Preface

This book, *Brain Computations and Connectivity* is an update to Rolls *Brain Computations: What and How* published by Oxford University Press in 2021. A key part of this updated version of *Brain Computations: What and How* is the addition of much new evidence that has emerged since 2021 on the connectivity of the human brain, which by analysing the effective or causal connectivity between 360 cortical regions, enriches our understanding of information processing streams in the human cerebral cortex. Knowing how one cortical region connects to other cortical regions helps to provide a deeper understanding of how each stage in a processing stream contributes to the computations being performed, as each processing stream is now becoming better defined.

The addition in *Brain Computations and Connectivity* of much new evidence on the connectivity of the human brain is leading to better understanding of what is computed in different human brain regions, which in turn has implications for how the computations are performed. The added emphasis in this book on the organisation, connectivity, and functions of 360 cortical regions in the human brain increases the application of new approaches taken to understanding how the brain works that are described in this book, by making the evidence very relevant to the human brain, and thereby to those who are interested in disorders of the human brain, including neurologists and psychiatrists, as well as to all those interested in understanding how the human brain works in health and disease. The enables the computational approaches to understanding brain function described in this book to be combined with and made highly relevant to understanding human brain function. It is hoped that these developments in understanding human brain function by including analysis of the connectivity of the 360 cortical regions in the Human Connectome Project Multimodal Parcellation (HCP-MMP) atlas (Glasser et al., 2016a; Huang et al., 2022) as described here will provide a foundation for future research that by using the HCP-MMP can be related to the connectivity and functions of these 360 cortical regions in the human brain that are described in this book. The title of this book, *Brain Computations and Connectivity*, refers to the importance of this type of connectivity in understanding what and how the brain computes.

Another feature of this book is that it adopts what was described as a ‘grand unifying approach’ in a review in the journal *Brain* (Manohar, 2022) of *Brain Computations: What and How* (Rolls, 2021b) in that it takes a biologically plausible approach to how the brain computes, rather than invoking the artificial intelligence approach of deep learning to try to account for brain computation. The approach to how the brain computes in this book is biologically plausible in that it utilises primarily local synaptic modification rules to set up the synaptic connections between neurons, and unsupervised learning, yet considers how far this can take us in understanding how the brain operates. This approach is quite different to the deep learning approach used now in much machine learning and AI, which backpropagates an error backwards through the network to correct every synaptic weight in all preceding layers of the network, but there is no connectivity in the brain for that. Moreover, the learning in the brain is largely unsupervised, whereas deep learning approaches typically require a supervisor for each output neuron, which in turn requires what must be computed for each output neuron to be specified by the designer of the deep network. The point is developed (in Chapter 19) that machine learning might benefit from understanding some of the unsupervised approaches used by the brain to solve complex problems, including navigation, attention, semantics, and

even syntax. The title of this book, *Brain Computations and Connectivity*, also refers to this concept that the actual connectivity at the local level of neurons and synapses that is found in the brain is important in understanding what and how it computes.

My aim in making this book Open Access is to make the scholarship and ideas in this book easily available to colleagues, in the interests of better understanding the human brain in health and disease. This book can be cited as Rolls, E. T. (2023) *Brain Computations and Connectivity*, Oxford University Press, Oxford. The book can be downloaded from <https://www.oxcns.org> or from the Oxford University Press website. An advantage of publication of this book as a .pdf is that it contains extensive hyperlinks, enabling readers to quickly cross-refer to other parts of the book or to citations. With the .pdf, figures can also be expanded to show details.

Many scientists, and many others, are interested in how the brain works. In order to understand this, we need to know **what** computations are performed by different brain systems; and **how** they are computed by each of these systems.

The aim of this book is to elucidate what is computed in different brain systems; and to describe current computational approaches and models of how each of these brain systems computes.

