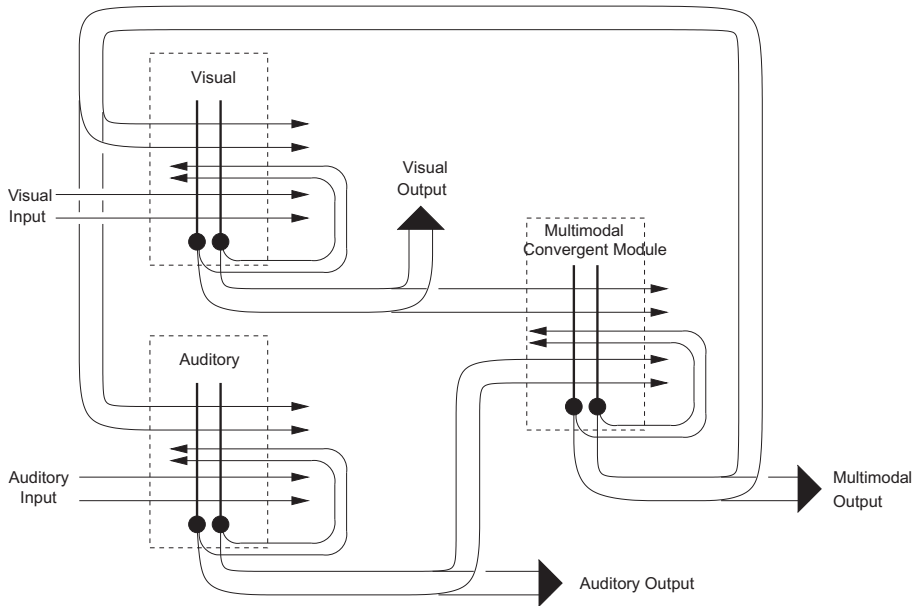

Fig. B.41 A two-layer set of attractor nets in which feedback from layer 2 can influence the states reached in layer 1. Layer 2 could be a higher cortical visual area with convergence from earlier cortical visual areas (see Chapter 2). Layer 2 could also be a multimodal area receiving inputs from unimodal visual and auditory cortical areas, as labelled. Each of the 3 modules has recurrent collateral synapses that are trained by an associative synaptic learning rule, and also inter-modular synaptic connections in the forward and backward direction that are also associatively trained. Attractors are formed within modules, the different modules interact, and attractors are also formed by the forward and backward inter-modular connections. The higher area may not only affect the states reached during attractor settling in the input layers, but may also, as a result of this, influence the representations that are learned in earlier cortical areas. A similar principle may operate in any multilayer hierarchical cortical processing system, such as the ventral visual system, in that the categories that can be formed only at later stages of processing may help earlier stages to form categories relevant to what can be diagnosed at later stages.

extreme, if the coupling parameter is strong, all the networks will operate as a single attractor network, together able to represent only one state (Renart, Parga and Rolls, 1999b). This critical value of the coupling parameter (at least for reciprocally connected networks with symmetric synaptic strengths) is relatively low, in the region of 0.024 (Renart, Parga and Rolls, 1999b). This is one reason why cortico-cortical backprojections are predicted to be quantitatively relatively weak, and for this reason it is suggested end on the apical parts of the dendrites of cortical pyramidal cells (see Section 9.3.8). In the strongly coupled regime when the system of networks operates as a single attractor, the total storage capacity (the number of patterns that can be stored and correctly retrieved) of all the networks will be set just by the number of synaptic connections onto any single neuron received from other neurons in the network, a number in the order of a few thousand (see Section B.3). This is one reason why connected cortical networks are thought not to act in the strongly coupled regime, because the total number of memories that could be represented in the whole of the cerebral cortex would be so small, in the order of a few thousand, depending on the sparseness of the patterns (see Equation B.15) (O’Kane and Treves, 1992).

Between these boundary conditions, that is in the region where the inter-modular coupling parameter g is in the range 0.002–0.024, it has been shown that interesting interactions can occur (Renart, Parga and Rolls, 1999b,a). In a bimodular architecture, with forward and backward connections between the modules, the capacity of one module can be increased, and an attractor is more likely to be found under noisy conditions, if there is a consistent pattern in the coupled attractor. By consistent we mean a pattern that during training was linked associatively by the forward and backward connections, with the pattern being retrieved in

the first module. This provides a quantitative model for understanding some of the effects that backprojections can produce by supporting particular states in earlier cortical areas (Renart, Parga and Rolls, 1999b). The total storage capacity of the two networks is however, in line with O’Kane and Treves (1992), not a great deal greater than the storage capacity of one of the modules alone. Thus the help provided by the attractors in falling into a mutually compatible global retrieval state (in e.g. the scenario of a hierarchical system) is where the utility of such coupled attractor networks must lie. Another interesting application of such weakly coupled attractor networks is in coupled perceptual and short-term memory systems in the brain, described in Section 13.6.1 and Chapter 13.

In a trimodular attractor architecture shown in Fig. B.41 (which is similar to the architecture of the multilayer competitive net illustrated in Fig. B.20 but has recurrent collateral connections within each module), further interesting interactions occur that account for effects such as the McGurk effect, in which what is seen affects what is heard (Renart, Parga and Rolls, 1999a). The effect was originally demonstrated with the perception of auditory syllables, which were influenced by what is seen (McGurk and MacDonald, 1976). The trimodular architecture (studied using similar methods to those used by Renart, Parga and Rolls (1999b) and frequently utilizing scenarios in which first a stimulus was presented to a module, then removed during a memory delay period in which stimuli were applied to other modules) showed a phase with $g < 0.005$ in which the modules operated in an isolated way.

With g in the range 0.005–0.012, an ‘independent’ regime existed in which each module could be in a separate state to the others, but in which interactions between the modules occurred, which could assist or hinder retrieval in a module depending on whether the states in the other modules were consistent or inconsistent. It is in this ‘independent’ regime that a module can be in a continuing attractor that can provide other modules with a persistent external modulatory input that is helpful for tasks such as making comparisons between stimuli processed sequentially (as in delayed match-to-sample tasks and visual search tasks) (see Section 13.6.1). In this regime, if the modules are initially quiescent, then application of a stimulus to one input module propagates to the central module, and from it to the non-stimulated input module as well (see Fig. B.41).

When g grows beyond 0.012, the picture changes and the independence between the modules is lost. The delay activity states found in this region (of the phase space) *always* involve the three modules in attractors correlated with consistent features associated in the synaptic connections. Also, since g is now larger, changes in the properties of the external stimuli have more impact on the delay activity states. The general trend seen in this phase under the change of stimulus after a previous consistent attractor has been reached is that, first, if the second stimulus is not effective enough (it is weak or brief), it is unable to move any of the modules from their current delay activity states. If the stimulus is made more effective, then as soon as it is able to change the state of the stimulated input module, the internal and non-stimulated input modules follow, and the whole network moves into the new consistent attractor selected by the second stimulus. In this case, the interaction between the modules is so large that it does not allow contradictory local delay activity states to coexist, and the network is described as being in a ‘locked’ state.

The conclusion is that the most interesting scenario for coupled attractor networks is when they are weakly coupled (in the trimodular architecture $0.005 < g < 0.012$), for then interactions occur whereby how well one module responds to its own inputs can be influenced by the states of the other modules, but it can retain partly independent representations. This emphasizes the importance of weak interactions between coupled modules in the brain (Renart, Parga and Rolls, 1999b,a, 2000).

These generally useful interactions between coupled attractor networks can be useful in implementing top-down constraint satisfaction (see Section 9.3.8) and short-term memory

(see Section 13.6.1). One type of constraint satisfaction in which they are also probably important is cross-modal constraint satisfaction, which occurs for example when the sight of the lips moving assists the hearing of syllables. If the experimenter mismatches the visual and auditory inputs, then auditory misperception can occur, as in the McGurk effect. In such experiments (McGurk and MacDonald, 1976) the subject receives one stimulus through the auditory pathway (e.g. the syllables *ga-ga*) and a *different* stimulus through the visual pathway (e.g. the lips of a person performing the movements corresponding to the syllables *ba-ba* on a video monitor). These stimuli are such that their acoustic waveforms as well as the lip motions needed to pronounce them are rather different. One can then assume that although they share the same vowel 'a', the internal representation of the syllables is dominated by the consonant, so that the representations of the syllables *ga-ga* and *ba-ba* are not correlated either in the primary visual cortical areas or in the primary auditory ones. At the end of the experiment, the subject is asked to repeat what he heard. When this procedure is repeated with many subjects, it is found that roughly 50% of them claim to have heard either the auditory stimulus (*ga-ga*), or the visual one (*ba-ba*). The rest of the subjects report to have heard neither the auditory nor the visual stimuli, but actually a combination of the two (e.g. *gabga*) or even something else including phonemes not presented auditorially or visually (e.g. *gagla*).

Renart, Parga and Rolls (1999a) were able to show that the McGurk effect can be accounted for by the operation of coupled attractor networks of the form shown in Fig. B.41. One input module is for the auditory input, the second is for the visual input, and both converge into a higher area which represents the syllable formed on the evidence of combination of the two inputs. There are backprojections from the convergent module back to the input modules. Persistent (continuing) inputs were applied to both the inputs, and during associative training of all the weights the visual and auditory inputs corresponded to the same syllable. When tested with inconsistent visual and auditory inputs, it was found for g between ~ 0.10 and ~ 0.11 , the convergent module can either remain in a symmetric state in which it represents a mixture of the two inputs, or choose between one of the inputs, with either situation being stable. For lower g the convergent module always settles into a state corresponding to the input in one of the input modules. It is the random fluctuations produced during the convergence to the attractor that determine the pattern selected by the convergent module. When the convergent module becomes correlated with *one* of its stored patterns, the signal back-projected to the input module stimulated with the feature associated with that pattern becomes stronger and the overlap in this module is increased. Thus, with low values of the inter-module coupling parameter g , situations are found in which sometimes the input to one module dominates, and sometimes the input to the other module dominates what is represented in the convergent module, and sometimes mixture states are stable in the convergent module. This model can thus account for the influences that visual inputs can have on what is heard, in for example the McGurk effect.

The interactions between coupled attractor networks can lead to the following effects. Facilitation can occur in a module if its external input is matched by an input from another module, whereas suppression in a module of its response to an external input can occur if the two inputs mismatch. This type of interaction can be used in imaging studies to identify brain regions where different signals interact with each other. One example is to locate brain regions where multimodal inputs converge. If the inputs in two sensory modalities are consistent based on previous experience, then facilitation will occur, whereas if they are inconsistent, suppression of the activity in a module can occur. This is one of the effects described in the bimodular and trimodular architectures investigated by Renart, Parga and Rolls (1999b), Renart, Parga and Rolls (1999a) and Rolls and Stringer (2001b), and found in architectures such as that illustrated in Fig. B.41.

If a multimodular architecture is trained with each of many patterns (which might be

visual stimuli) in one module associated with one of a few patterns (which might be mood states) in a connected module, then interesting effects due to this asymmetry are found, as described by Rolls and Stringer (2001b).

An interesting issue that arises is how rapidly a system of interacting attractor networks such as that illustrated in Fig. B.41 settles into a stable state. Is it sufficiently rapid for the interacting attractor effects described to contribute to cortical information processing? It is likely that the settling of the whole system is quite rapid, if it is implemented (as it is in the brain) with synapses and neurons that operate with continuous dynamics, where the time constant of the synapses dominates the retrieval speed, and is in the order of 15 ms for each module, as described in Section B.6 and by Panzeri, Rolls, Battaglia and Lavis (2001). In that Section, it is shown that a multimodular attractor network architecture can process information in approximately 15 ms per module (assuming an inactivation time constant for the synapses of 10 ms), and similarly fast settling may be expected of a system of the type shown in Fig. B.41.

B.10 Sequence memory implemented by adaptation in an attractor network

Sequence memory can be implemented by using synaptic adaptation (Rolls, 2016b) to effectively encode the order of the items in a sequence, as described by Deco and Rolls (2005c) and used in the model of syntax (Rolls and Deco, 2015a) (Section 14.5). Whenever the attractor system is quenched into inactivity, the next member of the sequence emerges out of the spontaneous activity, because the least recently activated member of the sequence has the least synaptic or neuronal adaptation. This mechanism could be implemented in recurrent networks such as the hippocampal CA3, prefrontal cortex, language areas of cortex, etc.

B.11 Perceptrons and one-layer error correction networks

The networks described in the next two Sections (B.11 and B.12) are capable of mapping a set of inputs to a set of required outputs using correction when errors are made. Although some of the networks are very powerful in the types of mapping they can perform, the power is obtained at the cost of learning algorithms that do not use local learning rules. A local learning rule specifies that synaptic strengths should be altered on the basis of information available locally at the synapse, for example the activity of the presynaptic and the post-synaptic neurons. Because the networks described here do not use local learning rules, their biological plausibility remains at present uncertain. One of the aims of future research must be to determine whether comparably difficult problems to those solved by the networks described in Sections B.11 and B.12 can be solved by biologically plausible neuronal networks.

We now describe one-layer networks taught by an error correction algorithm. The term *perceptron* refers strictly to networks with binary threshold activation functions. The outputs might take the values only 1 or 0 for example. The term perceptron arose from networks designed originally to solve perceptual problems (Rosenblatt, 1961; Minsky and Papert, 1969), and these networks are referred to briefly below. If the output neurons have continuous-valued firing rates, then a more general error-correcting rule called the delta rule is used, and is introduced in this Section (B.11). For such networks, the activation function may be linear, or it may be non-linear but monotonically increasing, without a sharp threshold, as in the sigmoid activation function (see Fig. 1.3).

Fig. B.42 One-layer perceptron.

B.11.1 Architecture and general description

The one-layer error-correcting network has a set of inputs that it is desired to map or classify into a set of outputs (see Fig. B.42). During learning, an input pattern is selected, and produces output firing by activating the output neurons through modifiable synapses, which then fire as a function of their typically non-linear activation function. The output of each neuron is then compared with a target output for that neuron given that input pattern, an error between the actual output and the desired output is determined, and the synaptic weights on that neuron are then adjusted to minimize the error. This process is then repeated for all patterns until the average error across patterns has reached a minimum. A one-layer error-correcting network can thus produce output firing for each pattern in a way that has similarities to a pattern associator. It can perform more powerful mappings than a pattern associator, but requires an error to be computed for each neuron, and for that error to affect the synaptic strength in a way that is not altogether local. A more detailed description follows.

These one-layer networks have a target for each output neuron (for each input pattern). They are thus an example of a supervised network. With the one-layer networks taught with the delta rule or perceptron learning rule described next, there is a separate teacher for each output neuron, as shown in Fig. B.42.

B.11.2 Generic algorithm for a one-layer error correction network

For each input pattern and desired target output:

1. Apply an input pattern to produce input firing \mathbf{x} , and obtain the activation of each neuron in the standard way by computing the dot product of the input pattern and the synaptic weight vector. The synaptic weight vector can be initially zero, or have random values.

$$h_i = \sum_j x_j w_{ij} \quad (\text{B.107})$$

where \sum_j indicates that the sum is over the C input axons (or connections) indexed by j to each neuron.

2. Apply an activation function to produce the output firing y_i :

$$y_i = f(h_i) . \quad (\text{B.108})$$

This activation function f may be sigmoid, linear, binary threshold, linear threshold, etc. If the activation function is non-linear, this helps to classify the inputs into distinct output patterns, but a linear activation function may be used if an optimal linear mapping is desired (see

Adaline and Madaline, below).

3. Calculate the difference for each cell i between the target output t_i and the actual output y_i produced by the input, which is the error Δ_i

$$\Delta_i = t_i - y_i. \quad (\text{B.109})$$

4. Apply the following learning rule, which corrects the (continuously variable) weights according to the error and the input firing x_j

$$\delta w_{ij} = k(t_i - y_i)x_j \quad (\text{B.110})$$

where k is a constant that determines the learning rate. This is often called the delta rule, the Widrow–Hoff rule, or the LMS (least mean squares) rule (see below).

5. Repeat steps 1–4 for all input pattern – output target pairs until the root mean square error becomes zero or reaches a minimum.

In general, networks taught by the delta rule may have linear, binary threshold, or non-linear but monotonically increasing (e.g. sigmoid) activation functions, and may be taught with binary or continuous input patterns (see Rolls and Treves (1998), Chapter 5). The properties of these variations are made clear next.

B.11.3 Capability and limitations of single-layer error-correcting networks

Perceptrons perform pattern classification. That is, each neuron classifies the input patterns it receives into classes determined by the teacher. This is thus an example of a supervised network, with a separate teacher for each output neuron. The classification is most clearly understood if the output neurons are binary, or are strongly non-linear, but the network will still try to obtain an optimal mapping with linear or near-linear output neurons.

When each neuron operates as a binary classifier, we can consider how many input patterns p can be classified by each neuron, and the classes of pattern that can be correctly classified. The result is that the maximum number of patterns that can be correctly classified by a neuron with C inputs is

$$p_{\max} = 2^C \quad (\text{B.111})$$

when the inputs have random continuous-valued inputs, but the patterns must be linearly separable (see Section A.2.1, and Hertz, Krogh and Palmer (1991)). For a one-layer network, no set of weights can be found that will perform the XOR (exclusive OR), or any other non-linearly separable function (see Appendix A).

Although the inability of one-layer networks with binary neurons to solve non-linearly separable problems is a limitation, it is not in practice a major limitation on the processing that can be performed in a neural network for a number of reasons. First, if the inputs can take continuous values, then if the patterns are drawn from a random distribution, the one-layer network can map up to 2^C of them. Second, as described for pattern associators, the perceptron could be preceded by an expansion recoding network such as a competitive network with more output than input neurons. This effectively provides a two-layer network for solving the problem, and multilayer networks are in general capable of solving arbitrary mapping problems. Ways in which such multilayer networks might be trained are discussed later in this Appendix.

We now return to the issue of the capacity of one-layer perceptrons, that is, how many patterns p can be correctly mapped to correct binary outputs if the input patterns are linearly separable.

B.11.3.1 Output neurons with continuous values, and random patterns

Before treating this case, I note that if the inputs are orthogonal, then just as in the pattern associator, C patterns can be correctly classified, where there are C inputs, x_j , ($j = 1, C$), per neuron. The argument is the same as for a pattern associator.

We consider next the capacity of a one-layer error-correcting network that learns patterns drawn from a random distribution. For neurons with continuous output values, whether the activation function is linear or not, the capacity (for fully distributed inputs) is set by the criterion that the set of input patterns must be linearly independent (see Hertz, Krogh and Palmer (1991)). (Three patterns are linearly independent if any one cannot be formed by addition (with scaling allowed) of the other two patterns – see Appendix A.) Given that there can be a maximum of C linearly independent patterns in a C -dimensional space (see Appendix A), the capacity of the perceptron with such patterns is C patterns. If we choose p random patterns with continuous values, then they will be linearly independent for $p \leq C$ (except for cases with very low probability when the randomly chosen values may not produce linearly independent patterns). (With random continuous values for the input patterns, it is very unlikely that the addition of any two, with scaling allowed, will produce a third pattern in the set.) Thus with continuous valued input patterns,

$$p_{\max} = C. \quad (\text{B.112})$$

If the inputs are not linearly independent, networks trained with the delta rule produce a least mean squares (LMS) error (optimal) solution (see below).

B.11.3.2 Output neurons with binary threshold activation functions

Let us consider here strictly defined perceptrons, that is, networks with (binary) threshold output neurons, and taught by the perceptron learning procedure.

Capacity with fully distributed output patterns

The condition here for correct classification is that described in Appendix A for the AND and XOR functions, that the patterns must be linearly separable. If we consider random continuous-valued inputs, then the capacity is

$$p_{\max} = 2C \quad (\text{B.113})$$

(see Cover (1965), Hertz, Krogh and Palmer (1991); this capacity is the case with C large, and the number of output neurons small). The interesting point to note here is that, even with fully distributed inputs, a perceptron is capable of learning more (fully distributed) patterns than there are inputs per neuron. This formula is in general valid for large C , but happens to hold also for the AND function illustrated in Appendix A.2.1.

Sparse encoding of the patterns

If the output patterns y are sparse (but still distributed), then just as with the pattern associator, it is possible to map many more than C patterns to correct outputs. Indeed, the number of different patterns or prototypes p that can be stored is

$$p \approx C/a \quad (\text{B.114})$$

where a is the sparseness of the target pattern \mathbf{t} . p can in this situation be much larger than C (cf. Rolls and Treves (1990), and Rolls and Treves (1998) Appendix A3).

Perceptron convergence theorem

It can be proved that such networks will learn the desired mapping in a finite number of steps (Block, 1962; Minsky and Papert, 1969; Hertz, Krogh and Palmer, 1991). (This of course depends on there being such a mapping, the condition for this being that the input patterns are linearly separable.) This is important, for it shows that single-layer networks can be proved to be capable of solving certain classes of problem.

As a matter of history, Minsky and Papert (1969) went on to emphasize the point that no one-layer network can correctly classify non-linearly separable patterns. Although it was clear that multilayer networks can solve such mapping problems, Minsky and Papert were pessimistic that an algorithm for training such a multilayer network would be found. Their emphasis that neural networks might not be able to solve general problems in computation, such as computing the XOR, which is a non-linearly separable mapping, resulted in a decline in research activity in neural networks. In retrospect, this was unfortunate, for humans are rather poor at solving parity problems such as the XOR (Thorpe, O'Regan and Pouget, 1989), yet can perform many other useful neural network operations very quickly. Algorithms for training multilayer perceptrons were gradually discovered by a number of different investigators, and became widely known after the publication of the algorithm described by Rumelhart, Hinton and Williams (1986b), and Rumelhart, Hinton and Williams (1986a). Even before this, interest in neural network pattern associators, autoassociators and competitive networks was developing (see Hinton and Anderson (1981), Kohonen (1977), Kohonen (1988)), but the acceptance of the backpropagation or error algorithm for training multilayer perceptrons led to a great rise in interest in neural networks, partly for use in connectionist models of cognitive function (McClelland and Rumelhart, 1986; McLeod, Plunkett and Rolls, 1998), and partly for use in applications (Bishop, 1995; LeCun, Bengio and Hinton, 2015; Lillicrap, Santoro, Marris, Akerman and Hinton, 2020).

In that perceptrons can correctly classify patterns provided only that they are linearly separable, but pattern associators are more restricted, perceptrons are more powerful learning devices than Hebbian pattern associators.

B.11.3.3 Gradient descent for neurons with continuous-valued outputs

We now consider networks trained by the delta (error correction) rule B.110, and having continuous-valued outputs. The activation function may be linear or non-linear, but provided that it is differentiable (in practice, does not include a sharp threshold), the network can be thought of as gradually decreasing the error on every learning trial, that is as performing some type of gradient descent down a continuous error function. The concept of gradient descent arises from defining an error ϵ for a neuron as

$$\epsilon = \sum_{\mu} (t^{\mu} - y^{\mu})^2 \quad (\text{B.115})$$

where μ indexes the patterns learned by the neuron. The error function for a neuron in the direction of a particular weight would have the form shown in Fig. B.43. The delta rule can be conceptualized as performing gradient descent of this error function, in that for the j th synaptic weight on the neuron

$$\delta w_j = -k \partial \epsilon / \partial w_j \quad (\text{B.116})$$

Fig. B.43 The error function ϵ for a neuron in the direction of a particular weight w .

where $\partial\epsilon/\partial w_j$ is just the slope of the error curve in the direction of w_j in Fig. B.43. This will decrease the weight if the slope is positive and increase the weight if the slope is negative. Given Equation B.109, and recalling that $h = \sum_j x_j w_j$, Equation B.43 becomes

$$\delta w_j = -k \partial/\partial w_j \sum_{\mu} [(t^{\mu} - f(h^{\mu}))^2] \quad (\text{B.117})$$

$$= 2k \sum_{\mu} [(t^{\mu} - y^{\mu})] f'(h) x_j \quad (\text{B.118})$$

where $f'(h)$ is the derivative of the activation function. Provided that the activation function is monotonically increasing, its derivative will be positive, and the sign of the weight change will only depend on the mean sign of the error. Equation B.118 thus shows one way in which, from a gradient descent conceptualization, Equation B.110 can be derived.

With linear output neurons, this gradient descent is proved to reach the correct mapping (see Hertz, Krogh and Palmer (1991)). (As with all single-layer networks with continuous-valued output neurons, a perfect solution is only found if the input patterns are linearly independent. If they are not, an optimal mapping is achieved, in which the sum of the squares of the errors is a minimum.) With non-linear output neurons (for example with a sigmoid activation function), the error surface may have local minima, and is not guaranteed to reach the optimal solution, although typically a near-optimal solution is achieved. Part of the power of this gradient descent conceptualization is that it can be applied to multilayer networks with neurons with non-linear but differentiable activation functions, for example with sigmoid activation functions (see Hertz, Krogh and Palmer (1991)).

B.11.4 Properties

The properties of single-layer networks trained with a delta rule (and of perceptrons) are similar to those of pattern associators trained with a Hebbian rule in many respects (see Section B.2). In particular, the properties of generalization and graceful degradation are similar, provided that (for both types of network) distributed representations are used. The main differences are in the types of pattern that can be separated correctly, the learning speed (in that delta-rule networks can take advantage of many training trials to learn to separate patterns that could not be learned by Hebbian pattern associators), and in that the delta-rule network needs an error term to be supplied for each neuron, whereas an error term does not have to be supplied for a pattern associator, just an unconditioned or forcing stimulus. Given these over-

all similarities and differences, the properties of one-layer delta-rule networks are considered here briefly.

B.11.4.1 Generalization

During recall, delta-rule one-layer networks with non-linear output neurons produce appropriate outputs if a recall cue vector \mathbf{x}_r is similar to a vector that has been learned already. This occurs because the recall operation involves computing the dot (inner) product of the input pattern vector \mathbf{x}_r with the synaptic weight vector \mathbf{w}_i , so that the firing produced, y_i , reflects the similarity of the current input to the previously learned input pattern \mathbf{x} . Distributed representations are needed for this property. If two patterns that a delta-rule network has learned to separate are very similar, then the weights of the network will have been adjusted to force the different outputs to occur correctly. At the same time, this will mean that the way in which the network generalizes in the space between these two vectors will be very sharply defined. (Small changes in the input vector will force it to be classified one way or the other.)

B.11.4.2 Graceful degradation or fault tolerance

One-layer delta-rule networks show graceful degradation provided that the input patterns \mathbf{x} are distributed.

B.11.4.3 Prototype extraction, extraction of central tendency, and noise reduction

These occur as for pattern autoassociators.

B.11.4.4 Speed

Recall is very fast in a one-layer pattern associator or perceptron, because it is a feedforward network (with no recurrent or lateral connections). Recall is also fast if the neuron has cell-like properties, because the stimulus input firings x_j ($j = 1, C$ axons) can be applied simultaneously to the synapses w_{ij} , and the activation h_i can be accumulated in one or two time constants of the synapses and dendrite (e.g. 10–20 ms) (see Section B.6.5). Whenever the threshold of the cell is exceeded, it fires. Thus, in effectively one time step, which takes the brain no more than 10–20 ms, all the output neurons of the delta-rule network can be firing with rates that reflect the input firing of every axon.

Learning is as fast ('one-shot') in perceptrons as in pattern associators if the input patterns are orthogonal. If the patterns are not orthogonal, so that the error correction rule has to work in order to separate patterns, then the network may take many trials to achieve the best solution (which will be perfect under the conditions described above).

B.11.4.5 Non-local learning rule

The learning rule is not truly local, as it is in pattern associators, autoassociators, and competitive networks, in that with one-layer delta-rule networks, the information required to change each synaptic weight is not available in the presynaptic terminal (reflecting the presynaptic rate) and the postsynaptic activation. Instead, an error for the neuron must be computed, possibly by another neuron, and then this error must be conveyed back to the postsynaptic neuron to provide the postsynaptic error term, which together with the presynaptic rate determines how much the synapse should change, as in equation B.110,

$$\delta w_{ij} = k(t_i - y_i)x_j$$

where $(t_i - y_i)$ is the error.

A rather special architecture would be required if the brain were to utilize delta-rule error-correcting learning. One such architecture might require each output neuron to be supplied

with its own error signal by another neuron. The possibility (Albus, 1971) that this is implemented in one part of the brain, the cerebellum, is described in Chapter 17. Another functional architecture would require each neuron to compute its own error by subtracting its current activation by its x inputs from another set of afferents providing the target activation for that neuron. A neurophysiological architecture and mechanism for this is not currently known.

B.11.4.6 Interference

Interference is less of a property of single-layer delta rule networks than of pattern autoassociators and autoassociators, in that delta rule networks can learn to separate patterns even when they are highly correlated. However, if patterns are not linearly independent, then the delta rule will learn a least mean squares solution, and interference can be said to occur.

B.11.4.7 Expansion recoding

As with pattern associators and autoassociators, expansion recoding can separate input patterns into a form that makes them learnable, or that makes learning more rapid with only a few trials needed, by delta rule networks. It has been suggested that this is the role of the granule cells in the cerebellum, which provide for expansion recoding by 1,000:1 of the mossy fibre inputs before they are presented by the parallel fibres to the cerebellar Purkinje cells (Marr, 1969; Albus, 1971; Rolls and Treves, 1998) (Chapter 17).

B.11.4.8 Utility of single-layer error-correcting networks in information processing by the brain

In the cerebellum, each output cell, a Purkinje cell, has its own climbing fibre, that distributes from its inferior olive cell its terminals throughout the dendritic tree of the Purkinje cell. It is this climbing fibre that controls whether learning of the x inputs supplied by the parallel fibres onto the Purkinje cell occurs, and it has been suggested that the function of this architecture is for the climbing fibre to bring the error term to every part of the postsynaptic neuron (Chapter 17). This rather special arrangement with each output cell apparently having its own teacher is probably unique in the brain, and shows the lengths to which the brain might need to go to implement a teacher for each output neuron. The requirement for error-correction learning is to have the neuron forced during a learning phase into a state that reflects its error while presynaptic afferents are still active, and rather special arrangements are needed for this.

B.12 Multilayer perceptrons: backpropagation of error networks

B.12.1 Introduction

So far, we have considered how error can be used to train a one-layer network using a delta rule. Minsky and Papert (1969) emphasized the fact that one-layer networks cannot solve certain classes of input–output mapping problems (as described above). It was clear then that these restrictions would not apply to the problems that can be solved by feedforward multilayer networks, if they could be trained. A multilayer feedforward network has two or more connected layers, in which connections allow activity to be projected forward from one layer to the next, and in which there are no lateral connections within a layer. Such a multilayer network has an output layer (which can be trained with a standard delta rule using an error provided for each output neuron), and one or more hidden layers, in which the neurons do not receive separate error signals from an external teacher. (Because they do not provide the

Fig. B.44 A two-layer perceptron. Inputs are applied to layer A through modifiable synapses. The outputs from layer A are applied through modifiable synapses to layer B. Layer B can be trained using a delta rule to produce firing y_i which will approach the target t_i . It is more difficult to modify the weights in layer A, because appropriate error signals must be backpropagated from layer B.

outputs of the network directly, and do not directly receive their own teaching error signal, these layers are described as hidden.) To solve an arbitrary mapping problem (in which the inputs are not linearly separable), a multilayer network could have a set of hidden neurons that would remap the inputs in such a way that the output layer can be provided with a linearly separable problem to solve using training of its weights with the delta rule. The problem was: how could the synaptic weights into the hidden neurons be trained in such a way that they would provide an appropriate representation? Minsky and Papert (1969) were pessimistic that such a solution would be found and, partly because of this, interest in computations in neural networks declined for many years. Although some work in neural networks continued in the following years (e.g. (Marr, 1969, 1970, 1971; Willshaw and Longuet-Higgins, 1969; Willshaw, 1981; Malsburg, 1973; Grossberg, 1976a,b; Arbib, 1964; Amari, 1982; Amari, Yoshida and Kanatani, 1977)), widespread interest in neural networks was revived by the type of approach to associative memory and its relation to human memory taken by the work described in the volume edited by Hinton and Anderson (1981), and by Kohonen (Kohonen, 1977, 1989). Soon after this, a solution to training a multilayer perceptron using backpropagation of error became widely known (Rumelhart, Hinton and Williams, 1986b,a) (although earlier solutions had been found), and very great interest in neural networks and also in neural network approaches to cognitive processing (connectionism) developed (Rumelhart and McClelland, 1986; McClelland and Rumelhart, 1986; McLeod, Plunkett and Rolls, 1998).

B.12.2 Architecture and algorithm

An introduction to the way in which a multilayer network can be trained by backpropagation of error is described next, with further details provided elsewhere (LeCun, Bengio and Hinton, 2015; Lillicrap, Santoro, Marris, Akerman and Hinton, 2020). Then we consider whether such a training algorithm is biologically plausible. More formal accounts of the training algorithm for multilayer perceptrons (sometimes abbreviated MLP) are given by Rumelhart, Hinton and Williams (1986b), Rumelhart, Hinton and Williams (1986a), Hertz, Krogh and Palmer (1991), LeCun, Bengio and Hinton (2015), and Lillicrap, Santoro, Marris, Akerman and Hinton (2020), and below.

Consider the two-layer network shown in Fig. B.44. Inputs to the hidden neurons in layer

A feed forward activity to the output neurons in layer B. The neurons in the network have a sigmoid activation function. One reason for such an activation function is that it is non-linear, and non-linearity is needed to enable multilayer networks to solve difficult (non-linearly separable) problems. (If the neurons were linear, the multilayer network would be equivalent to a one-layer network, which cannot solve such problems.) Neurons B1 and B2 of the output layer, B, are each trained using a delta rule and an error computed for each output neuron from the target output for that neuron when a given input pattern is being applied to the network. Consider now the error that needs to be used to train neuron A1 by a delta rule. This error clearly influences the error of neuron B1 in a way that depends on the magnitude of the synaptic weight from neuron A1 to B1; and on the error of neuron B2 in a way that depends on the magnitude of the synaptic weight from neuron A1 to B2. In other words, the error for neuron A1 depends on:

$$\begin{aligned} & \text{the weight from A1 to B1 } (w_{11}) \cdot \text{error of neuron B1} \\ + & \text{ the weight from A1 to B2 } (w_{21}) \cdot \text{error of neuron B2.} \end{aligned}$$

In this way, the error calculation can be propagated backwards through the network to any neuron in any hidden layer, so that each neuron in the hidden layer can be trained, once its error is computed, by a delta rule (which uses the computed error for the neuron and the presynaptic firing at the synapse to correct each synaptic weight). For this to work, the way in which each neuron is activated and sends a signal forward must be continuous (not binary), so that the extent to which there is an error in, for example, neuron B1 can be related back in a graded way to provide a continuously variable correction signal to previous stages. This is one of the requirements for enabling the network to descend a continuous error surface. The activation function must be non-linear (e.g. sigmoid) for the network to learn more than could be learned by a single-layer network. (Remember that a multilayer linear network can always be made equivalent to a single-layer linear network, and that there are some problems that cannot be solved by single-layer networks.) For the way in which the error of each output neuron should be taken into account to be specified in the error correction rule, the position at which the output neuron is operating on its activation function must also be taken into account. For this, the slope of the activation function is needed, and because the slope is needed, the activation function must be differentiable. Although we indicated use of a sigmoid activation function, other activation functions that are non-linear and monotonically increasing (and differentiable) can be used. (For further details, see Rumelhart, Hinton and Williams (1986b), Rumelhart, Hinton and Williams (1986a), and Hertz, Krogh and Palmer (1991)).

More formally, the operation of a backpropagation of error network can be described as follows (Fig. B.45) (LeCun, Bengio and Hinton, 2015; Lillicrap, Santoro, Marris, Akerman and Hinton, 2020). Fig. B.45a shows how a multilayer neural network (shown by the connected dots) can distort the input space to make the classes of data (examples of which are on the red and blue lines) linearly separable. Note how a regular grid (shown on the left) in the input space is also transformed (shown in the middle panel) by hidden units. This is an illustrative example with only two input units, two hidden units and one output unit, but the networks may contain hundreds of thousands of units.

Fig. B.45b shows how the chain rule of derivatives tells us how two small effects (that of a small change of x on y , and that of y on z) are composed. A small change Δx in x gets transformed first into a small change Δy in y by getting multiplied by $\partial y / \partial x$ (that is, the definition of partial derivative). Similarly, the change Δy creates a change Δz in z . Substituting one equation into the other gives the chain rule of derivatives – how Δx gets turned into Δz through multiplication by the product of $\partial y / \partial x$ and $\partial z / \partial y$. It also works when x , y and z are vectors (and the derivatives are Jacobian matrices).

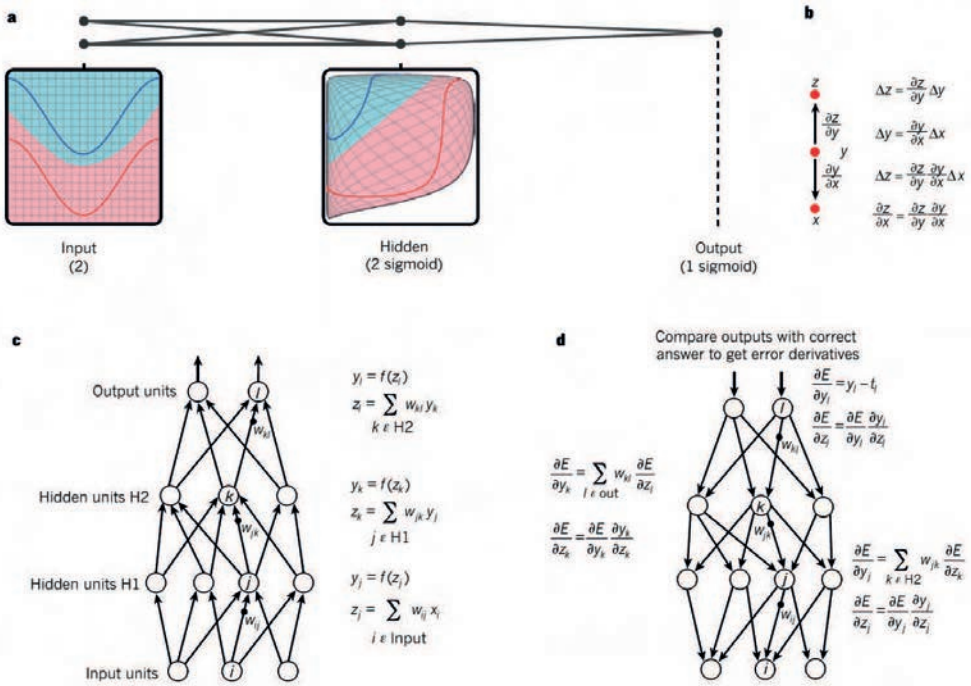

Fig. B.45 Multilayer neural networks and backpropagation (see text). a. How a multilayer neural network (shown by the connected dots) can distort the input space to make the classes of data (examples of which are on the red and blue lines) linearly separable. b. A chain rule of derivatives. c. Equations used for computing the forward pass in a neural net with two hidden layers and one output layer. d. The equations used for computing the backward pass (see text). Note that the indices use different conventions to those used in the remainder of this book. (Reproduced from Yann LeCun, Yoshua Bengio and Geoffrey Hinton (2015) Deep learning. Nature 521: 436–444. Copyright © Springer Nature.)

Fig. B.45c shows the equations used for computing the forward pass in a neural net with two hidden layers and one output layer, each constituting a module through which one can backpropagate gradients. At each layer, we first compute the total input z to each unit, which is a weighted sum of the outputs of the units in the layer below. Then a non-linear function $f(\cdot)$ is applied to z to get the output of the unit. For simplicity, bias terms are omitted. The non-linear function used is now typically the rectified linear unit (ReLU) $f(z) = \max(0, z)$ (known in neuroscience as a threshold linear activation function), although sigmoid activation functions have been used.

Fig. B.45d shows the equations used for computing the backward pass. At each hidden layer we compute the error derivative with respect to the output of each unit, which is a weighted sum of the error derivatives with respect to the total inputs to the units in the layer above. We then convert the error derivative with respect to the output into the error derivative with respect to the input by multiplying it by the gradient of $f(z)$. At the output layer, the error derivative with respect to the output of a unit is computed by differentiating the cost function. This gives $y_l - t_l$ if the cost function for unit l is $0.5(y_l - t_l)^2$, where t_l is the target value. Once the $\partial E / \partial z_k$ is known, the error-derivative for the weight w_{jk} on the connection from unit j in the layer below is $y_j \partial E / \partial z_k$.

Once we have this error derivative for a single neuron, we can update the weights into that neuron by performing a gradient descent step in the direction specified by the derivative to minimize the cost function (see LeCun, Bengio and Hinton (2015) and Lillicrap, Santoro, Marris, Akerman and Hinton (2020)).

Fig. B.46 Artificial neural feedforward network used for backpropagation of error learning. This network has three layers, but a deep network might have 100 layers. The mathematical symbols correspond to those used in Equation B.119. (Reproduced from Plebe,A. and Grasso,G. (2019) The unbearable shallow understanding of deep learning. Minds and Machines 29: 515–553. Copyright © Springer Nature.)

Another way of describing backpropagation of error learning is as follows (Plebe and Grasso, 2019). They start with a deep network with several layers that is in essence a feedforward network, shown in Fig. B.46. The values of the units are computed with the following equations:

$$\begin{aligned}
 \mathbf{x}_1 &= \mathbf{A}^{(I)} \mathbf{x} + \mathbf{b}^{(I)}, \\
 \hat{f}(\mathbf{x}) &= \mathbf{A}^{(O)} \mathbf{x}_N + \mathbf{b}^{(O)}, \\
 x_{i,k} &= h(\mathbf{w}_{i,k} \mathbf{x}_{i-1} - \theta_{i,k}) \quad 1 < i < N.
 \end{aligned}
 \tag{B.119}$$

The first (bottom) layer, ruled by Equations B.119, provides input values to the network, normalized with the linear operators $\mathbf{A}^{(I)}$ and $\mathbf{b}^{(I)}$. The top layer is where the output data appear. The entire feedforward network can be expressed as a function $\hat{f}(\mathbf{x})$ of the input vector \mathbf{x} , and, as described by Equations B.119, it is normalized again to meet the desired data range. The real work is done by the layers in between, according to Equation B.119. In a layer i , each unit $x_{i,k}$ sums up all the values from the previous level, weighted by parameters $\mathbf{w}_{i,k}$, and the result is modified by a non-linear activation function $h(\cdot)$, such as the sigmoid or the hyperbolic tangent.

The backpropagation learning rule specifies how to train the connections between the units, from examples of the desired function between known inputs and outputs. With \mathbf{w} the vector of all learnable parameters in a network, such as $\mathbf{w}_{i,k}$ in Equation B.119, and $\mathcal{L}(\mathbf{x}, \mathbf{w})$ a measure of the error of the network with parameters \mathbf{w} when applied to the sample \mathbf{x} , the backpropagation of error learning rule updates the parameters iteratively, according to the following formula:

$$\mathbf{w}_{t+1} = \mathbf{w}_{t+1} - \eta \nabla_{\mathbf{w}} \mathcal{L}(\mathbf{x}_t, \mathbf{w}_t)
 \tag{B.120}$$

where t spans over all available samples x_t , and η is the learning rate (Plebe and Grasso, 2019). By iterating this procedure many times, the network gradually converges to approximate the unknown function sampled at \mathbf{x}_t .

B.12.3 Properties of multilayer networks trained by error backpropagation

B.12.3.1 Arbitrary mappings

Arbitrary mappings of non-linearly separable patterns can be achieved. For example, such networks can solve the XOR problem, and parity problems in general of which XOR is a special case. (The parity problem is to determine whether the sum of the (binary) bits in a vector is odd or even.) Multilayer feedforward backpropagation of error networks are not guaranteed to converge to the best solution, and may become stuck in local minima in the error surface. However, they generally perform very well.

B.12.3.2 Fast operation

The network operates as a feedforward network, without any recurrent or feedback processing. Thus (once it has learned) the network operates very quickly, with a time proportional to the number of layers.

B.12.3.3 Learning speed

The learning speed can be very slow, taking many thousands of trials. The network learns to gradually approximate the correct input–output mapping required, but the learning is slow because of the credit assignment problem for neurons in the hidden layers. The credit assignment problem refers to the issue of how much to correct the weights of each neuron in the hidden layer. As the example above shows, the error for a hidden neuron could influence the errors of many neurons in the output layers, and the error of each output neuron reflects the error from many hidden neurons. It is thus difficult to assign credit (or blame) on any single trial to any particular hidden neuron, so an error must be estimated, and the net run until the weights of the crucial hidden neurons have become altered sufficiently to allow good performance of the network. Another factor that can slow learning is that if a neuron operates close to a horizontal part of its activation function, then the output of the neuron will depend rather little on its activation, and correspondingly the error computed to backpropagate will depend rather little on the activation of that neuron, so learning will be slow.

More general approaches to this issue suggest that the number of training trials for such a network will (with a suitable training set) be of the same order of magnitude as the number of synapses in the network (see Cortes, Jaekel, Solla, Vapnik and Denker (1996)).

B.12.3.4 Number of hidden neurons and generalization

Backpropagation networks are generally intended to discover regular mappings between the input and output, that is mappings in which generalization will occur usefully. If there were one hidden neuron for every combination of inputs that had to be mapped to an output, then this would constitute a look-up table, and no generalization between similar inputs (or inputs not yet received) would occur. The best way to ensure that a backpropagation network learns the structure of the problem space is to set the number of neurons in the hidden layers close to the minimum that will allow the mapping to be implemented. This forces the network not to operate as a look-up table. A problem is that there is no general rule about how many hidden neurons are appropriate, given that this depends on the types of mappings required. In practice, these networks are sometimes trained with different numbers of hidden neurons, until the minimum number required to perform the required mapping has been approximated.

The lack of biological plausibility of backpropagation of error deep networks in considered in Section 19.4, and limitations of current understanding have been highlighted (Plebe and Grasso, 2019; Sejnowski, 2020). One limitation of deep networks trained by backprop-

agation is that anything that requires reasoning (like programming or applying the scientific method), long-term planning, and algorithmic data manipulation is out of reach for deep-learning models, no matter how much data you throw at them (Plebe and Grasso, 2019). Deep networks trained by error backpropagation are not a solution to general artificial intelligence (Plebe and Grasso, 2019).

B.13 Deep learning using stochastic gradient descent

The most popular approach in deep learning is a slight modification of backpropagation, in Equation B.121 used for stochastic gradient descent (Plebe and Grasso, 2019), where \mathbf{w} is the vector of all learnable parameters in a network, such as $\mathbf{w}_{i,k}$ in Equation B.119, and $\mathcal{L}\mathbf{x}, \mathbf{w}$ a measure of the error of the network with parameters \mathbf{w} when applied to the sample \mathbf{x} :

$$\mathbf{w}_{t+1} = \mathbf{w}_t - \eta \nabla_{\mathbf{w}} \frac{1}{M} \sum_i^M \mathcal{L}(\mathbf{x}_i, \mathbf{w}_t) \quad (\text{B.121})$$

where instead of computing the gradients over a single sample t as in backpropagation (Equation B.120), a stochastic estimation is made over a random subset of size M of the entire dataset, and at each iteration step t a different subset, with the same size, is sampled. This way, the parameters at the next iteration step are determined by the parameters at the previous iteration step adjusted by the mean sampled gradient over M samples. The term ‘backpropagation’ is now out of fashion, and techniques related to Equation B.121 are referred to as stochastic gradient descent (Plebe and Grasso, 2019).

B.14 Deep convolutional networks

Although not biologically plausible, a class of artificial network that was inspired by neuroscience (Fukushima, 1980, 1988) is the convolution network (LeCun, Kavukcuoglu and Farabet, 2010; LeCun, Bengio and Hinton, 2015; Bengio, Goodfellow and Courville, 2017). This type of network is described here, to compare to biologically plausible networks. A deep convolutional network is a multilayer network that is trained by backpropagation of error and that has convergence from stage to stage.