To understand how our brains work, it is essential to know **what** is computed in each part of the brain. That can be addressed by utilising evidence relevant to computation from many areas of neuroscience. Knowledge of the connections between different brain regions is important, for this shows that the brain is organised as systems, with whole series of brain regions devoted for example to visual processing. That provides a foundation for examining the computation performed by each brain region, by comparing what is represented in a brain regions with what is represented in the preceding and following brain regions, using techniques of for example neurophysiology and functional neuroimaging. The ways in which effective connectivity is now available for 360 cortical regions are introduced in Chapter 1, with the results of these new analyses found throughout this book. Neurophysiology at the single neuron level is needed because this is the level at which information is transmitted between the computing elements of the brain, the neurons. Evidence from the effects of brain damage, including that available from neuropsychology, is needed to help understand what different parts of the system do, and indeed what each part is necessary for. Functional neuroimaging is useful to indicate where in the human brain different processes take place, and to show which functions can be dissociated from each other. So for each brain system, evidence on what is computed at each stage, and what the system as a whole computes, is essential.

To understand how our brains work, it is also essential to know **how** each part of the brain computes. That requires a knowledge of what is computed by each part of the brain, but it also requires knowledge of the network properties of each brain region. This involves knowledge of the connectivity between the neurons in each part of the brain, and knowledge of the synaptic and biophysical properties of the neurons. It also requires knowledge of the theory of what can be computed by networks with defined connectivity.

There are at least three key goals of the approaches described here. One is to understand ourselves better, and how we work and think. A second is to be better able to treat the system when it has problems, for example in mental illnesses. Medical applications are a very important aim of the type of research described here. A third, is to be able to emulate the operation of parts of our brains, which some in the field of artificial intelligence (AI) would like to do to produce useful computers that incorporate some of the principles of computation utilised by the brain. All of these goals require, and cannot get off the ground, without a firm foundation in what is computed by brain systems, and theories and models of how it is computed. To understand the operation of the whole brain, it is necessary to show how the different brain

systems operate together: but a necessary foundation for this is to know what is computed in each brain system, and the connectivity between the different regions involved.

Part of the enterprise here is to stimulate new theories and models of how parts of the brain work. The evidence on what is computed in different brain systems had advanced rapidly in the last 50 years, and provides a reasonable foundation for the enterprise, though there is much that remains to be learned. Theories of how the computation is performed are less advanced, but progress is being made, and current models are described in this book for many brain systems, in the expectation that before further advances are made, knowledge of the considerable current evidence on how the brain computes provides a useful starting point, especially as current theories do take into account the limitations that are likely to be imposed by the neural architectures present in our brains. In this book, the focus is on biologically plausible algorithms for brain computation, rather than for example deep learning which does not appear to be how the brain learns and computes (Sections B.12 and B.14).

The simplest way to delineate **brain computation** is to examine what information is represented at each stage of processing, and how this is different from stage to stage. For example in the primary visual cortex (V1), neurons respond to simple stimuli such as bars or edges or gratings and have small receptive fields. Little can be read off from the firing rates about for example whose face is represented from a small number of neurons in V1. On the other hand, after four or five stages of processing, in the inferior temporal visual cortex, information can be read from the firing rates of neurons about whose face is being viewed, and indeed there is remarkable invariance with respect to the position, size, contrast and even in some cases view of the face. That is a major computation, and indicates what can be achieved by biological neuronal network computation.

These approaches can only be taken to understand brain function because there is considerable localization of function in the brain, quite unlike a digital computer. One fundamental reason for localization of function in the brain is that this minimizes the total length of the connections between neurons, and thus brain size. Another is that it simplifies the genetic information that has to be provided in order to build the brain, because the connectivity instructions can refer considerably to local connections. These points are developed in my book *Cerebral Cortex: Principles of Operation* (Rolls, 2016b).

That brings me to what is different about the present book and *Cerebral Cortex: Principles of Operation* (Rolls, 2016b). *Cerebral Cortex: Principles of Operation* took on the enormous task of making progress with understanding how the major part of our brains, the cerebral cortex, works, by understanding its principles of operation. The present book builds on that approach, and uses it as background, but has the different aim of taking each of our brain systems, and describing *what* they compute, and then what is known about *how* each system computes. The issue of how they compute relies for many brain systems on how the cortex operates, so *Cerebral Cortex: Principles of Operation* provides an important complement to the present book.

With its focus on what and how each brain system computes, a field that includes computational neuroscience, this book is distinct from the many excellent books on neuroscience that describe much evidence about brain structure and function, but do not aim to provide an understanding of how the brain works at the computational level. This book aims to forge an understanding of how some key brain systems may operate at the computational level, so that we can understand how the brain actually performs some of its complex and necessarily computational functions in memory, perception, attention, decision-making, cognitive functions, and actions.

Indeed, as one of the key aims of this book is to describe **what computations** are performed by different brain systems, I have chosen to include in this book some of the key actual discoveries in neuroscience that I believe help to define what computations are performed in

different brain systems. Part of the aim of citing the original pioneering discoveries is to show how conceptual advances have been made in our understanding of what is computed in each region of our brains, for understanding the key discoveries provides a foundation for further advances.

That makes this book very different from many of the textbooks of neuroscience (such as *Principles of Neural Science* (Kandel et al., 2021)), and some of the textbooks of theoretical neuroscience that describe principles of operation of neurons or of networks of neurons (Dayan and Abbott, 2001; Hertz et al., 1991; Gerstner et al., 2014), but not in general what is computed in different brain systems, and how it is computed. Further, there are likely to be great developments in our understanding of *how* the brain computes, and this book is intended to set out a framework for new developments, by providing an analysis of what is computed by different brain systems, and providing some current approaches to how these computations may be performed. I believe that this book, and its predecessor *Brain Computations: What and How*, is pioneering in what I propose is the necessary approach to understanding brain function, understanding ‘What’ is computed by each brain region, and ‘How’ it is computed.

A test of whether one’s understanding is correct is to simulate the processing on a computer, and to show whether the simulation can perform the tasks performed by the brain, and whether the simulation has similar properties to the real brain. This approach to neural computation leads to a precise definition of how the computation is performed, and to precise and quantitative tests of the theories produced. How memory systems in the brain work is a paradigm example of this approach, because memory-like operations which involve altered functionality as a result of synaptic modification are at the heart of how many computations in the brain are performed. It happens that attention and decision-making can be understood in terms of interactions between and fundamental operations in memory systems in the cortex, and therefore it is natural to address these areas of cognitive neuroscience in this book. The same fundamental concepts based on the operation of neuronal circuitry can be applied to all these functions, as is shown in this book.

One of the distinctive properties of this book is that it links the neural computation approach not only firmly to neuronal neurophysiology, which provides much of the primary data about how the brain operates, but also to psychophysical studies (for example of attention); to neuropsychological studies of patients with brain damage; and to functional magnetic resonance imaging (fMRI) (and other neuroimaging) approaches. The empirical evidence that is brought to bear is largely from non-human primates and from humans, because of the considerable similarity of their cortical systems, and the major differences in their systems-level computational organization from that of rodents, as set out in Section 19.10.

Another feature of the book is that it aims to describe the principles of operation of the brain, and in doing that, frequently refers to the original research in which those principles were discovered. Another feature of the book is that I have also chosen to make each Chapter relatively understandable on its own, which may involve some information also present in other parts of the book, so that readers with an interest in one part of the brain can benefit by reading the relevant chapters, rather than necessarily having to read the whole book.

The overall aims of the book are developed further, and the plan of the book is described, in Chapter 1. Appendix B describes the fundamental operation of key networks of the type that are likely to be the building blocks of brain function. Appendix C describes quantitative, information theoretic, approaches to how information is represented in the brain, which is an essential framework for understanding what is computed in a brain system, and how it is computed. Appendix D describes Matlab software that has been made available with this book to provide simple demonstrations of the operation of some key neuronal networks related to cortical function; to show how the information represented by neurons can be measured; and to provide a tutorial version of the VisNet program for invariant visual object recognition

described in Chapter 2. The neural networks programs are also provided in Python. The programs are available at <https://www.oxcns.org>.