In more detail, the architecture of a typical convolution network (ConvNet) is structured as a series of stages (LeCun, Bengio and Hinton, 2015). The first few stages are composed of two types of layers: convolutional layers and pooling layers.

Units in a convolutional layer are organized in feature maps, within which each unit is connected to local patches in the feature maps of the previous layer through a set of weights called a filter bank. The result of this local weighted sum is then passed through a non-linearity such as a ReLU (a threshold-linear activation function). All units in a feature map share the same filter bank. To be more specific: the local patch of one layer that connects to a neuron in the next layer may be 3x3 units. Whatever weights are learned by backpropagation are the same for all the units across the layer, and this is achieved artificially, effectively by copying the weights laterally. There may be different feature maps in a layer (e.g. for different colors), and each uses a different filter bank. The reason for this architecture is twofold. First, in array data such as images, local groups of values are often highly correlated, forming distinctive local motifs that are easily detected. Second, the local statistics of images and other signals are invariant to location. In other words, if a motif can appear in one part of the image, it could appear anywhere, hence the idea of units at different locations sharing the

same weights and detecting the same pattern in different parts of the array. Mathematically, the filtering operation performed by a feature map is a discrete convolution, hence the name.

Although the role of the convolutional layer is to detect local conjunctions of features from the previous layer, the role of the pooling layer is to merge semantically similar features into one. Because the relative positions of the features forming a motif can vary somewhat, reliably detecting the motif can be done by coarse-graining the position of each feature. A typical pooling unit computes the maximum of a local patch of units in one feature map (or in a few feature maps). To be more specific: a pooling neuron may take the maximum input from a 2 unit x 2 unit patch of units in its input convolution layer. Neighbouring pooling units take input from patches that are shifted by more than one row or column, thereby reducing the dimension of the representation and creating an invariance to small shifts and distortions. The 'stride' may be 2. A convolution net architecture might have these tiny local convolution then pooling of 'max' operator pairs of layers stacked 140 or more on top of one another. Or the architecture might be varied, with several convolution layers before the next pooling layer. At the top of the system, there may be more convolutional and fully-connected pooling layers. To train a ConvNet, stochastic gradient descent is used in conjunction with the gradients computed by backpropagation of error to update the weights to minimize the errors of the output units. The targets for the individual units in the output layer are decided by the experimenter, and might include for one neuron cars, for another neuron bicycles, etc. The whole net is trained with in the order of one million exemplars.

Thus in a convolution network, layers typically alternate, with one layer performing the convolution and filtering followed by a non-linear function such as a threshold linear function (an 'S' layer), and the next layer performing 'pooling' over the neurons in the previous layer (a 'C' layer), to help with transform invariance. The alternation of 'S' and 'C' layers follows the suggestion of Hubel and Wiesel (1962) that complex cells might compute their responses by summing over a set of simple cells. However, there is no evidence for any alternation of S and C layers in most of the primate ventral visual system. The general idea though is that some neurons in the net need to learn to respond to feature combinations, and this is the function of the convolution layer; and the system also needs to do something to cope with transform invariance, and this is done by the max function layers.

The concept of copying weights laterally was used in the Neocognitron (Fukushima, 1980) (Section 2.6.6.2), and has the machine advantages that only one small region is learned, and that the 'filters' or neurons are uniformly good (or bad) throughout a layer. The convolution operator in a convolution network has this effect. This lateral copying is of course biologically implausible, and is not used in VisNet (Chapter 2).

With its powerful backpropagation training algorithm, and very large numbers of training trials, a convolution net can learn to activate the correct output neuron in the output layer for a category of object with good accuracy which may be commercially useful (LeCun, Bengio and Hinton, 2015). However, unlike VisNet, there is no attempt in general to teach the network transform invariance by presenting images with spatial continuity, and no attempt to take advantage of the statistics of the world to help it learn which transforms are probably of the same object by capitalising on temporal continuity. The network is very biologically implausible, in that each unit (or 'neuron') receives from only typically a 3 x 3 or 2 x 2 unit patch of the preceding area (i.e. the receptive fields are small); by using lateral weight copying within a layer; by having up to 140 or more layers stacked on top of each other in the hierarchy; by using the non biologically plausible backpropagation of error training algorithm; and by using a teacher for every neuron in the output layer (Rolls, 2021d; Bowers et al., 2023).

An attempt to compare the operation of such networks to the operation of the ventral

visual cortical stream (Yamins and DiCarlo, 2016; Rajalingham, Issa, Bashivan, Kar, Schmidt and DiCarlo, 2018) is evaluated in Section 2.9.4 (Rolls, 2021d).

B.15 Contrastive Hebbian learning: the Boltzmann machine

In a move towards a learning rule that is more local than in backpropagation networks, yet that can solve similar mapping problems in a multilayer architecture, we describe briefly contrastive Hebbian learning. The multilayer architecture has forward connections through the network to the output layer, and a set of matching backprojections from the output layer through each of the hidden layers to the input layer. The forward connection strength between any pair of neurons has the same value as the backward connection strength between the same two neurons, resulting in a symmetric set of forward and backward connection strengths. An input pattern is applied to the multilayer network, and an output is computed using normal feedforward activation processing with neurons with a sigmoid (non-linear and monotonically increasing) activation function. The output firing then via the backprojections is used to create firing of the input neurons. This process is repeated until the firing rates settle down, in an iterative way (which is similar to the settling of the autoassociative nets described in Section B.3). After settling, the correlations between any two neurons are remembered, for this type of unclamped operation, in which the output neurons fire at the rates that the process just described produces. The correlations reflect the normal presynaptic and postsynaptic terms used in the Hebb rule, e.g. $(x_j y_i)^{uc}$, where ‘uc’ refers to the unclamped condition, and as usual x_j is the firing rate of the input neuron, and y_i is the activity of the receiving neuron. The output neurons are then clamped to their target values, and the iterative process just described is repeated, to produce for every pair of synapses in the network $(x_j y_i)^c$, where the c refers now to the clamped condition. An error correction term for each synapse is then computed from the difference between the remembered correlation of the unclamped and the clamped conditions, to produce a synaptic weight correction term as follows:

$$\delta w_{ij} = k[(x_j y_i)^c - (x_j y_i)^{uc}], \quad (\text{B.122})$$

where k is a learning rate constant. This process is then repeated for each input pattern to output pattern to be learned. The whole process is then repeated many times with all patterns until the output neurons fire similarly in the clamped and unclamped conditions, that is until the errors have become small. Further details are provided by Hinton and Sejnowski (1986). The version described above is the mean field (or deterministic) Boltzmann machine (Peterson and Anderson, 1987; Hinton, 1989). It is sometimes called the ‘wake - sleep’ algorithm (Hinton et al., 1995), because when the system is unclamped, with no input, it might be likened to a sleeping or dreaming state. More traditionally, a Boltzmann machine updates one randomly chosen neuron at a time, and each neuron fires with a probability that depends on its activation (Ackley, Hinton and Sejnowski, 1985; Hinton and Sejnowski, 1986). The latter version makes fewer theoretical assumptions, while the former may operate an order of magnitude faster (Hertz, Krogh and Palmer, 1991).

In terms of biological plausibility, it certainly is the case that there are backprojections between adjacent cortical areas (see Chapters 1 and 9). Indeed, there are as many backprojections between adjacent cortical areas as there are forward projections. The backward projections seem to be more diffuse than the forward projections, in that they connect to a wider region of the preceding cortical area than the region that sends the forward projections. If the backward and the forward synapses in such an architecture were Hebb-modifiable, then there

is a possibility that the backward connections would be symmetric with the forward connections. Indeed, such a connection scheme would be useful to implement top-down recall, as summarized in Chapter 9 and described by Rolls and Treves (1998) in their Chapter 6. What seems less biologically plausible is that after an unclamped phase of operation, the correlations between all pairs of neurons would be remembered, there would then be a clamped phase of operation with each output neuron clamped to the required rate for that particular input pattern, and then the synapses would be corrected by an error correction rule that would require a comparison of the correlations between the neuronal firing of every pair of neurons in the unclamped and clamped conditions.

Although this algorithm has the disadvantages that it is not very biologically plausible, and does not operate as well as standard backpropagation, it has been made use of by O'Reilly and Munakata (2000) in approaches to connectionist modelling in cognitive neuroscience.

B.16 Deep Belief Networks

Another artificial network is a Deep Belief Network which is a probabilistic model composed of many Restricted Boltzmann Machines (RBMs) stacked on top of each other with each layer trained on the output of the previous one (Hinton et al., 2006). A restricted Boltzmann Machine (in contrast to a traditional Boltzmann Machine) has no lateral connections within layers, and the connectivity is relaxed to be undirected. This results in the units in a particular layer being conditionally independent given a set of observed activations in the other. This is a key difference that allows for the efficient learning and inference within these models. Each subsequent layer acts like constraints on the activities of the one below. This is a greedy training process and will probably not yield an optimum representation for the entire hierarchy, primarily because the individual layers are trained in isolation. (Once a layer is trained the weights are frozen.) This inefficiency however can be remedied by a relatively small amount of fine tuning (generative or discriminative) after the stack is complete (Hinton and Salakhutdinov, 2006). It should be noted that a Deep Belief Network itself is not a deep Restricted Boltzmann Machine. The lower layers do not themselves define an undirected model, and only the top-most two layers keep their undirected nature. However there has been work on modifications that restore the undirected nature of the lower layers allowing inference within the lower layers to make use of top-down connectivity as well as the usual bottom-up connectivity (Salakhutdinov and Larochelle, 2010).

The operation of deep belief networks can be summarized as follows (Plebe and Grasso, 2019). The procedure is to take two adjacent layers in a feedforward network, and train them as Boltzmann Machines. The procedure starts with the input and the first hidden layer, so that it is possible to use the inputs of the dataset to train the unsupervised Boltzmann Machine model. Then, this model is used to generate a new dataset, just by processing all the inputs. This new set is used to train the next couple of layers. This procedure is a sort of pre-training that gives a first shape to all the connections in the network, to be further refined by ordinary backpropagation using both the inputs and the known outputs of the dataset (Plebe and Grasso, 2019).

Deep belief networks do have the advantage, like VisNet, that they are unsupervised, and do not need a teacher for every output neuron to help teach the system how to respond. However, scaling such models to full-sized, high-dimensional images remains a difficult problem. To address this a pooling operation has been tested within a deep belief network, and this can help to form transform-invariant representations (Lee et al., 2011). However, their training algorithm remains very biologically implausible.

B.17 Reinforcement learning

In supervised networks, an error signal is provided for each output neuron in the network, and whenever an input to the network is provided, the error signals specify the magnitude and direction of the error in the output produced by each neuron. These error signals are then used to correct the synaptic weights in the network in such a way that the output errors for each input pattern to be learned gradually diminish over trials (see Sections B.11 and B.12). These networks have an architecture that might be similar to that of the pattern associator shown in Fig. B.1, except that instead of an unconditioned stimulus, there is an error correction signal provided for each output neuron. Such a network trained by an error correcting (or delta) rule is known as a one-layer perceptron. The architecture is not very plausible for most brain regions, in that it is not clear how an individual error signal could be computed for each of thousands of neurons in a network, and fed into each neuron as its error signal and then used in a delta rule synaptic correction (see Section B.11).

The architecture can be generalized to a multilayer feedforward architecture with many layers between the input and output (Rumelhart, Hinton and Williams, 1986a), but the learning is very non-local and rather biologically implausible (see Section B.12), in that an error term (magnitude and direction) for each neuron in the network must be computed from the errors and synaptic weights of all subsequent neurons in the network that any neuron influences, usually on a trial-by-trial basis, by a process known as error backpropagation. Thus although computationally powerful, an issue with perceptrons and multilayer perceptrons that makes them generally biologically implausible for many brain regions is that a separate error signal must be supplied for each output neuron, and that with multilayer perceptrons, computed error backpropagation must occur.

When operating in an environment, usually a simple binary or scalar signal representing success or failure of the whole network or organism is received. This is usually action-dependent feedback that provides a single evaluative measure of the success or failure. Evaluative feedback tells the learner whether or not, and possibly by how much, its behavior has improved; or it provides a measure of the ‘goodness’ of the behavior. Evaluative feedback does not directly tell the learner what it should have done, and although it may provide an index of the degree (i.e. magnitude) of success, it does not include directional information telling the learner how to change its behavior towards a target, as does error-correction learning (see Barto (1995)). Partly for this reason, there has been some interest in networks that can be taught with such a single reinforcement signal. In this Section (B.17), approaches to such networks are described. It is noted that such networks are classified as reinforcement networks in which there is a single teacher, and that these networks attempt to perform an optimal mapping between an input vector and an output neuron or set of neurons. They thus solve the same class of problems as single layer and multilayer perceptrons. They should be distinguished from pattern-association networks in the brain, which might learn associations between previously neutral stimuli and primary reinforcers such as taste (signals which might be interpreted appropriately by a subsequent part of the brain), but do not attempt to produce arbitrary mappings between an input and an output, using a single reinforcement signal.

A class of problems to which such reinforcement networks might be applied are motor-control problems. It was to such a problem that Barto and Sutton (Barto, 1985; Sutton and Barto, 1981, 2018) applied a reinforcement learning algorithm, the associative reward–penalty algorithm described next. The algorithm can in principle be applied to multilayer networks, and the learning is relatively slow. The algorithm is summarized in Section B.17.1 and by Hertz, Krogh and Palmer (1991). More recent developments in reinforcement learning (see Sections B.17.2 and B.17.3) have been described (Dayan and Abbott, 2001; Sutton and Barto,

Fig. B.47 A network trained by a single reinforcement input r . The inputs to each neuron are $x_j, j = 1, C$; and y is the output of one of the output neurons.

2018; Collins and Cockburn, 2020; Botvinick, Wang, Dabney, Miller and Kurth-Nelson, 2020).

B.17.1 Associative reward–penalty algorithm of Barto and Sutton

The terminology of Barto and Sutton is followed here (see Barto (1985)).

B.17.1.1 Architecture

The architecture, shown in Fig. B.47, uses a single reinforcement signal, $r, = +1$ for reward, and -1 for penalty. The inputs x_j take real (continuous) values. The output of a neuron, y , is binary, $+1$ or -1 . The weights on the output neuron are designated w_j .

B.17.1.2 Operation

1. An input vector is applied to the network, and produces activation, h , in the normal way as follows:

$$h = \sum_{j=1}^C x_j w_j \quad (\text{B.123})$$

where $\sum_{j=1}^C$ indicates that the sum is over the C input axons (or connections) indexed by j to each neuron.

2. The output y is calculated from the activation with a noise term η included. The principle of the network is that if the added noise on a particular trial helps performance, then whatever change it leads to should be incorporated into the synaptic weights, in such a way that the next time that input occurs, the performance is improved.

$$y = \begin{cases} +1 & \text{if } h + \eta \geq 0, \\ -1 & \text{else.} \end{cases} \quad (\text{B.124})$$

where η = the noise added on each trial.

3. Learning rule. The weights are changed as follows:

$$\delta w_j = \begin{cases} \rho(y - E[y|h])x_j & \text{if } r = +1, \\ \rho\lambda(-y - E[y|h])x_j & \text{if } r = -1. \end{cases} \quad (\text{B.125})$$

ρ and λ are learning-rate constants. (They are set so that the learning rate is higher when positive reinforcement is received than when negative reinforcement is received.) $E[y|h]$ is

the expectation of y given h (usually a sigmoidal function of h with the range ± 1). $E[y|h]$ is a (continuously varying) indication of how the neuron usually responds to the current input pattern, i.e. if the actual output y is larger than normally expected, by computing $h = \sum w_j x_j$, because of the noise term, and the reinforcement is +1, increase the weight from x_j ; and vice versa. The expectation could be the prediction generated before the noise term is incorporated.

This network combines an associative capacity with its properties of generalization and graceful degradation, with a single ‘critic’ or error signal for the whole network (Barto, 1985). [The term $y - E[y|h]$ in Equation B.125 can be thought of as an error for the output of the neuron: it is the difference between what occurred, and what was expected to occur. The synaptic weight is adjusted according to the sign and magnitude of the error of the postsynaptic firing, multiplied by the presynaptic firing, and depending on the reinforcement r received. The rule is similar to a Hebb synaptic modification rule (equation B.2), except that the postsynaptic term is an error instead of the postsynaptic firing rate, and the learning is modulated by the reinforcement.] The network can solve difficult problems (such as balancing a pole by moving a trolley that supports the pole from side to side, as the pole starts to topple). Although described for single-layer networks, the algorithm can be applied to multilayer networks. The learning rate is very slow, for there is a single reinforcement signal on each trial for the whole network, not a separate error signal for each neuron in the network as is the case in a perceptron trained with an error rule (see Section B.11).

This associative reward–penalty reinforcement-learning algorithm is certainly a move towards biological relevance, in that learning with a single reinforcer can be achieved. That single reinforcer might be broadcast throughout the system by a general projection system. It is not clear yet how a biological system might store the expected output $E[y|h]$ for comparison with the actual output when noise has been added, and might take into account the sign and magnitude of this difference. Nevertheless, this is an interesting algorithm, which is related to the temporal difference reinforcement learning algorithm described in Section B.17.3.

B.17.2 Reward prediction error or delta rule learning, and classical conditioning

In classical or Pavlovian associative learning, a number of different types of association may be learned (Rolls, 2014a; Cardinal, Parkinson, Hall and Everitt, 2002). This type of associative learning may be performed by networks with the general architecture and properties of pattern associators (see Section B.2 and Fig. B.1). However, the time course of the acquisition and extinction of these associations can be expressed concisely by a modified type of learning rule in which an error correction term is used (introduced in Section B.17.1), rather than the postsynaptic firing y itself as in Equation B.2. Use of this modified, error correction, type of learning also enables some of the properties of classical conditioning to be explained (see Dayan and Abbott (2001) for review), and this type of learning is therefore described briefly here. The rule is known in learning theory as the Rescorla–Wagner rule, after Rescorla and Wagner (1972).

The Rescorla–Wagner rule is a version of error correction or delta-rule learning (see Section B.11), and is based on a simple linear prediction of the expected reward value, denoted by v , associated with a stimulus representation x ($x = 1$ if the stimulus is present, and $x = 0$ if the stimulus is absent). The **expected reward value** v is expressed as the input stimulus variable x multiplied by a weight w

$$v = wx. \tag{B.126}$$

The **reward prediction error** is the difference between the expected reward value v and the actual **reward outcome** r obtained, i.e.

$$\Delta = r - v \quad (\text{B.127})$$

where Δ is the reward prediction error. The value of the weight w is learned by a rule designed to minimize the expected squared error $\langle (r - v)^2 \rangle$ between the actual reward outcome r and the predicted reward value v . The angle brackets indicate an average over the presentations of the stimulus and reward. The delta rule will perform the required type of learning:

$$\delta w = k(r - v)x \quad (\text{B.128})$$

where δw is the change of synaptic weight, k is a constant that determines the learning rate, and the term $(r - v)$ is the reward prediction error Δ (equivalent to the error in the postsynaptic firing, rather than the postsynaptic firing y itself as in Equation B.2). Application of this rule during conditioning with the stimulus x presented on every trial results in the weight w approaching the asymptotic limit $w = r$ exponentially over trials as the error Δ becomes zero. In extinction, when $r = 0$, the weight (and thus the output of the system) exponentially decays to $w = 0$. This rule thus helps to capture the time course over trials of the acquisition and extinction of conditioning. The rule also helps to account for a number of properties of classical conditioning, including blocking, inhibitory conditioning, and overshadowing (see Dayan and Abbott (2001)).

How this functionality is implemented in the brain is not yet clear. We consider one suggestion (Schultz et al., 1995b; Schultz, 2004, 2006, 2013) after we introduce a further sophistication of reinforcement learning which allows the time course of events within a trial to be taken into account.

B.17.3 Temporal Difference (TD) learning

An important advance in the area of reinforcement learning was the introduction of algorithms that allow for learning to occur when the reinforcement is delayed or received over a number of time steps, and which allow effects within a trial to be taken into account (Sutton and Barto, 1998, 1990, 2018). A solution to these problems is the addition of an adaptive critic that learns through a time difference (TD) algorithm how to predict the future value of the reinforcer. The time difference algorithm takes into account not only the current reinforcement just received, but also a temporally weighted average of errors in predicting future reinforcements. The temporal difference error is the error by which any two temporally adjacent error predictions are inconsistent (see Barto (1995)). The output of the critic is used as an effective reinforcer instead of the instantaneous reinforcement being received (see Sutton and Barto (1998), Sutton and Barto (1990), and Barto (1995)). This is a solution to the temporal credit assignment problem, and enables future rewards to be predicted. Summaries are provided by Doya (1999), Schultz, Dayan and Montague (1997), Dayan and Abbott (2001) and Sutton and Barto (2018). The application of temporal difference learning to invariant object and face recognition is described in Section 2.8.4.3.

In reinforcement learning, a learning agent takes an *action* $\mathbf{u}(t)$ in response to the *state* $\mathbf{x}(t)$ of the environment, which results in the change of the state

$$\mathbf{x}(t + 1) = \mathbf{F}(\mathbf{x}(t), \mathbf{u}(t)), \quad (\text{B.129})$$

and the delivery of the reinforcement signal, or *reward*

$$r(t + 1) = \mathbf{R}(\mathbf{x}(t), \mathbf{u}(t)). \quad (\text{B.130})$$

In the above equations, \mathbf{x} is a vector representation of inputs x_j , and Equation B.129 indicates that the next state $\mathbf{x}(t+1)$ at time $(t+1)$ is a function F of the state at the previous time step of the inputs and actions at that time step in a closed system. In equation B.130 the reward at the next time step is determined by a reward function R which uses the current sensory inputs and action taken. The time t may refer to time within a trial.

The goal is to find a *policy* function G which maps sensory inputs \mathbf{x} to actions

$$\mathbf{u}(t) = G(\mathbf{x}(t)) \quad (\text{B.131})$$

which maximizes the cumulative sum of the rewards based on the sensory inputs.

The current action $\mathbf{u}(t)$ affects all future states and accordingly all future rewards. The maximization is realized by the use of the *value function* V of the states to predict, given the sensory inputs \mathbf{x} , the cumulative sum (possibly discounted as a function of time) of all future rewards $V(\mathbf{x})$ (possibly within a learning trial) as follows:

$$V(\mathbf{x}) = E[r(t+1) + \gamma r(t+2) + \gamma^2 r(t+3) + \dots] \quad (\text{B.132})$$

where $r(t)$ is the reward at time t , and $E[\cdot]$ denotes the expected value of the sum of future rewards up to the end of the trial. $0 \leq \gamma \leq 1$ is a discount factor that makes rewards that arrive sooner more important than rewards that arrive later, according to an exponential decay function. (If $\gamma = 1$ there is no discounting.) It is assumed that the presentation of future cues and rewards depends only on the current sensory cues and not the past sensory cues. The right-hand side of Equation B.132 is evaluated for the dynamics in equations B.129–B.131 with the initial condition $\mathbf{x}(t) = \mathbf{x}$. The two basic ingredients in reinforcement learning are the estimation (which we term \hat{V}) of the value function V , and then the improvement of the policy or action \mathbf{u} using the value function (Sutton and Barto, 2018).

The basic algorithm for learning the value function is to minimize the *temporal difference* (TD) *error* $\Delta(t)$ for time t within a trial, and this is computed by a ‘critic’ for the estimated value predictions $\hat{V}(\mathbf{x}(t))$ at successive time steps as

$$\Delta(t) = [r(t) + \gamma \hat{V}(\mathbf{x}(t))] - \hat{V}(\mathbf{x}(t-1)) \quad (\text{B.133})$$

where $\hat{V}(\mathbf{x}(t)) - \hat{V}(\mathbf{x}(t-1))$ is the difference in the reward value prediction at two successive time steps, giving rise to the terminology temporal difference learning. If we introduce the term \hat{v} as the estimate of the cumulated reward by the end of the trial, we can define it as a function \hat{V} of the current sensory input $\mathbf{x}(t)$, i.e. $\hat{v} = \hat{V}(\mathbf{x})$, and we can also write equation B.133 as

$$\Delta(t) = r(t) + \gamma \hat{v}(t) - \hat{v}(t-1) \quad (\text{B.134})$$

which draws out the fact that it is differences at successive timesteps in the reward value predictions \hat{v} that are used to calculate Δ .

$\Delta(t)$ is used to improve the estimates $\hat{v}(t)$ by the ‘critic’, and can also be used (by an ‘actor’) to learn appropriate actions.

For example, when the value function is represented (in the critic) as

$$\hat{V}(\mathbf{x}(t)) = \sum_{j=1}^n w_j^C x_j(t) \quad (\text{B.135})$$

the learning algorithm for the (value) weight w_j^C in the critic is given by

$$\delta w_j^C = k_c \Delta(t) x_j(t-1) \quad (\text{B.136})$$

where δw_j^C is the change of synaptic weight, k_c is a constant that determines the learning rate for the sensory input x_j , and $\Delta(t)$ is the Temporal Difference error at time t . Under certain

conditions this learning rule will cause the estimate \hat{v} to converge to the true value (Dayan and Sejnowski, 1994).

A simple way of improving the policy of the actor is to take a stochastic action

$$u_i(t) = g\left(\sum_{j=1}^n w_{ij}^A x_j(t) + \mu_i(t)\right), \quad (\text{B.137})$$

where $g()$ is a scalar version of the policy function G , w_{ij}^A is a weight in the actor, and $\mu_i(t)$ is a noise term. The TD error $\Delta(t)$ as defined in Equation B.133 then signals the unexpected delivery of the reward $r(t)$ or the increase in the state value $\hat{V}(\mathbf{x}(t))$ above expectation, possibly due to the previous choice of action $u_i(t-1)$. The learning algorithm for the action weight w_{ij}^A in the actor is given by

$$\delta w_{ij}^A = k_a \Delta(t) (u_i(t-1) - \langle u_i \rangle) x_j(t-1), \quad (\text{B.138})$$

where $\langle u_i \rangle$ is the average level of the action output, and k_a is a learning rate constant in the actor.

Thus, the TD error $\Delta(t)$, which signals the error in the reward prediction at time t , works as the main teaching signal in both learning the value function (implemented in the critic), and the selection of actions (implemented in the actor). The usefulness of a separate critic is that it enables the TD error to be calculated based on the difference in reward value predictions at two successive time steps as shown in Equation B.133.

The algorithm has been applied to modelling the time course of classical conditioning (Sutton and Barto, 1990). The algorithm effectively allows the future reinforcement predicted from past history to influence the responses made, and in this sense allows behavior to be guided not just by immediate reinforcement, but also by ‘anticipated’ reinforcements. Different types of temporal difference learning are described by Sutton and Barto (2018). An application is to the analysis of decisions when future rewards are discounted with respect to immediate rewards (Dayan and Abbott, 2001; Tanaka et al., 2004). Another application is to the learning of sequences of actions to take within a trial (Suri and Schultz, 1998).

The possibility that dopamine neuron firing may provide an error signal useful in training neuronal systems to predict reward has been discussed in Section 16.4.3. It has been proposed that the firing of the dopamine neurons can be thought of as an error signal about reward prediction, in that the firing occurs in a task when a reward is given, but then moves forward in time within a trial to the time when a stimulus is presented that can be used to predict when the taste reward will be obtained (Schultz et al., 1995b; Schultz, 2013, 2017, 2019) (see Fig. 16.12). The argument is that there is no prediction error when the taste reward is obtained if it has been signalled by a preceding conditioned stimulus, and that is why the dopamine midbrain neurons do not respond at the time of taste reward delivery, but instead, at least during training, to the onset of the conditioned stimulus (Waelti, Dickinson and Schultz, 2001). If a different conditioned stimulus is shown that normally predicts that no taste reward will be given, there is no firing of the dopamine neurons to the onset of that conditioned stimulus.

This hypothesis has been built into models of learning in which the error signal is used to train synaptic connections in dopamine pathway recipient regions (such as presumably the striatum and orbitofrontal cortex) (Houk, Adams and Barto, 1995; Schultz, 2004; Schultz, Dayan and Montague, 1997; Waelti, Dickinson and Schultz, 2001; Dayan and Abbott, 2001; Schultz, 2013, 2016c). Some difficulties with the hypothesis are discussed in Section 16.4.3 on page 688. The difficulties include the fact that dopamine is released in large quantities by aversive stimuli (see Section 16.4.3); that error computations for differences between the

expected reward and the actual reward received on a trial are computed in the primate orbito-frontal cortex, where expected reward, actual reward, and error neurons are all found, and lesions of which impair the ability to use changes in reward contingencies to reverse behavior (see Section 11.3.4); that the tonic, sustained, firing of the dopamine neurons in the delay period of a task with probabilistic rewards may reflect reward uncertainty, and not the expected reward, nor the magnitude of the prediction error (see Section 16.4.3 and Shizgal and Arvanitogiannis (2003)); and that reinforcement learning is suited to setting up connections that might be required in fixed tasks such as motor habit or sequence learning, for reinforcement learning algorithms seek to set weights correctly in an ‘actor’, but are not suited to tasks where rules must be altered flexibly, as in rapid one-trial reversal, for which a very different type of mechanism is described in Section 11.5.3 (Deco and Rolls, 2005d; Rolls and Deco, 2016).

The temporal difference approach to reinforcement learning using an actor-critic approach has a weakness that although it can be used to predict internal signals during reinforcement learning in some tasks, it does not directly address learning with respect to actions that are not taken. Q-learning can be considered as an extension of TD learning which adds additional terms to take into account signals from actions that are not taken, for example information gained by observation of others (Montague, King-Casas and Cohen, 2006). In more detail, action-value-learning models do not learn about the values of states, and instead learn directly about the values of specific actions available within each given state. Thus, the corresponding TD prediction error is computed in accordance with differences in successive predictions about the values of actions as opposed to states. An action-value-learning model such as the Q-learning model may learn more quickly than the actor/critic model (Colas et al., 2017; O’Doherty et al., 2017).

Reinforcement learning models have been used to model in fMRI studies where reward prediction error may be represented in the brain, with one area in which reward prediction error is represented the ventral striatum (Hare et al., 2008; Colas et al., 2017; O’Doherty et al., 2017). A useful toolkit for estimating reward prediction error has been described (Piray et al., 2019) and is available at <https://payampiray.github.io/cbm>.

Overall, reinforcement learning algorithms are certainly a move towards biological relevance, in that learning with a single reinforcer can be achieved in systems that might learn motor habits or fixed sequences. Whether a single prediction error is broadcast throughout a neural system by a general projection system, such as the dopamine pathways in the brain, which distribute to large parts of the striatum and the prefrontal cortex, remains to be clearly established (see further Chapter 11, Section 16.4.3), though using a modulator of synaptic learning may be computationally useful (Fremaux and Gerstner, 2015).

B.18 Learning in the neocortex

The neocortex builds new representations. This happens in every sensory system, as described in Chapters 2 – 7. The representations might be of new objects, new faces, new voices, new flavors, etc. The representations formed are different from each other; are sparse but distributed; and need to be readable by simple neuronal networks such as pattern association and autoassociation networks. In this section I bring together some of the principles that appear to be involved, building on the principles described in earlier Chapters and models in this book, and in *Cerebral Cortex: Principles of Operation* (Rolls, 2016b).

A canonical circuit for neocortex is shown in Fig. 1.17, with the architectural anatomy and its computational implications discussed in Chapters 1 and 18 of *Cerebral Cortex* (Rolls, 2016b).

A first computational component is competitive learning, as described in Section B.4. This is the key feature, and involves primarily inputs from a preceding cortical area that synapse into pyramidal neurons, as shown in Fig. 1.17. If it is a primary sensory cortical area, the input is likely to come from the thalamus, and may be relayed through stellate cells in the granular layer 4. It is proposed that these inputs to the neocortex reach the thousands of synapses on the superficial pyramidal cells in layers 2 and 3 (L2/3 PC in Fig. 1.17), and form a competitive network (Rolls, 2021c). The synapses are associatively modifiable, and involve some type of long-term synaptic depression which tends to normalize the total synaptic strength from these inputs, as is required for a competitive network. The inhibition needed for the competitive learning is from the local inhibitory neurons, which provide feedback inhibition from the pyramidal cells. The inhibition is over a short range in the order of 2 mm, so that the neurons compete to learn different categories of input within that radius. The degree of inhibition sets the sparseness of the representation.

The competitive learning operates in conjunction with feedforward connectivity from stage to stage of the type illustrated in Fig. 2.2. This, in combination with the feature hierarchy approach described in Section 2.6.6, enables neurons at successive stage of a hierarchy to represent information that involves a convergence of information from preceding cortical areas that may itself involve feature combinations from the preceding cortical area. The multiple layer feature hierarchy approach is an elegant way of combining different types of information to form feature combination neurons that represent quite selective combinations that happen to be present in the environment, without requiring enormous numbers of synaptic connections onto the final categorising neurons. The information combined in this way need not be from a single processing stream. This would result in feature combination neurons, which then represent a category in the world. The information from a cortical area is passed up the hierarchy from the layer 2 and 3 pyramidal cells, as shown in Fig. 1.17 in which they are labelled ‘forward to next cortical area L4’, although they also synapse heavily onto the superficial pyramidal cells in the next layer. The operation of this hierarchy can be fast, because each cortical area receives inputs from the preceding cortical area on its superficial pyramidal cells, and those pyramidal cell pass their firing directly to the layer 2 and 3 pyramidal cells in the next cortical area in the hierarchy.

The categories learned in a cortical area could be influenced by top-down effects of back-projections from a higher part of the system that when it categorises better has backprojection information that may support the formation of useful categories at the earlier stage, as described in Section B.4.5. These backprojection synapses are shown in Fig. 1.17. These back-projection synapses need to be associatively modifiable in order to implement memory recall, as described in Chapter 9.

If invariant representations are needed, as in transform invariant object recognition, then learning from the statistics in the world over short time periods using trace rule (i.e. slow) learning appears to be a very useful way to assist the formation of the correct feature combination neurons that will respond to different transforms of the same object, as described in Section 2.8. The recurrent collateral connections rc between the superficial pyramidal cells may play an important role in such invariance learning, by operating as an attractor network that keeps the superficial pyramidal cells firing for short period in the order of 100 ms – 1 s to help with the short term memory trace rule learning described in Chapters 2 and 3. To implement such an attractor network, the recurrent collateral connections need to be associatively modifiable (Rolls, 2021c).

Once these category-forming processes involving especially competitive learning and a feedforward hierarchical convergence have resulted in neurons representing new categories, another key feature of neocortical architecture, the recurrent collateral connections between pyramidal cells within a short radius in the order or 2 mm, are likely to become involved.

These do not help in the formation of new categories, but operating as an autoassociation network, as described in Section B.3, will form associations between the features encoded by nearby neurons (Rolls, 2021c) (Fig. 19.1). This means that later on, if some of the usual features are missing, for example the eyes are not visible due to dark glasses, the same object or person representation will become active, because of the completion properties of auto-association networks described in Section B.3. Key evidence that this does occur is that if a stimulus is shown that is ambiguous for a category, perhaps because it is a morph between categories, then the neocortical network will fall into a state where it will represent one of the categories, or another (Akrami, Liu, Treves and Jagadeesh, 2009). This is likely to be useful, not only for taking advantage of the best set of inputs that best represent the category over a population of neurons, but also for the extremely important computation of allowing a short term memory of that category, and keeping it active, for example until another stimulus arrives in the environment to which associations can be learned; or in trace rule slow learning of invariant representations (Rolls, 2021d,c).

The recurrent collaterals between nearby neocortical pyramidal cells may also be useful in building semantic representations in the anterior temporal lobe, as described in Chapter 8.

The layer 5 pyramidal cells (L5 PC in Fig. 1.17) receive inputs from the pyramidal cells in the superficial cortical layers, and are an important source, if not the only source (Markov et al., 2013, 2014a), of the backprojections to layer 1 of the preceding cortical area referred to above. The neurons have their own highly developed recurrent collateral connections, which make operation as some form of attractor network likely (Rolls and Mills, 2017).

The layer 5 pyramidal cells also project to the striatum, which provides an important output of every cortical area, and that may help in the initiation of a single stream of movement and action, as described in Chapter 16. The layer 6 pyramidal cells receive from the layer 5 pyramidal cells, and project to the thalamus, where they may serve a feedback function to control the level of afferent input to each cortical area.

These principles of operation are elucidated and extended throughout this book, and what is in this section (B.18) is just a summary. Further evidence on the operation of cortical circuitry is provided in Rolls (2016b), Singer, Sejnowski and Rakic (2019), Rolls (2021c), and Rolls and Mills (2017).

B.19 Forgetting in cortical associative neural networks, and memory reconsolidation

Forgetting is an important feature of associative neural networks and the brain, and is important in their successful operation. There are a number of different mechanisms for forgetting, and a number of different reasons why forgetting is important in particular classes of network.

Consider attractor, that is autoassociation, networks, which are used for short-term memory, episodic memory, etc. These networks have a critical storage capacity, as described in Section B.3, and if this is exceeded, most of the memories in the network become unretrievable. It is therefore crucial to have a mechanism for forgetting in these networks.

One mechanism is decay of synaptic strength. The simple forgetting mechanism is just an exponential decay of the synaptic value back to its baseline, which may be exponential in time or in the number of learning changes incurred (Nadal, Toulouse, Changeux and Dehaene, 1986). This form of forgetting does not require keeping track of each individual change and preserves linear superposition, that is each memory is added linearly to previous memories, as provided for by Equation B.9 on page 833. In calculating the storage capacity of pattern associators and of autoassociators, the inclusion or exclusion of simple exponential decay does not change significantly the calculation of capacity, and only results in a different prefactor

(one 2.7 times the other) for the maximum number of associations that can be stored. Therefore a forgetting mechanism as simple as exponential decay is normally omitted, and one has just to remember that its inclusion would reduce the critical capacity obtained to roughly 0.37 of that without the decay. This type of memory has been called a palimpsest.

Another form of forgetting, which is potentially interesting in terms of biological plausibility, is implemented by setting limits to the range allowed for each synaptic strength or weight (Parisi, 1986). As a particular synapse hits the upper or lower limit on its range, it is taken to be unable to further modify in the direction that would take it beyond the limit. Only after modifications in the opposite direction have taken it away from the limit does the synapse regain its full plasticity. A forgetting scenario of this sort requires a slightly more complicated formal analysis (since it violates linear superposition of different memories), but it effectively results in a progressive, exponential degradation of older memories similar to that produced by straight exponential decay of synaptic weights.

A combined forgetting rule that may be particularly attractive in the context of modelling synapses between pyramidal cells is implemented by setting a lower limit, that is, zero, on the excitatory weight (just requiring that the associated conductance be a non-negative quantity!), and allowing exponential decay of the value of the weight with time. Again, this type of combined forgetting rule places demands on the analytical techniques that have to be used to calculate the storage capacity, but leads to functionally similar effects (Rolls and Treves, 1998).

Two conditions under which synaptic strengths may decrease are described in Fig. 1.6. Heterosynaptic long-term depression, which can occur for inactive presynaptic terminals on active postsynaptic neurons, can be useful computationally in the following ways. First, it is a useful way to subtract the effect of the mean presynaptic firing rate of each neuron in a pattern associator, which removes the effect of the mean firing rate in increasing the correlation between different input patterns used in the network, as is made evident in Equation B.7. This orthogonalizing effect helps to maximize the storage capacity of pattern associators. The same situation applies to autoassociation (attractor) networks (see Equation B.13). This decrease of firing rate for inactive inputs may of course result in some loss of memories previously stored in these association networks, if a particular synapse had been strengthened as part of a previous memory. Homosynaptic long-term depression might contribute to a similar function.

Heterosynaptic long-term depression (LTD) is also useful in competitive networks, for it provides a way for the synaptic weight vectors of different neurons to be kept of approximately equal length, and this is important to ensure that the different categories of input patterns find different output neurons to activate. In the case of competitive networks, the appropriate effect is achieved if the subtractive term in the presynaptic component depends on the existing strength of the synapse, as shown in Equation B.32. The fact that in studies of LTD it is sometimes remarked that LTD is easier to demonstrate after LTP has been induced lends support to the likelihood that LTD of the form indicated in Equation B.32 that depends on the existing synaptic strength is implemented in the brain. Because of the computational significance of LTD that depends on the existing strength of synapses for competitive networks, it would be useful to see further experimental exploration of this.

Forgetting in attractor networks takes two forms that can be clearly distinguished. One is that the current attractor state implemented by the continuing firing of one set of neurons in the network is labile, and may be interrupted by a strong new input which forces the network into a new attractor state, or may be interrupted by quenching effects through non-specific effects implemented through for example inhibitory neurons (Section 11.5.3). Both these effects could be facilitated by synaptic or neuronal adaptation, as described in Section 11.5.3.

The second form of forgetting in attractor networks is of the strengthened synaptic connections that specify each of the different attractor memories in the network. If the network is to be used for large numbers of different short-term memories, then these synaptic weights must decay or be overwritten by LTD as described above. This is likely to be required for short-term memory networks in the prefrontal cortex which must adapt themselves to be capable of storing the particular stimuli and actions that may be required in particular tasks (Rolls, 2016b), in short-term memory networks that implement the visuo-spatial scratchpad, etc. We may note that because short-term memory networks have these two different aspects, once an attractor set of synaptic connections has been imprinted in a network by synaptic modification, then no further synaptic modification is necessary to use that network repeatedly for holding the neurons in one of the stored attractors active to implement the short-term memory in a delay period (Kesner and Rolls, 2001).

Forgetting may be less important in semantic networks. (Semantic networks store structured information with appropriate associative links and hierarchical structure, for example a family tree, or one's geographical knowledge (McClelland and Rumelhart, 1986).) We may note that because any one associative memory network has a memory capacity that is related to the number of associative synapses onto each neuron from other neurons in the network, semantic memory is likely to involve connections between modules in the cortex, where each module might be defined by a 1–3 mm region of cortex with high local connectivity between the neurons. For this type of memory, forgetting is not so much the requirement as incorporating new semantic knowledge, that is making new appropriate links, and perhaps weakening existing links. In this scenario, the fact that when a memory is retrieved, as would occur when a semantic memory is being updated or extended, then it may need to be reconsolidated, suggests a possible useful function for memory reconsolidation (see below), as it could facilitate the restructuring of a semantic memory. In contrast, such restructuring would not be a very useful property of an episodic memory, in which each episode must be clearly distinguished from others.

Reconsolidation refers to a process in which after a memory has been stored, it may be weakened or lost if recall is performed during the presence of a protein synthesis inhibitor (Debiec, LeDoux and Nader, 2002; Debiec, Doyere, Nader and LeDoux, 2006; Haubrich and Nader, 2018). The implication that has been drawn is that whenever a memory is recalled, some reconsolidation process requiring protein synthesis may be needed.

One possible function of reconsolidation is that it may allow some restructuring of a memory, as described above, though this might be useful more in semantic than episodic memory systems.

A second possible computational function is that reconsolidation might be useful as a mechanism to ensure that whenever a memory is retrieved, additional LTP (long-term potentiation of synaptic strength) is not added to the existing LTP. This could be achieved if during the recall process the memory strength is reset to a low value from which it is then strengthened. Indeed, a potential problem with memory systems is what separates storage from recall, in that whenever recall occurs, pre- and post-synaptic activity is present at the relevant synapses for the memory, and thus one might expect another round of synaptic strengthening to occur. Reconsolidation, by effectively resetting the baseline of synaptic strength during recall, might then provide for the restrengthened synapses not to be stronger than they were before the memory recall. A relevant point here is that in associative memories, the amount of information stored and retrieved from any one synapse is quite low, in the order of 0.2–0.3 bits for autoassociators (Rolls and Treves, 1998; Treves and Rolls, 1991) and a little higher for pattern associators (Rolls and Treves, 1998), so that in any case having synaptic strengths that could be repeatedly strengthened by superposition of different memories with distributed

representations and with precision maintained at each strengthening would not appear to be a necessary property of the synapses in such memory systems. Under these circumstances, allowing during recall a weakening of a memory, and then its reconsolidation from a relatively fixed baseline might not lead to loss of useful information, and might be a possible solution to continually strengthening synapses every time a memory is recalled.

A third possible computational function of reconsolidation is that it could enable the selective retention of ‘useful’ memories (or in fact memories being used), and the forgetting of memories not being used, as follows. Consider a memory system in which there is slow exponential decay of synaptic strength with time, a not altogether unlikely scenario given the properties of a biological system. In this situation memories will gradually be lost, perhaps with a different time course in different memory systems, which might be in the order of days, weeks, months or years. In this scenario, if a piece of information was actually recalled because an environmental situation occurred in which for example there was a retrieval cue for a memory, then that memory (i.e. the synaptic strengths) would by reconsolidation be strengthened back to near its initial value. That memory would then be strong and available for future use, compared to other memories not recalled that would be passively decaying. The passive decay of memories not being recalled and reset by reconsolidation would be useful in cleaning out the memory stores so that any critical capacity was not reached, and at the same time in minimizing interference (due to generalization to similar patterns) between memories in store. An example might be the number of one’s hotel room, which while it is being repeatedly recalled for use while in that hotel and thus restored, would then decay passively and gradually be lost when it was not longer being actively recalled and hence reconsolidated. One could propose that in some memory systems the passive decay might be relatively rapid, occurring within hours or days. An example might be the dorsolateral prefrontal cortex, where depending on the requirements of the short-term memory or planning tasks being performed, synapses might by reconsolidation keep representations used in attractor networks available while a given task was being performed. However, when that task was no longer being performed, passive synaptic decay would mean that neurons allocated to that task would gradually decline, and instead new attractor landscapes (i.e. memories) could be set up for new tasks or planning, without interference from representations that were previously being used. There is some evidence at the phenomenological level that neuronal representations are made and kept relevant to whatever task is being performed (Miller et al., 2003; Everling et al., 2006), and I have just proposed a possible mechanism for this implemented by reconsolidation.

Memories stored early in life may be stored better, and later recalled better, than those stored later in life. There are a number of possible reasons for this. One is that the transmitters that generally facilitate synaptic modification, such as acetylcholine and noradrenaline (see Section 18.6.4), may become depleted with ageing.

Another mechanism, not necessarily independent, is that new synaptic modification, as assessed by long-term potentiation (LTP), appears to be less long-lasting with ageing (Burke and Barnes, 2006; Barnes, 2011). Another mechanism may be that storing memories in a flat energy landscape (i.e. without much prior synaptic modification) may help these memories to stand out from those added later. While this would not be a natural property of the type of autoassociation palimpsest memory described above, it could be a property of the way in which an episodic memory stored in the hippocampus may be retrieved into the neocortex where it can be incorporated into a semantic memory (see Chapter 9), the relevant example of which in this case would be an autobiographical memory.

In semantic memories, it could be that the first stored links tend to provide the framework around which other information is structured.

Another factor in the apparent strength of early memories may be that some may be stored with an affective component, and this may not only make the memory strong by activation of the cholinergic and related systems described in Section 18.6.4, but may also mean that part at least of the memory is stored in different brain structures such as the amygdala which may have relatively more persistent and less flexible or reversible memories than other memory systems.

Another factor in the importance and stability of synaptic modification early in life arises in perceptual systems, in which it is important to allow neurons to become tuned to the statistics of for example the visual environment, but once feature analyzers have been formed, stability of the feature analyzers in early cortical processing layers may be important so that later stages in the hierarchy can perform reliable object recognition which achieves stability only if the input filters to the system do not keep changing (see Chapter 2). This could be the importance of a critical period for learning early on in perceptual development.

Sleep has been proposed as a state in which useful forgetting or consolidation of memories could occur. One suggestion was that if deep basins of attraction formed in a memory network, then this could impair performance, as the memories in the basins would tend to be recalled whatever the retrieval cue. If noise, present in the disorganized patterns of neural firing during sleep, caused these memories to be recalled, this would indicate that they were ‘parasitic’, and the suggestion was that associative synaptic weakening (LTD) of synapses of neurons with high firing during sleep would tend to decrease the depth of those basins of attraction, and improve the performance of the memory (Crick and Mitchison, 1995). At least at the formal level of neural networks, the suggestion does have some merit as a possible way to ‘clean up’ associative networks, even if it is not a process implemented in the brain. Although the idea of some role of sleep in memory remains active, this remains to be fully established (Walker and Stickgold, 2006), and indeed there is evidence that quiet waking may be relevant rather than sleep per se (Dastgheib et al., 2022). That would fit much better with my theory of memory consolidation which proposes that recall from the hippocampus to the neocortex and active reorganization of the information during waking to organize it in relation to existing semantic information may be much more relevant (Rolls, 2022b) (Section 9.2.8.5).