Part of the material described in the book reflects work performed in collaboration with many colleagues, whose tremendous contributions are warmly appreciated. The contributions of many will be evident from the references cited in the text. Especial appreciation is due to Alessandro Treves, Gustavo Deco, Sylvia Wirth, and Simon M. Stringer, who have contributed greatly in always interesting and fruitful research collaborations on computational and related aspects of brain function, and to many neurophysiology and functional neuroimaging colleagues who have contributed to the empirical discoveries that provide the foundation to which the computational neuroscience must always be closely linked, and whose names are cited throughout the text. Charl Ning (University of Warwick) is thanked for help with translating the Matlab neural network programs described in Appendix D into Python. Dr Patrick Mills and Imogen Kruse are thanked for very helpful comments on an earlier version of this book. Much of the work described would not have been possible without financial support from a number of sources, particularly the Medical Research Council of the UK, the Human Frontier Science Program, the Wellcome Trust, and the James S. McDonnell Foundation. I am also grateful to many colleagues who I have consulted while writing this book. The Gatsby Foundation is thanked for a grant towards the cost of making this book Open Access. The book was typeset by the author using \LaTeX and WinEdt.

Updates to and .pdfs of many of the publications cited in this book are available at <https://www.oxcns.org>. Updates and corrections to the text and notes are also available at <https://www.oxcns.org>.

I dedicate this work to the overlapping group: my family, friends, and colleagues – in salutem praesentium, in memoriam absentium.

Contents

1	Introduction	1
1.1	What and how the brain computes: introduction	1
1.2	What and how the brain computes: plan of the book	3
1.3	Neurons	5
1.4	Neurons in a network	6
1.5	Synaptic modification	8
1.6	Long-term potentiation and long-term depression	10
1.6.1	Long-Term Potentiation	10
1.6.2	Long-Term Depression	13
1.6.3	Spike Timing-Dependent Plasticity	14
1.7	Information encoding by neurons, and distributed representations	15
1.7.1	Definitions	16
1.7.2	Advantages of sparse distributed encoding	17
1.8	Neuronal network approaches versus connectionism	18
1.9	Introduction to three neuronal network architectures	19
1.10	Systems-level analysis of brain function	22
1.11	Brodman areas	22
1.12	Human Connectome Project Multi-Modal Parcellation atlas of the human cortex	27
1.13	Connectivity of the human brain	36
1.13.1	Connections analyzed with diffusion tractography	37
1.13.2	Functional connectivity	37
1.13.3	Effective connectivity	37
1.14	The fine structure of the cerebral neocortex	39
1.14.1	The fine structure and connectivity of the neocortex	39
1.14.2	Excitatory cells and connections	40
1.14.3	Inhibitory cells and connections	41
1.14.4	Quantitative aspects of cortical architecture	44
1.14.5	Functional pathways through the cortical layers	46
1.14.6	The scale of lateral excitatory and inhibitory effects, and modules	51
2	The ventral visual system	53
2.1	Introduction and overview	53
2.1.1	Introduction	53
2.1.2	Overview of what is computed in the ventral visual system	53
2.1.3	Overview of how computations are performed in the ventral visual system	57
2.1.4	What is computed in the ventral visual system is unimodal, and is related to other 'what' systems after the inferior temporal visual cortex	58
2.2	What: V1 – primary visual cortex	60
2.3	What: V2 and V4 – intermediate processing areas in the ventral visual system	61
2.4	What: Invariant representations of faces and objects in the inferior temporal visual cortex	62
2.4.1	Reward value is not represented in the primate ventral visual system	62
2.4.2	Translation invariant representations	63
2.4.3	Reduced translation invariance in natural scenes	64