The idea that sleep could be a time when memories are unloaded from the hippocampus to be consolidated in long term, possibly semantic, memories during sleep (Marr, 1971) (allowing hippocampal episodic memories to then be overwritten by new episodic memories) continues to be explored. (David Marr heard this considered in a lecture at Cambridge by Larry Weiskrantz in 1967.) It has been shown for example that after hippocampal spatial representations have been altered by experience during the day, these changes are reflected in ‘replay’ neuronal activity in the neocortex during sleep (Wilson and McNaughton, 1993; Wilson, 2002; Chen and Wilson, 2017; Foster, 2017). The type of experience might involve repeated locomotion between two places, and the place fields of rat hippocampal neurons for those places may become associated with each other because of coactivity of the neurons representing the frequently visited places. The altered co-firing of the hippocampal neurons for those places may then be reflected in neocortical representations of those places. This could then result in altered representations in the neocortex, if LTP occurs during sleep in the neocortex. Of course, any change in neocortical neuronal activity might just reflect the altered representations in the hippocampus, which would be expected to influence the neocortical representations via hippocampo-neocortical backprojections, even without any neocortical learning (see Chapter 9). However, the evidence that sleep is critically involved in memory consolidation, and even that replay is involved in memory consolidation, is now receiving critical re-evaluation, for replay can occur in waking, and may represent trajectories never

taken by the animal (Findlay, Tononi and Cirelli, 2020).

In conclusion, we have seen in this Section that forgetting has important functions in the cortex, and is a necessary property of many different types of memory system if they are to continue to function efficiently and to allow new learning in the same networks in the brain. This is especially likely to apply to the episodic memory system implemented in the hippocampus, because there is a single network in CA3 (Chapter 9). In semantic memories in the anterior temporal lobe, the challenge is more to incorporate new information to update previous representations, rather than to over-write them (see Chapter 8).

B.20 Genes and self-organization build neural networks in the cortex

B.20.1 Introduction

Analysis of the structure and function of different cortical areas is starting to reveal how the operation of networks of neurons may implement the functions of each cortical area. The question then arises as part of understanding cortical and indeed brain function of how the networks found in different cortical and brain areas actually have evolved, and how their basic architecture may be specified by genes and then built using self-organisation and environmental input during development.

To address these fundamental issues, I compared the architecture and networks found in different brain areas, and in particular how they differ from each other, to formulate hypotheses about a set of parameters that may be specified by genes that could lead to the building during development of the neuronal network functional architectures found in different cortical regions (Rolls and Stringer, 2000). The choice of parameters was guided not only by comparison of the functional architecture of different brain regions, but also by what parameters, if specified by genes, could with a reasonably small set of genes actually build the networks found in different brain regions. The concept is that if these parameters are specified by different genes, then genetic reproduction and natural selection using these parameters could lead to the evolution of neuronal networks in our brains well adapted for different functions.

A second aim is to show how the sufficiency of the general approach, and the appropriateness of the particular parameters selected, can be tested and investigated using genetic algorithms which actually use the hypothesised genes to specify networks. We showed this by implementing a genetic algorithm, and testing whether it can search the high dimensional space provided by the suggested parameters to specify and build neuronal networks that will solve particular computational problems (Rolls and Stringer, 2000).

A third aim could be, if we start to understand how genes and self-organisation build networks in the brain using a set of biologically plausible components, to provide a foundation for building artificial neural networks with again relatively few ‘genes’, but with genes now able to specify much more powerful computer architectures than those found in the brain.

The computational problems we choose to test are simple and well defined problems that can be solved by one-layer networks, and that as shown in this book capture some of the architectural properties of different cortical areas, and are some of the building blocks of cortical function (Rolls and Stringer, 2000). These problems are pattern association, autoassociation, and unsupervised categorization as can be performed by a competitive network, which require quite different architectures for them to be solved (see Chapter 1 including Fig. 1.7 and earlier parts of this Appendix B).

Because the problems to be solved are well specified, we can define a good fitness measure for the operation of each class of network, which will be used to guide the evolution by reproduction involving genetic variation and selection in each generation. Although we do not suppose that the actual parameters chosen for illustration are necessarily those specified by mammalian genes, they have been chosen because they seem reasonable given the differences in the functional architecture of different brain areas, and allow illustration of the overall concept about how different network architectures found in different brain regions evolve.

Although these computational problems to be solved were chosen to have well understood one-layer neural network solutions, now that this general approach has been established (Rolls and Stringer, 2000), it will be of great interest in future to examine problems that are solved by multilayer networks in the brain (e.g. invariant object recognition (Chapter 2) and episodic memory (Chapter 9), in order to understand how brain mechanisms to solve complex problems may evolve and how they may operate.

The first example of the networks to be investigated was pattern association networks in which one input (e.g. an unconditioned stimulus) drives the output neurons through unmodifiable synapses, and a second input (e.g. a conditioned stimulus) has associatively modifiable synapses onto the output neurons, so that by associative learning it can come to produce the same output as the unconditioned stimulus (Section B.2). Pattern association memory may be implemented in structures such as the amygdala and orbitofrontal cortex to implement stimulus-reward. Pattern association learning may also be used in the connections of back-projecting neurons in the cerebral cortex onto the apical dendrites of neurons in the preceding cortical area to implement memory recall.

A second example is autoassociation networks characterized by recurrent collateral axons with associatively modifiable synapses (Section B.3), which may implement functions such as short term memory in the cerebral cortex, and episodic memory in the hippocampus.

A third example is competitive learning (Section B.4), where there is one major set of inputs to a network connected with associatively modifiable synapses, and mutual (e.g. lateral) inhibition between the output neurons (through e.g. inhibitory feedback neurons). Competitive networks can be used to build feature analyzers by learning to respond to clusters of inputs which tend to co-occur, and may be fundamental building blocks of perceptual systems. Allowing short range excitatory connections between neurons (as in the cerebral cortex) and longer range inhibitory connections can lead to the formation of topographic maps where the closeness in the map reflects the similarity between the inputs being mapped.

B.20.2 Hypotheses about the genes that could build different types of neuronal network in different brain areas

The hypotheses for the genes that might specify the different types of neuronal network in different brain areas are now introduced. The hypotheses are based on knowledge of the architectures of different brain regions, which are described in Chapter 1 and in sources such as the following (Shepherd, 2004; Shepherd and Grillner, 2010; Braitenberg and Schüz, 1991, 1998; Peters and Jones, 1984; Somogyi et al., 1998; Harris and Mrsic-Flogel, 2013; Kubota, 2014; Harris and Shepherd, 2015; Shepherd and Rowe, 2017), and on a knowledge of some of the parameters that influence the operation of neuronal networks. These genes were used in the simulations in which evolution of the architectures was explored using genetic algorithms. The emphasis in this section is on the rationale for suggesting different genes. A more formal specification of the genes, together with additional information on how they were implemented in the simulations, is provided in Section B.20.4.2. It may also be noted that large numbers of genes will be needed to specify for example the operation of a neuron. This Sect-

ion focusses on those genes that, given the basic building blocks of neurons, may specify the differences in the functional architecture of different regions of the cerebral cortex.

The overall concept is as follows. There are far too few genes (in humans 20,000–25,000 protein coding genes (Human Genome Sequencing, 2004)) to specify each synapse (i.e. which neuron is connected to which other neuron, and with what connection strength) in the brain. (The number of synapses in the human brain, with 10^{10} - 10^{11} neurons in the brain, and perhaps an average of 10,000 synapses each, is in the order of 10^{14} - 10^{15}). In any case, brain design is likely to be more flexible if the actual strength of each synapse is set up by self-organisation and experience. On the other hand, brain connectivity is far from random.

In more detail, a key constraint for building the cortex is that this has to be performed with relatively few genes for each cortical or brain region. Given that humans have fewer than 25,000 genes (with perhaps a further 5000 non-protein-coding regulators (Espinosa et al., 2022) that are likely to be important in humans (Zwir et al., 2022)), it is unlikely that more than 20% of the 25,000 (say 5000) are used to specify brain connectivity. If there are 180 cortical regions that can be identified in one hemisphere (in the HCP-MMP atlas (Glasser et al., 2016a; Huang et al., 2022)), then taking that number of 180, assuming that the other hemisphere uses many of the same genes, and the rest of the brain, might require say 250 brain regions to be specified. That might mean only 20 genes for specifying the specific connectivity of a brain region that makes it different from other brain regions. That type of argument leads to the hypothesis that the genes may specify to define one brain region as being different from another a few classes of neuron for each brain region that would have as specifiers what classes of other neurons they should connect to in the input and outputs regions of each brain region (Rolls and Stringer, 2000). This type of argument guided the hypotheses about what was being specified by genes to provide a basis on which self-organisation could build useful connectivity of individual networks in the brain, and also the whole brain. This is a key aspect of what is implied by the title of this book: *Brain Computations and Connectivity*: it is a fundamental part of understanding the brain to understand how its connectivity is built. Of course many more genes may be needed to specify each brain region, but those genes could be common among many brain regions. What is sought here are the specifiers that may define what is different about the connectivity of each brain region. Even though the actual hypotheses described so far for what these genes specify may develop over time, the overall approach taken here to how brains may be built by genes and self-organisation is what is important.

Some indications about what is specified can be gathered by considering the connectivity of the hippocampus (Chapter 9). The CA3 pyramidal cells each receive approximately 50 mossy fibre synapses from dentate granule cells, 12,000 synapses from other CA3 cells formed from recurrent collaterals, and 3,600 perforant path synapses originating from entorhinal cortex neurons (see Fig. 9.23). In the preceding stage, the 1,000,000 dentate granule cells (the numbers given are for the rat) receive one main source of input, from the entorhinal cortex, and each makes approximately 14 synapses with CA3 cells.

Specification of neuron classes, and of connection rules between classes

On the basis of considerations of this type for many different brain areas, it is postulated that for each class of cell the genome specifies the approximate numbers of synapses the class will receive from a specified other class (including itself, for recurrent collaterals), and the approximate number of synapses its axons will make onto specified classes of target cells (including itself). The individual neurons with which synapses are made are not specified, but are chosen randomly, though sometimes under a constraint (specified by another gene) about how far away the axon should travel in order to make connections with other neurons. One parameter value of the latter gene might specify the widespread recurrent collateral system of the CA3 neurons (Chapter 9). Another value for the latter might specify much more limited

spread of recurrent collaterals with the overall density decreasing rapidly from the cell of origin, which, as in the neocortex and if accompanied by longer range inhibitory processes implemented by feedback inhibitory neurons, would produce center-surround organisation, and tend to lead to the formation of topological maps (see Section B.4.6) and to local attractor networks.

The actual mechanism by which this specification of connection rules between classes of neuron is implemented would presumably involve some (genetically specified) chemical recognition process, together with the production of a limited quantity of a trophic substance that would limit the number of synapses from, and made to, each other class of cell. Consistent with this fundamental hypothesis, gene knockout investigations show that for example different genes specify the NMDA receptors in the cell classes: dentate gyrus, CA3, and CA1 (Nakazawa et al., 2002, 2003, 2004; Huerta et al., 2000). Genetic specifiers for connectivity in the neocortex are being considered (Schmidt and Polleux, 2021).

Some of these processes would of course be occurring primarily during development (ontogenesis), when simple rules such as making local connections as a function of distance away would be adequate to specify the connectivity, without the need for long pathway connection routes (such as between the substantia nigra and the striatum) to be genetically encoded. It is presumably because of the complex genetic specification that would be required to specify in the adult brain the route to reach all target neurons that epigenetic factors are so important in embryological development, and that as a general rule the formation of new neurons is not allowed in adult mammalian brains apart from in the hippocampal dentate gyrus (Section 9.3.6.6) (Rolls, 2016b).

It is a feature of brain neuronal network design that not only is which class of neuron to connect to apparently specified, but also approximately where on the dendrite the connections from each other class of neuron should be received. For example, in the CA3 system, the mossy fibres synapse closest to the cell body (where they can have a strong influence on the cell), the CA3 recurrent collaterals synapse on the next part of the dendrite, and the entorhinal inputs synapse on the more distal ends of the dendrites. The effect of the proximal relative to the more distal synapses will depend on a number of factors, including for distal inputs whether proximal inputs are active and thereby operating as current shunts producing division, and on the diameter of the dendrite, which will set its cable properties (Koch, 1999). If the dendritic cable diameter is specified as large, all inputs (including distal inputs) will sum reasonably linearly to inject current into the cell body.

Although inhibitory neurons have not been included in the examples already given, similar specifications would be applicable, including for example a simple specification of the different parts of the dendrite on which different classes of inhibitory neuron synapse (Kubota, 2014), and hence whether the effect is subtractive or shunting (Koch, 1999). In cortical areas, both feedforward and feedback inhibition (the latter from pyramidal cells via inhibitory neurons back to the same population of pyramidal cells) could be produced by a simple genetic specification of this type.

Specification of synaptic learning rules

Next, the nature of the synaptic connections, and the learning rule for synaptic modifiability, must be specified. One gene specifies in the simulation described later whether a given neuron class is excitatory or inhibitory. In the brain, this gene (or genes) would specify the transmitter (or transmitters in some cases) that are released, with the actual effects of for example glutamate being excitatory, and gamma-amino-butyric acid (GABA) inhibitory. The learning rule implemented at each synapse is determined by another gene (or genes). One possible effect specified is no synaptic modification. Another is a Hebb rule of associative synaptic plasticity (increase the synaptic strength if both presynaptic and postsynaptic activity are high,

the simple rule implemented by associative long-term potentiation (LTP)). For this, the genes might specify NMDA (n-methyl-d-aspartate) receptors on the post-synaptic neurons together with the linked intracellular processes that implement LTP (Bliss and Collingridge, 2013; Takeuchi et al., 2014; Bliss and Collingridge, 2019; Moser et al., 2021) (Section 1.6). Another possible effect is long-term depression (LTD). This may be heterosynaptic, that is the synaptic weight may be decreased if there is high post-synaptic activity but low presynaptic activity. Part of the utility of this in the brain is that when combined with LTP in pattern associators and autoassociators the effect is to remove the otherwise positive correlation that would be produced between different input patterns if all patterns are specified by positive-only firing rates, as they are in the brain. The effect of removing this correlation is to reduce interference between patterns, and to maximize the storage capacity (see earlier in this Appendix B). A further useful property of heterosynaptic LTD is that it can help to maintain the total synaptic strength onto a neuron constant, by decreasing synaptic strengths from inputs to a neuron which are inactive when the neuron is currently firing. This can be very useful in competitive networks to prevent some winning neurons from continually increasing their synaptic strength so that they win to all patterns, and can in addition be seen as part of the process by which the synaptic weight vector is moved to point in the direction of a current input pattern of neuronal activity (see Section B.4). Another type of LTD is homosynaptic, in which the synaptic strength decreases if there is high presynaptic activity but low or moderate postsynaptic activity. This might be useful in autoassociative synaptic networks, as combined with LTP and heterosynaptic LTD it can produce a covariance-like learning rule.

Another learning rule of potential biological importance is a trace learning rule, in which for example the post-synaptic term is a short term average in an associative Hebb-like learning rule. This encourages neurons to respond to the current stimulus in the same way as they did to previous stimuli. This is useful if the previous stimuli are different views etc of the same object (which they tend statistically to be in our visual world), because this promotes invariant responses to different versions of the same object. Use of such a rule has been proposed to be one way in which networks can learn invariant responses (Rolls, 2012d, 2021d) (Chapter 2). Such a trace could be implemented in real neurons by a number of different mechanisms, including slow unbinding of glutamate from the NMDA receptor (which may take 100 ms or more), and maintaining a trace of previous neuronal activity by using short term autoassociative attractor memories implemented by recurrent collaterals in the cerebral neocortex (Rolls and Treves, 1998) (Section 1.14.5 and Chapter 13).

Other types of synaptic modification that may be genetically specified include non-associative LTP (as may be implemented by the hippocampal mossy fibre synapses), and non-associative LTD. Other genes working with these may set parameters such as the rapidity with which synapses learn (which in a structure such as the hippocampus may be very fast, in one trial, to implement memory of a particular episode, and in structures such as the basal ganglia may be slow to enable the learning of motor habits based on very many trials of experience); and the initial and maximal values of synapses (e.g. the mossy fibre synapses onto hippocampal CA3 cells can achieve high values).

Specification of the operation of neurons

Another set of genes specifies some of the biophysical parameters that control the operation of individual neurons (see Koch (1999) for background). One gene (in a simulation, or biologically perhaps several) specifies how the activation h_i of a neuron i is calculated. A linear sum of the inputs r'_j weighted by the synaptic weights w_{ij} is the standard one used in most models of biologically plausible neuronal networks (Section 19.4), and those simulated here, as follows:

$$h_i = \sum_j r'_j w_{ij} \quad (\text{B.139})$$

where \sum_j indicates that the sum is over the C input axons (or connections) indexed by j . An alternative is that there is non-linearity in this process, produced for example by local interactions in dendrites, including local shunting, affected most notably by the cable diameter of the dendrite, which is what such genes may control. For most pyramidal cells, the dendrite diameter is sufficiently large that linear summation to produce the net current injected into the cell bodies is a reasonable approximation (Koch, 1999).

Several further genes set the activation function of the neuron. (The activation function is the relation between the activation of the neuron and its firing. Examples are shown in Fig. 1.3). One possibility is linear. A second, and the most biologically plausible, is to have a threshold, followed by a part of the curve where the firing rate increases approximately linearly with the activation, followed by a part of the curve where the firing rate gradually saturates to a maximum. This function can be captured by for example a sigmoid activation function as follows:

$$r_i = \frac{1}{1 + e^{-2\beta(h_i - \alpha)}} \quad (\text{B.140})$$

where α and β are the sigmoid threshold and slope, respectively. The output of this function, also sometimes known as the logistic function, is 0 for an input of $-\infty$, 0.5 for h_i equal to α , and 1 for $+\infty$. For this type of activation function, at least two genes would be needed (and biologically there would probably be several to specify the biophysical parameters), one to control the threshold, and a second to control the slope. A third possibility is to have a binary threshold, producing a neuron which moves from zero activity below threshold to maximal firing above threshold. This activation function is sometimes used in mathematical modelling because of its analytic tractability.

One variable that is controlled by the threshold (and to some extent the slope) of the activation function is the proportion of neurons in a population that are likely to be firing for any one input. This is the population sparseness of the representation. If the neurons have a binary activation function, the population sparseness may be measured just by the proportion of active neurons, and takes the value 0.5 for a fully distributed representation, in which half of the neurons are active. For neurons with continuous activation functions, the population sparseness a may be defined as

$$a = \frac{(\sum_i r_i / N)^2}{\sum_i r_i^2 / N} \quad (\text{B.141})$$

where N is the number of neurons in the population and r_i is the rate of the i th neuron in the population (Appendix B). This works also for binary neurons. To provide precise control of the sparseness in some of the simulations described below we made provision for this to be controlled as an option directly by one gene, rather than being determined indirectly by the threshold and slope gene-specified parameters of the sigmoid activation function shown in Eq. B.140.

B.20.3 Genetic selection of neuronal network parameters to produce different network architectures with different functions

Given the proposals just described for the types of parameter that are determined by different genes, we describe next how gene selection is postulated to lead to the evolution of neuronal networks adapted for particular (computational) functions. The description is phrased in terms of simulations of the processes using genetic algorithms, as investigations of this type enable the processes to be studied precisely. The processes involve reproduction, ontogenesis

Fig. B.48 A landscape with a broadly unimodal space but with many local optima that is susceptible to genetic search to find the top of the highest peak.

followed by tests of how well the offspring can learn to solve particular problems, and natural selection.

First, a selection of genes is made for a set of G genotypes in a population, which should be of a certain minimum size for evolution to work correctly. The genes are set out on a chromosome (or chromosomes). (Effects of gene linkage on a chromosome are not considered here.) Each set of genes is a genotype. The selection of individual genotypes from which to breed is made a probabilistic function which increases with the fitness of the genotype, measured by a fitness function that is quantified by how well that genotype builds an individual that can solve the computational problem that is set.

Having chosen two genotypes in this way, two genotypes to specify two new (haploid) offspring for the next generation are made by the genetic processes of sexual reproduction involving both gene recombination and mutation, which occur with specified probabilities. This process is repeated until G genotypes have been produced. Then G individuals are built with the network architectures specified by the G genotypes. The fitness of these individuals is then measured by how well they perform at the computational problem set.

In order to solve the computational problem, the networks are trained by presenting the set of input patterns, and adjusting the synaptic weights in the network according to the learning rules specified by the genotype of that individual. The individuals then breed again with a probability of being selected for reproduction that is proportional to their fitness relative to that of the whole population.

This process is allowed to proceed for many generations, during which the fitness of the best individual in the population, and the average fitness, both increase if evolution is working.

This type of genetic process is an efficient method of searching through a high dimensional space (the space specified by the genes), particularly where the space has many local optima so that simple hill climbing is inefficient, and where there is a single measure of fitness (Holland, 1975; Ackley, 1987; Goldberg, 1989). An example of such a landscape is shown in two dimensions in Fig. B.48. The sexual reproduction by allowing recombination of genes facilitates local hill-climbing in such a landscape. However, once the top of the local hill is reached, the process may become stuck at the top of the hill. Mutations have the effect of allowing a random jump to another part of the space, where the local hill-climbing can begin all over again. The combination of sexual reproduction and occasional mutations is an efficient way to find the top of the highest hill in the landscape, and this is part of the mathematical basis for how evolution works by using natural selection operating on changes made using both sexual reproduction and occasional mutations.

An additional useful feature of genetic search is that past gene combinations, useful possibly in other contexts, can remain in the population for a number of generations, and can then be reused later on, without the need to search for those gene combinations again. This re-use of past combinations is one of the features of genetic search that can make it powerful, rapid, and show sudden jumps forward.

B.20.4 Simulation of the evolution of neural networks using a genetic algorithm

Next I describe simulations of these processes using a genetic algorithm, in order to make explicit some of the parameters hypothesized. The aims of the simulations are to demonstrate the feasibility and details of the hypotheses and approach; to provide an indication of whether the proposed genes can be used to guide efficiently the evolution of networks that can solve computational problems of the type solved by the brain; and to provide a tool for investigating in more detail both the parameters that can best and biologically plausibly be genetically specified to define neural networks in the brain, and more complicated multilayer networks that operate to solve computationally difficult problems such as episodic memory or invariant visual object recognition. The proposals were tested to determine whether three different types of one-layer network with different architectures appropriate for solving different computational problems evolve depending on the computational problem set (Rolls and Stringer, 2000). The problems were those appropriate for the pattern associator, autoassociator, and competitive networks shown schematically in Fig. 1.7.

B.20.4.1 The neural networks

The neural networks considered have a number of classes of neuron. Within a class, a gene allows the number of neurons to vary from 1 up to N . For the simulations described here, N was set to 100. Within a class, the genetic specification of a neuron is homogeneous, with the neurons for that class having, for example, identical activation functions and connectivity probabilities. The number of classes will depend on the individual task, e.g. pattern association, autoassociation, competitive nets, etc, which can be described as one-layer networks, with one layer of computing elements between the input and output (see Fig. 1.7). However, in our simulations there is typically an input layer where patterns are presented, and an output layer where the performance of the network is tested. For the simulations described, the number of classes was set to allow one-layer networks such as these to be built, but the number of layers that could be formed is in principle under genetic control, and indeed multilayer networks can be formed if there is a sufficient number of classes of neuron. Regarding the implementation of inter-layer connection topologies, the neurons in individual layers exist in a circular arrangement, and connections to a cell in one layer are derived from a topologically related region of the preceding layer. Connections to individual neurons may then be established according to either a uniform or Gaussian probability distribution centered on the topologically corresponding location in the sending layer.

On discrete time steps each neuron i calculates a weighted sum of its inputs as shown in Equation B.139. This is in principle the subject of genetic modification (see below), but the gene specifying this was set for the simulations described here to this type of calculation of the neuronal activation. Next the neuronal firing r_i is calculated, using for example the standard sigmoid function shown in Equation B.140 and allowing α and β the sigmoid threshold and slope to evolve genetically. Next, there is an optional procedure that can be specified by the experimenter to be called to set the sparseness of the firing rates r_i of a class of neuron according to Equation B.141, with a being allowed to evolve. This specification is used in the simulations, but in the cortex in this and other similar cases a number of genes would specify factors that influence this, such as in this case the strength of the feedback inhibition implemented by inhibitory neurons. After the neuronal outputs r_i have been calculated, the synaptic weights w_{ij} are updated according to one of a number of different learning rules, which are capable of implementing for example both long term potentiation (LTP) and long term depression (LTD), as described below, and which are genetically selected. For example, the standard Hebb rule takes the form

$$\Delta w_{ij} = kr_i r'_j, \quad (\text{B.142})$$

where r'_j is the presynaptic firing rate and k is the learning rate.

B.20.4.2 The specification of the genes

The genes that specify the architecture and operation of the network are described next. In principle, each gene evolves genetically, but for particular runs, particular genes can be set to specified values to allow investigation of how other genes are selected when there are particular constraints.

Each neural network architecture is described by a genotype consisting of a single chromosome of the following form

$$\text{chromosome} = \begin{bmatrix} \mathbf{c}_1 \\ \mathbf{c}_2 \\ \vdots \\ \mathbf{c}_n \end{bmatrix} \quad (\text{B.143})$$

where \mathbf{c}_l is a vector containing the genes specifying the properties of neurons in class l , and n is the total number of classes that is set manually at the beginning of a run of the simulation. The vectors \mathbf{c}_l take the form

$$\mathbf{c}_l = \begin{bmatrix} \mathbf{g}_l \\ \mathbf{h}_{l1} \\ \mathbf{h}_{l2} \\ \vdots \\ \mathbf{h}_{ln} \end{bmatrix} \quad (\text{B.144})$$

where the vector \mathbf{g}_l contains the *intra*-class properties for class l , and the vectors \mathbf{h}_{lm} contain the *inter*-class connection properties to class l from class m where m is in the range 1 to n .

The vector of intra-class properties takes the form

$$\mathbf{g}_l = \begin{bmatrix} b_l \\ \alpha_l \\ \beta_l \\ a_l \end{bmatrix} \quad (\text{B.145})$$

where we have the following definitions for intra-class genes.

(1) b_l is the number of neurons in class l . b_l is an integer bounded between 2 and N , which was set to 100 for the simulations described here. Individual classes are restricted to contain more than one neuron since a key strategy we have adopted for enhancing the biological plausibility is to evolve classes composed of a number of neurons with homogeneous genetic specifications rather than to specify genetically the properties of individual single neurons.

(2) α_l is the threshold of the sigmoid transfer function in Equation B.140 for class l . α_l is a real number bounded within the interval [0.0,200.0].

(3) β_l is the slope of the sigmoid transfer function in Equation B.140 for class l . β_l is a real number bounded within the interval [0.0,200.0]. We note that low values of the slope will effectively specify a nearly linear activation function, whereas high values of the slope specify a nearly binary activation function (see Fig. 1.3).

(4) a_l is the sparseness of firing rates within class l as defined by Equation B.141. By definition a_l is a real number bounded within the interval $[0.0,1.0]$. However, in practice we ensure a minimum firing sparseness by setting a_l to lie within the interval $[1.0/b_l,1.0]$, where b_l is the number of neurons in class l . With binary neurons with output r equal to either 0 or 1, setting $a_l \geq 1.0/b_l$ ensures that at least one neuron is firing. For the simulations described in this Chapter, when this gene was being used, a was set to 0.5 and produced a binary firing rate distribution with a sparseness of 0.5 unless otherwise specified. The alternative way of calculating the firing rates was to allow genes α and β specifying the sigmoid activation function to evolve.

The vectors of inter-class connection genes specify the connections to class l from class m , and take the form

$$\mathbf{h}_{lm} = \begin{bmatrix} r_{lm} \\ s_{lm} \\ c_{lm} \\ e_{lm} \\ z_{lm} \\ t_{lm} \\ p_{lm} \\ \sigma_{lm} \\ q_{lm} \\ f_{lm} \\ k_{lm} \\ d_{lm} \\ u_{lm} \\ v_{lm} \end{bmatrix} \quad (\text{B.146})$$

where we have the following definitions for inter-class genes.

(1) r_{lm} controls the inter-layer connection topology in that it helps to govern which neurons in class m make connections with individual neurons in class l . The exact definition of r_{lm} depends on the type of probability distribution used to make the connections, which is governed by the gene s_{lm} described below. For $s_{lm} = 0$, connections are established according to a uniform distribution, and r_{lm} specifies the number of neurons within the spatial region from which connections may be made. For $s_{lm} = 1$, connections are established according to a Gaussian distribution, where r_{lm} specifies the standard deviation of the distribution. For the Gaussian distribution, individual connections originate with 68% probability from within a region of 1 standard deviation away. These real valued variates are then rounded to their nearest integer values. As noted in section B.20.2, connection topologies are characteristically different for different connection types such as CA3 recurrent collateral connections, which are widespread, and intra-module connections in the cerebral cortex. This parameter may also be set by genetic search to enable the region of effect of inhibitory feedback neurons to be just greater than the region within which excitatory neurons receive their input; and to enable topographic maps to be built by arranging for the lateral excitatory connections to operate within a smaller range than inhibitory connections. This parameter may also be set to enable multilayer networks to be built with feedforward connectivity which is from a small region of the preceding layer, but which over many layers allows an output neuron to receive from any part of the input space, as happens in many sensory systems in which topology is gradually lost and as is implemented in a model of the operation of the visual cortical areas (Chapter 2). For the simulations described here, this gene was set to 100 to allow global con-

nectivity, and thus to not specify local connectivity.

(2) s_{lm} specifies for the region gene r_{lm} the connection probability distribution to class l from class m . s_{lm} takes the following values.

- $s_{lm} = 0$: Connections are established according to a uniform probability distribution within the region r_{lm} .
- $s_{lm} = 1$: Connections are established according to a Gaussian probability distribution. r_{lm} specifies the size of the region from which there is a 68% probability of individual connections originating.

In the experiments described here, the values of s were set to 0.

(3) c_{lm} is the number of connections each neuron in class l receives from neurons in class m . c_{lm} takes integer values from 0 to b_m (the number of neurons within class m). These connections are made probabilistically, selecting for each class l of neuron c_{lm} connections from class m . The probabilistic connections are selected either from a uniform probability distribution (as used here), or according to a Gaussian probability distribution. In both cases the local spatial connectivity within the two classes l and m is specified by the region parameter gene r_{lm} .

(4) e_{lm} specifies whether synapses to class l from class m are excitatory or inhibitory. e_{lm} takes the following values.

- $e_{lm} = 0$: Connections are inhibitory
- $e_{lm} = 1$: Connections are excitatory

For inhibitory connections with $e=0$, the weights in Equation (B.139) are scaled by -1 , and no learning is allowed to take place.

(5) z_{lm} specifies whether connections from class m to class l are additive or divisive. z_{lm} takes the following values.

- $z_{lm} = 0$: Connections are divisive
- $z_{lm} = 1$: Connections are additive

This gene selects whether the neuronal activation h_i is calculated according to linear summation of the input firing rates r'_j weighted by the synaptic strengths w_{ij} , as specified by Eq. B.139, and as used throughout by setting $z_{lm} = 1$; or whether with $z_{lm} = 0$ there is local computation on a dendrite including perhaps local summation of excitatory inputs and shunting effects produced by inhibitory inputs or inputs close to the cell body. The most important physical property of a neuron that would implement the effects of this gene would be the diameter of the dendrite (see Section B.20.2 and (Koch, 1999)). If set so that $z_{lm} = 0$ for local multiplicative and divisive effects to operate, it would be reasonable and in principle straightforward to extend the genome to include genes which specify where on the dendrite with respect to the cell body synapses are made from class m to class l neurons, the cable properties of the dendrite, etc.

(6) t_{lm} specifies how the synaptic weights to class l from class m are initialised at the start of a simulation. t_{lm} takes the following values.

- $t_{lm} = 0$: Synaptic weights are set to zero. This might be optimal for the conditioned stimulus inputs for a pattern associator, or the recurrent collateral connections in an autoassociator, for then existing connections would not produce interference in the synaptic

connections being generated during the associative learning. This would produce a non-operating network if used in a competitive network, for an input could not produce any output.

- $t_{lm} = 1$: Synaptic weights are set to a uniform deviate in the interval $[0,1]$ scaled by the constant value encoded on the genome as q_{lm} (described below).
- $t_{lm} = 2$: Synaptic weights are set to the constant value encoded on the genome as q_{lm} (described below). This could be useful in an associative network if a learning rule that allowed synaptic weights to decrease as well as increase was specified genetically, because this would potentially allow correlations between the input patterns due to positive-only firing rates to be removed, yet prevent the synapses from hitting the floor of zero, which could lose information (Rolls and Treves, 1998).
- $t_{lm} = 3$: Synaptic weights are set to a Gaussian function of distance x away from the afferent neuron in class l . This function takes the form

$$f(x) = \frac{1}{\sigma\sqrt{2\pi}} e^{-x^2/2\sigma^2}$$

where σ is the standard deviation. This would be an alternative way to implement local spatial connectivity effects to those implemented by r_{lm} .

(7) p_{lm} is the scale factor used for synaptic weight initialisation with a Gaussian distribution (i.e. for $t_{lm} = 3$). p_{lm} is a real number bounded within the interval $[0.0,100.0]$.

(8) σ_{lm} is the standard deviation used for synaptic weight initialisation with a Gaussian distribution (i.e. for $t_{lm} = 3$). σ_{lm} is a real number bounded within the interval $[0.001,10.0]$. σ_{lm} is restricted to be greater than 0.001 to avoid a singularity that would occur in the Gaussian function for $\sigma_{lm} = 0.0$.

(9) q_{lm} is the scale factor used for synaptic weight initialisation for $t_{lm} = 1$ and $t_{lm} = 2$ (see above). q_{lm} is a real number bounded within the interval $[0.0,100.0]$. If t_{lm} is 1 or 2, q_{lm} would be expected to be small for pattern associators and autoassociators (as described above).

(10) f_{lm} specifies which learning rule is used to update weights at synapses to class l from class m . f_{lm} takes the following values.

- $f_{lm} = 0$: Learning rule 0 (no learning) $\Delta w_{ij} = 0$.
- $f_{lm} = 1$: Learning rule 1 (Hebb rule) $\Delta w_{ij} = kr_i r'_j$.
- $f_{lm} = 2$: Learning rule 2 (modified Hebb rule) $\Delta w_{ij} = kr_i(r'_j - \langle r'_j \rangle)$ where $\langle . \rangle$ indicates an average value. In this rule LTP is incorporated with heterosynaptic LTD set to keep the average weight unchanged. Use of this rule can help to remove the correlations between the input patterns produced by positive-only firing rates (Rolls and Treves, 1998). If this rule is selected, it will work best if the synaptic weight initialisation selected genetically is not zero (to allow the weights to decrease without hitting a floor), and is optimally a constant (so that noise is not added to the synaptic weights which implement the association).
- $f_{lm} = 3$: Learning rule 3 (modified Hebb rule) $\Delta w_{ij} = kr_i(r'_j - w_{ij})$. This rule has the effect of helping to maintain the sum of the synaptic weights on a neuron approximately constant, and is therefore helpful in competitive networks (Rolls and Treves, 1998). This rule accords with the neurophysiological observation that it is easier to demonstrate LTD after LTP has been produced.
- $f_{lm} = 4$: Learning rule 4 (covariance rule) $\Delta w_{ij} = k(r_i - \langle r_i \rangle)(r'_j - \langle r'_j \rangle)$.

- $f_{lm} = 5$: Learning rule 5 (homosynaptic LTD with LTP) $\Delta w_{ij} = k(r_i - < r_i >)r'_j$.
- $f_{lm} = 6$: Learning rule 6 (non-associative LTP) $\Delta w_{ij} = kr'_j$. This rule may be implemented in the hippocampal mossy fibre synapses.
- $f_{lm} = 7$: Learning rule 7 (non-associative LTD) $\Delta w_{ij} = -kr'_j$.
- $f_{lm} = 8$: Learning rule 8 (trace learning rule) $\Delta w_{ij} = k\bar{r}_i^\tau r_j^{\tau'}$ where the trace \bar{r}_i^τ is updated according to

$$\bar{r}_i^\tau = (1 - \eta)r_i^\tau + \eta\bar{r}_i^{\tau-1} \quad (\text{B.147})$$

and we have the following definitions: \bar{r}_i^τ is the trace value of the output of the neuron at time step τ , and η is a trace parameter which determines the time or number of presentations of exemplars of stimuli over which the trace decays exponentially. The optimal value of η varies with the presentation sequence length. Further details, and a hypothesis about how this type of learning rule could contribute to the learning of invariant representations, are provided in Chapter 2. For the simulations described by Rolls and Stringer (2000), this learning rule was disabled.

(11) k_{lm} is the learning rate k for synaptic weights to class l from class m . k_{lm} is a real number bounded within the interval $[0.0, 10.0]$.

(12) d_{lm} is the maximum size allowed for the absolute value of synaptic weight updates from class m to class l . d_{lm} is a real number bounded within the interval $[0.0, 10.0]$.

(13) u_{lm} is the maximum size allowed for synaptic weights to class l from class m . u_{lm} is a real number bounded within the interval $[-100.0, 100.0]$.

(14) v_{lm} is the minimum size allowed for synaptic weights to class l from class m . v_{lm} is a real number bounded within the interval $[-100.0, 100.0]$.

Implementation details are that v is bounded to be less than u ; and that during initialisation of the synaptic weights, v and u are applied after the other initialisation parameters have operated.

B.20.4.3 The genetic algorithm, and general procedure

The genetic algorithm used was a conventional one described by Goldberg (1989). Each individual genotype was a haploid chromosome of the type just defined. The values for the genes in the initial chromosome were chosen at random from the possible values. (In this simulation, if a value in the genotype was one of a large number of possible values, then a single integer or real-valued gene was used, whereas in the brain we would expect several genes to be used, with perhaps each of the several genes coding for different parts of the range with different precision. For example, c_{lm} , the number of synaptic connections to a neuron in class l from a neuron in class m , is to be chosen from 2 to 100 in the simulation, and uses a single integer. In the brain, where we might expect the number of connections per neuron to vary in the range 5 to 50,000, one possible scenario is that 5 different genes would be used, coding for the values 5, 50, 500, 5,000 and 50,000. We would thus expect that the number of genes required to specify the part of the genotype described here would increase by a factor in the order of 5 in the brain.)

There was a set number of genotypes (and hence individuals) per generation, which was 100 for the simulations described. (Too small a number reduces the amount of diversity in the population sufficiently to lead to poor performance of the genetic evolution.) From each

genotype an individual network was constructed, with all connections being chosen probabilistically within the values specified by the genotype, and with a uniform probability distribution (i.e. s_{lm} was set to 0 for the simulations described), and the initial values for the synapses were also chosen as proscribed by the genotype. That individual was then tested on the computation being studied, e.g. pattern association, and the fitness (performance) of the network was measured. The actual testing involved presenting the set of patterns to be learned (as specified below for each network) to the network while allowing learning to occur, and then testing the performance of the network by presenting the same, similar, or incomplete test patterns and measuring the output of the network. The fitness measure used for each class of network is defined below. This process was repeated until a fitness measure had been obtained for each of the genotypes.

The next generation of genotypes was then bred by reproduction from the previous genotypes. Two genotypes were selected for reproduction with a probability that was proportional to their fitness relative to the sum of the fitnesses of all individuals in that generation. That is, the probability P_i of an individual i being selected is given by

$$P_i = \frac{F_i}{\sum_j F_j} \quad (\text{B.148})$$

where F_j is the fitness of an individual genotype j , and the sum $\sum_j F_j$ is over all individuals in the population. The genotypes were then bred to produce two offspring genotypes using the processes of recombination and mutation. The probability of recombination was set to 0.4 (so that it occurred with a 40% chance for every breeding pair in every generation), and the probability of mutation of each gene was set to 0.05. The computational background to this is that recombination allows a non-linear search of a high dimensional space in which gene complexes or combinations may be important, allowing local performance hills in the space to be detected, and performance once in a local hill to improve. Mutation on the other hand enables occasional moves to be tried to other parts of the space, usually with poorer performance, but occasionally moving a genotype away from a well explored location to a new area to explore. Both processes enable the search to be much more efficient in a high dimensional space with multiple performance hills or mountains than with simple gradient ascent, which will climb the first hill found, and become stuck there (Ackley, 1987; Goldberg, 1989). The recombination took place with respect to a random point on the chromosome each time it occurred. The mutation also took place at a random place on the chromosome each time it occurred, and the single gene being mutated was altered to a new random value within the range specified for that gene.

This reproduction process was repeated until sufficient individual genotypes for the next generation (100 unless otherwise stated) had been produced. The fitness of those genotypes was then measured by building and testing the networks they specified as previously outlined. Then the whole reproduction, ontogenesis, and testing to measure fitness, processes were repeated for many generations, to determine whether the fitness would increase, and if so, what solutions were found for the successful networks.

B.20.4.4 Pattern association networks

The operation of the system simulated is described briefly for the three networks, emphasizing the generic points. Details of the simulations and the explorations with them are described by Rolls and Stringer (2000).

The computational problem set was to associate pairs of random binary patterns of 1s and 0s with sparseness of 0.5 (i.e. with half the elements 0 and the other half 1s), an appropriate problem for a pattern association net (Appendix B). There were 10 pattern pairs, which places

Fig. B.49 Fitness of the best genotype in the pattern association task as a function of the number of generations, together with the values of selected genes. The simulation is performed with the firing rates assigned binary values of 0 or 1 according to the neuronal activations, with the proportion of neurons firing set by the firing rate sparsity gene α . The parameters shown all refer to connections from class 1 (the input neurons) to class 2 (the output neurons). The final values of the parameters are shown at the end of each plot. For example, the genetic algorithm set the number of connections onto each output neuron as 90, a relatively high number (the maximum was 100), which results in a high memory capacity, which was what the fitness function was set to optimize. (After Rolls, E. T. and Stringer, S. M. 2000. On the design of neural networks in the brain by genetic evolution. *Prog Neurobiol* 61: 557-579.)

a reasonable load on the network (Rolls and Treves, 1998) (Section B.2). There were two classes of neuron. One of the patterns of the pair, the unconditioned stimulus, was set during learning to activate the 100 output neurons (class 2) during learning, while the other pattern of the pair, the conditioned stimulus, was provided by the firing of 100 input neurons (class 1). The fitness measure was obtained by providing each conditioned stimulus (or a fraction of it), and measuring the correlation of the output vector of firing rates, r_i where $i = 1$ to 100, with that which was presented as the unconditioned stimulus during learning. This correlation measure ranges from 1.0 for perfect recall to 0.0 (obtained for example if the output of the pattern associator is 0). The fitness measure that was used in most runs was the square of this correlation (used to increase the selectivity of the fitness function). (In practice, a pattern associator with associatively modifiable synapses, random patterns, and the sizes and loading of the networks used here can achieve a maximum correlation of approximately 1.000.) It may be noted that the genetics could form connections onto individual neurons of any number (up to $N = 100$, the number of input and output neurons in the network) and type between classes 1 to 2 (feedforward connections), and 2 to 2 (recurrent collaterals), 2 to 1, and 1 to 1. For the simulations performed, the operation of inhibitory feedback neurons was not explicitly studied, although when using the sigmoid activation function the neurons had to select a threshold (by altering α_l).

The values of the fitness measures for a typical run of the simulations are shown in Fig. B.49, along with the values of specific genes. The genes shown are key connection properties from class 1 to class 2, and are: learning rate k_{21} , number of connections c_{21} , weight scaling q_{21} , weight initialisation option t_{21} , and the learning rule f_{21} . The fitness measure is the fitness of the best genotype in the population, and for this run the sparseness of the output

representation was set to the value of 0.5 by using the sparseness gene set to this value. It is shown that evolution to produce genotypes that specify networks with high performance occurred over a number of generations. Some genes, such as that specifying the learning rule, settled down early, and changes in such genes can sometimes be seen to be reflected in jumps in the fitness measure. An example in Fig. B.49 is the learning rule, which settled down (for the best genotype) by generation 3 to a value of 4 which selects the covariance learning rule. Another example is that there is a jump in the fitness measure from generation 4 to 5 which occurs when the synaptic weight initialisation gene t_{21} changes from a Gaussian distribution to a constant value. This would be expected to increase the performance in these simulations. The increase in fitness from generation 7 to 8 occurred when the minimum weight gene v_{21} changed from 11.6 to -62.5 (not plotted), which would also be expected to increase performance. For other genes, where the impact is less or zero, the values of the genes can fluctuate throughout evolution, because they are not under selection pressure, in that they do not contribute greatly to fitness. Every run of the simulation eventually produced networks with perfect performance. The selection pressure (relative to other genotypes) could be increased by taking a power greater than 1 of the correlation fitness measure. A high value could produce very rapid evolution, but at the expense of minimising diversity early on in evolution so that potentially good genes were lost from the population, with then a longer time being taken later to reach optimal performance because of the need to rely on mutations. Low values resulted in slow evolution. In practice, raising the correlation fitness measure to a power of 1 (no change) or 2 produced the best evolution.

The best networks all had close to 100 excitatory feedforward connections (gene c_{21}) to each class 2 (output) neuron from the class 1 (input) neurons, which is the minimal number necessary for optimal performance of a fully loaded pattern associator and the maximum number allowed. Moreover, the excitatory feed forward connections for all the successful networks were specified as associative, and in particular f_{21} was selected for these networks as 2 or 4. distributions to achieve optimal results in a pattern associator.

To help understand in full detail the actual gene selections found by the genetic algorithm in the simulations, we were able to simulate the pattern associator with manually selected gene combinations for the feedforward connections from class 1 to class 2. In particular, we calculated the network fitnesses for particular combinations of learning rule f_{21} , weight initialisation option t_{21} , and weight scaling q_{21} . This optional facility of the simulator allowed systematic investigation of the effects of one gene, which could be held fixed at a particular value, on the values of the other genes selected during evolution. Examples of the usefulness of this approach are described by Rolls and Stringer (2000).

B.20.4.5 Autoassociative networks

The computational problem set was to learn random binary pattern vectors (of 1s and 0s with sparseness of 0.5, i.e. with half the elements 0 and the other half 1s), and then to recall the whole pattern when only half of it was presented. This is called completion, and is an appropriate test for an autoassociator (Section B.3). An additional criterion, inherent in the way the simulation was run, was to perform retrieval by using iterated processing in an attractor-like state of steady memory retrieval like that of continuing neuronal firing in a short-term memory (Section B.3).

Most runs of the simulation produced networks with optimal performance. The best networks all had close to 100 excitatory recurrent collateral feedback connections from the output neurons (class 1) to themselves, which is the minimal number necessary for optimal performance of a fully loaded autoassociator given that there are 100 output neurons and that this is the maximum number allowed. The successful networks also had all evolved to use ei-

ther the covariance or the heterosynaptic LTD learning rule (Rolls and Stringer, 2000), which are necessary for good performance of the autoassociation network (Section B.3).

B.20.4.6 Competitive networks

The computational problem set was to learn to place into separate categories 20 binary pattern vectors each 100 elements long. First, 5 exemplar patterns were randomly generated with 50 1s and 50 0s. Then, for each exemplar, 3 further patterns were created by mutating 20 of the bits from 0 to 1 or 1 to 0. This gave a total of 20 patterns that could be placed in 5 similarity categories. There were two classes of neuron. Class 1 was the input class, consisted of 100 neurons, and was set to fire according to which input pattern was being presented. Class 2 was the output class. Connections were possible from class 1 to 2, from class 1 to 1, from class 2 to 1, and from class 2 to 2. The network shown in Fig. B.15, if trained with learning rule 3 and given a powerful and widespread lateral inhibition scheme can solve this problem (Section B.4). The fitness measure used assessed how well the competitive net was able to classify the 20 patterns into their respective 5 categories.

The simulation runs typically converged to use learning rules 2 or 3, although learning rule 3 appeared to offer the best performance. Learning rule 3 involves LTP, plus LTD proportional to the existing value of the synaptic weight. This is the only rule which actually encourages the synaptic weight vectors of the different output (class 2) neurons to have a similar and limited total value. Use of a learning rule such as this (or explicit normalization of the length of the synaptic weight vector of each neuron), is advantageous in competitive networks, because it prevents any one neuron from learning to respond to all the input patterns (Section B.4). The fact that this learning rule was never chosen by the successful genotypes in the associative nets, but was generally chosen for the competitive nets, is evidence that the genetic evolution was leading to appropriate architectures for different computational problems. Learning rule 0 (no learning) was never chosen by the successful genotypes, and in addition we verified that good solutions to the problem set could not be produced without learning.

Another characteristic of the successful genotypes was that there appeared to be less selection pressure on c_{21} the number of connections to a class 2 from a class 1 neuron, with some highly fit nets having relatively low values for c_{21} . Such diluted connectivity can be useful in competitive networks, because it helps to ensure that different input patterns activate different output neurons (Section B.4) (Rolls, 2016f,b). Low values were never chosen for the best genotypes in the associative networks, where full connectivity is advantageous for full capacity.

B.20.5 Evaluation of the gene-based evolution of single-layer networks

The simulations described by Rolls and Stringer (2000) showed that the overall conception of using genes which control processes of the type described can, when combinations are searched through using genetic evolution utilising a single performance measure, lead to the specification of neural networks that can solve different computational problems, each of which requires a different functional architecture.

The actual genes hypothesized were based on a comparison of the functional neuronal network architectures of many mammalian brain regions, and were well able to specify the architectures described here. However, the research described is intended as a foundation for further exploration of exactly which genes are used biologically to specify real architectures in the mammalian brain which perform particular computations. We note in this context that it may be the case that exhaustive analysis of the genetic specification of an invertebrate with

a small number of neurons does not reveal the principles involved in building complex nervous systems and networks of the type addressed here. The genetic specification for simple nervous systems could be considerably different, with much more genetic specification of the properties of particular synapses to produce a particular more fixed network in terms both of which identified neuron is connected to which, and what the value of the synaptic connection strength between each neuron is. In contrast, in the approach taken here, there are not identifiable particular neurons with particular connections to other identifiable neurons, but instead a specification of the general statistics of the connectivity, with large numbers of neurons connecting according to general rules, and the performance of the network being greatly influenced by learning of the appropriate values of the connection strengths between neurons based on the co-activity of neurons, and the nature of the modifiable synaptic connection between them.

The particular hypotheses about the genes that could specify the functional architecture of simple networks in the brain were shown by the work described here to be sufficient to specify some different neuronal network architectures for use in a system that builds computationally useful architectures using a gene selection process based on fitness. The genes hypothesized may be taken as a guide to the types of genes that could be used to specify the functional architecture of real biological nervous systems, but the gene specification postulated and simulated can be simply revised based on empirical discoveries about the real genes. One choice made here was to specify the genes with respect to the receiving neuron. The reason for this, rather than specification with respect to the sending neuron, was that many of the controlling properties of the network architecture and performance are in the post-synaptic neuron. Examples of these properties include the type of post-synaptic receptor (e.g. NMDA receptors to specify associatively modifiable connections), and the cable properties of the postsynaptic neuron. The specification of the receiving neuron does include the appropriate information about the sending neuron, in that for example gene c_{lm} does specify (by identifier m) the identity of the sending population. This implies that when a neuron makes an output connection (through its synapses), the neuron class of the sending neuron is available (as a chemical recognition identifier) at the synaptic terminal. However, in principle, in terms of actually building a network, it would be possible to have the genetic specifiers listed as being properties of the sending neuron.

Another aspect of the gene specifiers hypothesized here is that there was no gene for how many output connections a class of neurons should make to another class. One reason for this is that the networks can be built numerically without such a specifier, as it is unnecessary if the total numbers of neurons of two classes is specified, and the number of connections received by one class of neuron from the other is specified. However, the number of output connections made to another class of neuron might be specified in real biological systems, and neuron numbers might adjust to reflect this type of constraint, which is a possible way to think about cell death during development. If there is local output connectivity within a certain spatial range, this will also act as a factor that determines the number of output connections made by neurons, and indeed this does seem a possible gene in real biological systems. Indeed, in real systems the single gene specifying the region of connectivity (r_{lm}) here might be replaced by different spatial genes specifying the extent of the dendrites of the receiving neuron, and extent of the axonal arborization for the outputs.

It is emphasized that a number of the genes specified here for the simulations might be replaced in real biological systems with several genes operating at a lower level, or in more detail, to implement the function proposed for each gene specified here. The reason for selecting the particular genes hypothesized here is that they serve as a guide to how in principle neuronal networks could be specified genetically in complex neural systems where the functional architecture is being selected for by genetic evolution. Specification of genes as op-

erating at the level described here provides a useful heuristic for investigation by simulation of how evolution may operate to produce neuronal networks with particular computational properties. Once the processes have been investigated and understood with genes operating at the level described here, subsequent investigations that use genes that are more and more biologically accurate and detailed would be facilitated and are envisaged. The approach allows continual updating of the genotype used in the simulations to help understand the implications of new discoveries in neurobiology.

The number of genes used in simulations of the type described here is now considered, remembering that biologically several genes might be required to specify at least some of the genes used in the simulations. The number of genes for each class of neuron in the simulations was $4 +$ (the number of classes of neuron from which the class receives connections $\times 14$). In the brain, if there were on average five classes of neuron from which each class of neuron received connections, this would result in $4 + 5 \times 14 = 74$ genes per class of neuron. If there were on average five classes of neuron per network, this would yield 370 genes per network. 100 such networks would require 37,000 genes, though in practice fewer might be needed, as some parameters might be assigned to be the same for many classes of neuron in different networks. For example, the overall functional architecture of the cerebral neocortex appears to follow the same general design for different architectonic areas (Braitenberg and Schüz, 1991; Peters and Jones, 1984; Somogyi et al., 1998; Douglas et al., 2004; Pandya et al., 2015), so much of the neocortex may use one generic network specification, with a few genes used to tweak the parameters for each different architectonic area. (An extension of the idea presented here would allow such a generic specification of the architecture of an area of the cerebral neocortex, and then allow genes to connect different areas with the same generic though locally tweaked architecture.) A factor working in the opposite direction is the fact that a single gene taking an integer or real value was used to specify some of the parameters in the simulation, whereas biologically several genes might be needed to represent such a wide range of parameter values with low, though sufficient, precision as described in Section B.20.4.3.

Although with 100 individuals per generation, and approximately 64 genes for each genotype (for networks with 2 classes of genes, each connected to each other as well as to themselves) each with several at least possible values, the search might be predicted to be long, in practice the genetic search was often quite short. Part of the reason for this is that some genes made a crucial difference, for example the gene specifying the learning rule, and were selected early on in evolution, usually being present in at least some of the genotypes in the initial population. Because these genes had such a dramatic effect on fitness, they were almost always selected for the next generation, and successive generations then had to search the smaller space of the remaining genes only some of which had a substantial impact on performance. Some genes, such as that specifying the learning rule, do indeed often settle down early, and changes in these genes can sometimes be seen to be reflected in jumps in the fitness measure. For other genes, where the impact is less or zero, the values of the genes can fluctuate throughout evolution, because they are not under selection pressure, in that they do not contribute greatly to fitness.

Although therefore in some senses the actual evolution investigated here takes place rapidly and apparently quite easily, this is part of the point of this research, that is to demonstrate that the particular genes identified as those which might allow the networks to be found in different brain areas to be built, and implemented in the simulations, can actually build these networks, and moreover can do so efficiently when using genetic search. However, the networks tested by Rolls and Stringer (2000) are single layer networks, and multilayer networks, with correspondingly more parameter combinations to be explored, will doubtless take longer to evolve in future simulations. Genetic search of the parameter space should then

become even more evident as a good procedure, because of its power in searching high dimensional spaces with many local optima and in which the parameters combine non-linearly; because of its use of a single measure of performance; and because of its ability to reuse genetic codes still present in a diverse population but originally developed for a different purpose. The intention however here is to specify the principles involved. Of course, there are many more details of the networks that could be explored by the existing gene specification, including inhibitory interneurons. Simulations of this type will not only enable the evolution and development of more complex multilayer networks to be explored, but will also enable the utility of the specification of different parameters by different genes to be explored, including details of where inputs end on dendrites, dendritic biophysical properties, and thus eventually networks that operate to simulate also the dynamics of the operation of real neural networks in the brain (Treves, 1993; Battaglia and Treves, 1998a; Panzeri et al., 2001; Rolls and Deco, 2010) (Section B.6).

B.20.6 The gene-based evolution of multi-layer cortical systems

We followed up these advances by simulating a two-layer network which was intended to show next how a two-layer network might evolve by the mathematical processes implemented by genetics. The system we chose was the dentate granule cells followed by the CA3 network. We used a cost function that was intended to capture the theoretical utility of the dentate granule cells acting as an orthogonalizing process to perform pattern separation to increase the storage capacity of the CA3 when correlated patterns were presented to the system (Chapter 9).

The results were disappointing. It seemed difficult for the fitness function to optimize the architecture of both the layers simultaneously. Perhaps the minima in this landscape were so dependent on what was happening in each of the layers that a solution was very difficult.

This leads me to the following new hypotheses. One hypothesis is that because of the complexity of the solution landscape being optimized by the fitness function and genetic variation and selection, a mechanism that may be used in evolution (with full generality to the whole process of evolution by neo-Darwinian mechanisms) is to allow one subsystem to evolve, fix its parameters, and then allow the next subsystem in the hierarchy to evolve, then fix this, and so on. In the context of cortical processing, the proposal is that the first cortical area (sometimes referred to here as layer in the network of cortical areas) in the system would evolve, and then become fixed, allowing little further variation, and providing stable inputs for the next layer to evolve to do what it can with the outputs of the preceding layer. This would be repeated for layer after layer in the hierarchy. The process would be efficient, in the sense that genetic evolution would need to search only one layer of the system at a time for a useful advance, measured by an increase in fitness. This would greatly simplify the exploration of high dimensional spaces being performed by genetic evolution. In this evolutionary process, each new added layer (i.e. cortical area) would have a useful function, implemented by the outputs taken from layers 5 and 6 of every cortical area to the basal ganglia, cerebellum, thalamus etc., thus providing a potential advantage for each new added cortical area.

This hypothesis raises the important question of how gene-based evolution would be switched on for an early layer of the system, but then switched off so that the next layer in the hierarchy could evolve later in evolutionary history. One possibility is that genes that have already built early layers of the system or hierarchy show less variation in terms of mutation and recombination, perhaps because of where they are located on a chromosome.

In the context of the brain, a related process may be that after an early layer in a cortical hierarchy has self-organized during development, learning in that cortical layer may be switched off, by switching off its synaptic plasticity, to leave a stable base for the next layer

to learn. Consistent with this, there is plasticity in the primary visual cortex, V1, in an early stage of cortical development, so that binocular neurons can be formed to implement stereopsis (Blakemore et al., 1978; LeVay et al., 1980). After a ‘critical period’, the plasticity in V1 is switched off, and later stages of the hierarchy can learn, and be subject to evolution by genetic variation and natural selection. Indeed, our evidence is that plasticity in the primate inferior temporal visual cortex remains present in adulthood (Rolls et al., 1989a).

There may thus be interesting computational advantages of ontogeny recapitulating phylogeny in this case. For both development, and for evolution, the process of finding useful solutions by selection may be simplified by allowing primarily one stage or layer in the system to be developing or evolving at any one time, to reduce the dimensionality of the space being searched at any one time.

An implication is that the inferior temporal visual cortex is not a fixed structure, and that any changes that genes make in its architecture can influence its function throughout life, and may thus have a strong impact on fitness. In any case, it is suggested that genetic variation and natural selection are largely switched off for early layers in the cortical hierarchy, so that genetic variation and natural selection operate mainly on the top layers of the hierarchy, enabling new processing layers to be added to an existing hierarchy and shaped by evolution to perform useful functions, without interference caused by simultaneous evolution of the early layers of the hierarchy. Consistent with this hypothesis, many genes are involved in timing when other genes are expressed.

B.20.7 Summary

1. Gene-based variation operated on by natural selection to promote fitness provides a basis for the design of the cortex during evolution.
2. It is proposed that genes specify a relatively small number of parameters for each class of neuron in a given cortical area, including the classes of neurons to which each class should make synapses. This provides a basis for one cortical area to make the appropriate connections to other cortical areas.
3. Specifying a few parameters for each class of cortical neuron enables relatively few genes, in the order of thousands, to specify the architecture and connectivity of the cerebral cortex.
4. Simulations are described which show that specification of relatively few parameters by genes can enable neural networks to evolve to optimise fitness functions that specify particular results of cortical computations. The genes specify relatively few rules of connectivity of the neural architecture, and learning in the phenotype sets the synaptic weights.

B.21 Highlights

1. The operation and properties of biologically plausible pattern association networks, auto-association networks, and competitive networks are described.
2. The operation of perceptrons, backpropagation networks, and deep learning networks is described.
3. Biological plausibility is a key issue when considering how computations are performed in the brain.
4. Some of the relatively unsupervised ways in which the brain learns are likely to be of interest for machine learning.

5. An interesting feature of brain connectivity and computation is how it evolves using genetic specification by a relatively few connection parameters for each brain region in combination with self-organisation.

Appendix 3 Neuronal encoding, and information theory

In order to understand what is computed in the brain, and how it is computed, it is essential to understand how information is represented in the brain. Is it by the firing rates of neurons, by the latency of neuronal responses, by the order in which action potentials arrive in different neurons, by any stimulus-dependent cross-correlations between the firing of different neurons, etc? It is essential to understand how information is encoded by single neurons, and by populations of neurons. Neuronal encoding, and the use of information theory to analyze it, are described in this Appendix, and by Rolls and Treves (2011).

We have seen that one parameter that influences the number of memories that can be stored in an associative memory is the sparseness of the representation, and it is therefore important to be able to quantify the sparseness of the representations.

We have also seen that the properties of an associative memory system depend on whether the representation is distributed or local (grandmother cell like), and it is important to be able to assess this quantitatively for neuronal representations.

It is also necessary to know how the information is encoded in order to understand how memory systems operate. Is the information that must be stored and retrieved present in the firing rates (the number of spikes in a fixed time), or is it present in synchronized firing of subsets of neurons? This has implications for how each stage of processing would need to operate. If the information is present in the firing rates, how much information is available from the spiking activity in a short period, of for example 20 or 50 ms? For each stage of cortical processing to operate quickly (in for example 20 ms), it is necessary for each stage to be able to read the code being provided by the previous cortical area within this order of time. Thus understanding the neural code is fundamental to understanding how each stage of processing works in the brain, and for understanding the speed of processing at each stage.

To treat all these questions quantitatively, we need quantitative ways of measuring sparseness, and also ways of measuring the information available from the spiking activity of single neurons and populations of neurons, and these are the topics addressed in this Appendix, together with some of the main results obtained, which provide answers to these questions.

Because single neurons are the computing elements of the brain and send the results of their processing by spiking activity to other neurons, we can understand brain processing by understanding what is encoded by the neuronal firing at each stage of the brain (e.g. each cortical area), and determining how what is encoded changes from stage to stage. Each neuron responds differently to a set of stimuli (with each neuron tuned differently to the members of the set of stimuli), and it is this that allows different stimuli to be represented. We can only address the richness of the representation therefore by understanding the differences in the responses of different neurons, and the impact that this has on the amount of information that is encoded. These issues can only be adequately and directly addressed at the level of the activity of single neurons and of populations of single neurons, and understanding at this neuronal level (rather than at the level of thousands or millions of neurons as revealed by functional neuroimaging) is essential for understanding brain computation.

Information theory provides the means for quantifying how much neurons communicate to other neurons, and thus provides a quantitative approach to fundamental questions about information processing in the brain. To investigate what in neuronal activity carries information, one must compare the amounts of information carried by different codes, that is different descriptions of the same activity, to provide the answer. To investigate the speed of information transmission, one must define and measure information rates from neuronal responses. To investigate to what extent the information provided by different cells is redundant or instead independent, again one must measure amounts of information in order to provide quantitative evidence. To compare the information carried by the number of spikes, by the timing of the spikes within the response of a single neuron, and by the relative time of firing of different neurons reflecting for example stimulus-dependent neuronal synchronization, information theory again provides a quantitative and well-founded basis for the necessary comparisons. To compare the information carried by a single neuron or a group of neurons with that reflected in the behavior of the human or animal, one must again use information theory, as it provides a single measure which can be applied to the measurement of the performance of all these different cases. In all these situations, there is no quantitative and well-founded alternative to information theory.

This Appendix briefly introduces the fundamental elements of information theory in Section C.1. A more complete treatment can be found in many books on the subject (e.g. Abramson (1963), Hamming (1990), and Cover and Thomas (1991)), including also Rieke, Warland, de Ruyter van Steveninck and Bialek (1997) which is specifically about information transmitted by neuronal firing. Section C.2 discusses the extraction of information measures from neuronal activity, in particular in experiments with mammals, in which the central issue is how to obtain accurate measures in conditions of limited sampling, that is where the numbers of trials of neuronal data that can be obtained are usually limited by the available recording time. Section C.3 summarizes some of the main results obtained so far on neuronal encoding. The essential terminology is summarized in a Glossary at the end of this Appendix in Section C.4. The approach taken in this Appendix is based on and updated from that provided by Rolls and Treves (1998), Rolls (2016b), and Rolls and Treves (2011).

Readers who wish to see the main findings on neuronal encoding and how information is represented by neuronal firing in the primate brain may wish to skip to Section C.3.

C.1 Information theory and its use in the analysis of formal models

Although information theory was a surprisingly late starter as a mathematical discipline, having being developed and formalized by C. Shannon (1948), the intuitive notion of information is immediate to us. It is also very easy to understand why we use logarithms in order to quantify this intuitive notion, of how much we know about something, and why the resulting quantity is always defined in relative rather than absolute terms. An introduction to information theory is provided next, with a more formal summary given in Section C.1.3.

C.1.1 The information conveyed by definite statements

Suppose somebody, who did not know, is told that Reading is a town west of London. How much information is he given? Well, that depends. He may have known it was a town in England, but not whether it was east or west of London; in which case the new information amounts to the fact that of two *a priori* (i.e. initial) possibilities (E or W), one holds (W). It is also possible to interpret the statement in the more precise sense, that Reading is west of

London, rather than east, north or south, i.e. one out of four possibilities; or else, west rather than north-west, north, etc. Clearly, the larger the number k of *a priori* possibilities, the more one is actually told, and a measure of information must take this into account. Moreover, we would like independent pieces of information to just add together. For example, our person may also be told that Cambridge is, out of l possible directions, north of London. Provided nothing was known on the mutual location of Reading and Cambridge, there are now overall $k \times l$ *a priori* (initial) possibilities, only one of which remains *a posteriori* (after receiving the information). Given that the number of possibilities for independent events are multiplicative, but that we would like the measure of information to be additive, we use logarithms when we measure information, as logarithms have this property. We thus define the amount I of information gained when we are informed in which of k possible locations Reading is located as

$$I(k) = \log_2 k. \quad (\text{C.1})$$

Then when we combine independent information, for example producing $k \times l$ possibilities from independent events with k and l possibilities respectively, we obtain

$$I(k \times l) = \log_2(k \times l) = \log_2 k + \log_2 l = I(k) + I(l). \quad (\text{C.2})$$

Thus in our example, the information about Cambridge adds up to that about Reading. We choose to take logarithms in base 2 as a mere convention, so that the answer to a yes/no question provides one unit, or bit, of information. Here it is just for the sake of clarity that we used different symbols for the number of possible directions with respect to which Reading and Cambridge are localized; if both locations are specified for example in terms of E, SE, S, SW, W, NW, N, NE, then obviously $k = l = 8$, $I(k) = I(l) = 3$ bits, and $I(k \times l) = 6$ bits. An important point to note is that the *resolution* with which the direction is specified determines the amount of information provided, and that in this example, as in many situations arising when analysing neuronal codings, the resolution could be made progressively finer, with a corresponding increase in information proportional to the log of the number of possibilities.

C.1.2 The information conveyed by probabilistic statements

The situation becomes slightly less trivial, and closer to what happens among neurons, if information is conveyed in less certain terms. Suppose for example that our friend is told, instead, that Reading has odds of 9 to 1 to be west, rather than east, of London (considering now just two *a priori* possibilities). He is certainly given some information, albeit less than in the previous case. We might put it this way: out of 18 equiprobable *a priori* possibilities (9 west + 9 east), 8 (east) are eliminated, and 10 remain, yielding

$$I = \log_2(18/10) = \log_2(9/5) \quad (\text{C.3})$$

as the amount of information given. It is simpler to write this in terms of probabilities

$$I = \log_2 P^{\text{posterior}}(\text{W})/P^{\text{prior}}(\text{W}) = \log_2(9/10)/(1/2) = \log_2(9/5). \quad (\text{C.4})$$

This is of course equivalent to saying that the amount of information given by an uncertain statement is equal to the amount given by the absolute statement

$$I = -\log_2 P^{\text{prior}}(\text{W}) \quad (\text{C.5})$$

minus the amount of uncertainty remaining after the statement, $I = -\log_2 P^{\text{posterior}}(\text{W})$. A successive clarification that Reading is indeed west of London carries

$$I' = \log_2((1)/(9/10)) \quad (\text{C.6})$$

bits of information, because 9 out of 10 are now the *a priori* odds, while *a posteriori* there is certainty, $P^{\text{posterior}}(\text{W}) = 1$. In total we would seem to have

$$I^{\text{TOTAL}} = I + I' = \log_2(9/5) + \log_2(10/9) = 1 \text{ bit} \quad (\text{C.7})$$

as if the whole information had been provided at one time. This is strange, given that the two pieces of information are clearly not independent, and only independent information should be additive. In fact, we have cheated a little. Before the clarification, there was still one residual possibility (out of 10) that the answer was ‘east’, and this must be taken into account by writing

$$I = P^{\text{posterior}}(\text{W}) \log_2 \frac{P^{\text{posterior}}(\text{W})}{P^{\text{prior}}(\text{W})} + P^{\text{posterior}}(\text{E}) \log_2 \frac{P^{\text{posterior}}(\text{E})}{P^{\text{prior}}(\text{E})} \quad (\text{C.8})$$

as the information contained in the first message. This little detour should serve to emphasize two aspects that are easy to forget when reasoning intuitively about information, and that in this example cancel each other. In general, when uncertainty remains, that is there is more than one possible *a posteriori* state, one has to average information values for each state with the corresponding *a posteriori* probability measure. In the specific example, the sum $I + I'$ totals slightly *more* than 1 bit, and the amount in excess is precisely the information ‘wasted’ by providing *correlated* messages.

C.1.3 Information sources, information channels, and information measures

In summary, the expression quantifying the information provided by a definite statement that event s , which had an *a priori* probability $P(s)$, has occurred is

$$I(s) = \log_2(1/P(s)) = -\log_2 P(s), \quad (\text{C.9})$$

whereas if the statement is probabilistic, that is several *a posteriori* probabilities remain non-zero, the correct expression involves summing over all possibilities with the corresponding probabilities:

$$I = \sum_s \left[P^{\text{posterior}}(s) \log_2 \frac{P^{\text{posterior}}(s)}{P^{\text{prior}}(s)} \right]. \quad (\text{C.10})$$

When considering a discrete set of mutually exclusive events, it is convenient to use the metaphor of a set of *symbols* comprising an *alphabet* S . The occurrence of each event is then referred to as the emission of the corresponding symbol by an information *source*. The *entropy* of the source, H , is the average amount of information per source symbol, where the average is taken across the alphabet, with the corresponding probabilities

$$H(S) = -\sum_{s \in S} P(s) \log_2 P(s). \quad (\text{C.11})$$

An information *channel* receives symbols s from an alphabet S and emits symbols s' from alphabet S' . If the *joint* probability of the channel receiving s and emitting s' is given by the product

$$P(s, s') = P(s)P(s') \quad (\text{C.12})$$

for any pair s, s' , then the input and output symbols are *independent* of each other, and the channel transmits zero information. Instead of joint probabilities, this can be expressed with

conditional probabilities: the conditional probability of s' given s is written $P(s'|s)$, and if the two variables are independent, it is just equal to the unconditional probability $P(s')$. In general, and in particular if the channel does transmit information, the variables are not independent, and one can express their joint probability in two ways in terms of conditional probabilities

$$P(s, s') = P(s'|s)P(s) = P(s|s')P(s'), \quad (\text{C.13})$$

from which it is clear that

$$P(s'|s) = P(s|s') \frac{P(s')}{P(s)}, \quad (\text{C.14})$$

which is called Bayes' theorem (although when expressed as here in terms of probabilities it is strictly speaking an identity rather than a theorem). The information transmitted by the channel conditional to its having emitted symbol s' (or specific transinformation, $I(s')$) is given by Equation C.10, once the unconditional probability $P(s)$ is inserted as the prior, and the conditional probability $P(s|s')$ as the posterior:

$$I(s') = \sum_s P(s|s') \log_2 \frac{P(s|s')}{P(s)}. \quad (\text{C.15})$$

Symmetrically, one can define the transinformation conditional to the channel having received symbol s

$$I(s) = \sum_{s'} P(s'|s) \log_2 \frac{P(s'|s)}{P(s')}. \quad (\text{C.16})$$

Finally, the average transinformation, or **mutual information**, can be expressed in fully symmetrical form

$$\begin{aligned} I &= \sum_s P(s) \sum_{s'} P(s'|s) \log_2 \frac{P(s'|s)}{P(s')} \\ &= \sum_{s, s'} P(s, s') \log_2 \frac{P(s, s')}{P(s)P(s')}. \end{aligned} \quad (\text{C.17})$$

The **mutual information** can also be expressed as the entropy of the source using alphabet S minus the *equivocation* of S with respect to the new alphabet S' used by the channel, written

$$I = H(S) - H(S|S') \equiv H(S) - \sum_{s'} P(s')H(S|s'). \quad (\text{C.18})$$

A channel is characterized, once the alphabets are given, by the set of conditional probabilities for the output symbols, $P(s'|s)$, whereas the unconditional probabilities of the input symbols $P(s)$ depend of course on the source from which the channel receives. Then, the *capacity* of the channel can be defined as the maximal mutual information across all possible sets of input probabilities $P(s)$. Thus, the information transmitted by a channel can range from zero to the lower of two independent upper bounds: the entropy of the source, and the capacity of the channel.

C.1.4 The information carried by a neuronal response and its averages

Considering the processing of information in the brain, we are often interested in the amount of information the response r of a neuron, or of a population of neurons, carries about an

event happening in the outside world, for example a stimulus s shown to the animal. Once the inputs and outputs are conceived of as sets of symbols from two alphabets, the neuron(s) may be regarded as an information channel. We may denote with $P(s)$ the *a priori* probability that the particular stimulus s out of a given set was shown, while the conditional probability $P(s|r)$ is the *a posteriori* probability, that is updated by the knowledge of the response r . The response-specific transinformation

$$I(r) = \sum_s P(s|r) \log_2 \frac{P(s|r)}{P(s)} \quad (\text{C.19})$$

takes the extreme values of $I(r) = -\log_2 P(s(r))$ if r unequivocally determines $s(r)$ (that is, $P(s|r)$ equals 1 for that one stimulus and 0 for all others); and $I(r) = \sum_s P(s) \log_2 (P(s)/P(s)) = 0$ if there is no relation between s and r , that is they are independent, so that the response tells us nothing new about the stimulus and thus $P(s|r) = P(s)$.

This is the information conveyed by each particular response. One is usually interested in further averaging this quantity over all possible responses r ,

$$\langle I \rangle = \sum_r P(r) \left[\sum_s P(s|r) \log_2 \frac{P(s|r)}{P(s)} \right]. \quad (\text{C.20})$$

The angular brackets $\langle \rangle$ are used here to emphasize the averaging operation, in this case over responses. Denoting with $P(s, r)$ the *joint probability* of the pair of events s and r , and using Bayes' theorem, this reduces to the symmetric form (equation C.18) for the **mutual information** $I(S, R)$

$$\langle I \rangle = \sum_{s,r} P(s, r) \log_2 \frac{P(s, r)}{P(s)P(r)} \quad (\text{C.21})$$

which emphasizes that responses tell us about stimuli just as much as stimuli tell us about responses. This is, of course, a general feature, independent of the two variables being in this instance stimuli and neuronal responses. In fact, what is of interest, besides the mutual information of Equations C.20 and C.21, is often the information specifically conveyed about each stimulus,

$$I(s) = \sum_r P(r|s) \log_2 \frac{P(r|s)}{P(r)} \quad (\text{C.22})$$

which is a direct quantification of the variability in the responses elicited by that stimulus, compared to the overall variability. Since $P(r)$ is the probability distribution of responses averaged across stimuli, it is again evident that the stimulus-specific information measure of Equation C.22 depends not only on the stimulus s , but also on all other stimuli used. Likewise, the mutual information measure, despite being of an average nature, is dependent on what set of stimuli has been used in the average. This emphasizes again the relative nature of all information measures. More specifically, it underscores the relevance of using, while measuring the information conveyed by a given neuronal population, stimuli that are either representative of real-life stimulus statistics, or of particular interest for the properties of the population being examined²⁹.

²⁹The quantity $I(s, R)$, which is what is shown in Equation C.22 and where R draws attention to the fact that this quantity is calculated across the full set of responses R , has also been called the stimulus-specific surprise, see DeWeese and Meister (1999). Its average across stimuli is the mutual information $I(S, R)$.

C.1.4.1 A numerical example

To make these notions clearer, we can consider a specific example in which the response of a neuron to the presentation of, say, one of four visual stimuli (A, B, C, D) is recorded for 10 ms, during which the neuron emits either 0, 1, or 2 spikes, but no more. Imagine that the neuron tends to respond more vigorously to visual stimulus B, less to C, even less to A, and never to D, as described by the table of conditional probabilities $P(r|s)$ shown in Table C.1. Then, if different visual stimuli are presented with equal probability, the table of joint

Table C.1 The conditional probabilities $P(r|s)$ that different neuronal responses ($r=0, 1, \text{ or } 2$ spikes) will be produced by each of four stimuli (A–D).

	$r=0$	$r=1$	$r=2$
$s=A$	0.6	0.4	0.0
$s=B$	0.0	0.2	0.8
$s=C$	0.4	0.5	0.1
$s=D$	1.0	0.0	0.0

probabilities $P(s, r)$ will be as shown in Table C.2. From these two tables one can compute

Table C.2 Joint probabilities $P(s, r)$ that different neuronal responses ($r=0, 1, \text{ or } 2$ spikes) will be produced by each of four equiprobable stimuli (A–D).

	$r=0$	$r=1$	$r=2$
$s=A$	0.15	0.1	0.0
$s=B$	0.0	0.05	0.2
$s=C$	0.1	0.125	0.025
$s=D$	0.25	0.0	0.0

various information measures by directly applying the definitions above. Since visual stimuli are presented with equal probability, $P(s) = 1/4$, the entropy of the stimulus set, which corresponds to the maximum amount of information any transmission channel, no matter how efficient, could convey on the identity of the stimuli, is $H_s = -\sum_s [P(s) \log_2 P(s)] = -4[(1/4) \log_2(1/4)] = \log_2 4 = 2$ bits. There is a more stringent upper bound on the mutual information that this cell's responses convey on the stimuli, however, and this second bound is the channel capacity T of the cell. Calculating this quantity involves maximizing the mutual information across prior visual stimulus probabilities, and it is a bit complicated to do, in general. In our particular case the maximum information is obtained when only stimuli B and D are presented, each with probability 0.5. The resulting capacity is $T = 1$ bit. We can easily calculate, in general, the entropy of the responses. This is not an upper bound characterizing the source, like the entropy of the stimuli, nor an upper bound characterizing the channel, like the capacity, but simply a bound on the mutual information for this specific combination of source (with its related visual stimulus probabilities) and channel (with its conditional probabilities). Since only three response levels are possible within the short recording window, and they occur with uneven probability, their entropy is considerably lower than H_s , at $H_r = -\sum_r P(r) \log_2 P(r) = -P(0) \log_2 P(0) - P(1) \log_2 P(1) - P(2) \log_2 P(2) = -0.5 \log_2 0.5 - 0.275 \log_2 0.275 - 0.225 \log_2 0.225 = 1.496$ bits. The actual average information I that the responses transmit about the stimuli, which is a measure of the correlation in the variability of stimuli and responses, does not exceed the absolute variability of either stimuli (as quantified by the first bound) or responses (as quantified by the last bound),

nor the capacity of the channel. An explicit calculation using the joint probabilities of the second table in expression C.21 yields $I = 0.733$ bits. This is of course only the average value, averaged both across stimuli and across responses.

The information conveyed by a particular response can be larger. For example, when the cell emits two spikes it indicates with a relatively large probability stimulus B, and this is reflected in the fact that it then transmits, according to expression C.19, $I(r = 2) = 1.497$ bits, more than double the average value.

Similarly, the amount of information conveyed about each individual visual stimulus varies with the stimulus, depending on the extent to which it tends to elicit a differential response. Thus, expression C.22 yields that only $I(s = C) = 0.185$ bits are conveyed on average about stimulus C, which tends to elicit responses with similar statistics to the average statistics across stimuli, and are therefore not easily interpretable. On the other hand, exactly 1 bit of information is conveyed about stimulus D, since this stimulus never elicits any response, and when the neuron emits no spike there is a probability of $1/2$ that the stimulus was stimulus D.

C.1.5 The information conveyed by continuous variables

A general feature, relevant also to the case of neuronal information, is that if, among a *continuum* of *a priori* possibilities, only one, or a discrete number, remains *a posteriori*, the information is strictly infinite. This would be the case if one were told, for example, that Reading is exactly $10'$ west, $1'$ north of London. The *a priori* probability of precisely this set of coordinates among the continuum of possible ones is zero, and then the information diverges to infinity. The problem is only theoretical, because in fact, with continuous distributions, there are always one or several factors that limit the resolution in the *a posteriori* knowledge, rendering the information finite. Moreover, when considering the mutual information in the conjoint probability of occurrence of two sets, e.g. stimuli and responses, it suffices that at least one of the sets is discrete to make matters easy, that is, finite. Nevertheless, the identification and appropriate consideration of these resolution-limiting factors in practical cases may require careful analysis.

C.1.5.1 Example: the information retrieved from an autoassociative memory

One example is the evaluation of the information that can be retrieved from an autoassociative memory. Such a memory stores a number of firing patterns, each one of which can be considered, as in Appendix B, as a vector \mathbf{r}^μ with components the firing rates $\{r_i^\mu\}$, where the subscript i indexes the neuron (and the superscript μ indexes the pattern). In retrieving pattern μ , the network in fact produces a distinct firing pattern, denoted for example simply as \mathbf{r} . The quality of retrieval, or the similarity between \mathbf{r}^μ and \mathbf{r} , can be measured by the average mutual information

$$\begin{aligned} \langle I(\mathbf{r}^\mu, \mathbf{r}) \rangle &= \sum_{\mathbf{r}^\mu, \mathbf{r}} P(\mathbf{r}^\mu, \mathbf{r}) \log_2 \frac{P(\mathbf{r}^\mu, \mathbf{r})}{P(\mathbf{r}^\mu)P(\mathbf{r})} \\ &\approx \sum_i \sum_{r_i^\mu, r_i} P(r_i^\mu, r_i) \log_2 \frac{P(r_i^\mu, r_i)}{P(r_i^\mu)P(r_i)}. \end{aligned} \quad (\text{C.23})$$

In this formula the ‘approximately equal’ sign \approx marks a simplification that is not necessarily a reasonable approximation. If the simplification is valid, it means that in order to extract an information measure, one need not compare whole vectors (the entire firing patterns) with each other, and may instead compare the firing rates of individual cells at storage and retrieval, and sum the resulting single-cell information values. The validity of the simplification is a matter that will be discussed later and that has to be verified, in the end, experimentally, but

for the purposes of the present discussion we can focus on the single-cell terms. If either r_i or r_i^μ has a continuous distribution of values, as it will if it represents not the number of spikes emitted in a fixed window, but more generally the firing rate of neuron i computed by convolving the firing train with a smoothing kernel, then one has to deal with probability densities, which we denote as $p(r)dr$, rather than the usual probabilities $P(r)$. Substituting $p(r)dr$ for $P(r)$ and $p(r^\mu, r)drdr^\mu$ for $P(r^\mu, r)$, one can write for each single-cell contribution (omitting the cell index i)

$$\langle I(r^\mu, r) \rangle_i = \int dr^\mu dr p(r^\mu, r) \log_2 \frac{p(r^\mu, r)}{p(r^\mu)p(r)} \quad (\text{C.24})$$

and we see that the differentials $dr^\mu dr$ cancel out between numerator and denominator inside the logarithm, rendering the quantity well defined and finite. If, however, r^μ were to *exactly* determine r , one would have

$$p(r^\mu, r)dr^\mu dr = p(r^\mu)\delta(r - r(r^\mu))dr^\mu dr = p(r^\mu)dr^\mu \quad (\text{C.25})$$

and, by losing one differential on the way, the mutual information would become infinite. It is therefore important to consider what prevents r^μ from fully determining r in the case at hand – in other words, to consider the sources of noise in the system. In an autoassociative memory storing an extensive number of patterns (see Appendix A4 of Rolls and Treves (1998)), one source of noise always present is the interference effect due to the concurrent storage of all other patterns. Even neglecting other sources of noise, this produces a finite resolution width ρ , which allows one to write an expression of the type $p(r|r^\mu)dr = \exp -(r - r(r^\mu))^2 / 2\rho^2 dr$ which ensures that the information is finite as long as the resolution ρ is larger than zero.

One further point that should be noted, in connection with estimating the information retrievable from an autoassociative memory, is that the mutual information between the current distribution of firing rates and that of the stored pattern does not coincide with the information *gain* provided by the memory device. Even when firing rates, or spike counts, are all that matter in terms of information carriers, as in the networks considered in this book, one more term should be taken into account in evaluating the information gain. This term, to be subtracted, is the information contained in the external input that elicits the retrieval. This may vary a lot from the retrieval of one particular memory to the next, but of course an efficient memory device is one that is able, when needed, to retrieve much more information than it requires to be present in the inputs, that is, a device that produces a large information gain.

Finally, one should appreciate the conceptual difference between the information a firing pattern carries about another one (that is, about the pattern stored), as considered above, and two different notions: (a) the information produced by the network in selecting the correct memory pattern and (b) the information a firing pattern carries about something in the outside world. Quantity (a), the information intrinsic to selecting the memory pattern, is ill defined when analysing a real system, but is a well-defined and particularly simple notion when considering a formal model. If p patterns are stored with equal strength, and the selection is errorless, this amounts to $\log_2 p$ bits of information, a quantity often, but not always, small compared with the information in the pattern itself. Quantity (b), the information conveyed about some outside correlate, is not defined when considering a formal model that does not include an explicit account of what the firing of each cell represents, but is well defined and measurable from the recorded activity of real cells. It is the quantity considered in the numerical example with the four visual stimuli, and it can be generalized to the information carried by the activity of several cells in a network, and specialized to the case that the network operates as an associative memory. One may note, in this case, that the capacity to

retrieve memories with high fidelity, or high information content, is only useful to the extent that the representation to be retrieved carries that amount of information about something relevant – or, in other words, that it is pointless to store and retrieve with great care largely meaningless messages. This type of argument has been used to discuss the role of the mossy fibres in the operation of the CA3 network in the hippocampus (Treves and Rolls, 1992; Rolls and Treves, 1998).

C.2 Estimating the information carried by neuronal responses

C.2.1 The limited sampling problem

We now discuss in more detail the application of these general notions to the information transmitted by neurons. Suppose, to be concrete, that an animal has been presented with stimuli drawn from a discrete set, and that the responses of a set of C cells have been recorded following the presentation of each stimulus. We may choose any quantity or set of quantities to characterize the responses; for example let us assume that we consider the firing rate of each cell, r_i , calculated by convolving the spike response with an appropriate smoothing kernel. The response space is then C times the continuous set of all positive real numbers, $(\mathbf{R}/2)^C$. We want to evaluate the average information carried by such responses about which stimulus was shown. In principle, it is straightforward to apply the above formulas, e.g. in the form

$$\langle I(s, \mathbf{r}) \rangle = \sum_s P(s) \int \prod_i dr_i p(\mathbf{r}|s) \log_2 \frac{p(\mathbf{r}|s)}{p(\mathbf{r})} \quad (\text{C.26})$$

where it is important to note that $p(\mathbf{r})$ and $p(\mathbf{r}|s)$ are now probability densities defined over the high-dimensional vector space of multi-cell responses. The product sign \prod signifies that this whole vector space has to be integrated over, along all its dimensions. $p(\mathbf{r})$ can be calculated as $\sum_s p(\mathbf{r}|s)P(s)$, and therefore, in principle, all one has to do is to estimate, from the data, the conditional probability densities $p(\mathbf{r}|s)$ – the distributions of responses following each stimulus. In practice, however, in contrast to what happens with formal models, in which there is usually no problem in calculating the exact probability densities, real data come in limited amounts, and thus sample only sparsely the vast response space. This limits the accuracy with which, from the experimental *frequency* of each possible response, we can estimate its *probability*, in turn seriously impairing our ability to estimate $\langle I \rangle$ correctly. We refer to this as the limited sampling problem. This is a purely technical problem that arises, typically when recording from mammals, because of external constraints on the duration or number of repetitions of a given set of stimulus conditions. With computer simulation experiments, and also with recordings from, for example, insects, sufficient data can usually be obtained that straightforward estimates of information are accurate enough (Strong, Koberle, de Ruyter van Steveninck and Bialek, 1998; Golomb, Kleinfeld, Reid, Shapley and Shraiman, 1994). The problem is, however, so serious in connection with recordings from monkeys and rats in which limited numbers of trials are usually available for neuronal data, that it is worthwhile to discuss it, in order to appreciate the scope and limits of applying information theory to neuronal processing.

In particular, if the responses are continuous quantities, the probability of observing exactly the same response twice is infinitesimal. In the absence of further manipulation, this would imply that each stimulus generates its own set of unique responses, therefore any response that has actually occurred could be associated unequivocally with one stimulus, and

the mutual information would always equal the entropy of the stimulus set. This absurdity shows that in order to estimate probability densities from experimental frequencies, one has to resort to some *regularizing* manipulation, such as smoothing the point-like response values by convolution with suitable kernels, or binning them into a finite number of discrete bins.

C.2.1.1 Smoothing or binning neuronal response data

The issue is how to estimate the underlying probability distributions of neuronal responses to a set of stimuli from only a limited number of trials of data (e.g. 10–30) for each stimulus. Several strategies are possible. One is to discretize the response space into bins, and estimate the probability density as the histogram of the fraction of trials falling into each bin. If the bins are too narrow, almost every response is in a different bin, and the estimated information will be overestimated. Even if the bin width is increased to match the standard deviation of each underlying distribution, the information may still be overestimated. Alternatively, one may try to ‘smooth’ the data by convolving each response with a Gaussian with a width set to the standard deviation measured for each stimulus. Setting the standard deviation to this value may actually lead to an underestimation of the amount of information available, due to oversmoothing. Another possibility is to make a bold assumption as to what the general shape of the underlying densities should be, for example a Gaussian. This may produce closer estimates. Methods for regularizing the data are discussed further by Rolls and Treves (1998) in their Appendix A2, where a numerical example is given.

C.2.1.2 The effects of limited sampling

The crux of the problem is that, whatever procedure one adopts, limited sampling tends to produce distortions in the estimated probability densities. The resulting mutual information estimates are intrinsically biased. The bias, or average error of the estimate, is upward if the raw data have not been regularized much, and is downward if the regularization procedure chosen has been heavier. The bias can be, if the available trials are few, much larger than the true information values themselves. This is intuitive, as fluctuations due to the finite number of trials available would tend, on average, to either produce or emphasize differences among the distributions corresponding to different stimuli, differences that are preserved if the regularization is ‘light’, and that are interpreted in the calculation as carrying genuine information. This is illustrated with a quantitative example by Rolls and Treves (1998) in their Appendix A2.

Choosing the right amount of regularization, or the best regularizing procedure, is not possible *a priori*. Hertz, Kjaer, Eskander and Richmond (1992) have proposed the interesting procedure of using an artificial neural network to regularize the raw responses. The network can be trained on part of the data using backpropagation, and then used on the remaining part to produce what is in effect a clever data-driven regularization of the responses. This procedure is, however, rather computer intensive and not very safe, as shown by some self-evident inconsistency in the results (Heller, Hertz, Kjaer and Richmond, 1995). Obviously, the best way to deal with the limited sampling problem is to try and use as many trials as possible. The improvement is slow, however, and generating as many trials as would be required for a reasonably unbiased estimate is often, in practice, impossible.

C.2.2 Correction procedures for limited sampling

The above point, that data drawn from a single distribution, when artificially paired, at random, to different stimulus labels, results in ‘spurious’ amounts of apparent information, suggests a simple way of checking the reliability of estimates produced from real data (Optican, Gawne, Richmond and Joseph, 1991). One can disregard the true stimulus associated with

each response, and generate a randomly reshuffled pairing of stimuli and responses, which should therefore, being not linked by any underlying relationship, carry no mutual information about each other. Calculating, with some procedure of choice, the spurious information obtained in this way, and comparing with the information value estimated with the same procedure for the real pairing, one can get a feeling for how far the procedure goes into eliminating the apparent information due to limited sampling. Although this spurious information, I_s , is only indicative of the amount of bias affecting the original estimate, a simple heuristic trick (called ‘bootstrap’³⁰) is to subtract the spurious from the original value, to obtain a somewhat ‘corrected’ estimate. This procedure can result in quite accurate estimates (see Rolls and Treves (1998), Tovee, Rolls, Treves and Bellis (1993))³¹.

A different correction procedure (called ‘jack-knife’) is based on the assumption that the bias is proportional to $1/N$, where N is the number of responses (data points) used in the estimation. One computes, beside the original estimate $\langle I_N \rangle$, N auxiliary estimates $\langle I_{N-1} \rangle_k$, by taking out from the data set response k , where k runs across the data set from 1 to N . The corrected estimate

$$\langle I \rangle = N \langle I_N \rangle - (1/N) \sum_k (N-1) \langle I_{N-1} \rangle_k \quad (\text{C.27})$$

is free from bias (to leading order in $1/N$), if the proportionality factor is more or less the same in the original and auxiliary estimates. This procedure is very time-consuming, and it suffers from the same imprecision of any algorithm that tries to determine a quantity as the result of the subtraction of two large and nearly equal terms; in this case the terms have been made large on purpose, by multiplying them by N and $N-1$.

A more fundamental approach (Miller, 1955) is to derive an analytical expression for the bias (or, more precisely, for its leading terms in an expansion in $1/N$, the inverse of the sample size). This allows the estimation of the bias from the data itself, and its subsequent subtraction, as discussed in Treves and Panzeri (1995) and Panzeri and Treves (1996). Such a procedure produces satisfactory results, thereby lowering the size of the sample required for a given accuracy in the estimate by about an order of magnitude (Golomb, Hertz, Panzeri, Treves and Richmond, 1997). However, it does not, in itself, make possible measures of the information contained in very complex responses with few trials. As a rule of thumb, the number of trials per stimulus required for a reasonable estimate of information, once the subtractive correction is applied, is of the order of the effectively independent (and utilized) bins in which the response space can be partitioned (Panzeri and Treves, 1996). This correction procedure is the one that we use standardly (Rolls, Treves, Tovee and Panzeri, 1997d; Rolls, Critchley and Treves, 1996a; Rolls, Treves, Robertson, Georges-François and Panzeri, 1998b; Booth and Rolls, 1998; Rolls, Tovee and Panzeri, 1999b; Rolls, Franco, Aggelopoulos and Jerez, 2006b).