2.4.4	Size and spatial frequency invariance	67
2.4.5	Combinations of features in the correct spatial configuration	67
2.4.6	A view-invariant representation	69
2.4.7	Learning in the inferior temporal cortex	71
2.4.8	A sparse distributed representation is what is computed in the ventral visual system	74
2.4.9	Face expression, gesture, and view	80
2.4.10	Specialized regions in the temporal cortical visual areas	80
2.5	The connectivity of the ventral visual pathways in humans	85
2.5.1	A Ventrolateral Visual Cortical Stream to the inferior temporal visual cortex for object and face representations	86
2.5.2	A Visual Cortical Stream to the cortex in the inferior bank of the superior temporal sulcus involved in semantic representations	89
2.5.3	A Visual Cortical Stream to the cortex in the superior bank of the superior temporal sulcus involved in multimodal semantic representations including visual motion, auditory, somatosensory and social information	89
2.6	How the computations are performed: approaches to invariant object recognition	92
2.6.1	Feature spaces	93
2.6.2	Structural descriptions and syntactic pattern recognition	94
2.6.3	Template matching and the alignment approach	96
2.6.4	Invertible networks that can reconstruct their inputs	97
2.6.5	Deep learning	98
2.6.6	Feature hierarchies	98
2.7	Hypotheses about how the computations are performed in a feature hierarchy approach	104
2.8	VisNet: a model of how the computations are performed in the ventral visual system	107
2.8.1	The architecture of VisNet	108
2.8.2	Initial experiments with VisNet	117
2.8.3	The optimal parameters for the temporal trace used in the learning rule	124
2.8.4	Different forms of the trace learning rule, and error correction	126
2.8.5	The issue of feature binding, and a solution	134
2.8.6	Operation in a cluttered environment	147
2.8.7	Learning 3D transforms	154
2.8.8	Capacity of the architecture, and an attractor implementation	159
2.8.9	Vision in natural scenes – effects of background versus attention	162
2.8.10	The representation of multiple objects in a scene	170
2.8.11	Learning invariant representations using spatial continuity	172
2.8.12	Lighting invariance	173
2.8.13	Deformation-invariant object recognition	175
2.8.14	Learning invariant representations of scenes and places	176
2.8.15	Finding and recognising objects in natural scenes	178
2.8.16	Non-accidental properties, and transform invariant object recognition	181
2.9	Further approaches to invariant object recognition	183
2.9.1	Other types of slow learning	183
2.9.2	HMAX	183
2.9.3	Minimal recognizable configurations	188
2.9.4	Hierarchical convolutional deep neural networks	189
2.9.5	Sigma-Pi synapses	190
2.9.6	A principal dimensions approach to coding in the inferior temporal visual cortex	190
2.10	Visuo-spatial scratchpad memory, and change blindness	192
2.11	Processes involved in object identification	194
2.12	Top-down attentional modulation is implemented by biased competition	195
2.13	Highlights on how the computations are performed in the ventral visual system	198
3	The dorsal visual system	201
3.1	Introduction, and overview of the dorsal cortical visual stream	201