C.2.3 The information from multiple cells: decoding procedures

The bias of information measures grows with the dimensionality of the response space, and for all practical purposes the limit on the number of dimensions that can lead to reasonably accurate direct measures, even when applying a correction procedure, is quite low, two to three. This implies, in particular, that it is not possible to apply Equation C.26 to extract

³⁰In technical usage bootstrap procedures utilize random pairings of responses with stimuli with replacement, while shuffling procedures utilize random pairings of responses with stimuli without replacement.

³¹Subtracting the ‘square’ of the spurious fraction of information estimated by this bootstrap procedure as used by Optican, Gawne, Richmond and Joseph (1991) is unfounded and does not work correctly (see Rolls and Treves (1998) and Tovee, Rolls, Treves and Bellis (1993)).

the information content in the responses of several cells (more than two to three) recorded simultaneously. One way to address the problem is then to apply some strong form of regularization to the multiple cell responses. Smoothing has already been mentioned as a form of regularization that can be tuned from very soft to very strong, and that preserves the structure of the response space. Binning is another form, which changes the nature of the responses from continuous to discrete, but otherwise preserves their general structure, and which can also be tuned from soft to strong. Other forms of regularization involve much more radical transformations, or changes of variables.

Of particular interest for information estimates is a change of variables that transforms the response space into the stimulus set, by applying an algorithm that derives a predicted stimulus from the response vector, i.e. the firing rates of all the cells, on each trial. Applying such an algorithm is called decoding. Of course, the predicted stimulus is not necessarily the same as the actual one. Therefore the term decoding should not be taken to imply that the algorithm works successfully, each time identifying the actual stimulus. The predicted stimulus is simply a function of the response, as determined by the algorithm considered. Just as with any regularizing transform, it is possible to compute the mutual information between actual stimuli s and predicted stimuli s' , instead of the original one between stimuli s and responses r . Since information about (real) stimuli can only be lost and not be created by the transform, the information measured in this way is bound to be lower in value than the real information in the responses. If the decoding algorithm is efficient, it manages to preserve nearly all the information contained in the raw responses, while if it is poor, it loses a large portion of it. If the responses themselves provided all the information about stimuli, and the decoding is optimal, then predicted stimuli coincide with the actual stimuli, and the information extracted equals the entropy of the stimulus set.

The procedure for extracting information values after applying a decoding algorithm is indicated in Fig. C.1 (in which s is s'). The underlying idea indicated in Fig. C.1 is that if we know the average firing rate of each cell in a population to each stimulus, then on any single trial we can guess (or decode) the stimulus that was present by taking into account the responses of all the cells. The decoded stimulus is s' , and the actual stimulus that was shown is s . What we wish to know is how the percentage correct, or better still the information, based on the evidence from any single trial about which stimulus was shown, increases as the number of cells in the population sampled increases. We can expect that the more cells there are in the sample, the more accurate the estimate of the stimulus is likely to be. If the encoding was local, the number of stimuli encoded by a population of neurons would be expected to rise approximately linearly with the number of neurons in the population. In contrast, with distributed encoding, provided that the neuronal responses are sufficiently independent, and are sufficiently reliable (not too noisy), information from the ensemble would be expected to rise linearly with the number of cells in the ensemble, and (as information is a log measure) the number of stimuli encodable by the population of neurons might be expected to rise exponentially as the number of neurons in the sample of the population was increased.

Table C.3 Decoding. s' is the decoded stimulus, i.e. that predicted from the neuronal responses r .

The procedure is schematized in Table C.3 where the double arrow indicates the transformation from stimuli to responses operated by the nervous system, while the single arrow indicates the further transformation operated by the decoding procedure. $I(s, s')$ is the mut-

How well can one predict which stimulus was shown on a single trial from the mean responses of different neurons to each stimulus?

Fig. C.1 Decoding which stimulus (S1–S3) was present with a set of neuronal responses on a single trial to stimulus ‘S?’. The information available from multiple cells can then be calculated by comparing the decoded stimuli to the real stimuli that were presented. The figure shows the average response for each of several cells (Cell 1, etc.) to each of several stimuli (S1, etc.). The change of firing rate from the spontaneous rate is indicated by the vertical line above or below the horizontal line, which represents the spontaneous rate. We can imagine guessing or predicting from such a table the predicted stimulus S? (i.e. s') that was present on any one trial. (After Rolls, E. T., Treves, A. and Tovee, M. J. (1997) The representational capacity of the distributed encoding of information provided by populations of neurons in the primate temporal visual cortex. *Experimental Brain Research* 114: 149–162. © Springer Nature.)

ual information between the actual stimuli s and the stimuli s' that are predicted to have been shown based on the decoded responses.

A slightly more complex variant of this procedure is a decoding step that extracts from the response on each trial not a single predicted stimulus, but rather probabilities that each of the possible stimuli was the actual one. The joint probabilities of actual and posited stimuli can be averaged across trials, and information computed from the resulting probability matrix ($S \times S$). Computing information in this way takes into account the relative uncertainty in assigning a predicted stimulus to each trial, an uncertainty that is instead not considered by the previous procedure based solely on the identification of the maximally likely stimulus (Treves, 1997). *Maximum likelihood* information values I_{ml} based on a single stimulus tend therefore to be higher than *probability* information values I_p based on the whole set of stimuli, although in very specific situations the reverse could also be true.

The same correction procedures for limited sampling can be applied to information values computed after a decoding step. Values obtained from maximum likelihood decoding, I_{ml} , suffer from limited sampling more than those obtained from probability decoding, I_p , since each trial contributes a whole ‘brick’ of weight $1/N$ (N being the total number of trials),

whereas with probabilities each brick is shared among several slots of the ($S \times S$) probability matrix. The neural network procedure devised by Hertz, Kjaer, Eskander and Richmond (1992) can in fact be thought of as a decoding procedure based on probabilities, which deals with limited sampling not by applying a correction but rather by strongly regularizing the original responses.

When decoding is used, the rule of thumb becomes that the minimal number of trials per stimulus required for accurate information measures is roughly equal to the size of the stimulus set, if the subtractive correction is applied (Panzeri and Treves, 1996). This correction procedure is applied as standard in our multiple cell information analyses that use decoding (Rolls, Treves and Tovee, 1997b; Booth and Rolls, 1998; Rolls, Treves, Robertson, Georges-François and Panzeri, 1998b; Franco, Rolls, Aggelopoulos and Treves, 2004; Aggelopoulos, Franco and Rolls, 2005; Rolls, Franco, Aggelopoulos and Jerez, 2006b).

C.2.3.1 Decoding algorithms

Any transformation from the response space to the stimulus set could be used in decoding, but of particular interest are the transformations that either approach optimality, so as to minimize information loss and hence the effect of decoding, or else are implementable by mechanisms that *could* conceivably be operating in the real system, so as to extract information values that could be extracted by the system itself.

The optimal transformation is in theory well-defined: one should estimate from the data the conditional probabilities $P(r|s)$, and use Bayes' rule to convert them into the conditional probabilities $P(s'|r)$. Having these for any value of r , one could use them to estimate I_p , and, after selecting for each particular real response the stimulus with the highest conditional probability, to estimate I_{ml} . To avoid biasing the estimation of conditional probabilities, the responses used in estimating $P(r|s)$ should not include the particular response for which $P(s'|r)$ is going to be derived (jack-knife cross-validation). In practice, however, the estimation of $P(r|s)$ in usable form involves the fitting of some simple function to the responses. This need for fitting, together with the approximations implied in the estimation of the various quantities, prevents us from defining the really optimal decoding, and leaves us with various algorithms, depending essentially on the fitting function used, which are hopefully close to optimal in some conditions. We have experimented extensively with two such algorithms, that both approximate Bayesian decoding (Rolls, Treves and Tovee, 1997b). Both these algorithms fit the response vectors produced over several trials by the cells being recorded to a product of conditional probabilities for the response of each cell given the stimulus. In one case, the single cell conditional probability is assumed to be Gaussian (truncated at zero); in the other it is assumed to be Poisson (with an additional weight at zero). Details of these algorithms are given by Rolls, Treves and Tovee (1997b).

Biologically plausible decoding algorithms are those that limit the algebraic operations used to types that could be easily implemented by neurons, e.g. dot product summations, thresholding and other single-cell non-linearities, and competition and contrast enhancement among the outputs of nearby cells. There is then no need for ever fitting functions or other sophisticated approximations, but of course the degree of arbitrariness in selecting a particular algorithm remains substantial, and a comparison among different choices based on which yields the higher information values may favour one choice in a given situation and another choice with a different data set.

To summarize, the key idea in decoding, in our context of estimating information values, is that it allows substitution of a possibly very high-dimensional response space (which is difficult to sample and regularize) with a reduced object much easier to handle, that is with a discrete set equivalent to the stimulus set. The mutual information between the new set and the stimulus set is then easier to estimate even with limited data, and if the assumptions

about population coding, underlying the particular decoding algorithm used, are justified, the value obtained approximates the original target, the mutual information between stimuli and responses. For each response recorded, one can use all the responses except for that one to generate estimates of the average response vectors (the average response for each neuron in the population) to each stimulus. Then one considers how well the selected response vector matches the average response vectors, and uses the degree of matching to estimate, for all stimuli, the probability that they were the actual stimuli. The form of the matching embodies the general notions about population encoding, for example the ‘degree of matching’ might be simply the dot product between the current vector and the average vector (\mathbf{r}^{av}), suitably normalized over all average vectors to generate probabilities

$$P(s'|\mathbf{r}(s)) = \frac{\mathbf{r}(s) \cdot \mathbf{r}^{\text{av}}(s')}{\sum_{s''} \mathbf{r}(s) \cdot \mathbf{r}^{\text{av}}(s'')} \quad (\text{C.28})$$

where s'' is a dummy variable. (This is called dot product decoding in Fig. 2.18.) One ends up, then, with a table of conjoint probabilities $P(s, s')$, and another table obtained by selecting for each trial the most likely (or predicted) single stimulus s^{p} , $P(s, s^{\text{p}})$. Both s' and s^{p} stand for all possible stimuli, and hence belong to the same set S . These can be used to estimate mutual information values based on probability decoding (I_{p}) and on maximum likelihood decoding (I_{ml}):

$$\langle I_{\text{p}} \rangle = \sum_{s \in S} \sum_{s' \in S} P(s, s') \log_2 \frac{P(s, s')}{P(s)P(s')} \quad (\text{C.29})$$

and

$$\langle I_{\text{ml}} \rangle = \sum_{s \in S} \sum_{s^{\text{p}} \in S} P(s, s^{\text{p}}) \log_2 \frac{P(s, s^{\text{p}})}{P(s)P(s^{\text{p}})} . \quad (\text{C.30})$$

Examples of the use of these procedures are available (Rolls, Treves and Tovee, 1997b; Booth and Rolls, 1998; Rolls, Treves, Robertson, Georges-François and Panzeri, 1998b; Rolls, Aggelopoulos, Franco and Treves, 2004; Franco, Rolls, Aggelopoulos and Treves, 2004; Rolls, Franco, Aggelopoulos and Jerez, 2006b), and some of the results obtained are described in Section C.3.

C.2.4 Information in the correlations between the spikes of different cells: a decoding approach

Simultaneously recorded neurons sometimes shows cross-correlations in their firing, that is the firing of one is systematically related to the firing of the other cell. One example of this is neuronal response synchronization. The cross-correlation, to be defined below, shows the time difference between the cells at which the systematic relation appears. A significant peak or trough in the cross-correlation function could reveal a synaptic connection from one cell to the other, or a common input to each of the cells, or any of a considerable number of other possibilities. If the synchronization occurred for only some of the stimuli, then the presence of the significant cross-correlation for only those stimuli could provide additional evidence separate from any information in the firing rate of the neurons about which stimulus had been shown. Information theory in principle provides a way of quantitatively assessing the relative contributions from these two types of encoding, by expressing what can be learned from each type of encoding in the same units, bits of information.

Figure C.2 illustrates how synchronization occurring only for some of the stimuli could be used to encode information about which stimulus was presented. In the Figure the spike

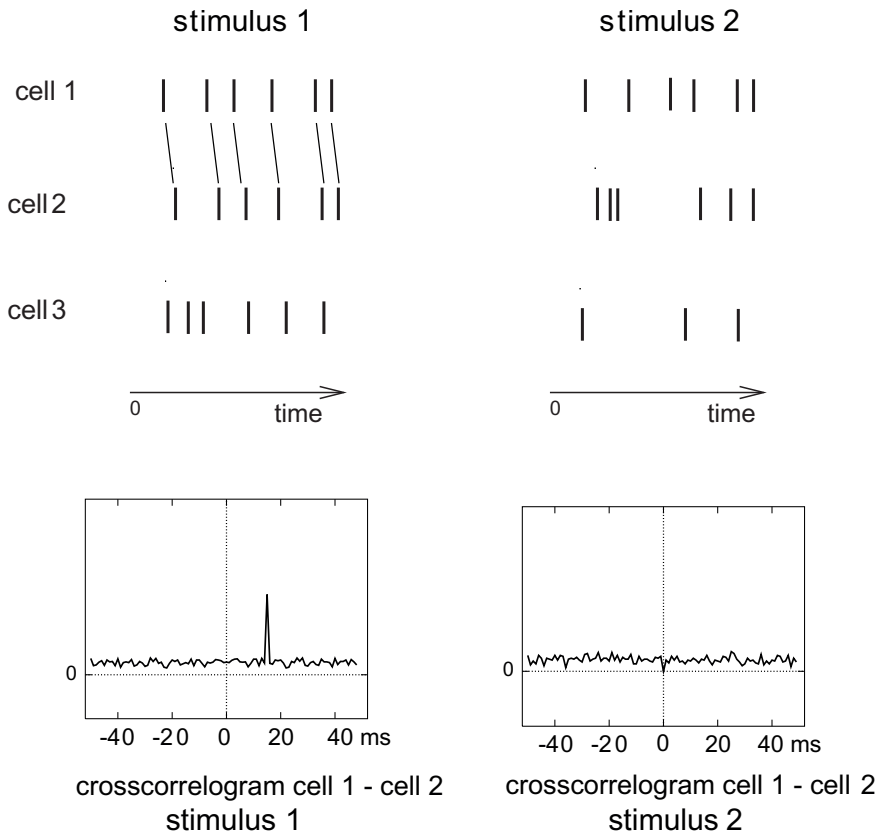

Fig. C.2 Stimulus-dependent cross-correlations between the spike trains of different neurons might encode information. The responses of three cells to two different stimuli are shown on one trial. Cell 3 reflects which stimulus was shown in the number of spikes produced, and this can be measured as spike count or rate information. Cells 1 and 2 have no spike count or rate information, because the number of spikes is not different for the two stimuli. Cells 1 and 2 do show some synchronization, reflected in the cross-correlogram, that is stimulus dependent, as the synchronization is present only when stimulus 1 is shown. The contribution of this effect is measured as the stimulus-dependent synchronization information. (From Rolls, E. T. and Treves, A. (2011) *The neuronal encoding of information in the brain*. Progress in Neurobiology 95: 448–490. © Elsevier Ltd.)

trains of three neurons are shown after the presentation of two different stimuli on one trial. As shown by the cross-correlogram in the lower part of the figure, the responses of cell 1 and cell 2 are synchronized when stimulus 1 is presented, as whenever a spike from cell 1 is emitted, another spike from cell 2 is emitted after a short time lag. In contrast, when stimulus 2 is presented, synchronization effects do not appear. Thus, based on a measure of the synchrony between the responses of cells 1 and 2, it is possible to obtain some information about what stimulus has been presented. The contribution of this effect is measured as the stimulus-dependent synchronization information. Cells 1 and 2 have no information about what stimulus was presented from the number of spikes, as the same number is found for both stimuli. Cell 3 carries information in the spike count in the time window (which is also called the firing rate) about what stimulus was presented. (Cell 3 emits 6 spikes for stimulus 1 and 3 spikes for stimulus 2.)

The example shown in Fig. C.2 is for the neuronal responses on a single trial. Given that the neuronal responses are variable from trial to trial, we need a method to quantify the information that is gained from a single trial of spike data in the context of the measured variability in the responses of all of the cells, including how the cells' responses covary in a

way which may be partly stimulus-dependent, and may include synchronization effects. The direct approach is to apply the Shannon mutual information measure (Shannon, 1948; Cover and Thomas, 1991)

$$I(s, \mathbf{r}) = \sum_{s \in S} \sum_{\mathbf{r}} P(s, \mathbf{r}) \log_2 \frac{P(s, \mathbf{r})}{P(s)P(\mathbf{r})}, \quad (\text{C.31})$$

where $P(s, \mathbf{r})$ is a probability table embodying a relationship between the variable s (here, the stimulus) and \mathbf{r} (a vector where each element is the firing rate of one neuron).

However, because the probability table of the relation between the neuronal responses and the stimuli, $P(s, \mathbf{r})$, is so large (given that there may be many stimuli, and that the response space which has to include spike timing is very large), in practice it is difficult to obtain a sufficient number of trials for every stimulus to generate the probability table accurately, at least with data from mammals in which the experiment cannot usually be continued for many hours of recording from a whole population of cells. To circumvent this undersampling problem, Rolls, Treves and Tovee (1997b) developed a decoding procedure (described in Section C.2.3), in which an estimate (or guess) of which stimulus (called s') was shown on a given trial is made from a comparison of the neuronal responses on that trial with the responses made to the whole set of stimuli on other trials. One then obtains a conjoint probability table $P(s, s')$, and then the mutual information based on probability estimation (PE) decoding (I_p) between the estimated stimuli s' and the actual stimuli s that were shown can be measured:

$$\langle I_p \rangle = \sum_{s \in S} \sum_{s' \in S} P(s, s') \log_2 \frac{P(s, s')}{P(s)P(s')} \quad (\text{C.32})$$

$$= \sum_{s \in S} P(s) \sum_{s' \in S} P(s'|s) \log_2 \frac{P(s'|s)}{P(s')}. \quad (\text{C.33})$$

These measurements are in the low dimensional space of the number of stimuli, and therefore the number of trials of data needed for each stimulus is of the order of the number of stimuli, which is feasible in experiments. In practice, it is found that for accurate information estimates with the decoding approach, the number of trials for each stimulus should be at least twice the number of stimuli (Franco, Rolls, Aggelopoulos and Treves, 2004).

The nature of the decoding procedure is illustrated in Fig. C.3. The left part of the diagram shows the average firing rate (or equivalently spike count) responses of each of 3 cells (labelled as Rate Cell 1,2,3) to a set of 3 stimuli. The last row (labelled Response single trial) shows the data that might be obtained from a single trial and from which the stimulus that was shown (St. ?) must be estimated or decoded, using the average values across trials shown in the top part of the table, and the probability distribution of these values. The decoding step essentially compares the vector of responses on trial St.? with the average response vectors obtained previously to each stimulus. This decoding can be as simple as measuring the correlation, or dot (inner) product, between the test trial vector of responses and the response vectors to each of the stimuli. This procedure is very neuronally plausible, in that the dot product between an input vector of neuronal activity and the synaptic response vector on a single neuron (which might represent the average incoming activity previously to that stimulus) is the simplest operation that it is conceived that neurons might perform (Rolls and Treves, 1998; Rolls and Deco, 2002; Rolls, 2016b). Other decoding procedures include a Bayesian procedure based on a Gaussian or Poisson assumption of the spike count distributions as described in detail by Rolls, Treves and Tovee (1997b). The Gaussian one is what we have used (Franco, Rolls, Aggelopoulos and Treves, 2004; Aggelopoulos, Franco and Rolls, 2005), and it is described below.

Fig. C.3 Decoding stimulus-dependent cross-correlations between the spike trains of different neurons that might encode information. The left part of the diagram shows the average firing rate (or equivalently spike count) responses of each of 3 cells (labelled as Rate Cell 1,2,3) to a set of 3 stimuli. The right two columns show a measure of the cross-correlation (averaged across trials) for some pairs of cells (labelled as CorrIn Cells 1–2 and 2–3). The last row (labelled Response single trial) shows the data that might be obtained from a single trial and from which the stimulus that was shown (St. ? or s') must be estimated or decoded, using the average values across trials shown in the top part of the table. From the responses on the single trial, the most probable decoded stimulus is stimulus 2, based on the values of both the rates and the cross-correlations. (After Franco, L., Rolls, E. T., Aggelopoulos, N.C. and Treves, A. (2004) The use of decoding to analyze the contribution to the information of the correlations between the firing of simultaneously recorded neurons. *Experimental Brain Research* 155: 370–384. © Springer Nature.)

The new step taken by Franco, Rolls, Aggelopoulos and Treves (2004) is to introduce into the Table Data(s, r) shown in the upper part of Fig. C.3 new columns, shown on the right of the diagram, containing a measure of the cross-correlation (averaged across trials in the upper part of the table) for some pairs of cells (labelled as CorrIn Cells 1–2 and 2–3). The decoding procedure can then take account of any cross-correlations between pairs of cells, and thus measure any contributions to the information from the population of cells that arise from cross-correlations between the neuronal responses. If these cross-correlations are stimulus-dependent, then their positive contribution to the information encoded can be measured. This is the new concept for information measurement from neuronal populations introduced by Franco, Rolls, Aggelopoulos and Treves (2004). We describe next how the cross-correlation information can be introduced into the Table, and then how the information analysis algorithm can be used to measure the contribution of different factors in the neuronal responses to the information that the population encodes.

To test different hypotheses, the decoding can be based on all the columns of the Table (to provide the total information available from both the firing rates and the stimulus-dependent synchronization), on only the columns with the firing rates (to provide the information available from the firing rates), and only on the columns with the cross-correlation values (to provide the information available from the stimulus-dependent cross-correlations). Any information from stimulus-dependent cross-correlations will not necessarily be orthogonal to the rate information, and the procedures allow this to be checked by comparing the total information to that from the sum of the two components. If cross-correlations are present but are

not stimulus-dependent, these will not contribute to the information available about which stimulus was shown.

The measure of the synchronization introduced into the Table Data(s, r) on each trial is, for example, the value of the Pearson cross-correlation coefficient calculated for that trial at the appropriate lag for cell pairs that have significant cross-correlations (Franco, Rolls, Aggelopoulos and Treves, 2004). This value of this Pearson cross-correlation coefficient for a single trial can be calculated from pairs of spike trains on a single trial by forming for each cell a vector of 0s and 1s, the 1s representing the time of occurrence of spikes with a temporal resolution of 1 ms. Resulting values within the range -1 to 1 are shifted to obtain positive values. An advantage of basing the measure of synchronization on the Pearson cross-correlation coefficient is that it measures the amount of synchronization between a pair of neurons independently of the firing rate of the neurons. The lag at which the cross-correlation measure was computed for every single trial, and whether there was a significant cross-correlation between neuron pairs, can be identified from the location of the peak in the cross-correlogram taken across all trials. The cross-correlogram is calculated by, for every spike that occurred in one neuron, incrementing the bins of a histogram that correspond to the lag times of each of the spikes that occur for the other neuron. The raw cross-correlogram is corrected by subtracting the “shift predictor” cross-correlogram (which is produced by random re-pairings of the trials), to produce the corrected cross-correlogram.

Further details of the decoding procedures are as follows (see Rolls, Treves and Tovee (1997b) and Franco, Rolls, Aggelopoulos and Treves (2004)). The full probability table estimator (PE) algorithm uses a Bayesian approach to extract $P(s'|\mathbf{r})$ for every single trial from an estimate of the probability $P(\mathbf{r}|s')$ of a stimulus–response pair made from all the other trials (as shown in Bayes’ rule shown in Equation C.34) in a cross-validation procedure described by Rolls et al. (1997b).

$$P(s'|\mathbf{r}) = \frac{P(\mathbf{r}|s')P(s')}{P(\mathbf{r})}. \quad (\text{C.34})$$

where $P(\mathbf{r})$ (the probability of the vector containing the firing rate of each neuron, where each element of the vector is the firing rate of one neuron) is obtained as:

$$P(\mathbf{r}) = \sum_{s'} P(\mathbf{r}|s')P(s'). \quad (\text{C.35})$$

This requires knowledge of the response probabilities $P(\mathbf{r}|s')$ which can be estimated for this purpose from $P(\mathbf{r}, s')$, which is equal to $P(s') \prod_c P(r_c|s')$, where r_c is the firing rate of cell c . I note that $P(r_c|s')$ is derived from the responses of cell c from all of the trials except for the current trial for which the probability estimate is being made. The probabilities $P(r_c|s')$ are fitted with a Gaussian (or Poisson) distribution whose amplitude at r_c gives $P(r_c|s')$. By summing over different test trial responses to the same stimulus s , we can extract the probability that by presenting stimulus s the neuronal response is interpreted as having been elicited by stimulus s' ,

$$P(s'|s) = \sum_{\mathbf{r} \in \text{test}} P(s'|\mathbf{r})P(\mathbf{r}|s). \quad (\text{C.36})$$

After the decoding procedure, the estimated relative probabilities (normalized to 1) were averaged over all ‘test’ trials for all stimuli, to generate a (Regularized) table $P^R_N(s, s')$ describing the relative probability of each pair of actual stimulus s and posited stimulus s' (computed with N trials). From this probability table the mutual information measure (I_p) was calculated as described above in Equation C.33.

We also generate a second (Frequency) table $P^F_N(s, s^P)$ from the fraction of times an actual stimulus s elicited a response that led to a predicted (single most likely) stimulus s^P . From this probability Table the mutual information measure based on maximum likelihood decoding (I_{ml}) was calculated with Equation C.37:

$$\langle I_{ml} \rangle = \sum_{s \in S} \sum_{s^P \in S} P(s, s^P) \log_2 \frac{P(s, s^P)}{P(s)P(s^P)}. \quad (\text{C.37})$$

A detailed comparison of maximum likelihood and probability decoding is provided by Rolls, Treves and Tovee (1997b), but I note here that probability estimate decoding is more regularized (see below) and therefore may be safer to use when investigating the effect on the information of the number of cells. For this reason, the results described by Franco, Rolls, Aggelopoulos and Treves (2004) were obtained with probability estimation (PE) decoding. The maximum likelihood decoding does give an immediate measure of the percentage correct.

Another approach to decoding is the dot product (DP) algorithm which computes the normalized dot products between the current firing vector \mathbf{r} on a “test” (i.e. the current) trial and each of the mean firing rate response vectors in the “training” trials for each stimulus s' in the cross-validation procedure. (The normalized dot product is the dot or inner product of two vectors divided by the product of the length of each vector. The length of each vector is the square root of the sum of the squares.) Thus, what is computed are the cosines of the angles of the test vector of cell rates with, in turn for each stimulus, the mean response vector to that stimulus. The highest dot product indicates the most likely stimulus that was presented, and this is taken as the predicted stimulus s^P for the probability table $P(s, s^P)$. (It can also be used to provide percentage correct measures.)

I note that any decoding procedure can be used in conjunction with information estimates both from the full probability table (to produce I_p), and from the most likely estimated stimulus for each trial (to produce I_{ml}).

Because the probability tables from which the information is calculated may be unregularized with a small number of trials, a bias correction procedure to correct for the under-sampling is applied, as described in detail by Rolls, Treves and Tovee (1997b) and Panzeri and Treves (1996). In practice, the bias correction that is needed with information estimates using the decoding procedures described by Franco, Rolls, Aggelopoulos and Treves (2004) and by Rolls et al. (1997b) is small, typically less than 10% of the uncorrected estimate of the information, provided that the number of trials for each stimulus is in the order of twice the number of stimuli. We also note that the distortion in the information estimate from the full probability table needs less bias correction than that from the predicted stimulus table (i.e. maximum likelihood) method, as the former is more regularized because every trial makes some contribution through much of the probability table (see Rolls et al. (1997b)). We further note that the bias correction term becomes very small when more than 10 cells are included in the analysis (Rolls et al., 1997b).

Examples of the use of these procedures are available (Franco, Rolls, Aggelopoulos and Treves, 2004; Aggelopoulos, Franco and Rolls, 2005), and some of the results obtained are described in Section C.3.

C.2.5 Information in the correlations between the spikes of different cells: a second derivative approach

Another information theory-based approach to stimulus-dependent cross-correlation information has been developed as follows by Panzeri, Schultz, Treves and Rolls (1999a) and Rolls,

Franco, Aggelopoulos and Reece (2003b). A problem that must be overcome is the fact that with many simultaneously recorded neurons, each emitting perhaps many spikes at different times, the dimensionality of the response space becomes very large, the information tends to be overestimated, and even bias corrections cannot save the situation. The approach described in this Section (C.2.5) limits the problem by taking short time epochs for the information analysis, in which low numbers of spikes, in practice typically 0, 1, or 2, spikes are likely to occur from each neuron.

In a sufficiently short time window, at most two spikes are emitted from a population of neurons. Taking advantage of this, the response probabilities can be calculated in terms of pairwise correlations. These response probabilities are inserted into the Shannon information formula C.38 to obtain expressions quantifying the impact of the pairwise correlations on the information $I(t)$ transmitted in a short time t by groups of spiking neurons:

$$I(t) = \sum_{s \in \mathcal{S}} \sum_{\mathbf{r}} P(s, \mathbf{r}) \log_2 \frac{P(s, \mathbf{r})}{P(s)P(\mathbf{r})} \quad (\text{C.38})$$

where \mathbf{r} is the firing rate response vector comprised by the number of spikes emitted by each of the cells in the population in the short time t , and $P(s, \mathbf{r})$ refers to the joint probability distribution of stimuli with their respective neuronal response vectors.

The information depends upon the following two types of correlation:

C.2.5.1 The correlations in the neuronal response variability from the average to each stimulus (sometimes called “noise” correlations) γ :

$\gamma_{ij}(s)$ (for $i \neq j$) is the fraction of coincidences above (or below) that expected from uncorrelated responses, relative to the number of coincidences in the uncorrelated case (which is $\bar{n}_i(s)\bar{n}_j(s)$, the bar denoting the average across trials belonging to stimulus s , where $n_i(s)$ is the number of spikes emitted by cell i to stimulus s on a given trial)

$$\gamma_{ij}(s) = \frac{\overline{n_i(s)n_j(s)}}{(\bar{n}_i(s)\bar{n}_j(s))} - 1, \quad (\text{C.39})$$

and is named the ‘scaled cross-correlation density’. It can vary from -1 to ∞ ; negative $\gamma_{ij}(s)$ ’s indicate anticorrelation, whereas positive $\gamma_{ij}(s)$ ’s indicate correlation³². $\gamma_{ij}(s)$ can be thought of as the amount of trial by trial concurrent firing of the cells i and j , compared to that expected in the uncorrelated case. $\gamma_{ij}(s)$ (for $i \neq j$) is the ‘scaled cross-correlation density’ (Aertsen, Gerstein, Habib and Palm, 1989; Panzeri, Schultz, Treves and Rolls, 1999a), and is sometimes called the “noise” correlation (Gawne and Richmond, 1993; Shadlen and Newsome, 1995, 1998; Panzeri, Moroni, Safaai and Harvey, 2022).

³² $\gamma_{ij}(s)$ is an alternative, which produces a more compact information analysis, to the neuronal cross-correlation based on the Pearson correlation coefficient $\rho_{ij}(s)$ (equation C.40), which normalizes the number of coincidences above independence to the standard deviation of the number of coincidences expected if the cells were independent. The normalization used by the Pearson correlation coefficient has the advantage that it quantifies the strength of correlations between neurons in a rate-independent way. For the information analysis, it is more convenient to use the scaled correlation density $\gamma_{ij}(s)$ than the Pearson correlation coefficient, because of the compactness of the resulting formulation, and because of its scaling properties for small t . $\gamma_{ij}(s)$ remains finite as $t \rightarrow 0$, thus by using this measure we can keep the t expansion of the information explicit. Keeping the time-dependence of the resulting information components explicit greatly increases the amount of insight obtained from the series expansion. In contrast, the Pearson noise-correlation measure applied to short timescales approaches zero at short time windows:

$$\rho_{ij}(s) \equiv \frac{\overline{n_i(s)n_j(s)} - \bar{n}_i(s)\bar{n}_j(s)}{\sigma_{n_i(s)}\sigma_{n_j(s)}} \simeq t \quad \gamma_{ij}(s) = \sqrt{\overline{n_i(s)n_j(s)}}, \quad (\text{C.40})$$

where $\sigma_{n_i(s)}$ is the standard deviation of the count of spikes emitted by cell i in response to stimulus s .

C.2.5.2 The correlations in the mean responses of the neurons across the set of stimuli (sometimes called “signal” correlations) ν :

$$\nu_{ij} = \frac{\langle \bar{n}_i(s)\bar{n}_j(s) \rangle_s}{\langle \bar{n}_i(s) \rangle_s \langle \bar{n}_j(s) \rangle_s} - 1 = \frac{\langle \bar{r}_i(s)\bar{r}_j(s) \rangle_s}{\langle \bar{r}_i(s) \rangle_s \langle \bar{r}_j(s) \rangle_s} - 1 \quad (C.41)$$

where $\bar{r}_i(s)$ is the mean rate of response of cell i (among C cells in total) to stimulus s over all the trials in which that stimulus was present. ν_{ij} can be thought of as the degree of similarity in the mean response profiles (averaged across trials) of the cells i and j to different stimuli. ν_{ij} is sometimes called the “signal” correlation (Gawne and Richmond, 1993; Shadlen and Newsome, 1995, 1998; Panzeri, Moroni, Safaai and Harvey, 2022).

Stimulus-independent ‘noise’ correlations can decrease the amount of encoded information about a stimulus if they increase the overlap between the distributions of the neuronal rates from the population. This is probably the typical case, though the opposite might occur (Panzeri et al., 2022). Stimulus-dependent ‘noise’ correlations, that vary in sign and/or strength across stimuli, might provide a separate channel for stimulus information encoding and might increase the amount of information that could be decoded. An example might be temporal synchronisation of the responses of different neurons only on trials on which a particular stimulus was shown (Panzeri et al., 2022). One way to measure how the effects of the correlations in the activity of populations of simultaneously recorded neurons influence the total information that can be encoded is to shuffle the data across trials for each neuron in the population (Panzeri et al., 2022). In practice, ‘noise’ correlations tend to decrease the information that can be decoded from populations of neurons (Panzeri et al., 2022). However, many of these analyses (Panzeri et al., 2022) assume that for example temporal synchrony between the firing of particular pairs of neurons is actually being measured in the brain and taken into account in decoding the information, and that is not at all clear. Overall, ‘noise’ correlations are not likely to increase the information that is used in the brain, and if anything may decrease the information that is being used by the brain. Further evidence is provided in Section C.3.7.

C.2.5.3 Information in the cross-correlations in short time periods

In the short timescale limit, the first (I_t) and second (I_{tt}) information derivatives describe the information $I(t)$ available in the short time t

$$I(t) = t I_t + \frac{t^2}{2} I_{tt} . \quad (C.42)$$

(The zeroth order, time-independent term is zero, as no information can be transmitted by the neurons in a time window of zero length. Higher order terms are also excluded as they become negligible.)

The instantaneous information rate I_t is³³

$$I_t = \sum_{i=1}^C \left\langle \bar{r}_i(s) \log_2 \frac{\bar{r}_i(s)}{\langle \bar{r}_i(s') \rangle_{s'}} \right\rangle_s . \quad (C.43)$$

This formula shows that this information rate (the first time derivative) should not be linked to a high signal to noise ratio, but only reflects the extent to which the mean responses of each

³³Note that s' is used in Equations C.43 and C.44 just as a dummy variable to stand for s , as there are two summations performed over s .

cell are distributed across stimuli. It does not reflect anything of the variability of those responses, that is of their noisiness, nor anything of the correlations among the mean responses of different cells.

The effect of (pairwise) correlations between the cells begins to be expressed in the second time derivative of the information. The expression for the instantaneous information ‘acceleration’ I_{tt} (the second time derivative of the information) breaks up into three terms:

$$\begin{aligned}
 I_{tt} = & \frac{1}{\ln 2} \sum_{i=1}^C \sum_{j=1}^C \langle \bar{r}_i(s) \rangle_s \langle \bar{r}_j(s) \rangle_s \left[\nu_{ij} + (1 + \nu_{ij}) \ln \left(\frac{1}{1 + \nu_{ij}} \right) \right] \\
 & + \sum_{i=1}^C \sum_{j=1}^C \left[\langle \bar{r}_i(s) \bar{r}_j(s) \gamma_{ij}(s) \rangle_s \right] \log_2 \left(\frac{1}{1 + \nu_{ij}} \right) \\
 & + \sum_{i=1}^C \sum_{j=1}^C \left\langle \bar{r}_i(s) \bar{r}_j(s) (1 + \gamma_{ij}(s)) \log_2 \left[\frac{(1 + \gamma_{ij}(s)) \langle \bar{r}_i(s') \bar{r}_j(s') \rangle_{s'}}{\langle \bar{r}_i(s') \bar{r}_j(s') (1 + \gamma_{ij}(s')) \rangle_{s'}} \right] \right\rangle_s. \quad (\text{C.44})
 \end{aligned}$$

The first of these terms is all that survives if there is no noise correlation at all. Thus the *rate component* of the information is given by the sum of I_t (which is always greater than or equal to zero) and of the first term of I_{tt} (which is instead always less than or equal to zero).

The second term is non-zero if there is some correlation in the variance to a given stimulus, even if it is independent of which stimulus is present; this term thus represents the contribution of *stimulus-independent noise correlation* to the information.

The third component of I_{tt} represents the contribution of *stimulus-modulated noise correlation*, as it becomes non-zero only for stimulus-dependent noise correlations. These last two terms of I_{tt} together are referred to as the correlational components of the information.

The application of this approach to measuring the information in the relative time of firing of simultaneously recorded cells, together with further details of the method, are described by Panzeri, Treves, Schultz and Rolls (1999b), Rolls, Franco, Aggelopoulos and Reece (2003b), and Rolls, Aggelopoulos, Franco and Treves (2004), and in Section C.3.7.

Further approaches to measuring how the correlations in the activity of populations of simultaneously recorded neurons influences the total information that can be encoded include shuffling the data across trials for each neuron in the population (Panzeri et al., 2022).

C.3 Neuronal encoding: results obtained from applying information-theoretic analyses

How is information encoded in cortical areas such as the inferior temporal visual cortex? Can we read the code being used by the cortex? What are the advantages of the encoding scheme used for the neuronal network computations being performed in different areas of the cortex? These are some of the key issues considered in this Section (C.3). Because information is exchanged between the computing elements of the cortex (the neurons) by their spiking activity, which is conveyed by their axon to synapses onto other neurons, the appropriate level of analysis is how single neurons, and populations of single neurons, encode information in their firing. More global measures that reflect the averaged activity of large numbers of neurons (for example, PET (positron emission tomography) and fMRI (functional magnetic resonance imaging), EEG (electroencephalographic recording), and ERPs (event-related potentials)) cannot reveal how the information is represented, or how the computation is being performed.

Although information theory provides the natural mathematical framework for analysing the performance of neuronal systems, its applications in neuroscience have been for many years rather sparse and episodic (e.g. MacKay and McCulloch (1952); Eckhorn and Popel (1974); Eckhorn and Popel (1975); Eckhorn, Grusser, Kroller, Pellnitz and Popel (1976); Rolls and Treves (2011); Meshulam, Gauthier, Brody, Tank and Bialek (2017); and Panzeri et al. (2022)). One reason for this limited application of information theory has been the great effort that was apparently required, due essentially to the limited sampling problem, in order to obtain accurate results. Another reason has been the hesitation in analysing as a single complex ‘black-box’ large neuronal systems all the way from some external, easily controllable inputs, up to neuronal activity in some central cortical area of interest, for example including all visual stations from the periphery to the end of the ventral visual stream in the temporal lobe. In fact, two important bodies of work, that have greatly helped revive interest in applications of the theory in recent years, both sidestep these two problems. The problem with analyzing a huge black-box is avoided by considering systems at the sensory periphery; the limited sampling problem is avoided either by working with insects, in which sampling can be extensive (Bialek, Rieke, de Ruyter van Steveninck and Warland, 1991; de Ruyter van Steveninck and Laughlin, 1996; Rieke, Warland, de Ruyter van Steveninck and Bialek, 1997), or by utilizing a formal model instead of real data (Atick and Redlich, 1990; Atick, 1992). Both approaches have provided insightful quantitative analyses that have been extended to more central mammalian systems (see e.g. Atick, Griffin and Relich (1996)).

In the treatment provided here, we focus on applications to the mammalian brain, using examples from a whole series of investigations on information representation in visual cortical areas, the original papers on which refer to related publications.

C.3.1 The sparseness of the distributed encoding used by the brain

Some of the types of representation that might be found at the neuronal level are summarized next (cf. Section 1.7). A **local representation** is one in which all the information that a particular stimulus or event occurred is provided by the activity of one of the neurons. This is sometimes called a grandmother cell representation, because in a famous example, a single neuron might be active only if one’s grandmother was being seen (see Barlow (1995)). A **fully distributed representation** is one in which all the information that a particular stimulus or event occurred is provided by the activity of the full set of neurons. If the neurons are binary (for example, either active or not), the most distributed encoding is when half the neurons are active for any one stimulus or event. A **sparse distributed representation** is a distributed representation in which a small proportion of the neurons is active at any one time.

C.3.1.1 Single neuron sparseness a^s

Equation C.45 defines a measure of the single neuron sparseness, a^s :

$$a^s = \frac{(\sum_{s=1}^S y_s / S)^2}{(\sum_{s=1}^S y_s^2) / S} \quad (\text{C.45})$$

where y_s is the mean firing rate of the neuron to stimulus s in the set of S stimuli (Rolls and Treves, 1998). For a binary representation, a^s is 0.5 for a fully distributed representation, and $1/S$ if a neuron responds to one of a set of S stimuli. Another measure of sparseness is the kurtosis of the distribution, which is the fourth moment of the distribution. It reflects the length of the tail of the distribution. (An actual distribution of the firing rates of a neuron to a

set of 65 stimuli is shown in Fig. C.4. The sparseness a^s for this neuron was 0.69 (see Rolls, Treves, Tovee and Panzeri (1997d).)

It is important to understand and quantify the sparseness of representations in the brain, because many of the useful properties of neuronal networks such as generalization and completion only occur if the representations are not local (see Appendix B), and because the value of the sparseness is an important factor in how many memories can be stored in such neural networks. Relatively sparse representations (low values of a^s) might be expected in memory systems as this will increase the number of different memories that can be stored and retrieved. Less sparse representations might be expected in sensory systems, as this could allow more information to be represented (see Table B.2).

Barlow (1972) proposed a single neuron doctrine for perceptual psychology. He proposed that sensory systems are organized to achieve as complete a representation as possible with the minimum number of active neurons. He suggested that at progressively higher levels of sensory processing, fewer and fewer cells are active, and that each represents a more and more specific happening in the sensory environment. He suggested that 1,000 active neurons (which he called cardinal cells) might represent the whole of a visual scene. An important principle involved in forming such a representation was the reduction of redundancy. The implication of Barlow's (1972) approach was that when an object is being recognized, there are, towards the end of the visual system, a small number of neurons (the cardinal cells) that are so specifically tuned that the activity of these neurons encodes the information that one particular object is being seen. (He thought that an active neuron conveys something of the order of complexity of a word.) The encoding of information in such a system is described as local, in that knowing the activity of just one neuron provides evidence that a particular stimulus (or, more exactly, a given 'trigger feature') is present. Barlow (1972) eschewed 'combinatorial rules of usage of nerve cells', and believed that the subtlety and sensitivity of perception results from the mechanisms determining when a single cell becomes active. In contrast, with distributed or ensemble encoding, the activity of several or many neurons must be known in order to identify which stimulus is present, that is, to read the code. It is the relative firing of the different neurons in the ensemble that provides the information about which object is present.

At the time Barlow (1972) wrote, there was little actual evidence on the activity of neurons in the higher parts of the visual and other sensory systems. There is now considerable evidence, which is now described.

First, it has been shown that the representation of which particular object (face) is present is actually rather distributed. Baylis, Rolls and Leonard (1985) showed this with the responses of temporal cortical neurons that typically responded to several members of a set of five faces, with each neuron having a different profile of responses to each face (see examples in Fig. 2.17 on page 76). It would be difficult for most of these single cells to tell which of even five faces, let alone which of hundreds of faces, had been seen. (At the same time, the neurons discriminated between the faces reliably, as shown by the values of d' , taken, in the case of the neurons, to be the number of standard deviations of the neuronal responses that separated the response to the best face in the set from that to the least effective face in the set. The values of d' were typically in the range 1–3.)

Second, the distributed nature of the representation can be further understood by the finding that the firing rate probability distribution of single neurons, when a wide range of natural visual stimuli are being viewed, is approximately exponential, with rather few stimuli producing high firing rates, and increasingly large numbers of stimuli producing lower and lower firing rates, as illustrated in Fig. C.5a (Rolls and Tovee, 1995b; Baddeley, Abbott, Booth, Sengpiel, Freeman, Wakeman and Rolls, 1997; Treves, Panzeri, Rolls, Booth and Wakeman, 1999; Franco, Rolls, Aggelopoulos and Jerez, 2007).

Fig. C.4 Single neuron sparseness. Firing rate distribution of a single neuron in the temporal visual cortex to a set of 23 face (F) and 45 non-face images of natural scenes. The firing rate to each of the 68 stimuli is shown. The neuron does not respond to just one of the 68 stimuli. Instead, it responds to a small proportion of stimuli with high rates, to more stimuli with intermediate rates, and to many stimuli with almost no change of firing. This is typical of the distributed representations found in temporal cortical visual areas. (After Rolls, E. T. and Tovee, M.J. (1995) Sparseness of the neuronal representation of stimuli in the primate temporal visual cortex. *Journal of Neurophysiology* 73: 713–726.)

For example, the responses of a set of temporal cortical neurons to 23 faces and 42 non-face natural images were measured, and a distributed representation was found (Rolls and Tovee, 1995b). The tuning was typically graded, with a range of different firing rates to the set of faces, and very little response to the non-face stimuli (see example in Fig. C.4). The spontaneous firing rate of the neuron in Fig. C.4 was 20 spikes/s, and the histogram bars indicate the change of firing rate from the spontaneous value produced by each stimulus. Stimuli that are faces are marked F, or P if they are in profile. B refers to images of scenes that included either a small face within the scene, sometimes as part of an image that included a whole person, or other body parts, such as hands (H) or legs. The non-face stimuli are unlabelled. The neuron responded best to three of the faces (profile views), had some response to some of the other faces, and had little or no response, and sometimes had a small decrease of firing rate below the spontaneous firing rate, to the non-face stimuli. The sparseness value a^s for this cell across all 68 stimuli was 0.69, and the response sparseness a_r^s (based on the evoked responses minus the spontaneous firing of the neuron) was 0.19. It was found that the sparseness of the representation of the 68 stimuli by each neuron had an average across all neurons of 0.65 (Rolls and Tovee, 1995b). This indicates a rather distributed representation. (If neurons had a continuum of firing rates equally distributed between zero and maximum

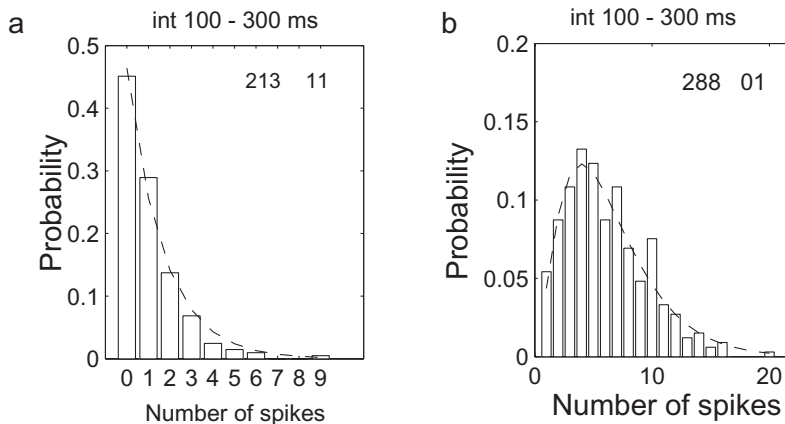

Fig. C.5 Firing rate probability distributions. These are shown for two neurons in the inferior temporal visual cortex tested with a set of 20 face and non-face stimuli. (a) A neuron with a good fit to an exponential probability distribution (dashed line). (b) A neuron that did not fit an exponential firing rate distribution (but which could be fitted by a gamma distribution, dashed line). The firing rates were measured in an interval 100–300 ms after the onset of the visual stimuli, and similar distributions are obtained in other intervals. (After Franco, L., Rolls, E. T., Aggelopoulos, N. C. and Jerez, J. M. (2007) Neuronal selectivity, population sparseness, and ergodicity in the inferior temporal visual cortex. *Biological Cybernetics* 96: 547–560. © Springer Nature.)

rate, a^s would be 0.75, while if the probability of each response decreased linearly, to reach zero at the maximum rate, a^s would be 0.67).