3.2	Global motion in the dorsal visual system	202
3.3	Invariant object-based motion in the dorsal visual system	204
3.4	What is computed in the dorsal visual system: visual coordinate transforms	206
3.4.1	The transform from retinal to head-based coordinates	207
3.4.2	The transform from head-based to allocentric bearing coordinates	208
3.4.3	A transform from allocentric bearing coordinates to allocentric spatial view coordinates	209
3.5	How visual coordinate transforms are computed in the dorsal visual system	211
3.5.1	Gain modulation	211
3.5.2	Mechanisms of gain modulation using a trace learning rule	211
3.5.3	Gain modulation by eye position to produce a head-centered representation in Layer 1 of VisNetCT	213
3.5.4	Gain modulation by head direction to produce an allocentric bearing to a landmark in Layer 2 of VisNetCT	214
3.5.5	Gain modulation by place to produce an allocentric spatial view representation in Layer 3 of VisNetCT	215
3.5.6	The utility of the coordinate transforms in the dorsal visual system	216
3.6	The human Dorsal Visual Cortical Stream	217
3.6.1	Dorsal stream visual division regions	217
3.6.2	MT+ complex regions (FST, LO1, LO2, LO3, MST, MT, PH, V3CD and V4t)	218
3.6.3	Intraparietal sulcus posterior parietal cortex, regions (AIP, LIPd, LIPv, MIP, VIP; with IP0, IP1 and IP2)	219
3.6.4	Area 7 regions	220
4	The taste and flavor system	221
4.1	Introduction and overview	221
4.1.1	Introduction	221
4.1.2	Overview of what is computed in the taste and flavor system	221
4.1.3	Overview of how computations are performed in the taste and flavor system	223
4.2	Taste and related pathways: what is computed	223
4.2.1	Hierarchically organised anatomical pathways	223
4.2.2	Taste neuronal tuning become more selective through the taste hierarchy	226
4.2.3	The primary, insular, taste cortex represents what taste is present and its intensity	228
4.2.4	The secondary, orbitofrontal, taste cortex, and its representation of the reward value and pleasantness of taste	229
4.2.5	Sensory-specific satiety is computed in the orbitofrontal cortex	231
4.2.6	Oral texture is represented in the primary and secondary taste cortex: viscosity and fat texture	234
4.2.7	Vision and olfaction converge using associative learning with taste to represent flavor in the secondary but not primary taste cortex	236
4.2.8	Top-down attention and cognition can modulate taste and flavor representations in the taste cortical areas	238
4.2.9	The tertiary taste cortex in the anterior cingulate cortex provides the rewards for action-reward outcome learning	240
4.2.10	Taste, oral texture and flavor provide the rewards for eating, and the gut provides satiety signals	241
4.3	Taste and related pathways: how the computations are performed	245
4.3.1	Increased selectivity of taste and flavor neurons through the hierarchy by competitive learning and convergence	245
4.3.2	Pattern association learning of associations of visual and olfactory stimuli with taste	245
4.3.3	Rule-based reversal of visual to taste associations in the orbitofrontal cortex	246
4.3.4	Sensory-specific satiety is implemented by adaptation of synapses onto orbitofrontal cortex neurons	246
4.3.5	Top-down cognitive and attentional modulation is implemented by biased activation	247
5	The olfactory system	251

5.1	Introduction	251
5.1.1	Overview of what is computed in the olfactory system	251
5.1.2	Overview of how the computations are performed in the olfactory system	252
5.2	What is computed in the olfactory system	253
5.2.1	1000 gene-encoded olfactory receptor types, and 1000 corresponding glomerulus types in the olfactory bulb	253
5.2.2	The primary olfactory, pyriform, cortex: olfactory feature combinations are what is represented	255
5.2.3	Orbitofrontal cortex: olfactory neuronal response selectivity	256
5.2.4	Orbitofrontal cortex: olfactory to taste convergence	257
5.2.5	Orbitofrontal cortex: olfactory to taste association learning and reversal	257
5.2.6	Orbitofrontal cortex: olfactory reward value is represented	259
5.2.7	Cognitive influences on olfactory representations in the orbitofrontal cortex	260
5.3	How computations are performed in the olfactory system	262
5.3.1	Olfactory receptors, and the olfactory bulb	262
5.3.2	Olfactory (pyriform) cortex	263
5.3.3	Orbitofrontal cortex	267
6	The somatosensory system	268
6.1	What is computed in the somatosensory system	268
6.1.1	The receptors and periphery	268
6.1.2	The anterior somatosensory cortex, areas 1, 2, 3a, and 3b, in the anterior parietal cortex	268
6.1.3	The ventral somatosensory stream: areas S2 and PV, in the lateral parietal cortex	269
6.1.4	The dorsal somatosensory stream to area 5 and then 7b, in the posterior parietal cortex	270
6.1.5	Somatosensory representations in the insula	272
6.1.6	Somatosensory and temperature inputs to the orbitofrontal cortex, affective value, pleasant touch, and pain	272
6.1.7	Decision-making in the somatosensory system	276
6.1.8	Somatosensory cortical regions and connectivity in humans	278
6.2	How computations are performed in the somatosensory system	284
6.2.1	Hierarchical computation in the somatosensory system	284
6.2.2	Computations for pleasant touch and pain	284
6.2.3	The mechanisms for somatosensory decision-making	285
7	The auditory system	286
7.1	Introduction, and overview of computations in the auditory system	286