I comment that these values for a do not seem very sparse. But these values are calculated using the raw firing rates of the neurons, on the basis that these would be what a receiving neuron would receive as its input representation. However, neocortical neurons have a spontaneous firing rate of several spikes/s (with a lower value of 0.75 spikes/s for hippocampal pyramidal cells), and if this spontaneous value is subtracted from the firing rates to yield a ‘response sparseness’ a_r , this value is considerably lower. For example, the sparseness a of inferior temporal cortex responses to a set of 68 stimuli had an average across all neurons that we analyzed in this study of 0.65 (Rolls and Tovee, 1995b). If the spontaneous firing rate was subtracted from the firing rate of the neuron to each stimulus, so that the changes of firing rate, i.e., the responses of the neurons, were used in the sparseness calculation, then the ‘response sparseness’ had a lower value, with a mean of $a_r=0.33$ for the population of neurons, or 0.60 if calculated over the set of faces rather than over all the face and non-face stimuli. Further, the true sparseness of the representation is probably much less than this, for this is calculated only over the neurons that had responses to some of these stimuli. There were many more neurons that had no response to the stimuli. At least 10 times the number of inferior temporal cortex neurons had no responses to this set of 68 stimuli. So the true sparseness would be much lower than this value of 0.33. Further, it is important to remember the relative nature of sparseness measures, which (like the information measures to be discussed below) depend strongly on the stimulus set used. Thus we can reject a cardinal cell representation. As shown below, the readout of information from these cells is actually much better in any case than would be obtained from a local representation, and this makes it unlikely that there is a further population of neurons with very specific tuning that use local encoding.

These data provide a clear answer to whether these neurons are grandmother cells: they are not, in the sense that each neuron has a graded set of responses to the different members of a set of stimuli, with the prototypical distribution similar to that of the neuron illustrated in Fig. C.4. On the other hand, each neuron does respond very much more to some stimuli than to many others, and in this sense is tuned to some stimuli.

Figure C.5 shows data of the type shown in Fig. C.4 as firing rate probability density

Fig. C.6 Firing rate probability distribution for a single neuron, using natural world image statistics. The probability of different firing rates measured in short (e.g. 100 ms or 500 ms) time windows of a temporal cortex neuron calculated over a 5 min period in which the macaque watched a video showing natural scenes, including faces. An exponential fit (+) to the data (diamonds) is shown. (After Baddeley, R.J., Abbott, L.F., Booth, M.J.A., Sengpiel, F., Freeman, T., Wakeman, E.A., and Rolls, E. T. (1997) Responses of neurons in primary and inferior temporal visual cortices to natural scenes. *Proceedings of the Royal Society B* 264: 1775-1783.)

functions, that is as the probability that the neuron will be firing with particular rates. These data were from inferior temporal cortex neurons, and show when tested with a set of 20 face and non-face stimuli how fast the neuron will be firing in a period 100–300 ms after the visual stimulus appears (Franco, Rolls, Aggelopoulos and Jerez, 2007). Figure C.5a shows an example of a neuron where the data fit an exponential firing rate probability distribution, with many occasions on which the neuron was firing with a very low firing rate, and decreasingly few occasions on which it fired at higher rates. This shows that the neuron can have high firing rates, but only to a few stimuli. Figure C.5b shows an example of a neuron where the data do not fit an exponential firing rate probability distribution, with insufficiently few very low rates. Of the 41 responsive neurons in this data set, 15 had a good fit to an exponential firing rate probability distribution; the other 26 neurons did not fit an exponential but did fit a gamma distribution in the way illustrated in Fig. C.5b. For the neurons with an exponential distribution, the mean firing rate across the stimulus set was 5.7 spikes/s, and for the neurons with a gamma distribution was 21.1 spikes/s ($t=4.5$, $df=25$, $p < 0.001$). It may be that neurons with high mean rates to a stimulus set tend to have few low rates ever, and this accounts for their poor fit to an exponential firing rate probability distribution, which fits when there are many low firing rate values in the distribution as in Fig. C.5a.

The large set of 68 stimuli used by Rolls and Tovee (1995b) was chosen to produce an approximation to a set of stimuli that might be found to natural stimuli in a natural environment, and thus to provide evidence about the firing rate distribution of neurons to natural stimuli. Another approach to the same fundamental question was taken by Baddeley, Abbott, Booth, Sengpiel, Freeman, Wakeman, and Rolls (1997) who measured the firing rates over short periods of individual inferior temporal cortex neurons while monkeys watched continuous videos of natural scenes. They found that the firing rates of the neurons were again approximately exponentially distributed (see Fig. C.6), providing further evidence that this type of representation is characteristic of inferior temporal cortex (and indeed also V1) neurons.

The actual distribution of the firing rates to a wide set of natural stimuli is of interest, because it has a rather stereotypical shape, typically following a graded unimodal distribution with a long tail extending to high rates (see for example Figs. C.5a and C.6). The mode of the distribution is close to the spontaneous firing rate, and sometimes it is at zero firing. If the number of spikes recorded in a fixed time window is taken to be constrained by a fixed maximum rate, one can try to interpret the distribution observed in terms of optimal information transmission (Shannon, 1948), by making the additional assumption that the coding is noiseless. An exponential distribution, which maximizes entropy (and hence information transmission for noiseless codes) is the most efficient in terms of energy consumption if its mean takes an optimal value that is a decreasing function of the relative metabolic cost of emitting a spike (Levy and Baxter, 1996). This argument would favour sparser coding schemes the more energy expensive neuronal firing is (relative to rest). Although the tail of actual firing rate distributions is often approximately exponential (see for example Figs. C.5a and C.6; Baddeley, Abbott, Booth, Sengpiel, Freeman, Wakeman and Rolls (1997); Rolls, Treves, Tovee and Panzeri (1997d); and Franco, Rolls, Aggelopoulos and Jerez (2007)), the maximum entropy argument cannot apply as such, because noise is present and the noise level varies as a function of the rate, which makes entropy maximization different from information maximization. Moreover, a mode at low but non-zero rate, which is often observed (see e.g. Fig. C.5b), is inconsistent with the energy efficiency hypothesis.

A simpler explanation for the characteristic firing rate distribution arises by appreciating that the value of the activation of a neuron across stimuli, reflecting a multitude of contributing factors, will typically have a Gaussian distribution; and by considering a physiological input–output transform (i.e. activation function), and realistic noise levels. In fact, an input–output transform that is supralinear in a range above threshold results from a fundamentally linear transform and fluctuations in the activation, and produces a variance in the output rate, across repeated trials, that increases with the rate itself, consistent with common observations. At the same time, such a supralinear transform tends to convert the Gaussian tail of the activation distribution into an approximately exponential tail, without implying a fully exponential distribution with the mode at zero. Such basic assumptions yield excellent fits with observed distributions (Treves, Panzeri, Rolls, Booth and Wakeman, 1999), which often differ from exponential in that there are too few very low rates observed, and too many low rates (Rolls, Treves, Tovee and Panzeri, 1997d; Franco, Rolls, Aggelopoulos and Jerez, 2007).

This peak at low but non-zero rates may be related to the low firing rate spontaneous activity that is typical of many cortical neurons. Keeping the neurons close to threshold in this way may maximize the speed with which a network can respond to new inputs (because time is not required to bring the neurons from a strongly hyperpolarized state up to threshold). The advantage of having low spontaneous firing rates may be a further reason why a curve such as an exponential cannot sometimes be exactly fitted to the experimental data.

A conclusion of this analysis was that the firing rate distribution may arise from the threshold non-linearity of neurons combined with short-term variability in the responses of neurons (Treves, Panzeri, Rolls, Booth and Wakeman, 1999).

However, given that the firing rate distribution for some neurons is approximately exponential, some properties of this type of representation are worth elucidation. The sparseness of such an exponential distribution of firing rates is 0.5. This has interesting implications, for to the extent that the firing rates are exponentially distributed, this fixes an important parameter of cortical neuronal encoding to be close to 0.5. Indeed, only one parameter specifies the shape of the exponential distribution, and the fact that the exponential distribution is at least a close approximation to the firing rate distribution of some real cortical neurons implies that the sparseness of the cortical representation of stimuli is kept under precise control. The utility of this may be to ensure that any neuron receiving from this representation can

Fig. C.7 The set of 20 stimuli used to investigate the tuning of inferior temporal cortex neurons by Franco, Rolls, Aggelopoulos and Jerez 2007. These objects and faces are typical of those encoded in the ways described here by inferior temporal cortex neurons. The code can be read off simply from the firing rates of the neurons about which object or face was shown, and many of the neurons have invariant responses. (After Franco, L., Rolls, E. T., Aggelopoulos, N.C. and Jerez, J.M. (2007) Neuronal selectivity, population sparseness, and ergodicity in the inferior temporal visual cortex. *Biological Cybernetics* 96: 547-560. © Springer Nature.)

perform a dot product operation between its inputs and its synaptic weights that produces similarly distributed outputs; and that the information being represented by a population of cortical neurons is kept high. It is interesting to realize that the representation that is stored in an associative network (see Appendix B) may be more sparse than the 0.5 value for an exponential firing rate distribution, because the non-linearity of learning introduced by the voltage dependence of the NMDA receptors (see Appendix B) effectively means that synaptic modification in, for example, an autoassociative network will occur only for the neurons with relatively high firing rates, i.e. for those that are strongly depolarized.

The single neuron selectivity reflects response distributions of individual neurons across time to different stimuli. As we have seen, part of the interest of measuring the firing rate probability distributions of individual neurons is that one form of the probability distribution, the exponential, maximizes the entropy of the neuronal responses for a given mean firing rate, which could be used to maximize information transmission consistent with keeping the firing rate on average low, in order to minimize metabolic expenditure (Levy and Baxter, 1996; Baddeley, Abbott, Booth, Sengpiel, Freeman, Wackman and Rolls, 1997). Franco, Rolls, Aggelopoulos and Jerez (2007) showed that while the firing rates of some single inferior temporal cortex neurons (tested in a visual fixation task to a set of 20 face and non-face stimuli illustrated in Fig. C.7) do fit an exponential distribution, and others with higher spontaneous firing rates do not, as described above, it turns out that there is a very close fit to an exponential distribution of firing rates if all spikes from all the neurons are considered together. This interesting result is shown in Fig. C.8.

One implication of the result shown in Fig. C.8 is that a neuron with inputs from the inferior temporal visual cortex will receive an exponential distribution of firing rates on its afferents, and this is therefore the type of input that needs to be considered in theoretical models of neuronal network function in the brain (see Appendix B). The second implication is that at the level of single neurons, an exponential probability density function is consistent with minimizing energy utilization, and maximizing information transmission, for a given mean

Fig. C.8 The firing rate probability distribution of single neurons is approximately exponential. An exponential firing rate probability distribution obtained by pooling the firing rates of a population of 41 inferior temporal cortex neurons tested to a set of 20 face and non-face stimuli. The firing rate probability distribution for the 100–300 ms interval following stimulus onset was formed by adding the spike counts from all 41 neurons, and across all stimuli. The fit to the exponential distribution (dashed line) was high. (After Franco, L., Rolls, E. T., Aggelopoulos, N.C. and Jerez, J.M. (2007) Neuronal selectivity, population sparseness, and ergodicity in the inferior temporal visual cortex. *Biological Cybernetics* 96: 547–560. © Springer Nature.)

firing rate (Levy and Baxter, 1996; Baddeley, Abbott, Booth, Sengpiel, Freeman, Wokeman and Rolls, 1997).

C.3.1.2 Population sparseness a^P

If instead we consider the responses of a population of neurons taken at any one time (to one stimulus), we might also expect a sparse graded distribution, with few neurons firing fast to a particular stimulus. It is important to measure the population sparseness, for this is a key parameter that influences the number of different stimuli that can be stored and retrieved in networks such as those found in the cortex with recurrent collateral connections between the excitatory neurons, which can form autoassociation or attractor networks if the synapses are associatively modifiable (Hopfield, 1982; Treves and Rolls, 1991; Rolls and Treves, 1998; Rolls and Deco, 2002; Rolls, 2016b) (see Appendix B). Further, in physics, if one can predict the distribution of the responses of the system at any one time (the population level) from the distribution of the responses of a component of the system across time, the system is described as ergodic, and a necessary condition for this is that the components are uncorrelated (Lehky, Sejnowski and Desimone, 2005). Considering this in neuronal terms, the average sparseness of a population of neurons over multiple stimulus inputs must equal the average selectivity to the stimuli of the single neurons within the population provided that the responses of the neurons are uncorrelated (Földiák, 2003).

The sparseness a^P of the population code may be quantified (for any one stimulus) as

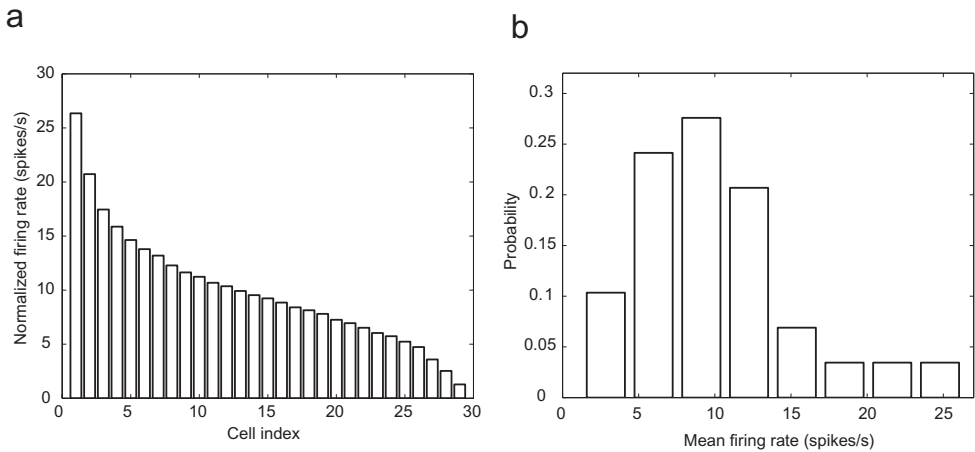

Fig. C.9 Population sparseness. (a) The firing rates of a population of inferior temporal cortex neurons to any one stimulus from a set of 20 face and non-face stimuli. The rates of each neuron were normalized to the same average value of 10 spikes/s, then for each stimulus, the cell firing rates were placed in rank order, and then the mean firing rates of the first ranked cell, second ranked cell, etc. were taken. The graph thus shows how, for any one stimulus picked at random, the expected normalized firing rates of the population of neurons. (b) The population normalized firing rate probability distributions for any one stimulus. This was computed effectively by taking the probability density function of the data shown in (a). (After Franco, L., Rolls, E. T., Aggelopoulos, N.C. and Jerez, J.M. (2007) Neuronal selectivity, population sparseness, and ergodicity in the inferior temporal visual cortex. *Biological Cybernetics* 96: 547–560. © Springer Nature.)

$$a^p = \frac{\left(\sum_{n=1}^N y_n/N\right)^2}{\left(\sum_{n=1}^N y_n^2\right)/N} \quad (\text{C.46})$$

where y_n is the mean firing rate of neuron n in the set of N neurons.

This measure, a^p , of the sparseness of the representation of a stimulus by a population of neurons has a number of advantages. One is that it is the same measure of sparseness that has proved to be useful and tractable in formal analyses of the capacity of associative neural networks and the interference between stimuli that use an approach derived from theoretical physics (Rolls and Treves, 1990; Treves, 1990; Treves and Rolls, 1991; Rolls and Treves, 1998) (see Appendix B). I note that high values of a^p indicate broad tuning of the population, and that low values of a^p indicate sparse population encoding.

Franco, Rolls, Aggelopoulos and Jerez (2007) measured the population sparseness of a set of 29 inferior temporal cortex neurons to a set of 20 stimuli that included faces and objects (see Fig. C.7). Figure C.9a shows, for any one stimulus picked at random, the normalized firing rates of the population of neurons. The rates are ranked with the neuron with the highest rate on the left. For different stimuli, the shape of this distribution is on average the same, though with the neurons in a different order. (The rates of each neuron were normalized to a mean of 10 spikes/s before this graph was made, so that the neurons can be combined in the same graph, and so that the population sparseness has a defined value, as described by Franco, Rolls, Aggelopoulos and Jerez (2007).) The population sparseness a^p of this normalized (i.e. scaled) set of firing rates is 0.77.

Figure C.9b shows the probability distribution of the normalized firing rates of the population of (29) neurons to any stimulus from the set. This was calculated by taking the probability distribution of the data shown in Fig. C.9a. This distribution is not exponential because of the normalization of the firing rates of each neuron, but becomes exponential as shown in Fig. C.8 without the normalization step.

A very interesting finding of Franco, Rolls, Aggelopoulos and Jerez (2007) was that when

the single cell sparseness a^s and the population sparseness a^p were measured from the same set of neurons in the same experiment, the values were very close, in this case 0.77. (This was found for a range of measurement intervals after stimulus onset, and also for a larger population of 41 neurons.)

The single cell sparseness a^s and the population sparseness a^p can take the same value if the response profiles of the neurons are uncorrelated, that is each neuron is independently tuned to the set of stimuli (Lehky et al., 2005). Franco, Rolls, Aggelopoulos and Jerez (2007) tested whether the response profiles of the neurons to the set of stimuli were uncorrelated in two ways. In a first test, they found that the mean (Pearson) correlation between the response profiles computed over the 406 neuron pairs was low, 0.049 ± 0.013 (sem). In a second test, they computed how the multiple cell information available from these neurons about which stimulus was shown increased as the number of neurons in the sample was increased, and showed that the information increased approximately linearly with the number of neurons in the ensemble. The implication is that the neurons convey independent (non-redundant) information, and this would be expected to occur if the response profiles of the neurons to the stimuli are uncorrelated.

We now consider the concept of ergodicity. The single neuron selectivity, a^s , reflects response distributions of individual neurons across time and therefore stimuli in the world (and has sometimes been termed “lifetime sparseness”). The population sparseness a^p reflects response distributions across all neurons in a population measured simultaneously (to for example one stimulus). The similarity of the average values of a^s and a^p (both 0.77 for inferior temporal cortex neurons (Franco, Rolls, Aggelopoulos and Jerez, 2007)) indicates, we believe for the first time experimentally, that the representation (at least in the inferior temporal cortex) is ergodic. The representation is ergodic in the sense of statistical physics, where the average of a single component (in this context a single neuron) across time is compared with the average of an ensemble of components at one time (cf. Masuda and Aihara (2003) and Lehky et al. (2005)). This is described further next.

In comparing the neuronal selectivities a^s and population sparsenesses a^p , we formed a table in which the columns represent different neurons, and the stimuli different rows (Földiák, 2003). We are interested in the probability distribution functions (and not just their summary values a^s , and a^p), of the columns (which represent the individual neuron selectivities) and the rows (which represent the population tuning to any one stimulus). We could call the system strongly ergodic (cf. Lehky et al. (2005)) if the selectivity (probability density or distribution function) of each individual neuron is the same as the average population sparseness (probability density function). (Each neuron would be tuned to different stimuli, but have the same shape of the probability density function.) We have seen that this is not the case, in that the firing rate probability distribution functions of different neurons are different, with some fitting an exponential function, and some a gamma function (see Fig. C.5). We can call the system weakly ergodic if individual neurons have different selectivities (i.e. different response probability density functions), but the average selectivity (measured in our case by $\langle a^s \rangle$) is the same as the average population sparseness (measured by $\langle a^p \rangle$), where $\langle \dots \rangle$ indicates the ensemble average. We have seen that for inferior temporal cortex neurons the neuron selectivity probability density functions are different (see Fig. C.5), but that their average $\langle a^s \rangle$ is the same as the average (across stimuli) $\langle a^p \rangle$ of the population sparseness, 0.77, and thus conclude that the representation in the inferior temporal visual cortex of objects and faces is weakly ergodic (Franco, Rolls, Aggelopoulos and Jerez, 2007).

I note that weak ergodicity necessarily occurs if $\langle a^s \rangle$ and $\langle a^p \rangle$ are the same and the neurons are uncorrelated, that is each neuron is independently tuned to the set of stimuli (Lehky et al., 2005). The fact that both hold for the inferior temporal cortex neurons studied by Franco, Rolls, Aggelopoulos and Jerez (2007) thus indicates that their responses

are uncorrelated, and this is potentially an important conclusion about the encoding of stimuli by these neurons. This conclusion is confirmed by the linear increase in the information with the number of neurons which is the case not only for this set of neurons (Franco, Rolls, Aggelopoulos and Jerez, 2007), but also in other data sets for the inferior temporal visual cortex (Rolls, Treves and Tovee, 1997b; Booth and Rolls, 1998). Both types of evidence thus indicate that the encoding provided by at least small subsets (up to e.g. 20 neurons) of inferior temporal cortex neurons is approximately independent (non-redundant), which is an important principle of cortical encoding.

C.3.1.3 Comparisons of sparseness between areas: the hippocampus, insula, orbitofrontal cortex, and amygdala

In the study of Franco, Rolls, Aggelopoulos and Jerez (2007) on inferior temporal visual cortex neurons, the selectivity of individual cells for the set of stimuli, or single cell sparseness a^s , had a mean value of 0.77. This is close to a previously measured estimate, 0.65, which was obtained with a larger stimulus set of 68 stimuli (Rolls and Tovee, 1995b). Thus the single neuron probability density functions in these areas do not produce very sparse representations. Therefore the goal of the computations in the inferior temporal visual cortex may not be to produce sparse representations (as has been proposed for V1 (Field, 1994; Olshausen and Field, 1997; Vinje and Gallant, 2000; Olshausen and Field, 2004)). Instead one of the goals of the computations in the inferior temporal visual cortex may be to compute invariant representations of objects and faces (Rolls, 2000a; Rolls and Deco, 2002; Rolls, 2007e; Rolls and Stringer, 2006b) (see Chapter 2), and to produce not very sparse distributed representations in order to maximize the information represented (see Table B.2 on page 831). In this context, it is very interesting that the representations of different stimuli provided by a population of inferior temporal cortex neurons are decorrelated, as shown by the finding that the mean (Pearson) correlation between the response profiles to a set of 20 stimuli computed over 406 neuron pairs was low, 0.049 ± 0.013 (sem) (Franco, Rolls, Aggelopoulos and Jerez, 2007). The implication is that decorrelation is being achieved in the inferior temporal visual cortex, but not by forming a sparse code. It will be interesting to investigate the mechanisms for this.

In contrast, the representation in some memory systems may be more sparse (Rolls and Treves, 2011; Rolls, 2023d). For example, in the hippocampus in which spatial view cells are found in macaques, further analysis (Rolls and Treves, 2011) of data described by Rolls, Treves, Robertson, Georges-François and Panzeri (1998b) shows that for the representation of 64 locations around the walls of the room, the mean single cell sparseness a^s was 0.34 ± 0.13 (sd), and the mean population sparseness a^p was 0.33 ± 0.11 . The more sparse representation is consistent with the view that the hippocampus is involved in storing memories, and that for this, more sparse representations than in perceptual areas are relevant. These sparseness values are for spatial view neurons, but it is possible that when neurons respond to combinations of spatial view and object (Rolls, Xiang and Franco, 2005c), or of spatial view and reward (Rolls and Xiang, 2005), the representations are more sparse. It is of interest that the mean firing rate of these spatial view neurons across all spatial views was 1.77 spikes/s (Rolls, Treves, Robertson, Georges-François and Panzeri, 1998b). (The mean spontaneous firing rate of the neurons was 0.1 spikes/s, and the average across neurons of the firing rate for the most effective spatial view was 13.2 spikes/s.) It is also notable that weak ergodicity is implied for this brain region too (given the similar values of a^s and a^p), and the underlying basis for this is that the response profiles of the different hippocampal neurons to the spatial views are uncorrelated. Further support for these conclusions is that the information about spatial view increases linearly with the number of hippocampal spatial view neurons (Rolls, Treves, Robertson, Georges-François and Panzeri, 1998b), again providing evidence

that the response profiles of the different neurons are uncorrelated. The representations in the hippocampus may be more sparse than this, in line with the observation that in rodents, hippocampal neurons may have place fields in only one of several environments.

Further evidence is now available on ergodicity in three further brain areas, the macaque insular primary taste cortex, the orbitofrontal cortex, and the amygdala (Rolls, Critchley, Verhagen and Kadohisa, 2010a). In all these brain areas sets of neurons were tested with an identical set of 24 oral taste, temperature, and texture stimuli. (The stimuli were: Taste - 0.1 M NaCl (salt), 1 M glucose (sweet), 0.01 M HCl (sour), 0.001 M quinine HCl (bitter), 0.1 M monosodium glutamate (umami), and water; Temperature - 10°C, 37°C and 42°C; flavor - blackcurrant juice; viscosity - carboxymethyl-cellulose 10 cPoise, 100 cPoise, 1000 cPoise and 10000 cPoise; fatty / oily - single cream, vegetable oil, mineral oil, silicone oil (100 cPoise), coconut oil, and safflower oil; fatty acids - linoleic acid and lauric acid; capsaicin; and gritty texture.) Further analysis of data described by Verhagen, Kadohisa and Rolls (2004) showed that in the primary taste cortex the mean value of a^s across 58 neurons was 0.745 and of a^p (normalized) was 0.708. Further analysis of data described by Rolls, Verhagen and Kadohisa (2003e), Verhagen, Rolls and Kadohisa (2003), Kadohisa, Rolls and Verhagen (2004) and Kadohisa, Rolls and Verhagen (2005a) showed that in the orbitofrontal cortex the mean value of a^s across 30 neurons was 0.625 and of a^p was 0.611. Further analysis of data described by Kadohisa, Rolls and Verhagen (2005b) showed that in the amygdala the mean value of a^s across 38 neurons was 0.811 and of a^p was 0.813. Thus in all these cases, the mean value of a^s is close to that of a^p , and weak ergodicity is implied (Rolls and Treves, 2011). The values of a^s and a^p are also relatively high, implying the importance of representing large amounts of information in these brain areas about this set of stimuli by using a very distributed code, and also perhaps about the stimulus set, some members of which may be rather similar to each other.

C.3.2 The information from single neurons

Examples of the responses of single neurons (in this case in the inferior temporal visual cortex) to sets of objects and/or faces (of the type illustrated in Fig. C.7) are shown in Figs. 2.16, 2.17 and C.4. We now consider how much information these types of neuronal response convey about the set of stimuli S , and about each stimulus s in the set. The mutual information $I(S, R)$ that the set of responses R encode about the set of stimuli S is calculated with Equation C.21 and corrected for the limited sampling using the analytic bias correction procedure described by Panzeri and Treves (1996) as described in detail by Rolls, Treves, Tovee and Panzeri (1997d). The information $I(s, R)$ about each single stimulus s in the set S , termed the stimulus-specific information (Rolls, Treves, Tovee and Panzeri, 1997d) or stimulus-specific surprise (DeWeese and Meister, 1999), obtained from the set of the responses R of the single neuron is calculated with Equation C.22 and corrected for the limited sampling using the analytic bias correction procedure described by Panzeri and Treves (1996) as described in detail by Rolls, Treves, Tovee and Panzeri (1997d). (The average of $I(s, R)$ across stimuli is the mutual information $I(S, R)$.)

Figure C.10 shows the stimulus-specific information $I(s, R)$ available in the neuronal response about each of 20 face stimuli calculated for the neuron (am242) whose firing rate response profile to the set of 65 stimuli is shown in Fig. C.4. Unless otherwise stated, the information measures given are for the information available on a single trial from the firing rate of the neuron in a 500 ms period starting 100 ms after the onset of the stimuli. It is shown in Fig. C.10 that 2.2, 2.0, and 1.5 bits of information were present about the three face stimuli to which the neuron had the highest firing rate responses. The neuron conveyed some but smaller amounts of information about the remaining face stimuli. The average information

Fig. C.10 The stimulus-specific information $I(s, R)$ available in the response of the same single neuron as in Fig. C.4 about each of the stimuli in the set of 20 face stimuli (abscissa), with the firing rate of the neuron to the corresponding stimulus plotted as a function of this on the ordinate. The horizontal line shows the mean firing rate across all stimuli. (Reproduced from Rolls, E. T., Treves, A., Tovee, M. and Panzeri, S. (1997) Information in the neuronal representation of individual stimuli in the primate temporal visual cortex. *Journal of Computational Neuroscience* 4: 309–333. © Springer Nature.)

$I(S, R)$ about this set (S) of 20 faces for this neuron was 0.55 bits. The average firing rate of this neuron to these 20 face stimuli was 54 spikes/s. It is clear from Fig. C.10 that little information was available from the responses of the neuron to a particular face stimulus if that response was close to the average response of the neuron across all stimuli. At the same time, it is clear from Fig. C.10 that information was present depending on how far the firing rate to a particular stimulus was from the average response of the neuron to the stimuli. Of particular interest, it is evident that information is present from the neuronal response about which face was shown if that neuronal response was below the average response, as well as when the response was greater than the average response.

One intuitive way to understand the data shown in Fig. C.10 is to appreciate that low probability firing rate responses, whether they are greater than or less than the mean response rate, convey much information about which stimulus was seen. This is of course close to the definition of information. Given that the firing rates of neurons are always positive, and follow an asymmetric distribution about their mean, it is clear that deviations above the mean have a different probability to occur than deviations by the same amount below the mean. One may attempt to capture the relative likelihood of different firing rates above and below the mean by computing a z score obtained by dividing the difference between the mean response to each stimulus and the overall mean response by the standard deviation of the response to that stimulus. The greater the number of standard deviations (i.e. the greater the z score) from the mean response value, the greater the information might be expected to be. We therefore show in Fig. C.11 the relation between the z score and $I(s, R)$. (The z score was calculated by obtaining the mean and standard deviation of the response of a neuron to a particular stimulus s , and dividing the difference of this response from the mean response to all stimuli by the

Fig. C.11 The relation for a single cell between the number of standard deviations the response to a stimulus was from the average response to all stimuli (see text, z score) plotted as a function of $I(s, R)$, the information available about the corresponding stimulus, s . (Reproduced from Rolls, E. T., Treves, A., Tovee, M. and Panzeri, S. (1997) Information in the neuronal representation of individual stimuli in the primate temporal visual cortex. *Journal of Computational Neuroscience* 4: 309–333. © Springer Nature.)

calculated standard deviation for that stimulus.) This results in a C-shaped curve in Figs. C.10 and C.11, with more information being provided by the cell the further its response to a stimulus is in spikes per second or in z scores either above or below the mean response to all stimuli (which was 54 spikes/s). The specific C-shape is discussed further in Section C.3.4.

The information $I(s, R)$ about each stimulus in the set of 65 stimuli is shown in Fig. C.12 for the same neuron, am242. The 23 face stimuli in the set are indicated by a diamond, and the 42 non-face stimuli by a cross. Using this much larger and more varied stimulus set, which is more representative of stimuli in the real world, a C-shaped function again describes the relation between the information conveyed by the cell about a stimulus and its firing rate to that stimulus. In particular, this neuron reflected information about most, but not all, of the faces in the set, that is those faces that produced a higher firing rate than the overall mean firing rate to all the 65 stimuli, which was 31 spikes/s. In addition, it conveyed information about the majority of the 42 non-face stimuli by responding at a rate below the overall mean response of the neuron to the 65 stimuli. This analysis usefully makes the point that the information available in the neuronal responses about which stimulus was shown is relative to (dependent upon) the nature and range of stimuli in the test set of stimuli.

This evidence makes it clear that a single cortical visual neuron tuned to faces conveys information not just about one face, but about a whole set of faces, with the information conveyed on a single trial related to the difference in the firing rate response to a particular stimulus compared to the average response to all stimuli.

The analyses just described for neurons with visual responses are general, in that they apply in a very similar way to olfactory neurons recorded in the macaque orbitofrontal cortex (Rolls, Critchley and Treves, 1996a; Rolls, Critchley, Verhagen and Kadohisa, 2010a).

The neurons in this sample reflected in their firing rates for the post-stimulus period 100 to 600 ms on average 0.36 bits of mutual information about which of 20 face stimuli was

Fig. C.12 The information $I(s, R)$ available in the response of the same neuron about each of the stimuli in the set of 23 face and 42 non-face stimuli (abscissa), with the firing rate of the neuron to the corresponding stimulus plotted as a function of this on the ordinate. The 23 face stimuli in the set are indicated by a diamond, and the 42 non-face stimuli by a cross. The horizontal line shows the mean firing rate across all stimuli. (Reproduced from Rolls, E. T., Treves, A., Tovee, M. and Panzeri, S. (1997) Information in the neuronal representation of individual stimuli in the primate temporal visual cortex. *Journal of Computational Neuroscience* 4: 309–333. © Springer Nature.)

presented (Rolls, Treves, Tovee and Panzeri, 1997d). Similar values have been found in other experiments (Tovee, Rolls, Treves and Bellis, 1993; Tovee and Rolls, 1995; Rolls, Tovee and Panzeri, 1999b; Rolls, Franco, Aggelopoulos and Jerez, 2006b). The information in short temporal epochs of the neuronal responses is described in Section C.3.4.

C.3.3 The information from single neurons: temporal codes versus rate codes within the spike train of a single neuron

In the third of a series of papers that analyze the response of single neurons in the primate inferior temporal cortex to a set of static visual stimuli, Optican and Richmond (1987) applied information theory in a particularly direct and useful way. To ascertain the relevance of stimulus-locked temporal modulations in the firing of those neurons, they compared the amount of information about the stimuli that could be extracted from just the firing rate, computed over a relatively long interval of 384 ms, with the amount of information that could be extracted from a more complete description of the firing, that included temporal modulation. To derive this latter description (the temporal code within the spike train of a single neuron) they applied principal component analysis (PCA) to the temporal response vectors recorded for each neuron on each trial. The PCA helped to reduce the dimensionality of the neuronal response measurements. A temporal response vector was defined as a vector with as components the firing rates in each of 64 successive 6 ms time bins. The (64×64) covariance matrix was calculated across all trials of a particular neuron, and diagonalized. The first few eigenvectors of the matrix, those with the largest eigenvalues, are the principal components

of the response, and the weights of each response vector on these four to five components can be used as a reduced description of the response, which still preserves, unlike the single value giving the mean firing rate along the entire interval, the main features of the temporal modulation within the interval. Thus a four- to five-dimensional temporal code could be contrasted with a one-dimensional rate code, and the comparison made quantitative by measuring the respective values for the mutual information with the stimuli.

Although the initial claim (Optican, Gawne, Richmond and Joseph, 1991; Eskandar, Richmond and Optican, 1992), that the temporal code carried nearly three times as much information as the rate code, was later found to be an artefact of limited sampling, and more recent analyses tend to minimize the additional information in the temporal description (Tovee, Rolls, Treves and Bellis, 1993; Heller, Hertz, Kjaer and Richmond, 1995), this type of application has immediately appeared straightforward and important, and it has led to many developments. By concentrating on the code expressed in the output rather than on the characterization of the neuronal channel itself, this approach is not affected much by the potential complexities of the preceding black box. Limited sampling, on the other hand, is a problem, particularly because it affects much more codes with a larger number of components, for example the four to five components of the PCA temporal description, than the one-dimensional firing rate code. This is made evident in the paper by Heller, Hertz, Kjaer and Richmond (1995), in which the comparison is extended to several more detailed temporal descriptions, including a binary vector description in which the presence or not of a spike in each 1 ms bin of the response constitutes a component of a 320-dimensional vector. Obviously, this binary vector must contain at least all the information present in the reduced descriptions, whereas in the results of Heller, Hertz, Kjaer and Richmond (1995), despite the use of a sophisticated neural network procedure to control limited sampling biases, the binary vector appears to be the code that carries the least information of all. In practice, with the data samples available in the experiments that have been done, and even when using analytic procedures to control limited sampling (Panzeri and Treves, 1996), reliable comparison can be made only with up to two- to three-dimensional codes.

Tovee, Rolls, Treves and Bellis (1993) and Tovee and Rolls (1995) obtained further evidence that little information was encoded in the temporal aspects of firing within the spike train of a single neuron in the inferior temporal cortex by taking short epochs of the firing of neurons, lasting 20 ms or 50 ms, in which the opportunity for temporal encoding would be limited (because there were few spikes in these short time intervals). They found that a considerable proportion (30%) of the information available in a long time period of 400 ms utilizing temporal encoding within the spike train was available in time periods as short as 20 ms when only the number of spikes was taken into account.

Overall, the main result of these analyses applied to the responses to static stimuli in the temporal visual cortex of primates is that not much more information (perhaps only up to 10% more) can be extracted from temporal codes than from the firing rate measured over a judiciously chosen interval (Tovee, Rolls, Treves and Bellis, 1993; Heller, Hertz, Kjaer and Richmond, 1995). Indeed, it turns out that even this small amount of 'temporal information' is related primarily to the onset latency of the neuronal responses to different stimuli, rather than to anything more subtle (Tovee, Rolls, Treves and Bellis, 1993). Consistent with this point, in earlier visual areas the additional 'temporally encoded' fraction of information can be larger, due especially to the increased relevance, earlier on, of precisely locked transient responses (Kjaer, Hertz and Richmond, 1994; Golomb, Kleinfeld, Reid, Shapley and Shraiman, 1994; Heller, Hertz, Kjaer and Richmond, 1995). This is because if the responses to some stimuli are more transient and to others more sustained, this will result in more information if the temporal modulation of the response of the neuron is taken into account. However, the relevance of more substantial temporal codes for static visual stimuli remains to be demonstrated.

Fig. C.13 Decoding rate and temporal measures of neural responses that might encode information about which stimulus had been presented on a single trial. The upper left part of the diagram shows the average firing rate (or equivalently spike count) responses of each of 3 cells (labelled as Rate Cell 1,2,3) to a set of 3 stimuli. The upper right three columns show the average across trials of a measure of temporal aspects of the neural response, for example latency for each cell. The bottom row (labelled Response single trial) shows the data that might be obtained from a single trial and from which the stimulus that was shown (St. ? or s') must be estimated or decoded, using the average values across trials shown in the top part of the table. From the responses on the single trial, the most probable decoded stimulus is stimulus 2, based on the values of both the rates and the temporal measures. With this decoding procedure, the information can then be measured with the multiple cell information algorithm described by Rolls, Treves and Tovee (1997b) Rolls, Treves and Tovee (1997b). (From Verhagen, J.V., Baker, K.L., Vasan, G., Pieribone, V.A. and Rolls, E. T. (2023) Odor encoding by signals in the olfactory bulb. *Journal of Neurophysiology* 129:431-444. doi: 10.1152/jn.00449.2022.)

For non-static visual stimuli and for other cortical systems, similar analyses have largely yet to be carried out, although clearly one expects to find much more prominent temporal effects e.g. in the auditory system (Nelken, Prut, Vaadia and Abeles, 1994; deCharms and Merzenich, 1996), for reasons similar to those just annunciated.

Evidence that is consistent with what has just been described for the visual system has been found in another brain system, the olfactory system. We measured the information available about which of six odors had been presented by measuring the presynaptic signals from populations of 28–57 glomeruli in the olfactory bulb of the mouse using optical imaging (Verhagen, Baker, Vasan, Pieribone and Rolls, 2023) (see Section 5.2.1). The information was measured with the multiple cell information analysis method described in Section C.2.4 with the code available as described in Section D.7 and the decoding procedure for temporal aspects of neuronal responses illustrated in Fig. C.13.

We found that although there was a little information in the time course of the response (effectively the latency), there was much more information in the activity (reflecting the neuronal firing rates) of the glomeruli about which odor had been presented (Fig. C.14). Importantly, the total information from both the rates and the latencies was not greater than that from the rates alone, showing that the latency information is redundant with respect to the rate information. (The total information from the rates and latencies was a little lower than from the rates alone, because the latency values added noise to what could be decoded from the rates.) Thus in this olfactory system too, the information is encoded in the rates, and useful extra information is not provided by the latency / time course of the neural response.

Fig. C.14 The information about which of 6 odors was presented from signals in the mouse olfactory bulb glomeruli from the 'Rate', latency ('Temporal'), and from both the rates and time courses ('Total'). The mean and standard error of the information was measured in 10 experiments in each of which the information from a population of 28–57 glomeruli was measured with the multiple cell information algorithm described by Rolls, Treves and Tovee (1997b). (Data from Verhagen, J.V., Baker, K.L., Vasan, G., Pieribone, V.A. and Rolls, E. T. (2023) Odor encoding by signals in the olfactory bulb. *Journal of Neurophysiology* 129: 431-444. doi: 10.1152/jn.00449.2022.)

C.3.4 The information from single neurons: the speed of information transfer

It is intuitive that if short periods of firing of single cells are considered, there is less time for temporal modulation effects. The information conveyed about stimuli by the firing rate and that conveyed by more detailed temporal codes become similar in value. When the firing periods analyzed become shorter than roughly the mean interspike interval, even the statistics of firing rate values on individual trials cease to be relevant, and the information content of the firing depends solely on the mean firing rates across all trials with each stimulus. This is expressed mathematically by considering the amount of information provided as a function of the length t of the time window over which firing is analyzed, and taking the limit for $t \rightarrow 0$ (Skaggs, McNaughton, Gothard and Markus, 1993; Panzeri, Biella, Rolls, Skaggs and Treves, 1996). To first order in t , only two responses can occur in a short window of length t : either the emission of an action potential, with probability tr_s , where r_s is the mean firing rate calculated over many trials using the same window and stimulus; or no action potential, with probability $1 - tr_s$. Inserting these conditional probabilities into Equation C.22, taking the limit and dividing by t , one obtains for the derivative of the stimulus-specific transinformation

$$dI(s)/dt = r_s \log_2(r_s / \langle r \rangle) + (\langle r \rangle - r_s) / \ln 2, \quad (\text{C.47})$$

where $\langle r \rangle$ is the grand mean rate across stimuli. This formula thus gives the rate, in bits/s, at which information about a stimulus begins to accumulate when the firing of a cell is recorded. Such an information rate depends only on the mean firing rate to that stimulus and on the grand mean rate across stimuli. As a function of r_s , it follows the U-shaped curve in Fig. C.15. The curve is universal, in the sense that it applies irrespective of the detailed firing statistics of the cell, and it expresses the fact that the emission or not of a spike in a short window conveys information in as much as the mean response to a given stimulus is above or below the overall mean rate. No information is conveyed about those stimuli the mean response to which is the same as the overall mean. In practice, although the curve describes

Fig. C.15 Time derivative of the stimulus-specific information as a function of firing rate, for a cell firing at a grand mean rate of 50 Hz. For different grand mean rates, the graph would simply be rescaled.

only the universal behavior of the initial slope of the specific information as a function of time, it approximates well the full stimulus-specific information $I(s, R)$ computed even over rather long periods (Rolls, Critchley and Treves, 1996a; Rolls, Treves, Tovee and Panzeri, 1997d).

Averaging Equation C.47 across stimuli one obtains the time derivative of the mutual information. Further dividing by the overall mean rate yields the adimensional quantity

$$\chi = \sum_s P(s) \langle r_s / \langle r \rangle \rangle \log_2 \langle r_s / \langle r \rangle \rangle \quad (\text{C.48})$$

which measures, in bits, the mutual information per spike provided by the cell (Bialek, Rieke, de Ruyter van Steveninck and Warland, 1991; Skaggs, McNaughton, Gothard and Markus, 1993). One can prove that this quantity can range from 0 to $\log_2(1/a)$

$$0 < \chi < \log_2(1/a), \quad (\text{C.49})$$

where a is the single neuron sparseness a^s defined in Section C.3.1.1. For mean rates r_s distributed in a nearly binary fashion, χ is close to its upper limit $\log_2(1/a)$, whereas for mean rates that are nearly uniform, or at least unimodally distributed, χ is relatively close to zero (Panzeri, Biella, Rolls, Skaggs and Treves, 1996). In practice, whenever a large number of more or less ‘ecological’ stimuli are considered, mean rates are not distributed in arbitrary ways, but rather tend to follow stereotyped distributions (which for some neurons approximate an exponential distribution of firing rates – see Section C.3.1 (Treves, Panzeri, Rolls, Booth and Wakenan, 1999; Baddeley, Abbott, Booth, Sengpiel, Freeman, Wakenan and Rolls, 1997; Rolls and Treves, 1998; Rolls and Deco, 2002; Franco, Rolls, Aggelopoulos and Jerez, 2007; Rolls, 2016b; Rolls and Treves, 2011)), and as a consequence χ and a (or, equivalently, its logarithm) tend to covary (rather than to be independent variables (Skaggs and McNaughton, 1992)). Therefore, measuring sparseness is in practice nearly equivalent to measuring information per spike, and the rate of rise in mutual information, $\chi < r \rangle$, is largely determined by the sparseness a and the overall mean firing rate $\langle r \rangle$.

An important point to note from the above is that the ‘bits per spike’ information measure (Skaggs et al., 1993) is in practice closely equivalent to measuring the sparseness a of the representation, and is not a true measure of information that takes into account the variability of the relation between the stimulus and the neuronal firing. An intuitive understanding is that if a representation is sparse, then when a neuron does fire, the ‘bits per spike’ will be high, because a spike is a low probability event with sparse representations, and therefore when a spike does occur, it can be thought of as a high information event. The ‘bits per spike’

measure I_b is calculated as follows for firing rates accumulated in different bins each with a different duration, where the bins might correspond to stimuli, spatial locations, etc.

$$I_b = \sum_i \frac{\lambda_i}{\bar{\lambda}} \log_2 \left(\frac{\lambda_i}{\bar{\lambda}} \right) p_i \quad (\text{C.50})$$

where λ_i is the firing rate in bin i , $\bar{\lambda}$ is the mean firing rate, and p_i is the fraction of the time spent in bin i .

The important point to note about the single-cell information rate $\chi < r >$ is that, to the extent that different cells express non-redundant codes, as discussed below, the instantaneous *information flow* across a population of C cells can be taken to be simply $C\chi < r >$, and this quantity can easily be measured directly without major limited sampling biases, or else inferred indirectly through measurements of the sparseness a . Values for the information rate $\chi < r >$ that have been published range from 2–3 bits/s for rat hippocampal cells (Skaggs, McNaughton, Gothard and Markus, 1993), to 10–30 bits/s for primate temporal cortex visual cells (Rolls, Treves and Tovee, 1997b), and could be compared with analogous measurements in the sensory systems of frogs and crickets, in the 100–300 bits/s range (Rieke, Warland and Bialek, 1993).