7.6.3	Dorsal auditory cortical streams	295
7.6.4	Other auditory system cortical connectivities	297
7.7	How the computations are performed in the auditory system	298
8	The temporal cortex	299
8.1	Introduction and overview	299
8.2	Middle temporal gyrus and face expression and gesture	299
8.3	Semantic representations in the temporal lobe neocortex	301
8.3.1	Neurophysiology of the medial temporal lobe, including concept cells	301

8.3.2	Neuropsychology	303
8.3.3	Functional neuroimaging	303
8.3.4	Brain stimulation	304
8.4	Connectivity and functions of the human temporal lobe regions related to semantics	305
8.4.1	Group 1 semantic regions that include regions in the ventral bank of the Superior Temporal Sulcus	306
8.4.2	Group 3 semantic regions that include regions in the dorsal bank of the Superior Temporal Sulcus	309
8.5	The mechanisms for semantic learning in the human anterior temporal lobe	311
9	The hippocampus, memory, and spatial function	313
9.1	Introduction and overview	313
9.1.1	Overview of what is computed by the hippocampal system	313
9.1.2	Overview of how the computations are performed by the hippocampal system	315
9.2	What is computed in the hippocampus	316
9.2.1	Systems-level anatomy	316
9.2.2	Evidence from the effects of damage to the hippocampus	319
9.2.3	Episodic memories need to be recalled from the hippocampus, and can be used to help build neocortical semantic memories	321
9.2.4	Systems-level neurophysiology of the primate including human hippocampus	324
9.2.5	Spatial view cells in primates including humans, and foveal vision	342
9.2.6	Head direction cells in the presubiculum	344
9.2.7	Perirhinal cortex, recognition memory, and long-term familiarity memory	346
9.2.8	Connectivity of the human hippocampal system	353
9.3	How computations are performed in the hippocampal system	364
9.3.1	Historical development of the theory of the hippocampus	364
9.3.2	Hippocampal circuitry	366
9.3.3	Medial entorhinal cortex, spatial processing streams, and grid cells	369
9.3.4	Lateral entorhinal cortex, object processing streams, and the generation of time cells in the hippocampus	372
9.3.5	CA3 as an autoassociation memory	378
9.3.6	Dentate granule cells	397
9.3.7	CA1 cells	400
9.3.8	Backprojections to the neocortex, memory recall, and consolidation	405
9.3.9	Backprojections to the neocortex – quantitative aspects	409
9.3.10	Simulations of hippocampal operation	413
9.3.11	The learning of spatial view and place cell representations	414
9.3.12	Linking the inferior temporal visual cortex to spatial view and place cells	416
9.3.13	A scientific theory of the art of memory: scientia artis memoriae	418
9.3.14	How navigation is performed	419
9.3.15	Navigational computations using neuron types found in primates including humans	423
9.4	Tests of the theory of hippocampal cortex operation	432
9.4.1	Dentate gyrus (DG) subregion of the hippocampus	432
9.4.2	CA3 subregion of the hippocampus	435
9.4.3	CA1 subregion of the hippocampus	442
9.5	Comparison of spatial processing and computations in primates including humans vs rodents	445
9.5.1	Similarities and differences between the spatial representations in primates and rodents	445
9.5.2	Hippocampal computational similarities and differences between primates and rodents	447
9.6	Synthesis: the hippocampus: memory, navigation, or both?	450
9.7	Comparison with other theories of hippocampal function	454