If the first time-derivative of the mutual information measures information flow, successive derivatives characterize, at the single-cell level, different firing modes. This is because whereas the first derivative is universal and depends only on the mean firing rates to each stimulus, the next derivatives depend also on the variability of the firing rate around its mean value, across trials, and take different forms in different firing regimes. Thus they can serve as a measure of discrimination among firing regimes with limited variability, for which, for example, the second derivative is large and positive, and firing regimes with large variability, for which the second derivative is large and negative. Poisson firing, in which in every short period of time there is a fixed probability of emitting a spike irrespective of previous firing, is an example of large variability, and the second derivative of the mutual information can be calculated to be

$$d^2I/dt^2 = [\ln a + (1 - a)] < r >^2 / (a \ln 2), \quad (\text{C.51})$$

where a is the single neuron sparseness a^s defined in Section C.3.1.1. This quantity is always negative. Strictly periodic firing is an example of zero variability, and in fact the second time-derivative of the mutual information becomes infinitely large in this case (although actual information values measured in a short time interval remain of course finite even for exactly periodic firing, because there is still some variability, ± 1 , in the number of spikes recorded in the interval). Measures of mutual information from short intervals of firing of temporal cortex visual cells have revealed a degree of variability intermediate between that of periodic and of Poisson regimes (Rolls, Treves, Tovee and Panzeri, 1997d). Similar measures can also be used to contrast the effect of the graded nature of neuronal responses, once they are analyzed over a finite period of time, with the information content that would characterize neuronal activity if it reduced to a binary variable (Panzeri, Biella, Rolls, Skaggs and Treves, 1996). A binary variable with the same degree of variability would convey information at the same instantaneous rate (the first derivative being universal), but in for example 20–30% reduced amounts when analyzed over times of the order of the interspike interval or longer.

Utilizing these approaches, Tovee, Rolls, Treves and Bellis (1993) and Tovee and Rolls (1995) measured the information available in short epochs of the firing of single neurons, and found that a considerable proportion of the information available in a long time period of 400 ms was available in time periods as short as 20 ms and 50 ms. For example, in periods of 20 ms, 30% of the information present in 400 ms using temporal encoding with the first three

Fig. C.16 The average information $I(S,R)$ available in short temporal epochs (50 ms as compared to 400 ms) of the spike trains of single inferior temporal cortex neurons about which face had been shown. (From Tovee, M.J. and Rolls, E.T. (1995) Information encoding in short firing rate epochs by single neurons in the primate temporal visual cortex. *Visual Cognition* 2: 35–58. © Informa Ltd.)

principal components was available. Moreover, the exact time when the epoch was taken was not crucial, with the main effect being that rather more information was available if information was measured near the start of the spike train, when the firing rate of the neuron tended to be highest (see Figs. C.16 and C.17). The conclusion was that much information was available when temporal encoding could not be used easily, that is in very short time epochs of 20 or 50 ms.

It is also useful to note from Figs. C.16, C.17 and 2.16 the typical time course of the responses of many temporal cortex visual neurons in the awake behaving primate. Although the firing rate and availability of information is highest in the first 50–100 ms of the neuronal response, the firing is overall well sustained in the 500 ms stimulus presentation period. Cortical neurons in the primate temporal lobe visual system, in the taste cortex (Rolls, Yaxley and Sienkiewicz, 1990), and in the olfactory cortex (Rolls, Critchley and Treves, 1996a), do not in general have rapidly adapting neuronal responses to sensory stimuli. This may be important for associative learning: the outputs of these sensory systems can be maintained for sufficiently long while the stimuli are present for synaptic modification to occur. Although rapid synaptic adaptation within a spike train is seen in some experiments in brain slices (Markram and Tsodyks, 1996; Abbott, Varela, Sen and Nelson, 1997), it is not a very marked effect in at least some brain systems in vivo, when they operate in normal physiological conditions with normal levels of acetylcholine, etc.

To pursue this issue of the speed of processing and information availability even further, Rolls, Tovee, Purcell, Stewart and Azzopardi (1994b) and Rolls and Tovee (1994) limited the period for which visual cortical neurons could respond by using backward masking. In this paradigm, a short (16 ms) presentation of the test stimulus (a face) was followed after a delay of 0, 20, 40, 60, etc. ms by a masking stimulus (which was a high contrast set of letters) (see Fig. C.18). They showed that the mask did actually interrupt the neuronal response, and that at the shortest interval between the stimulus and the mask (a delay of 0 ms, or a ‘Stimulus Onset

Fig. C.17 The average information $I(S,R)$ available in short temporal epochs (20 ms and 100 ms) of the spike trains of single inferior temporal cortex neurons about which face had been shown. (From Tovee, M.J. and Rolls, E.T. (1995) Information encoding in short firing rate epochs by single neurons in the primate temporal visual cortex. *Visual Cognition* 2: 35–58. © Informa Ltd.)

Asynchrony' of 20 ms), the neurons in the temporal cortical areas fired for approximately 30 ms (see Fig. C.19). Under these conditions, the subjects could identify which of five faces had been shown much better than chance. Interestingly, under these conditions, when the inferior temporal cortex neurons were firing for 30 ms, the subjects felt that they were guessing, and conscious perception was minimal (Rolls, Tovee, Purcell, Stewart and Azzopardi, 1994b), the neurons conveyed on average 0.10 bits of information (Rolls, Tovee and Panzeri, 1999b). With a stimulus onset asynchrony of 40 ms, when the inferior temporal cortex neurons were firing for 50 ms, not only did the subjects' performance improve, but the stimuli were now perceived clearly, consciously, and the neurons conveyed on average 0.16 bits of information. This has contributed to the view that consciousness has a higher threshold of activity *in a given pathway*, in this case a pathway for face analysis, than does unconscious processing and performance using the same pathway (Rolls, 2003, 2006a).

The issue of how rapidly information can be read from neurons is crucial and fundamental to understanding how rapidly memory systems in the brain could operate in terms of reading the code from the input neurons to initiate retrieval, whether in a pattern associator or auto-association network (see Appendix B). This is also a crucial issue for understanding how any stage of cortical processing operates, given that each stage includes associative or competitive network processes that require the code to be read before it can pass useful output to the next stage of processing (see Chapter 2; Rolls and Deco (2002); Rolls (2016b); and Panzeri, Rolls, Battaglia and Lavis (2001)). For this reason, we have performed further analyses of the speed of availability of information from neuronal firing, and the neuronal code. A rapid readout of information from any one stage of for example visual processing is important, for the ventral visual system is organized as a hierarchy of cortical areas, and the neuronal response latencies are approximately 100 ms in the inferior temporal visual cortex, and 40–50

Fig. C.18 Backward masking paradigm. The visual stimulus appeared at time 0 for 16 ms. The time between the start of the visual stimulus and the masking image is the Stimulus Onset Asynchrony (SOA). A visual fixation task was being performed to ensure correct fixation of the stimulus. In the fixation task, the fixation spot appeared in the middle of the screen at time -500 ms, was switched off 100 ms before the test stimulus was shown, and was switched on again at the end of the mask stimulus. Then when the fixation spot dimmed after a random time, fruit juice could be obtained by licking. No eye movements could be performed after the onset of the fixation spot. (After Rolls, E. T. and Tovee, M.J. (1994) Processing speed in the cerebral cortex and the neurophysiology of visual masking. *Proceedings of the Royal Society, B*, 257: 9–15. © Royal Society.)

ms in the primary visual cortex, allowing only approximately 50–60 ms of processing time for V1–V2–V4–inferior temporal cortex (Baylis, Rolls and Leonard, 1987; Nowak and Bullier, 1997; Rolls and Deco, 2002). There is much evidence that the time required for each stage of processing is relatively short. For example, in addition to the evidence already presented, visual stimuli presented in succession approximately 15 ms apart can be separately identified (Keysers and Perrett, 2002); and the reaction time for identifying visual stimuli is relatively short and requires a relatively short cortical processing time (Rolls, 2003; Bacon-Mace et al., 2005).

In this context, Delorme and Thorpe (2001) have suggested that just one spike from each neuron is sufficient, and indeed it has been suggested that the order of the first spike in different neurons may be part of the code (Delorme and Thorpe, 2001; Thorpe, Delorme and Van Rullen, 2001; VanRullen, Guyonneau and Thorpe, 2005). (Implicit in the spike order hypothesis is that the first spike is particularly important, for it would be difficult to measure the order for anything other than the first spike.) An alternative view is that the number of spikes in a fixed time window over which a postsynaptic neuron could integrate information is more realistic, and this time might be in the order of 20 ms for a single receiving neuron, or much longer if the receiving neurons are connected by recurrent collateral associative synapses and so can integrate information over time (Deco and Rolls, 2006; Rolls and Deco, 2002; Panzeri, Rolls, Battaglia and Lavis, 2001; Rolls, 2016b). Although the number of spikes in a short time window of e.g. 20 ms is likely to be 0, 1, or 2, the information available may be more than that from the first spike alone, and Rolls, Franco, Aggelopoulos and Jerez (2006b) examined this by measuring neuronal activity in the inferior temporal visual cortex, and then applying quantitative information theoretic methods to measure the information transmitted by single spikes, and within short time windows.

The cumulative single cell information about which of the twenty stimuli (Fig. C.7) was shown from all spikes and from the first spike starting at 100 ms after stimulus onset is shown in Fig. C.20. A period of 100 ms is just longer than the shortest response latency of the

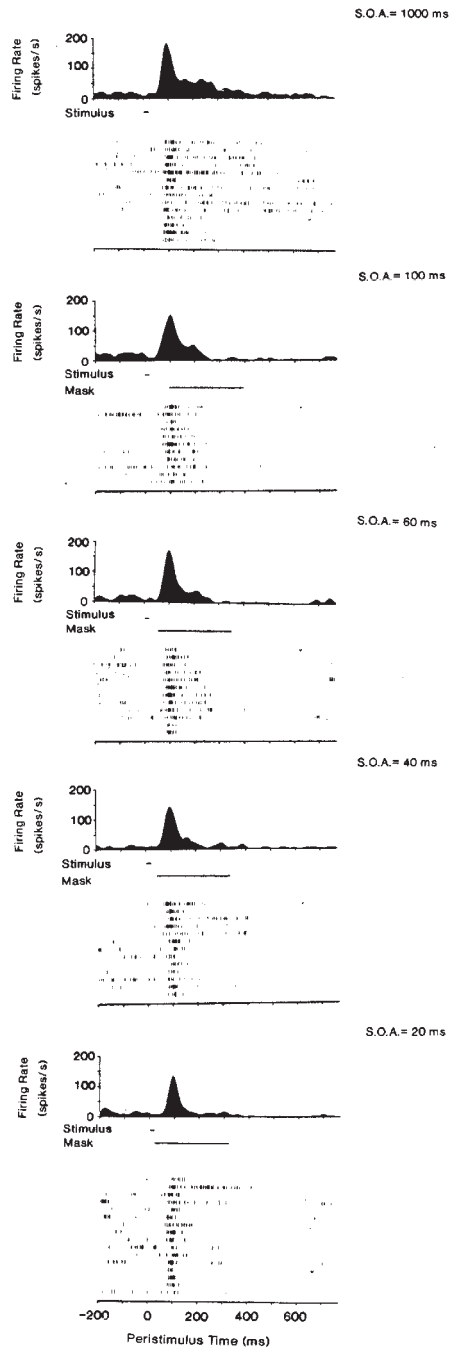

Fig. C.19 Firing of a temporal cortex cell to a 20 ms presentation of a face stimulus when the face was followed with different stimulus onset asynchronies (SOAs) by a masking visual stimulus. At an SOA of 20 ms, when the mask immediately followed the face, the neuron fired for only approximately 30 ms, yet identification above chance (by 'guessing') of the face at this SOA by human observers was possible. (After Rolls, E. T. and Tovee, M.J. (1994) Processing speed in the cerebral cortex and the neurophysiology of visual masking. *Proceedings of the Royal Society, B*, 257: 9–15; and Rolls, E. T., Tovee, M.J., Purcell, D.G., Stewart, A.L. and Azzopardi, P. (1994) The responses of neurons in the temporal cortex of primates, and face identification and detection. *Experimental Brain Research* 101: 473–484. © Springer Nature.)

Fig. C.20 Speed of information availability in the inferior temporal visual cortex from single neurons. Cumulative single cell information from all spikes and from the first spike with the analysis starting at 100 ms after stimulus onset. The mean and sem over 21 neurons are shown. (After Rolls, E. T., Franco, L., Aggelopoulos, N. C. and Perez, J. M. (2006) Information in the first spike, the order of spikes, and the number of spikes provided by neurons in the inferior temporal visual cortex. *Vision Research* 46: 4193–4205. © Elsevier Ltd.)

neurons from which recordings were made, so starting the measure at this time provides the best chance for the single spike measurement to catch a spike that is related to the stimulus. The means and standard errors across the 21 different neurons are shown. The cumulated information from the total number of spikes is larger than that from the first spike, and this is evident and significant within 50 ms of the start of the time epoch. In calculating the information from the first spike, just the first spike in the analysis window starting in this case at 100 ms after stimulus onset was used.

Because any one neuron receiving information from the population being analyzed has multiple inputs, we show in Fig. C.21 the cumulative information that would be available from multiple cells (21) about which of the 20 stimuli was shown, taking both the first spike after the time of stimulus onset (0 ms), and the total number of spikes after 0 ms from each neuron. The cumulative information even from multiple cells is much greater when all the spikes rather than just the first spike are used.

An attractor network might be able to integrate the information arriving over a long time period of several hundred milliseconds (see Section 11.5.1), and might produce the advantage shown in Fig. C.21 for the whole spike train compared to the first spike only. However a single layer pattern association network might only be able to integrate the information over the time constants of its synapses and cell membrane, which might be in the order of 15–30 ms (Panzeri, Rolls, Battaglia and Lavis, 2001; Rolls and Deco, 2002) (see Section B.2). In a hierarchical processing system such as the visual cortical areas, there may only be a short time during which each stage may decode the information from the preceding stage, and then pass on information sufficient to support recognition to the next stage (Rolls and Deco, 2002) (see Chapter 2). We therefore analyzed the information that would be available in short epochs from multiple inputs to a neuron, and show the multiple cell information for the population of 21 neurons in Fig. C.22 (for 20 ms and 50 ms epochs). We see in this case that the first spike information, because it is being made available from many different neurons (in this case 21 selective neurons discriminating between the stimuli each with $p < 0.001$ in an ANOVA), fares better relative to the information from all the spikes in these short epochs, but is still less than the information from all the spikes (particularly in the 50 ms epoch). In particular, for the epoch starting 100 ms after stimulus onset in Fig. C.23 the information in the 20 ms epoch is

Fig. C.21 Speed of information availability in the inferior temporal visual cortex from a population of neurons. Cumulative multiple cell information from all spikes and first spike starting at the time of stimulus onset (0 ms) for the population of 21 neurons about the set of 20 stimuli. (After Rolls, E. T., Franco, L., Aggelopoulos, N.C. and Perez, J.M. (2006) Information in the first spike, the order of spikes, and the number of spikes provided by neurons in the inferior temporal visual cortex. *Vision Research* 46: 4193–4205. © Elsevier Ltd.)

0.37 bits, and from the first spike is 0.24 bits. Correspondingly, for a 50 ms epoch, the values in the epoch starting at 100 ms post stimulus were 0.66 bits for the 50 ms epoch, and 0.40 bits for the first spike. Thus with a population of neurons, having just one spike from each can allow considerable information to be read if only a limited period (of e.g. 20 or 50 ms) is available for the readout, though even in these cases, more information was available if all the spikes in the short window are considered (Fig. C.22).

To show how the information increases with the number of neurons in the ensemble in these short epochs, we show in Fig. C.23 the information from different numbers of neurons for a 20 ms epoch starting at time = 100 ms with respect to stimulus onset, for both the first spike condition and the condition with all the spikes in the 20 ms window. The linear increase in the information in both cases indicates that the neurons provide independent information, which could be because there is no redundancy or synergy, or because these cancel (Rolls, Franco, Aggelopoulos and Reece, 2003b,b). It is also clear from Fig. C.23 that even with the population of neurons, and with just a short time epoch of 20 ms, more information is available from the population if all the spikes in 20 ms are considered, and not just the first spike. The 20 ms epoch analyzed for Fig. C.23 is for the post-stimulus time period of 100–120 ms.

To assess whether there is information that is specifically related to the order in which the spikes arrive from the different neurons, Rolls, Franco, Aggelopoulos and Jerez (2006b) computed for every trial the order across the different simultaneously recorded neurons in which the first spike arrived to each stimulus, and used this in the information theoretic analysis. The control condition was to randomly allocate the order values for each trial between the neurons that had any spikes on that trial, thus shuffling or scrambling the order of the spike arrival times in the time window. In both cases, just the first spike in the time window was used in the information analysis. (In both the order and the shuffled control conditions, on some trials some neurons had no spikes, and this itself, in comparison with the fact that

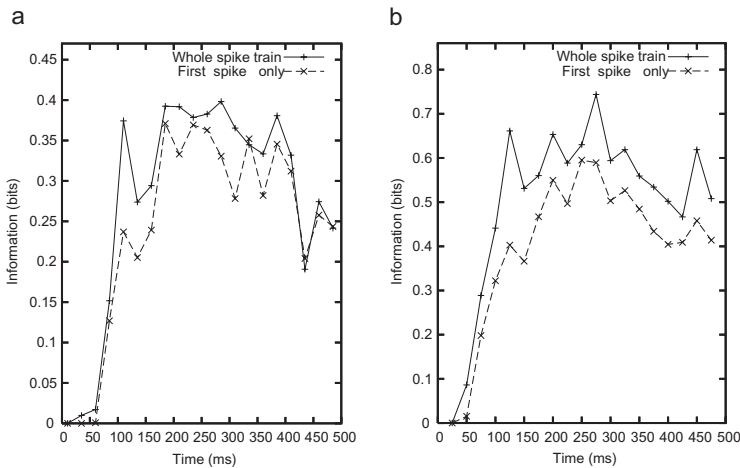

Fig. C.22 Speed of information availability in the inferior temporal visual cortex from a population of neurons. (a) Multiple cell information from all spikes and 1 spike in 20 ms time windows taken at different post-stimulus times starting at time 0. (b) Multiple cell information from all spikes and 1 spike in 50 ms time windows taken at different post-stimulus times starting at time 0. (After Rolls, E. T., Franco, L., Aggelopoulos, N. C. and Perez, J. M. (2006) Information in the first spike, the order of spikes, and the number of spikes provided by neurons in the inferior temporal visual cortex. *Vision Research* 46: 4193–4205. © Elsevier Ltd.)

some neurons had spiked on that trial, provided some information about which stimulus had been shown. However, by explicitly shuffling in the control condition the order of the spikes for the neurons that had spiked on that trial, comparison of the control with the unshuffled order condition provides a clear measure of whether the order of spike arrival from the different neurons itself carries useful information about which stimulus was shown.) The data set was 36 cells with significantly different ($p < 0.05$) responses to the stimulus set where it was possible to record simultaneously from groups of 3 and 4 cells (so that the order on each trial could be measured) in 11 experiments. Taking a 75 ms time window starting 100 ms after stimulus onset, the information with the order of arrival times of the spikes was 0.142 ± 0.02 bits, and in the control (shuffled order) condition was 0.138 ± 0.02 bits (mean across the 11 experiments \pm sem). Thus the information increase by taking into account the order of spike arrival times relative to the control condition was only $(0.142 - 0.138) = 0.004$ bits per experiment (which was not significant). For comparison, the information calculated for the first spike using the same dot product decoding as described above was 0.136 ± 0.03 bits per experiment. Analogous results were obtained for different time windows. Thus taking the spike order into account compared to a control condition in which the spike order was scrambled made essentially no difference to the amount of information that was available from the populations of neurons about which stimulus was shown.

The results show that although considerable information is present in the first spike, more information is available under the more biologically realistic assumption that neurons integrate spikes over a short time window (depending on their time constants) of for example 20 ms. The results shown in Fig. C.23 are of considerable interest, for they show that even when one increases the number of neurons in the population, the information available from the number of spikes in a 20 ms time window is larger than the information available from just the first spike. Thus although intuitively one might think that one can compensate by taking a population of neurons rather than just a single neuron when using just the first spike instead of the number of spikes available in a fixed time window, this compensation by increasing neuron numbers is insufficient to make the first spike code as efficient as taking the number of spikes.

Fig. C.23 Speed of information availability in the inferior temporal visual cortex from populations of neurons. Multiple cell information from all spikes and 1 spike in a 20 ms time window starting at 100 ms after stimulus onset as a function of the number of neurons in the ensemble. (After Rolls, E. T., Franco, L., Aggelopoulos, N.C. and Perez, J.M. (2006) Information in the first spike, the order of spikes, and the number of spikes provided by neurons in the inferior temporal visual cortex. *Vision Research* 46: 4193–4205. © Elsevier Ltd.)

Further, in this first empirical test of the hypothesis that there is information that is specifically related to the order in which the spikes arrive from the different neurons, which has been proposed by Thorpe et al (Delorme and Thorpe, 2001; Thorpe, Delorme and Van Rullen, 2001; VanRullen, Guyonneau and Thorpe, 2005), we found that in the inferior temporal visual cortex there was no significant evidence that the order of the spike arrival times from different simultaneously recorded neurons is important. Indeed, the evidence found in the experiments was that the number of spikes in the time window is the important property that is related to the amount of information encoded by the spike trains of simultaneously recorded neurons. The fact that there was also more information in the number of spikes in a fixed time window than from the first spike only is also evidence that is not consistent with the spike order hypothesis, for the order between neurons can only be easily read from the first spike, and just using information from the first spike would discard extra information available from further spikes even in short time windows.

The encoding of information that uses the number of spikes in a short time window that is supported by the analyses described by Rolls, Franco, Aggelopoulos and Jerez (2006b) deserves further elaboration. It could be thought of as a rate code, in that the number of spikes in a short time window is relevant, but is not a rate code in the rather artificial sense considered by Thorpe et al. (Delorme and Thorpe, 2001; Thorpe et al., 2001; VanRullen et al., 2005) in which a rate is estimated from the interspike interval. This is not just artificial, but also begs the question of how, once the rate is calculated from the interspike interval, this decoded rate is passed on to the receiving neurons, or how, if the receiving neurons calculate the interspike interval at every synapse, they utilize it. In contrast, the spike count code in a

short time window that is considered here is very biologically plausible, in that each spike would inject current into the post-synaptic neuron, and the neuron would integrate all such currents in a dendrite over a time period set by the synaptic and membrane time constants, which will result in an integration time constant in the order of 15–20 ms. Explicit models of exactly this dynamical processing at the integrate-and-fire neuronal level have been described to define precisely these operations (Deco and Rolls, 2003, 2005d; Deco, Rolls and Horwitz, 2004; Deco and Rolls, 2005b; Rolls and Deco, 2002; Rolls, 2016b). Even though the number of spikes in a short time window of e.g. 20 ms is likely to be 0, 1, or 2, it can be 3 or more for effective stimuli (Rolls, Franco, Aggelopoulos and Jerez, 2006b), and this is more efficient than using the first spike.

To add some detail here, a neuron receiving information from a population of inferior temporal cortex neurons of the type described here would have a membrane potential that varied continuously in time reflecting with a time constant in the order of 15–20 ms (resulting from a time constant of order 10 ms for AMPA synapses, 100 ms for NMDA synapses, and 20 ms for the cell membrane) a dot (inner) product over all synapses of each spike count and the synaptic strength. This continuously time varying membrane potential would lead to spikes whenever the results of this integration process produced a depolarization that exceeded the firing threshold. The result is that the spike train of the neuron would reflect continuously with a time constant in the order of 15–20 ms the likelihood that the input spikes it was receiving matched its set of synaptic weights. The spike train would thus indicate in continuous time how closely the stimulus or input matched its most effective stimulus (for a dot product is essentially a correlation). In this sense, no particular starting time is needed for the analysis, and in this respect it is a much better component of a dynamical system than is a decoding that utilizes an order in which the order of the spike arrival times is important and a start time for the analysis must be assumed.

I note that an autoassociation or attractor network implemented by recurrent collateral connections between the neurons can, using its short-term memory, integrate its inputs over much longer periods, for example over 500 ms in a model of how decisions are made (Deco and Rolls, 2006) (see Section 11.5.1), and thus if there is time, the extra information available in more than the first spike or even the first few spikes that is evident in Figs. C.20 and C.21 could be used by the brain.

The conclusions from the single cell information analyses are thus that most of the information is encoded in the spike count; that large parts of this information are available in short temporal epochs of e.g. 20 ms or 50 ms; and that any additional information which appears to be temporally encoded is related to the latency of the neuronal response, and reflects sudden changes in the visual stimuli. Therefore a neuron in the next cortical area would obtain considerable information within 20–50 ms by measuring the firing rate of a single neuron. Moreover, if it took a short sample of the firing rate of many neurons in the preceding area, then very much information is made available in a short time, as shown above and in Section C.3.5.

C.3.5 The information from multiple cells: independent information versus redundancy across cells

The rate at which a single cell provides information translates into an instantaneous information flow across a population (with a simple multiplication by the number of cells) only to the extent that different cells provide different (independent) information. To verify whether this condition holds, one cannot extend to multiple cells the simplified formula for the first time-derivative, because it is made simple precisely by the assumption of independence between spikes, and one cannot even measure directly the full information provided by multiple

Fig. C.24 The information available from populations of neurons. (a) The information available about which of 20 faces had been seen that is available from the responses measured by the firing rates in a time period of 500 ms (+) or a shorter time period of 50 ms (x) of different numbers of temporal cortex cells. (b) The corresponding percentage correct from different numbers of cells. (From Rolls, E. T., Treves, A. and Tovee, M. J. (1997) The representational capacity of the distributed encoding of information provided by populations of neurons in the primate temporal visual cortex. *Experimental Brain Research* 114: 149–162. © Springer Nature.)

(more than two to three) cells, because of the limited sampling problem discussed above. Therefore one has to analyze the degree of independence (or conversely of redundancy) either directly among pairs – at most triplets – of cells, or indirectly by using decoding procedures to transform population responses. Obviously, the results of the analysis will vary a great deal with the particular neural system considered and the particular set of stimuli, or in general of neuronal correlates, used. For many systems, before undertaking to quantify the analysis in terms of information measures, it takes only a simple qualitative description of the responses to realize that there is a lot of redundancy and very little diversity in the responses. For example, if one selects pain-responsive cells in the somatosensory system and uses painful electrical stimulation of different intensities, most of the recorded cells are likely to convey pretty much the same information, signalling the intensity of the stimulation with the intensity of their single-cell response. Therefore, an analysis of redundancy makes sense only for a neuronal system that functions to represent, and enable discriminations between, a large variety of stimuli, and only when using a set of stimuli representative, in some sense, of that large variety.

Rolls, Treves and Tovee (1997b) measured the information available from a population of inferior temporal cortex neurons using the decoding method described in Section C.2.3, and found that the information increased approximately linearly, as shown in Fig. 2.18 on page 77, and in Fig. C.24 for a 50 ms interval as well as for a 500 ms measuring period. (It is shown below that the increase is limited only by the information ceiling of 4.32 bits necessary to encode the 20 stimuli. If it were not for this approach to the ceiling, the increase would be approximately linear (Rolls, Treves and Tovee, 1997b).) To the extent that the information increases linearly with the number of neurons, the neurons convey independent information,

and there is no redundancy, at least with numbers of neurons in this range. Although these and some of the other results described in this Appendix are for face-selective neurons in the inferior temporal visual cortex, similar results were obtained for neurons responding to objects in the inferior temporal visual cortex (Booth and Rolls, 1998), and for neurons responding to spatial view in the hippocampus (Rolls, Treves, Robertson, Georges-François and Panzeri, 1998b).

Although those neurons were not simultaneously recorded, a similar approximately linear increase in the information from *simultaneously* recorded cells as the number of neurons in the sample increased also occurs (Rolls, Franco, Aggelopoulos and Reece, 2003b; Rolls, Aggelopoulos, Franco and Treves, 2004; Franco, Rolls, Aggelopoulos and Treves, 2004; Aggelopoulos, Franco and Rolls, 2005; Rolls, Franco, Aggelopoulos and Jerez, 2006b). These findings imply little redundancy, and that the number of stimuli that can be encoded increases approximately exponentially with the number of neurons in the population, as illustrated in Figs. 2.19 and C.24.

The issue of redundancy is considered in more detail now. Redundancy can be defined with reference to a multiple channel of capacity $T(C)$ which can be decomposed into C separate channels of capacities $T_i, i = 1, \dots, C$:

$$R = 1 - T(C) / \sum_i T_i \quad (\text{C.52})$$

so that when the C channels are multiplexed with maximal efficiency, $T(C) = \sum_i T_i$ and $R = 0$. What is measured more easily, in practice, is the redundancy defined with reference to a specific source (the set of stimuli with their probabilities). Then in terms of mutual information

$$R' = 1 - I(C) / \sum_i I_i. \quad (\text{C.53})$$

Gawne and Richmond (1993) measured the redundancy R' among pairs of nearby primate inferior temporal cortex visual neurons, in their response to a set of 32 Walsh patterns. They found values with a mean $\langle R' \rangle = 0.1$ (and a mean single-cell transinformation of 0.23 bits). Since to discriminate 32 different patterns takes 5 bits of information, in principle one would need at least 22 cells each providing 0.23 bits of strictly orthogonal information to represent the full entropy of the stimulus set. Gawne and Richmond reasoned, however, that, because of the overlap, y , in the information they provided, more cells would be needed than if the redundancy had been zero. They constructed a simple model based on the notion that the overlap, y , in the information provided by any two cells in the population always corresponds to the average redundancy measured for nearby pairs. A redundancy $R' = 0.1$ corresponds to an overlap $y = 0.2$ in the information provided by the two neurons, since, counting the overlapping information only once, two cells would yield 1.8 times the amount transmitted by one cell alone. If a fraction of $1 - y = 0.8$ of the information provided by a cell is novel with respect to that provided by another cell, a fraction $(1 - y)^2$ of the information provided by a third cell will be novel with respect to what was known from the first pair, and so on, yielding an estimate of $I(C) = I(1) \sum_{i=0}^{C-1} (1 - y)^i$ for the total information conveyed by C cells. However such a sum saturates, in the limit of an infinite number of cells, at the level $I(\infty) = I(1)/y$, implying in their case that even with very many cells, no more than $0.23/0.2 = 1.15$ bits could be read off their activity, or less than a quarter of what was available as entropy in the stimulus set! Gawne and Richmond (1993) concluded, therefore, that the average overlap among non-nearby cells must be considerably lower than that measured for cells close to each other.

The model above is simple and attractive, but experimental verification of the actual scaling of redundancy with the number of cells entails collecting the responses of several cells interspersed in a population of interest. Gochin, Colombo, Dorfman, Gerstein and Gross (1994) recorded from up to 58 cells in the primate temporal visual cortex, using sets of two to five visual stimuli, and applied decoding procedures to measure the information content in the population response. The recordings were not simultaneous, but comparison with simultaneous recordings from a smaller number of cells indicated that the effect of recording the individual responses on separate trials was minor. The results were expressed in terms of the *novelty* N in the information provided by C cells, which being defined as the ratio of such information to C times the average single-cell information, can be expressed as

$$N = 1 - R' \quad (\text{C.54})$$

and is thus the complement of the redundancy. An analysis of two different data sets, which included three information measures per data set, indicated a behavior $N(C) \approx 1/\sqrt{C}$, reminiscent of the improvement in the overall noise-to-signal ratio characterizing C independent processes contributing to the same signal. The analysis neglected however to consider limited sampling effects, and more seriously it neglected to consider saturation effects due to the information content approaching its ceiling, given by the entropy of the stimulus set. Since this ceiling was quite low, for 5 stimuli at $\log_2 5 = 2.32$ bits, relative to the mutual information values measured from the population (an average of 0.26 bits, or 1/9 of the ceiling, was provided by single cells), it is conceivable that the novelty would have taken much larger values if larger stimulus sets had been used.

A simple formula describing the approach to the ceiling, and thus the saturation of information values as they come close to the entropy of the stimulus set, can be derived from a natural extension of the Gawne and Richmond (1993) model. In this extension, the information provided by single cells, measured as a fraction of the ceiling, is taken to coincide with the average overlap among pairs of randomly selected, not necessarily nearby, cells from the population. The actual value measured by Gawne and Richmond would have been, again, $1/22 = 0.045$, below the overlap among nearby cells, $y = 0.2$. The assumption that y , measured across any pair of cells, would have been as low as the fraction of information provided by single cells is equivalent to conceiving of single cells as ‘covering’ a random portion y of information space, and thus of randomly selected pairs of cells as overlapping in a fraction $(y)^2$ of that space, and so on, as postulated by the Gawne and Richmond (1993) model, for higher numbers of cells. The approach to the ceiling is then described by the formula

$$I(C) \approx H\{1 - \exp[C \ln(1 - y)]\} \quad (\text{C.55})$$

that is, a simple exponential saturation to the ceiling. This simple law indeed describes remarkably well the trend in the data analyzed by Rolls, Treves and Tovee (1997b). Although the model has no reason to be exact, and therefore its agreement with the data should not be expected to be accurate, the crucial point it embodies is that deviations from a purely linear increase in information with the number of cells analyzed are due solely to the ceiling effect. Aside from the ceiling, due to the sampling of an information space of finite entropy, the information contents of different cells’ responses are independent of each other. Thus, in the model, the observed redundancy (or indeed the overlap) is purely a consequence of the finite size of the stimulus set. If the population were probed with larger and larger sets of stimuli, or more precisely with sets of increasing entropy, and the amount of information conveyed by single cells were to remain approximately the same, then the fraction of space ‘covered’ by each cell, again y , would get smaller and smaller, tending to eliminate redundancy for very large stimulus entropies (and a fixed number of cells). The actual data were obtained

with limited numbers of stimuli, and therefore cannot probe directly the conditions in which redundancy might reduce to zero. The data are consistent, however, with the hypothesis embodied in the simple model, as shown also by the near exponential approach to lower ceilings found for information values calculated with reduced subsets of the original set of stimuli (Rolls, Treves and Tovee, 1997b).

The implication of this set of analyses, some performed towards the end of the ventral visual stream of the monkey, is that the representation of at least some classes of objects in those areas is achieved with minimal redundancy by cells that are allocated each to analyze a different aspect of the visual stimulus. This minimal redundancy is what would be expected of a self-organizing system in which different cells acquired their response selectivities through a random process, with or without local competition among nearby cells (see Section B.4). At the same time, such low redundancy could also very well result in a system that is organized under some strong teaching input, so that the emerging picture is compatible with a simple random process, but could be produced in other ways. The finding that, at least with small numbers of neurons, redundancy may be effectively minimized, is consistent not only with the concept of efficient encoding, but also with the general idea that one of the functions of the early visual system is to progressively minimize redundancy in the representation of visual stimuli (Attneave, 1954; Barlow, 1961). However, the ventral visual system does much more than produce a non-redundant representation of an image, for it transforms the representation from an image to an invariant representation of objects, as described in Chapter 2. Moreover, what is shown in this section is that the information about objects can be read off from just the spike count of a population of neurons, using decoding as simple as the simplest that could be performed by a receiving neuron, dot product decoding. In this sense, the information about objects is made explicit in the firing rate of the neurons in the inferior temporal cortex, in that it can be read off in this way.

We consider in Section C.3.7 whether there is more to it than this. Does the synchronization of neurons (and it would have to be stimulus-dependent synchronization) add significantly to the information that could be encoded by the number of spikes, as has been suggested by some?

Before this, we consider why encoding by a population of neurons is more powerful than the encoding than is possible by single neurons, adding to previous arguments that a distributed representation is much more computationally useful than a local representation, by allowing properties such as generalization, completion, and graceful degradation in associative neuronal networks (see Appendix B).

C.3.6 Should one neuron be as discriminative as the whole organism, in object encoding systems?

In the analysis of random dot motion with a given level of correlation among the moving dots, single neurons in area MT in the dorsal visual system of the primate can be approximately as sensitive or discriminative as the psychophysical performance of the whole animal (Zohary, Shadlen and Newsome, 1994). The arguments and evidence presented here (e.g. in Section C.3.5) suggest that this is not the case for the ventral visual system, concerned with object identification. Why should there be this difference?

Rolls and Treves (1998) suggest that the dimensionality of what is being computed may account for the difference. In the case of visual motion (at least in the study referred to), the problem was effectively one-dimensional, in that the direction of motion of the stimulus along a line in 2D space was extracted from the activity of the neurons. In this low-dimensional stimulus space, the neurons may each perform one of a few similar computations on a particular (local) portion of 2D space, with the side effect that, by averaging over a larger receptive

field than in V1, one can extract a signal of a more global nature. Indeed, in the case of more global motion, it is the average of the neuronal activity that can be computed by the larger receptive fields of MT neurons that specifies the average or global direction of motion.

In contrast, in the higher dimensional space of objects, in which there are very many different objects to represent as being different from each other, and in a system that is not concerned with location in visual space but on the contrary tends to be relatively invariant with respect to location, the goal of the representation is to reflect the many aspects of the input information in a way that enables many different objects to be represented, in what is effectively a very high dimensional space. This is achieved by allocating cells, each with an intrinsically limited discriminative power, to sample as thoroughly as possible the many dimensions of the space. Thus the system is geared to use efficiently the parallel computations of all its neurons precisely for tasks such as that of face discrimination, which was used as an experimental probe. Moreover, object representation must be kept higher dimensional, in that it may have to be decoded by dot product decoders in associative memories, in which the input patterns must be in a space that is as high-dimensional as possible (i.e. the activity on different input axons should not be too highly correlated). In this situation, each neuron should act somewhat independently of its neighbours, so that each provides its own separate contribution that adds together with that of the other neurons (in a linear manner, see above and Figs. 2.18, C.24 and 2.19) to provide *in toto* sufficient information to specify which out of perhaps several thousand visual stimuli was seen. The computation involves in this case not an average of neuronal activity (which would be useful for e.g. head direction (Robertson, Rolls, Georges-François and Panzeri, 1999)), but instead comparing the dot product of the activity of the population of neurons with a previously learned vector, stored in, for example, associative memories as the weight vector on a receiving neuron or neurons.

Zohary, Shadlen and Newsome (1994) put forward another argument which suggested to them that the brain could hardly benefit from taking into account the activity of more than a very limited number of neurons. The argument was based on their measurement of a small (0.12) correlation between the activity of simultaneously recorded neurons in area MT. They suggested that there would be decreasing signal-to-noise ratio advantages as more neurons were included in the population, and that this would limit the number of neurons that it would be useful to decode to approximately 100. However, a measure of correlations in the activity of different neurons depends entirely on the way the space of neuronal activity is sampled, that is on the task chosen to probe the system. Among face cells in the temporal cortex, for example, much higher correlations would be observed when the task is a simple two-way discrimination between a face and a non-face, than when the task involves finer identification of several different faces. (It is also entirely possible that some face cells could be found that perform as well in a given particular face / non-face discrimination as the whole animal.) Moreover, their argument depends on the type of decoding of the activity of the population that is envisaged (see further Robertson, Rolls, Georges-François and Panzeri (1999)). It implies that the average of the neuronal activity must be estimated accurately. If a set of neurons uses dot product decoding, and then the activity of the decoding population is scaled or normalized by some negative feedback through inhibitory interneurons, then the effect of such correlated firing in the sending population is reduced, for the decoding effectively measures the relative firing of the different neurons in the population to be decoded. This is equivalent to measuring the angle between the current vector formed by the population of neurons firing, and a previously learned vector, stored in synaptic weights. Thus, with for example this biologically plausible decoding, it is not clear whether the correlation Zohary, Shadlen and Newsome (1994) describe would place a severe limit on the ability of the brain to utilize the information available in a population of neurons.

The main conclusion from this and the preceding Section is that the information available

from a set or ensemble of temporal cortex visual neurons increases approximately linearly as more neurons are added to the sample. This is powerful evidence that distributed encoding is used by the brain; and the code can be read just by knowing the firing rates in a short time of the population of neurons. The fact that the code can be read off from the firing rates, and by a principle as simple and neuron-like as dot product decoding, provides strong support for the general approach taken in this book to brain function.

It is possible that more information would be available in the relative time of occurrence of the spikes, either within the spike train of a single neuron, or between the spike trains of different neurons, and it is to this that we now turn.

C.3.7 The information from multiple cells: the effects of cross-correlations between cells

Using the second derivative methods described in Section C.2.5 (see Rolls, Franco, Aggelopoulos and Reece (2003b)), the information available from the number of spikes vs that from the cross-correlations between simultaneously recorded cells has been analyzed for a population of neurons in the inferior temporal visual cortex (Rolls, Aggelopoulos, Franco and Treves, 2004). The stimuli were a set of 20 objects, faces, and scenes presented while the monkey performed a visual discrimination task. If synchronization was being used to bind the parts of each object into the correct spatial relationship to other parts, this might be expected to be revealed by stimulus-dependent cross-correlations in the firing of simultaneously recorded groups of 2–4 cells using multiple single-neuron microelectrodes.

A typical result from the information analysis described in Section C.2.5 on a set of three simultaneously recorded cells from this experiment is shown in Fig. C.25. This shows that most of the information available in a 100 ms time period was available in the rates, and that there was little contribution to the information from stimulus-dependent ('noise') correlations (which would have shown as positive values if for example there was stimulus-dependent synchronization of the neuronal responses); or from stimulus-independent 'noise' correlation effects, which might if present have reflected common input to the different neurons so that their responses tended to be correlated independently of which stimulus was shown.

The results for the 20 experiments with groups of 2–4 simultaneously recorded inferior temporal cortex neurons are shown in Table C.4. (The total information is the total from equations C.43 and C.44 in a 100 ms time window, and is not expected to be the sum of the contributions shown in Table C.4 because only the information from the cross terms (for $i \neq j$) is shown in the table for the contributions related to the stimulus-dependent contributions and the stimulus-independent contributions arising from the 'noise' correlations.) The results show that the greatest contribution to the information is that from the rates, that is from the numbers of spikes from each neuron in the time window of 100 ms. The average value of -0.05 for the cross term of the stimulus independent 'noise' correlation-related contribution is consistent with on average a small amount of common input to neurons in the inferior temporal visual cortex. A positive value for the cross term of the stimulus-dependent 'noise' correlation related contribution would be consistent with on average a small amount of stimulus-dependent synchronization, but the actual value found, 0.04 bits, is so small that for 17 of the 20 experiments it is less than that which can arise by chance statistical fluctuations of the time of arrival of the spikes, as shown by MonteCarlo control rearrangements of the same data. Thus on average there was no significant contribution to the information from stimulus-dependent synchronization effects (Rolls, Aggelopoulos, Franco and Treves, 2004).

Thus, this data set provides evidence for considerable information available from the number of spikes that each cell produces to different stimuli, and evidence for little impact of common input, or of synchronization, on the amount of information provided by

Fig. C.25 Most of the information is present in the firing rates, with little in stimulus-dependent cross-correlations between the spikes of different neurons. A typical result from the information analysis described in Section C.2.5 on a set of 3 simultaneously recorded inferior temporal cortex neurons in an experiment in which 20 complex stimuli effective for IT neurons (objects, faces and scenes) were shown. The graphs show the contributions to the information from the different terms in Equations C.43 and C.44 on page 989, as a function of the length of the time window, which started 100 ms after stimulus onset, which is when IT neurons start to respond. The rate information is the sum of the term in Equation C.43 and the first term of Equation C.44. The contribution of the stimulus-independent noise correlation to the information is the second term of Equation C.44, and is separated into components arising from the correlations between cells (the cross component, for $i \neq j$) and from the autocorrelation within a cell (the auto component, for $i = j$). This term is non-zero if there is some correlation in the variance to a given stimulus, even if it is independent of which stimulus is present. The contribution of the stimulus-dependent noise correlation to the information is the third term of Equation C.44, and only the cross term is shown (for $i \neq j$), as this is the term of interest. (From Rolls, E. T., Aggelopoulos, N.C., Franco, L., and Treves, A. (2004) Information encoding in the inferior temporal cortex: contributions of the firing rates and correlations between the firing of neurons. *Biological Cybernetics* 90: 19–32. © Springer Nature.)

Table C.4 The average contributions (in bits) of different components of Equations C.43 and C.44 to the information available in a 100 ms time window from 13 sets of simultaneously recorded inferior temporal cortex neurons when shown 20 stimuli effective for the cells.

rate	0.26
stimulus-dependent “noise” correlation-related, cross term	0.04
stimulus-independent “noise” correlation-related, cross term	-0.05
total information	0.31

sets of *simultaneously recorded* inferior temporal cortex neurons. Further supporting data for the inferior temporal visual cortex are provided by Rolls, Franco, Aggelopoulos and Reece (2003b). In that parts as well as whole objects are represented in the inferior temporal cortex (Perrett, Rolls and Caan, 1982), and in that the parts must be bound together in the correct spatial configuration for the inferior temporal cortex neurons to respond (Rolls, Tovee, Purcell, Stewart and Azzopardi, 1994b), we might have expected temporal synchrony, if used to implement feature binding, to have been evident in these experiments.

We have also explored neuronal encoding under natural scene conditions in a task in which top-down attention must be used, a visual search task. We applied the decoding information theoretic method of Section C.2.4 to the responses of neurons in the inferior temporal visual cortex recorded under conditions in which feature binding is likely to be needed, that is when the monkey had to choose to touch one of two simultaneously presented objects, with the stimuli presented in a complex natural background (Aggelopoulos, Franco and Rolls, 2005). The investigation is thus directly relevant to whether stimulus-dependent synchrony

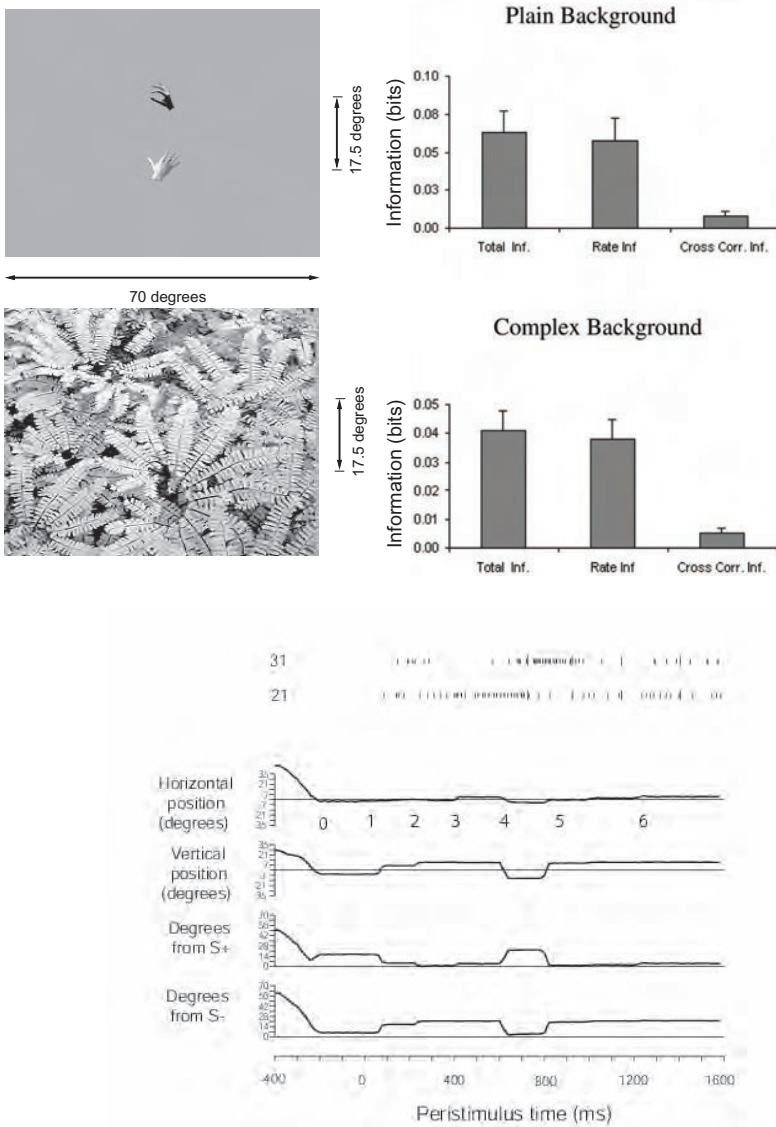

Fig. C.26 Even in complex natural scenes, most of the information is in the firing rates and not in the cross-correlations between the neurons. Left: the objects against the plain background, and in a natural scene. Right: the information available from the firing rates (Rate Inf) or from stimulus-dependent synchrony (Cross-Corr Inf) from populations of simultaneously recorded inferior temporal cortex neurons about which stimulus had been presented in a complex natural scene. The total information (Total Inf) is that available from both the rate and the stimulus-dependent synchrony, which do not necessarily contribute independently. Bottom: eye position recordings and spiking activity from two neurons on a single trial of the task. (Neuron 31 tended to fire more when the macaque looked at one of the stimuli, S-, and neuron 21 tended to fire more when the macaque looked at the other stimulus, S+. Both stimuli were within the receptive field of the neuron.) (After Aggelopoulos, N.C., Franco, L. and Rolls, E. T. (2005) Object perception in natural scenes: encoding by inferior temporal cortex simultaneously recorded neurons. *Journal of Neurophysiology* 93: 1342–1357. © American Physiological Society.)

contributes to encoding under natural conditions, and when an attentional task was being performed. In the attentional task, the monkey had to find one of two objects and to touch it to obtain reward. This is thus an object-based attentional visual search task, where the top-down bias is for the object that has to be found in the scene (Aggelopoulos, Franco and Rolls,

2005). The objects could be presented against a complex natural scene background. Neurons in the inferior temporal visual cortex respond in some cases to object features or parts, and in other cases to whole objects provided that the parts are in the correct spatial configuration (Perrett, Rolls and Caan, 1982; Desimone, Albright, Gross and Bruce, 1984; Rolls, Tovee, Purcell, Stewart and Azzopardi, 1994b; Tanaka, 1996), and so it is very appropriate to measure whether stimulus-dependent synchrony contributes to information encoding in the inferior temporal visual cortex when two objects are present in the visual field, and when they must be segmented from the background in a natural visual scene, which are the conditions in which it has been postulated that stimulus-dependent synchrony would be useful (Singer, 1999, 2000).

Aggelopoulos, Franco and Rolls (2005) found that between 99% and 94% of the information was present in the firing rates of inferior temporal cortex neurons, and less than 5% in any stimulus-dependent synchrony that was present, as illustrated in Fig. C.26. The implication of these results is that any stimulus-dependent synchrony that is present is not quantitatively important as measured by information theoretic analyses under natural scene conditions. This has been found for the inferior temporal visual cortex, a brain region where features are put together to form representations of objects (Rolls, 2016b) (Chapter 2), where attention has strong effects, at least in scenes with blank backgrounds (Rolls, Aggelopoulos and Zheng, 2003a), and in an object-based attentional search task.

The finding as assessed by information theoretic methods of the importance of firing rates and not stimulus-dependent synchrony is consistent with previous information theoretic approaches (Rolls, Franco, Aggelopoulos and Reece, 2003b; Rolls, Aggelopoulos, Franco and Treves, 2004; Franco, Rolls, Aggelopoulos and Treves, 2004). It would of course also be of interest to test the same hypothesis in earlier visual areas, such as V4, with quantitative, information theoretic, techniques. In connection with rate codes, it should be noted that the findings indicate that the number of spikes that arrive in a given time is what is important for very useful amounts of information to be made available from a population of neurons; and that this time can be very short, as little as 20–50 ms (Tovee and Rolls, 1995; Rolls and Tovee, 1994; Rolls, Tovee and Panzeri, 1999b; Rolls and Deco, 2002; Rolls, Tovee, Purcell, Stewart and Azzopardi, 1994b; Rolls, 2003; Rolls, Franco, Aggelopoulos and Jerez, 2006b). Further, it was shown that there was little redundancy (less than 6%) between the information provided by the spike counts of the simultaneously recorded neurons, making spike counts an efficient population code with a high encoding capacity.

The findings (Aggelopoulos, Franco and Rolls, 2005) are consistent with the hypothesis that feature binding is implemented by neurons that respond to features in the correct relative spatial locations (Rolls and Deco, 2002; Elliffe, Rolls and Stringer, 2002; Rolls, 2016b, 2012d) (Chapter 2), and not by temporal synchrony and attention (Malsburg, 1990; Singer, Gray, Engel, Konig, Artola and Brocher, 1990; Abeles, 1991; Hummel and Biederman, 1992; Singer and Gray, 1995; Singer, 1999, 2000; Rolls, 2016b). In any case, the computational point made in Section 2.8.5.1 is that even if stimulus-dependent synchrony was useful for grouping, it would not without much extra machinery be useful for binding the relative spatial positions of features within an object, or for that matter of the positions of objects in a scene which appears to be encoded in a different way (Aggelopoulos and Rolls, 2005) (see Section 2.8.10).

So far, we know of no analyses that have shown with information theoretic methods that considerable amounts of information are available about the stimulus from the stimulus-dependent correlations between the responses of neurons in the primate ventral visual system. The use of such methods is needed to test quantitatively the hypothesis that stimulus-dependent synchronization contributes substantially to the encoding of information by neurons.

As described in Section C.2.5, one way to measure how the effects of the correlations in the activity of populations of simultaneously recorded neurons influence the total information that can be encoded is to shuffle the data across trials for each neuron in the population (Panzeri et al., 2022). In practice, ‘noise’ correlations tend to decrease the information that can be decoded from populations of neurons (Panzeri et al., 2022). However, many of these analyses (Panzeri et al., 2022) assume that for example temporal synchrony between the firing of particular pairs of neurons is actually being measured in the brain and taken into account in decoding the information, and that is not at all clear. Overall, ‘noise’ correlations are not likely to increase the information that is used in the brain, and if anything decrease the information that is being used by the brain (Panzeri et al., 2022).

C.3.8 Conclusions on cortical neuronal encoding

The conclusions emerging from this set of information theoretic analyses, many in cortical areas towards the end of the ventral visual stream of the monkey, and others in the hippocampus for spatial view cells (Rolls, Treves, Robertson, Georges-François and Panzeri, 1998b), in the presubiculum for head direction cells (Robertson, Rolls, Georges-François and Panzeri, 1999), and in the orbitofrontal cortex and related areas for olfactory and taste cells (Rolls, Critchley and Treves, 1996a; Rolls, Critchley, Verhagen and Kadohisa, 2010a) for which subsequent analyses have shown a linear increase in information with the number of cells in the population, are as follows (see also Rolls and Treves (2011)).

The representation of at least some classes of objects in those areas is achieved with minimal redundancy by cells that are allocated each to analyze a different aspect of the visual stimulus (Abbott, Rolls and Tovee, 1996; Rolls, Treves and Tovee, 1997b) (as shown in Sections C.3.5 and C.3.7). This minimal redundancy is what would be expected of a self-organizing system in which different cells acquired their response selectivities through processes that include some randomness in the initial connectivity, and local competition among nearby cells (see Appendix B). Towards the end of the ventral visual stream redundancy may thus be effectively minimized, a finding consistent with the general idea that one of the functions of the early visual system is indeed that of progressively minimizing redundancy in the representation of visual stimuli (Attneave, 1954; Barlow, 1961). Indeed, the evidence described in Sections C.3.5, C.3.7 and C.3.4 shows that the exponential rise in the number of stimuli that can be decoded when the firing rates of different numbers of neurons are analyzed indicates that the encoding of information using firing rates (in practice the number of spikes emitted by each of a large population of neurons in a short time period) is a very powerful coding scheme used by the cerebral cortex, and that the information carried by different neurons is close to independent provided that the number of stimuli being considered is sufficiently large.

Quantitatively, the encoding of information using firing rates (in practice the number of spikes emitted by each of a large population of neurons in a short time period) is likely to be far more important than temporal encoding, in terms of the number of stimuli that can be encoded. Moreover, the information available from an ensemble of cortical neurons when only the firing rates are read, that is with no temporal encoding within or between neurons, is made available very rapidly (see Figs. C.16 and C.17 and Section C.3.4). Further, the neuronal responses in most ventral or ‘what’ processing streams of behaving monkeys show sustained firing rate differences to different stimuli (see for example Fig. 2.16 for visual representations, for the olfactory pathways Rolls, Critchley and Treves (1996a), for spatial view cells in the hippocampus Rolls, Treves, Robertson, Georges-François and Panzeri (1998b), and for head direction cells in the presubiculum Robertson, Rolls, Georges-François and Panzeri (1999)), so that it may not usually be necessary to invoke temporal encoding for the information about

the stimulus. Further, as indicated in Section C.3.7, information theoretic approaches have enabled the information that is available from the firing rate and from the relative time of firing (synchronization) of inferior temporal cortex neurons to be directly compared with the same metric, and most of the information appears to be encoded in the numbers of spikes emitted by a population of cells in a short time period, rather than by the temporal synchronization of the responses of different neurons when certain stimuli appear (see Section C.3.7 and Aggelopoulos, Franco and Rolls (2005)).

Information theoretic approaches have also enabled different types of readout or decoding that could be performed by the brain of the information available in the responses of cell populations to be compared (Rolls, Treves and Tovee, 1997b; Robertson, Rolls, Georges-François and Panzeri, 1999). It has been shown for example that the multiple cell representation of information used by the brain in the inferior temporal visual cortex (Rolls, Treves and Tovee, 1997b; Aggelopoulos, Franco and Rolls, 2005), olfactory cortex (Rolls, Critchley and Treves, 1996a), hippocampus (Rolls, Treves, Robertson, Georges-François and Panzeri, 1998b), and presubiculum (Robertson, Rolls, Georges-François and Panzeri, 1999) can be read fairly efficiently by the neuronally plausible dot product decoding, and that the representation has all the desirable properties of generalization and graceful degradation, as well as exponential coding capacity (see Sections C.3.5 and C.3.7).

Information theoretic approaches have also enabled the information available about different aspects of stimuli to be directly compared. For example, it has been shown that inferior temporal cortex neurons make explicit much more information about what stimulus has been shown rather than where the stimulus is in the visual field (Tovee, Rolls and Azzopardi, 1994), and this is part of the evidence that inferior temporal cortex neurons provide translation invariant representations. In a similar way, information theoretic analysis has provided clear evidence that view invariant representations of objects and faces are present in the inferior temporal visual cortex, in that for example much information is available about what object has been shown from any single trial on which any view of any object is presented (Booth and Rolls, 1998).

Information theory has also helped to elucidate the way in which the inferior temporal visual cortex provides a representation of objects and faces, in which information about which object or face is shown is made explicit in the firing of the neurons in such a way that the information can be read off very simply by memory systems such as the orbitofrontal cortex, amygdala, and perirhinal cortex / hippocampal systems. The information can be read off using dot product decoding, that is by using a synaptically weighted sum of inputs from inferior temporal cortex neurons (see further Section 9.2.7 and Chapter 2). Moreover, information theory has helped to show that for many neurons considerable invariance in the representations of objects and faces are shown by inferior temporal cortex neurons (e.g. Booth and Rolls (1998)). Examples of some of the types of objects and faces that are encoded in this way are shown in Fig. C.7. Information theory has also helped to show that inferior temporal cortex neurons maintain their object selectivity even when the objects are presented in complex natural backgrounds (Aggelopoulos, Franco and Rolls, 2005) (see further Chapter 2 and Section 9.2.7).

Information theory has also enabled the information available in neuronal representations to be compared with that available to the whole animal in its behavior (Zohary, Shadlen and Newsome, 1994) (but see Section C.3.6).

Finally, information theory also provides a metric for directly comparing the information available from neurons in the brain (see Chapter 2 and this Appendix) with that available from single neurons and populations of neurons in simulations of visual information processing (see Chapter 2).

In summary, the evidence from the application of information theoretic and related approaches to how information is encoded in the visual, hippocampal, and olfactory cortical systems described during behavior leads to the following working hypotheses:

1. Much information is available about the stimulus presented in the number of spikes emitted by single neurons in a fixed time period, the firing rate.
2. Much of this firing rate information is available in short periods, with a considerable proportion available in as little as 20 ms. This rapid availability of information enables the next stage of processing to read the information quickly, and thus for multistage processing to operate rapidly. This time is the order of time over which a receiving neuron might be able to utilize the information, given its synaptic and membrane time constants. In this time, a sending neuron is most likely to emit 0, 1, or 2 spikes.
3. This rapid availability of information is confirmed by population analyses, which indicate that across a population of neurons, much information is available in short time periods.
4. More information is available using this rate code in a short period (of e.g. 20 ms) than from just the first spike.
5. Little information is available by time variations within the spike train of individual neurons for static visual stimuli (in periods of several hundred milliseconds), apart from a small amount of information from the onset latency of the neuronal response. A static stimulus encompasses what might be seen in a single visual fixation, what might be tasted with a stimulus in the mouth, what might be smelled in a single sniff, etc. For a time-varying stimulus, clearly the firing rate will vary as a function of time.
6. Across a population of neurons, the firing rate information provided by each neuron tends to be independent; that is, the information increases approximately linearly with the number of neurons. This applies of course only when there is a large amount of information to be encoded, that is with a large number of stimuli. The outcome is that the number of stimuli that can be encoded rises exponentially in the number of neurons in the ensemble. (For a small stimulus set, the information saturates gradually as the amount of information available from the neuronal population approaches that required to code for the stimulus set.) This applies up to the number of neurons tested and the stimulus set sizes used, but as the number of neurons becomes very large, this is likely to hold less well. An implication of the independence is that the response profiles to a set of stimuli of different neurons are uncorrelated.
7. The information in the firing rate across a population of neurons can be read moderately efficiently by a decoding procedure as simple as a dot product. This is the simplest type of processing that might be performed by a neuron, as it involves taking a dot product of the incoming firing rates with the receiving synaptic weights to obtain the activation (e.g. depolarization) of the neuron. This type of information encoding ensures that the simple emergent properties of associative neuronal networks such as generalization, completion, and graceful degradation (see Appendix B) can be realized very naturally and simply.
8. There is little additional information to the great deal available in the firing rates from any stimulus-dependent cross-correlations or synchronization that may be present. Stimulus-dependent synchronization might in any case only be useful for grouping different neuronal populations, and would not easily provide a solution to the binding problem in vision. In-

stead, the binding problem in vision may be solved by the presence of neurons that respond to combinations of features in a given spatial position with respect to each other.

9. There is little information available in the order of the spike arrival times of different neurons for different stimuli that is separate or additional to that provided by a rate code. The presence of spontaneous activity in cortical neurons facilitates rapid neuronal responses, because some neurons are close to threshold at any given time, but this also would make a spike order code difficult to implement.

10. Analysis of the responses of single neurons to measure the sparseness of the representation indicates that the representation is distributed, and not grandmother cell like (or local). Moreover, the nature of the distributed representation, that it can be read by dot product decoding, allows simple emergent properties of associative neuronal networks such as generalization, completion, and graceful degradation (see Appendix B) to be realized very naturally and simply. The evidence becoming available from humans is consistent with this summary (Fried, Rutishauser, Cerf and Kreiman, 2014; Rolls, 2015c, 2017a).

11. The representation is not very sparse in the perceptual systems studied (as shown for example by the values of the single cell sparseness a^s), and this may allow much information to be represented. At the same time, the responses of different neurons to a set of stimuli are decorrelated, in the sense that the correlations between the response profiles of different neurons to a set of stimuli are low. Consistent with this, the neurons convey independent information, at least up to reasonable numbers of neurons. The representation may be more sparse in memory systems such as the hippocampus, and this may help to maximize the number of memories that can be stored in associative networks.

12. The nature of the distributed representation can be understood further by the firing rate probability distribution, which has a long tail with low probabilities of high firing rates. The firing rate probability distributions for some neurons fit an exponential distribution, and for others there are too few very low rates for a good fit to the exponential distribution. An implication of an exponential distribution is that this maximizes the entropy of the neuronal responses for a given mean firing rate under some conditions. It is of interest that in the inferior temporal visual cortex, the firing rate probability distribution is very close to exponential if a large number of neurons are included without scaling of the firing rates of each neuron. An implication is that a receiving neuron would see an exponential firing rate probability distribution.

13. The population sparseness a^p , that is the sparseness of the firing of a population of neurons to a given stimulus (or at one time), is the important measure for setting the capacity of associative neuronal networks. In populations of neurons studied in the inferior temporal cortex, hippocampus, and orbitofrontal cortex, it takes the same value as the single cell sparseness a^s , and this is a situation of weak ergodicity that occurs if the response profiles of the different neurons to a set of stimuli are uncorrelated.

Understanding the neuronal code, the subject of this Appendix, is fundamental for understanding how memory and related perceptual systems in the brain operate, as follows:

Understanding the neuronal code helps to clarify what neuronal operations would be useful in memory and in fact in most mammalian brain systems (e.g. dot product decoding, that is taking a sum in a short time of the incoming firing rates weighted by the synaptic weights).

It clarifies how rapidly memory and perceptual systems in the brain could operate, in terms of how long it takes a receiving neuron to read the code.

It helps to confirm how the properties of those memory systems in terms of generalization, completion, and graceful degradation occur, in that the representation is in the correct form for these properties to be realized.

Understanding the neuronal code also provides evidence essential for understanding the storage capacity of memory systems, and the representational capacity of perceptual systems.

Understanding the neuronal code is also important for interpreting functional neuroimaging, for it shows that functional imaging that reflects incoming firing rates and thus currents injected into neurons, and probably not stimulus-dependent synchronization, is likely to lead to useful interpretations of the underlying neuronal activity and processing. Of course, functional neuroimaging cannot address the details of the representation of information in the brain in the way that is essential for understanding how neuronal networks in the brain could operate, for this level of understanding (in terms of all the properties and working hypotheses described above) comes only from an understanding of how single neurons and populations of neurons encode information.

C.4 Information theory terms – a short glossary

1. The **amount of information**, or **surprise**, in the occurrence of an event (or symbol) s_i of probability $P(s_i)$ is

$$I(s_i) = \log_2(1/P(s_i)) = -\log_2 P(s_i). \quad (\text{C.56})$$

(The measure is in bits if logs to the base 2 are used.) This is also the amount of **uncertainty** removed by the occurrence of the event.

2. The average amount of information per source symbol over the whole alphabet (S) of symbols s_i is the **entropy**,

$$H(S) = -\sum_i P(s_i) \log_2 P(s_i) \quad (\text{C.57})$$

(or *a priori* entropy).

3. The probability of the pair of symbols s and s' is denoted $P(s, s')$, and is $P(s)P(s')$ only when the two symbols are **independent**.

4. Bayes theorem (given the output s' , what was the input s ?) states that

$$P(s|s') = \frac{P(s'|s)P(s)}{P(s')} \quad (\text{C.58})$$

where $P(s'|s)$ is the **forward** conditional probability (given the input s , what will be the output s' ?), and $P(s|s')$ is the **backward** (or posterior) conditional probability (given the output s' , what was the input s ?). The prior probability is $P(s)$.

5. **Mutual information**. Prior to reception of s' , the probability of the input symbol s was $P(s)$. This is the *a priori* probability of s . After reception of s' , the probability that the input symbol was s becomes $P(s|s')$, the conditional probability that s was sent given that s' was received. This is the *a posteriori* probability of s . The difference between the *a priori* and

a posteriori uncertainties measures the gain of information due to the reception of s' . Once averaged across the values of both symbols s and s' , this is the **mutual information**, or **transinformation**

$$\begin{aligned} I(S, S') &= \sum_{s, s'} P(s, s') \{ \log_2[1/P(s)] - \log_2[1/P(s|s')] \} & \text{(C.59)} \\ &= \sum_{s, s'} P(s, s') \log_2[P(s|s')/P(s)]. \end{aligned}$$

Alternatively,

$$I(S, S') = H(S) - H(S|S'). \quad \text{(C.60)}$$

$H(S|S')$ is sometimes called the **equivocation** (of S with respect to S').

C.5 Highlights

1. The encoding of information by neuronal responses is described using Shannon information theory.
2. Information is encoded by sparse distributed place coded representations, with almost independent information conveyed by each neuron, up to reasonable numbers of neurons.
3. Place cell encoding conveys much more information than stimulus-dependent synchronicity ('oscillations', coherence) of firing of groups of neurons in the awake behaving animal.
4. Code translated into Matlab that was used for the single neuron information analysis (Rolls, Treves, Tovee and Panzeri, 1997d) and multiple single neuron information analysis (Rolls, Treves and Tovee (1997b) is described in Section D.7 and is available at <https://www.oxcns.org/software>.

Appendix 4 Simulation software for neuronal networks, and information analysis of neuronal encoding

D.1 Introduction

This Appendix of *Brain Computations and Connectivity* (Oxford University Press) (Rolls, 2023a) describes the Matlab software that has been made available with this book to provide simple demonstrations of the operation of some key neuronal networks related to cortical function. Previous versions of some of this software are provided in connection with *Cerebral Cortex: Principles of Operation* (Oxford University Press) (Rolls, 2016b) and *Emotion and Decision-Making Explained* (Oxford University Press) (Rolls, 2014a). The aim of providing the software is to enable those who are learning about these networks to understand how they operate and their properties by running simulations and by providing the programs. The code has been kept simple, but can easily be edited to explore the properties of these networks. The code itself contains comments that help to explain how the code works.

The programs are intended to be used with the descriptions of the networks and their properties provided in Appendix B of this book *Brain Computations and Connectivity* (Rolls, 2023a). Most of the papers cited in this Appendix can be found at <https://www.oxcns.org>. Exercises are suggested below that will provide insight into the properties of these networks, and will make the software suitable for class use. The code is available at <https://www.oxcns.org>. The programs are written in Matlab™ (Mathworks Inc). The programs should work in any version of Matlab, whether it is running under Windows, Linux, or Apple software. The programs will also work under GNU Octave, which is available for free download. In addition, for those who use Python, Python versions of these programs are also provided at <https://www.oxcns.org>.

To get started, copy the Matlab program files `PatternAssociationDemo.m`, `AutoAssociationDemo.m`, `CompetitiveNetDemo.m` and `SOMdemo.m`, and the function files `NormVecLen.m` and `spars.m`, into a directory, and in Matlab cd into that directory.

The corresponding programs for Python are `PatternAssociationDemo.py`, `AutoAssociationDemo.py`, `CompetitiveNetDemo.py` and `SOMdemo.py`, and the function files `NormVecLen.py` and `spars.py`.

Sections D.2–D.4 describe these tutorial neuronal network programs.

In addition, Section D.6 describes tutorial software written in Matlab that illustrates some of the principles of operation of VisNet, the model of invariant visual object recognition described in Section 2.8 of this book (Rolls, 2023a) and by Rolls (2012d). The software is also available at <https://www.oxcns.org>.

Section D.7 describes code translated into Matlab that was used for the single neuron information analyses described by Rolls, Treves, Tovee and Panzeri (1997d) and the multiple single neuron information analyses described by Rolls, Treves and Tovee (1997b), and in Appendix C. The software is also available at <https://www.oxcns.org>.

Section D.8 describes Matlab code to illustrate the use of spatial view cells and allocentric

bearing to a landmark cells in Navigation described in Section 9.3.15 (Rolls, 2021f). The software is available at <https://www.oxcns.org/software>.

D.2 Autoassociation or attractor networks

The operation and properties of autoassociation (or attractor) neuronal networks are described in this book (Rolls, 2023a) Appendix B.3.

D.2.1 Running the simulation

In the command window of Matlab, after you have performed a 'cd' into the directory where the source files are, type 'AutoAssociationDemo' (with every command followed by 'Enter' or 'Return'). The program will run for a bit, and then pause so that you can inspect what has been produced so far. A paused state is indicated by the words 'Paused: Press any key' in the bottom of the Matlab window. Press 'Enter' to move to the next stage, until the program finishes and the command prompt reappears. You can edit the code to comment out some of the 'pause' statements if you do not want them, or to add a 'pause' statement if you would like the program to stop at a particular place so that you can inspect the results. To stop the program and exit from it, use 'Ctrl-C'. When at the command prompt, you can access variables by typing the variable name followed by 'Enter'. (Note: if you set '*display = 0*' near the beginning of the program, there will be no pauses, and you will be able to collect data quickly.)

The fully connected autoassociation network has $N=100$ neurons with the dendrites that receive the synapses shown as vertical columns in the generated figures, and $nSyn = N$ synapses onto each neuron. At the first pause, you will see a figure showing the 10 random binary training patterns with firing rates of 1 or 0, and with a *Sparseness* (referred to as a in the equations below) of 0.5. As these are binary patterns, the *Sparseness* parameter value is the same as the proportion of high firing rates or 1s. At the second pause you will see distorted versions of these patterns to be used as recall cues later. The number of bits that have been flipped $nFlipBits=14$.

Next you will see a figure showing the synaptic matrix being trained with the 10 patterns. Uncomment the pause in the training loop if you wish to see each pattern being presented sequentially. The synaptic weight matrix *SynMat* (the elements of which are referred to as w_{ij} in the equations below) is initialized to zero, and then each pattern is presented as an external input to set the firing rates of the neurons (the postsynaptic term), which because of the recurrent collaterals become also the presynaptic input. Each time a training pattern is presented, the weight change is calculated by a covariance learning rule

$$\delta w_{ij} = \alpha(y_i - a)(y_j - a) \quad (D.1)$$

where α is a learning rate constant, and y_j is the presynaptic firing rate. This learning rule includes (in proportion to y_i the firing rate of the i th postsynaptic neuron) increasing the synaptic weight if $(y_j - a) > 0$ (long-term potentiation), and decreasing the synaptic weight if $(y_j - a) < 0$ (heterosynaptic long-term depression). As these are random binary patterns with sparseness a (the parameter *Sparseness* in AutoassociationDemo.m), a is the average activity $\langle y_j \rangle$ of an axon across patterns, and a is also the average activity $\langle y_i \rangle$ of a neuron across patterns. In the exercises, you can try a form of this learning rule that is more biologically plausible, with only heterosynaptic long-term depression. The change of weight is added to the previous synaptic weight. In the figures generated by the code, the maximum weights are shown as white, and the minimum weights are black. Although both these rules

lead to some negative synaptic weights, which are not biologically plausible, this limitation can be overcome, as shown in the exercises. In the display of the synaptic weights, remember that each column represents the synaptic weights on a single neuron. The thin row below the synaptic matrix represents the firing rates of the neurons, and the thin column to the left of the synaptic weight matrix the firing rates of the presynaptic input, which are usually the same during training. Rates of 1 are shown as white, and of 0 as black.

Next, testing with the distorted patterns starts, with the output rates allowed to recirculate through the recurrent collateral axons for 9 recall epochs to produce presynaptic inputs that act through the synaptic weight matrix to produce the firing rate for the next recall epoch. The distorted recall cue is presented only on epoch 1 in what is described as the clamped condition, and after that is removed so that the network has a chance to settle into a perfect recall state representing the training pattern without being affected by the distorted recall cue. (In the cortex, this may be facilitated by the greater adaptation of the thalamic inputs than of the recurrent collaterals (Rolls, 2016b)). (Thus on epoch 1 the distorted recall cue is shown as the PreSynaptic Input column on the left of the display, and the Activation row and the Firing Rate row below the synaptic weight matrix are the Activations and Rates produced by the recall cue. On later epochs, the Presynaptic Input column shows the output firing Rate from the preceding epoch, recirculated by the recurrent collateral connections.)

We are interested in how perfect the recall is, that is how correlated the recalled firing rate state is with the original training pattern, with this correlation having a maximum value of 1. Every time you press 'Enter' a new recall epoch is performed, and you will see that over one to several recall epochs the recall usually will become perfect, that is the correlation, which is provided for you in the command window, will become 1. However, on some trials, the network does not converge to perfect recall, and this occurs if by chance the distorted recall cue happened to be much closer to one of the other stored patterns. Do note that with randomly chosen training patterns in relatively small networks this will sometimes occur, and that this 'statistical fluctuation' in how close some of the training patterns are to each other, and how close the distorted test patterns are to individual training patterns, is to be expected. These effects smooth out as the network become larger. (Remember that cortical neurons have in the order of 10,000 recurrent collateral inputs to each neuron, so these statistical fluctuations will be largely smoothed out. Do note also that the performance of the network will be different each time it is run, because the random number generator is set with a different seed on each run.) (Near the beginning of the program, you could uncomment the command that causes the same seed to be used for the random number generator for each run, to help with further program development that you may try.)

After the last test pattern has been presented, the percentage of the patterns that were correctly recalled is shown, using as a criterion that the correlation of the recalled firing rate with the training pattern $r \geq 0.98$. For the reasons just described related to the random generation of the training and distorted test patterns, the percentage correct will vary from run to run, so taking the average of several runs is recommended.

Note that the continuing stable firing after the first few recall epochs models the implementation of short-term memory in the cerebral cortex (Rolls, 2008d, 2016b, 2023a).

Note that the retrieval of the correct pattern from a distorted version that includes missing 1s models completion in the cerebral cortex, which is important in episodic memory as implemented in the hippocampus in which the whole of the episodic memory can be retrieved from any part (Rolls, 2008d, 2016b; Kesner and Rolls, 2015) (Chapter 9).

Note that the retrieval of the correct pattern from a distorted version that includes missing 1s or has 1s instead of 0s models correct memory retrieval in the cerebral cortex and hippocampus even if there is some distortion of the recall cue (Rolls, 2016b, 2023a). This also enables generalization to similar patterns or stimuli that have been encountered previously,

which is highly behaviorally adaptive (Rolls, 2016b, 2023a). These processes are also important in completion in episodic memory as implemented in the hippocampus in which the whole of the episodic memory can be retrieved from any part (Rolls, 2008d, 2016b; Kesner and Rolls, 2015) (Chapter 9).

D.2.2 Exercises

1. Measure the percent correct as you increase the number of patterns from 10 to 15 with the Sparseness remaining at 0.5. Plot the result. How close is your result to that found by Hopfield (1982), which was $0.14N$ for a sparseness a of 0.5? You could try increasing N by 10 (to 1000) and multiplying the number of training patterns by 10 and increasing $nFlipBits$ to say 100 to see whether your results, with smaller statistical fluctuations, approximate more closely to the theoretical value.

2. Test the effect of reducing the Sparseness (a) to 0.1, which will increase the number of patterns that can be stored and correctly recalled, i.e. the capacity of the network (Treves and Rolls, 1991; Rolls, 2016b, 2023a). (Hint: try a number of patterns in the region of 30.) You could also plot the capacity of the network as a function of the Sparseness (a) with values down to say 0.01 in larger networks, with theoretical results provided by Treves and Rolls (1991) and Rolls (2023a).

3. Test the effect of altering the learning rule, from the covariance rule to the rule with heterosynaptic long term depression (LTD), which is as follows (Rolls, 2023a):

$$\delta w_{ij} = \alpha(y_i)(y_j - a). \quad (\text{D.2})$$

(Hint: in the training loop in the program, at about line 102, comment in the heterosynaptic LTD rule.)

4. Test whether the network operates with positive-only synaptic weights. (Hint: there are two lines (close to 131) just after the training loop that if uncommented will add a constant to all the numbers in the synaptic weight matrix to make all the numbers positive (with the minimum synaptic weight clipped at 0).

5. What happens to the recall if you train more patterns than the critical capacity? (Hint: see Rolls (2023a) Section B.16.)

6. Does it in practice make much difference if you allow self-connections, especially in large networks? (Hint: in the program in the training loop if you comment out the line 'if syn ~= neuron' and its corresponding 'end', self-connections will be allowed.)

D.3 Pattern association networks

The operation and properties of pattern association networks are described in this book (Rolls, 2023a) Appendix B.2.

D.3.1 Running the simulation

In the command window of Matlab, after you have performed a 'cd' into the directory where the source files are, type 'PatternAssociationDemo'. The program will run for a bit, and then

pause so that you can inspect what has been produced so far. A paused state is indicated by the words ‘Paused: Press any key’. Press ‘Enter’ to move to the next stage, until the program finishes and the command prompt reappears. You can edit the code to comment out some of the ‘pause’ statements if you do not want them, or to add a ‘pause’ statement if you would like the program to stop at a particular place so that you can inspect the results. To stop the program and exit from it, use ‘Ctrl-C’. When at the command prompt, you can access variables by typing the variable name followed by ‘Enter’. (Note: if you set ‘display = 0’ near the beginning of the program, there will be few pauses, and you will be able to collect data quickly.)

The fully connected pattern association network has $N=8$ output neurons with the dendrites that receive the synapses shown as vertical columns in the generated figures, and $nSyn=64$ synapses onto each neuron. At the first pause, you will see the 8 random binary conditioned stimulus (CS) training patterns with firing rates of 1 or 0, and with a sparseness of 0.25 (*InputSparseness*). As these are binary patterns, the sparseness is the same as the proportion of high firing rates or 1s. At the second pause you will see distorted versions of these patterns to be used as recall cues later. The number of bits that have been flipped $nFlipBits=8$.

Next you will see the synaptic matrix being trained with the 8 pattern associations between each conditioned stimulus (CS) and its unconditioned stimulus (US), the output firing. In this simulation, the default is for each US pattern to have one bit on, so that the sparseness of the US, *OutputSparseness* is $1/N$. Uncomment the pause in the training loop if you wish to see each pattern being presented sequentially. The synaptic weight matrix *SynMat* (elements of which are referred to as w_{ij} below) is initialized to zero, and then each pattern pair is presented as a CS and US pair, with the CS specifying the presynaptic input, and the US the firing rate in the N neurons present when the CS is presented. Each time a training pattern pair is presented, the weight change is calculated by an associative learning rule that includes heterosynaptic long term depression

$$\delta w_{ij} = \alpha(y_i)(x_j - a). \quad (D.3)$$

where α is a learning rate constant, and x_j is the presynaptic firing rate. This learning rule includes (in proportion to y_i the firing rate of the i^{th} postsynaptic neuron produced by the US) increasing the synaptic weight if $(y_j - a) > 0$ (long-term potentiation), and decreasing the synaptic weight if $(x_j - a) < 0$ (heterosynaptic long-term depression). As the CS patterns are random binary patterns with sparseness a (the parameter *InputSparseness*), a is the average activity $\langle x_j \rangle$ of an axon across patterns. The reasons for the use of this learning rule are described in Rolls (2023a) Section B.3.3.6. In the exercises, you can try a Hebbian associative learning rule that does not include this heterosynaptic long-term depression. The change of weight is added to the previous synaptic weight. In the figures generated by the code, the maximum weights are shown as white, and the minimum weights are black. Although both these rules lead to some negative synaptic weights, which are not biologically plausible, this limitation can be overcome, as shown in the exercises. In the display of the synaptic weights, remember that each column represents the synaptic weights on a single neuron. The top thin row below the synaptic matrix represents the activations of the neurons, the bottom thin row the firing rates of the neurons, and the thin column to the left of the synaptic weight matrix the firing rates of the presynaptic input, i.e. the recall (CS) stimulus. Rates of 1 are shown as white, and of 0 as black.

Next, testing with the distorted CS patterns starts. We are interested in how the pattern association network generalizes with distorted inputs to produce the correct US output that should be produced if there were no distortion. The recall performance is measured by how correlated the recalled firing rate state (the Conditioned Response, CR) is with the output

that should be produced to the original training CS pattern, with this correlation having a maximum value of 1. Every time you press ‘Enter’ a new CS is presented. Do note that with randomly chosen distortions of the CS patterns to produce the recall cue, in relatively small networks the distorted CS will sometimes be close of another CS, and that this ‘statistical fluctuation’ in how close some of the distorted CSs are to the original CSs is to be expected. These effects smooth out as the network become larger. (Remember that cortical neurons have in the order of 10,000 inputs to each neuron (in addition to the recurrent collaterals, Rolls (2023a)), so these statistical fluctuations will be largely smoothed out. Do note also that the performance of the network will be different each time it is run, because the random number generator is set with a different seed on each run. (Near the beginning of the program, you could uncomment the command that causes the same seed to be used for the random number generator for each run, to help with further program development that you may try.)

After the last distorted testing CS pattern has been presented, the percentage of the patterns that were correctly recalled is shown, using a criterion for the correlation of the recalled firing rate with the training pattern $r \geq 0.98$. For the reasons just described related to the random generation of the distorted test patterns, the percentage correct will vary from run to run, so taking the average of several runs is recommended.

Note that the retrieval of the correct output (conditioned response, CR) pattern from a distorted CS recall stimulus models generalization in the cerebral cortex, which is highly behaviorally adaptive (Rolls, 2016b, 2023a).

D.3.2 Exercises

1. Test how well the network generalizes to distorted recall cues, by altering $nFlipBits$ to values between 0 and 14. Remember to take the average of several simulation runs.

2. Test the effect of altering the learning rule, from the rule with heterosynaptic long term depression (LTD) as in Eqn. D.3, to a simple associative synaptic modification rule which is as follows (Rolls, 2023a):

$$\delta w_{ij} = \alpha(y_i)(x_j). \quad (D.4)$$

(Hint: in the training loop in the program, at about line 110, comment out the heterosynaptic LTD rule, and uncomment the associative rule.)

If you see little difference, can you suggest conditions under which there may be a difference, such as higher loading? (Hint: check Rolls (2023a) Section B.2.7.)

3. Describe how the threshold non-linearity in the activation function helps to remove interference from other training patterns, and from distortions in the recall cue. (Hint: compare the activations to the firing rates of the output neurons.)

4. In the pattern associator, the conditioned stimulus (CS) retrieves the unconditioned response (UR), that is the effects produced by the unconditioned stimulus (US) with which it has been paired during learning. Can the opposite occur, that is, can the US be used to retrieve the CS? If not, in what type of network is the retrieval symmetrical? (Hint: if you are not sure, read Rolls (2023a) Sections B.2 and B.3.)

5. The network simulated uses local representations for the US, with only one neuron on for each US. If you can program in Matlab, can you write code that would generate distributed representations for the US patterns? Then can you produce new CS patterns with random binary representations and sparsenesses in the range 0.1–0.5, like those used for the

autoassociator, so that you can then investigate the storage capacity of pattern association networks. (Hint: reference to Rolls (2023a) Section B.2.7 and B.2.8 may be useful.)

D.4 Competitive networks and Self-Organizing Maps

The operation and properties of competitive networks are described in this book (Rolls, 2023a) Appendix B.4. This is a self-organizing network, with no teacher. The input patterns are presented in random sequence, and the network learns how to categorise the patterns, placing similar patterns into the same category, and different patterns into different categories. The particular neuron or neurons that represent each category depend on the initial random synaptic weight vectors as well as the learning, so the output neurons are different from simulation run to simulation run. Self-organizing maps are investigated in Exercise 4.

D.4.1 Running the simulation

In the command window of Matlab, after you have performed a 'cd' into the directory where the source files are, type 'CompetitiveNetDemo'. The program will run for a bit, and then pause so that you can inspect what has been produced so far. A paused state is indicated by the words 'Paused: Press any key'. Press 'Enter' to move to the next stage, until the program finishes and the command prompt reappears. You can edit the code to comment out some of the 'pause' statements if you do not want them, or to add a 'pause' statement if you would like the program to stop at a particular place so that you can inspect the results. To stop the program and exit from it, use 'Ctrl-C'. When at the command prompt, you can access variables by typing the variable name followed by 'Enter'. (Note: if you set '*display = 0*' near the beginning of the program, there will be few pauses, and you will be able to collect data quickly.)

The fully connected competitive network has $N=100$ output neurons with the dendrites that receive the synapses shown as vertical columns, and $n_{Syn}=100$ synapses onto each neuron. With the display on (*display = 1*), at the first pause, you will see the 28 binary input patterns for training with firing rates of 1 or 0. Each pattern is 20 elements long, and each pattern is shifted down 3 elements with respect to the previous pattern, with the parameters supplied. (Each pattern thus overlaps in 17 / 20 locations with its predecessor.)

Next you will see the synaptic matrix being trained with the 28 input patterns, which are presented 20 times each (*nepochs = 20*) in random permuted sequence. Uncomment the pause in the training loop if you wish to see each pattern being presented sequentially. The synaptic weight matrix *SynMat* is initialized so that each neuron has random synaptic weights, with the synaptic weight vector on each neuron normalized to have a length of 1. Normalizing the length of the vector during training is important, for it ensures that no one neuron increases its synaptic strengths to very high values and thus wins for every input pattern. (Biological approximations to this are described by Rolls (2023a) in Section B.4.9.2, and involve a type of heterosynaptic long-term depression of synaptic strength that is large when the postsynaptic term is high, and the presynaptic firing is low.) (In addition, for convenience, each input pattern is normalized to a length of 1, so that when the dot product is computed with a synaptic weight vector on a neuron, the maximum activation of a neuron will be 1.)

The firing rate of each neuron is computed using a binary threshold activation function (which can be changed in the code to threshold linear). The sparseness of the firing rate representation can be set in the code using *OutputSparseness*, and as supplied is set to 0.01 for the first demonstration, which results in one of the $N=100$ output neurons having a high firing

rate. Because the (initially random) synaptic weight vectors of each neuron are different, the activations of each of the neurons will be different.

Learning then occurs, using an associative learning rule with synapses increasing between presynaptic neurons with high rates and postsynaptic neurons with high rates. Think of this as moving the synaptic weight vector of a high firing neuron to point closer to the input pattern that is making the neuron fire. At the same time, the other synapses on the same neuron become weaker due to the synaptic weight normalization, so the synaptic weight vector of the neuron moves away from other, different, patterns. In this way, the neurons self-organize so that some neurons point towards some patterns, and other neurons towards other patterns. You can watch these synaptic weight changes during the learning in the figure generated by the code, in which some of the synapses will become stronger (white) on a neuron and correspond to one or several of the patterns, and at the same time the other synapses on the neuron will become weaker (black). In the display of the synaptic weights, remember that each column represents the synaptic weights on a single neuron. The top thin row below the synaptic matrix represents the activations of the neurons, the bottom thin row the firing rates of the neurons, and the thin column to the left of the synaptic weight matrix the firing rates of the presynaptic input, i.e. the pattern currently being presented. Rates of 1 are shown as white, and of 0 as black. Neurons that remain unallocated, and do not respond to any of the input patterns, appear as vertical columns of random synaptic weights onto a neuron. These neurons remain available to potentially categorise different input patterns.

Next, testing with the different patterns starts. We are interested in whether similar input patterns activate the same output neurons; and different input patterns different output neurons. This is described as categorisation (Rolls, 2023a). With the display on ($display = 1$), each time you press ‘Enter’ the program will step through the patterns in sequence. You will notice in the synaptic matrix that with these initial parameters, only a few neurons have learned. When you step through each testing pattern in sequence, you will observe that one of the neurons responds to several patterns in the sequence, and these patterns are quite closely correlated with each other. Then another neuron becomes active for a further set of close patterns. This is repeated as other patterns are presented, and shows you that similar patterns tend to activate the same output neuron or neurons, and different input patterns tend to activate different output neurons. This illustrates by simulation the categorisation performed by competitive networks.

To illustrate these effects more quantitatively, after the patterns have been presented, you are shown first the correlations between the input patterns, and after that the correlations between the output firing rates produced by each pattern. These results are shown as correlation matrices. You should observe that with the network parameters supplied, the firing rates are grouped into several categories, each corresponding to several input patterns that are highly correlated in the output firing that they produce. The correlation matrix between the output firing rate for the different patterns thus illustrates how a competitive network can categorise similar patterns as similar to each other, and different patterns as different.

D.4.2 Exercises

1. Test the operation of the system with no learning, most easily achieved by setting `nepochs = 0`. This results in the input patterns being mapped to output rates through the random synaptic weight vectors for each neuron. What is your interpretation of what is shown by the correlation matrix between the output firing rates?

(Hint: the randomizing effect of the random synaptic weight vectors on each neuron is to separate out the patterns, with many of the patterns having no correlation with other patterns. In this mode, pattern separation is produced, and not categorisation in that similar inputs

are less likely to produce similar outputs, a key property in perception and memory (Rolls, 2023a). Pattern separation is important in its own right as a process (Rolls, 2016f), and is implemented for example by the random non-associatively modifiable connections of the dentate mossy fibre synapses onto the CA3 neurons (Treves and Rolls, 1992; Rolls, 2016b, 2013b; Kesner and Rolls, 2015; Rolls, 2023a.)

2. Investigate and describe the effects of altering the similarity between the patterns on the categorization, by for example altering the value of *shift* in the range 2–20.

3. Investigate and describe the effects of making the output firing rate representation (*OutputSparseness*) less sparse. It is suggested that values in the range 0.01–0.1 are investigated.

4. If there is lateral facilitation of nearby neurons, which might be produced by short-range recurrent collaterals in the cortex, then self-organizing maps can be generated, providing a model of topographic maps in the cerebral cortex (Section B.4.6 and Rolls (2023a) Section B.4.6). Investigate this with the modified competitive network ‘SOMdemo’. The map is made clear during the testing, in which the patterns are presented in order, and the neurons activated appear in different mapped positions in the firing rate array. Run the program several times to show that the details of the map are different each time, but that the principles are the same, that nearby neurons tend to respond to similar patterns, and that singularities (discontinuities) in the map can occur, just as are found in the primary visual cortex, V1.

The important change of ‘SOMdemo’ from ‘CompetitiveNetDemo’ is a local spatial filter for the firing rate array to simulate the effect of facilitation of the firing rates of nearby neurons by the short-range excitatory recurrent collateral connections between nearby cortical pyramidal cells. This is implemented by the *SpatialFilter* kernel the range of which is set by *FilterRange*. Investigate the effects of altering *FilterRange* from its default value of 11 on the topographic maps that are formed. Other changes to produce ‘SOMdemo’ include modifying the *OutPutSparseness* of the Firing Rate representation to 0.3. Investigate the effect of modifying this on the maps being formed. Another alteration was to alter the activation function from binary threshold to linear threshold to enable graded firing rate representations to be formed.

What are the advantages of the representations formed when self-organizing maps are present? (Hint: Think of interpolation of untrained input patterns close to those already trained; and check Rolls (2023a) Section B.4.6.)

D.5 Further developments

The neuronal network simulation code supplied and described above may provide a route for readers to develop their own programs. Further examples of Matlab code used to investigate neural systems are available in Anastasio (2010). Matlab itself has a Neural Network Toolbox, with an introduction to its use in modelling simple networks provided in Wallisch et al. (2009).

D.6 Matlab code for a tutorial version of VisNet

Tutorial software written in Matlab that illustrates some of the principles of operation of VisNet, the model of invariant visual object recognition described in Section 2.8 of this book (Rolls, 2023a) and by Rolls (2021d), is available at <https://www.oxcns.org/software>. This is

not the full version of VisNet used for most of the research described in Section 2.8, but it may be useful to illustrate some of the principles of operation of VisNet.

D.7 Matlab code for information analysis of neuronal encoding

Code translated into Matlab that was used for the single neuron information analyses described by Rolls, Treves, Tovee and Panzeri (1997d) and the multiple single neuron information analyses described by Rolls, Treves and Tovee (1997b), and in Appendix C, is also available at <https://www.oxcns.org/software>.

D.8 Matlab code to illustrate the use of spatial view cells in navigation

Matlab code to illustrate the use of spatial view cells (NavSVC.m), allocentric bearing to a landmark cells (NavABL.m), and combinations of allocentric bearing to a landmark cells using triangulation for navigation (NavTRI.m) described by (Rolls, 2021f) and in Section 9.3.15 is also available at <https://www.oxcns.org/software>.

D.9 The Automated Anatomical Labelling Atlas 3, AAL3

The Automated Anatomical Labelling Atlas 3, AAL3 (Rolls, Huang, Lin, Feng and Joliot, 2020d), used for some of the research described in this book, is available at <https://www.oxcns.org/software>.

D.10 The extended Human Connectome Project extended atlas, HCPex

The extended Human Connectome Project Multimodal Parcellation atlas, HCPex (Huang, Rolls, Feng and Lin, 2022), used for some of the research described in this book, is available at <https://www.oxcns.org/software>.

D.11 Highlights

1. Appendix D describes Matlab software that has been made available with *Brain Computations and Connectivity* (Rolls, 2023a) at <https://www.oxcns.org> to provide simple demonstrations of the operation of some key neuronal networks related to cortical function.
2. The software demonstrates the operation of pattern association networks, autoassociation / attractor networks, competitive networks, and self-organizing maps.
3. The availability of software to illustrate the operation of VisNet, a model of invariant visual object recognition, has also been described.
4. The availability of software to analyze the encoding of information by single neurons, and by populations of single neurons, has also been described.