10	The parietal cortex, spatial functions, and navigation	459
10.1	Introduction and overview	459
10.1.1	Overview of what is computed in the parietal cortex	459
10.1.2	Overview of how the computations are performed in the parietal cortex	460
10.2	Inferior parietal cortex somatosensory stream, PF regions	460
10.3	Intraparietal sulcus posterior parietal cortex, regions AIP, LIPd, LIPv, MIP, VIP, IPO, IP1, and IP2	464
10.4	Posterior superior parietal cortex, regions 7AL, 7Am, 7PC, 7PL, and 7Pm	466
10.5	Inferior parietal cortex, visual regions PFm, PGi, PGs and PGp	467
10.5.1	Region PGi	469
10.5.2	Region PGs	470
10.5.3	Region PFm	470
10.5.4	Region PGp	471
10.6	Navigation: What computations are performed in the parietal and related cortex	473
10.7	How the computations are performed in the parietal cortex	474
11	The orbitofrontal cortex, amygdala, reward value, emotion, and decision-making	475
11.1	Introduction and overview	475
11.1.1	Introduction	475
11.1.2	Overview of what is computed in the orbitofrontal cortex	475
11.1.3	Overview of how the computations are performed by the orbitofrontal cortex	478
11.2	The topology and connections of the orbitofrontal cortex	479
11.2.1	Inputs to the orbitofrontal cortex	480
11.2.2	Outputs of the orbitofrontal cortex	482
11.3	What is computed in the orbitofrontal cortex	483
11.3.1	The orbitofrontal cortex represents reward value	483
11.3.2	Neuroeconomic value is represented in the orbitofrontal cortex	490
11.3.3	A representation of face and voice expression and other socially relevant stimuli in the orbitofrontal cortex	492
11.3.4	Negative reward prediction error neurons in the orbitofrontal cortex	495
11.3.5	The human medial orbitofrontal cortex represents rewards, and the lateral orbitofrontal cortex non-reward and punishers	500
11.3.6	Decision-making in the orbitofrontal / ventromedial prefrontal cortex	502
11.3.7	The ventromedial prefrontal cortex and memory	504
11.3.8	The orbitofrontal cortex and emotion	506
11.3.9	Emotional orbitofrontal vs rational routes to action	508
11.3.10	The connectivity of the human orbitofrontal cortex, and its relation to function	521
11.3.11	Mental problems associated with the orbitofrontal cortex	528
11.4	What is computed in the amygdala for emotion	529
11.4.1	Overview of the functions of the amygdala in emotion	529
11.4.2	The amygdala and the associative processes involved in emotion-related learning	530
11.4.3	Connections of the amygdala	531
11.4.4	Effects of amygdala lesions	532
11.4.5	Amygdala lesions in primates	532
11.4.6	Amygdala lesions in rats	534
11.4.7	Neuronal activity in the primate amygdala to reinforcing stimuli	535
11.4.8	Neuronal responses in the amygdala to faces	536
11.4.9	Evidence from humans	538
11.4.10	Connectivity of the human amygdala	539
11.5	How the computations are performed in the orbitofrontal cortex	544
11.5.1	Decision-making in attractor networks in the brain	544
11.5.2	Analyses of reward-related decision-making mechanisms in the orbitofrontal cortex	549
11.5.3	A model for reversal learning in the orbitofrontal cortex	554

11.5.4	A theory and model of non-reward neural mechanisms in the orbitofrontal cortex	559
11.6	Highlights: the special computational roles of the orbitofrontal cortex	560
12	The cingulate cortex	564
12.1	Introduction to and overview of the cingulate cortex	564
12.1.1	Introduction	564
12.1.2	Overview of what is computed in the cingulate cortex	565
12.1.3	Overview of how the computations are performed by the cingulate cortex	567
12.2	Anterior cingulate cortex	568
12.2.1	Anterior cingulate cortex anatomy and connections in primates	568
12.2.2	Anterior cingulate cortex: A framework	569
12.2.3	Anterior cingulate cortex and action-outcome representations	571
12.2.4	Anterior cingulate cortex lesion effects	572
12.2.5	Anterior cingulate cortex and ventromedial prefrontal cortex connectivity and functions in humans	572
12.2.6	Pregenua anterior cingulate representations of reward value, and supracallosal anterior cingulate representations of punishers and non-reward	575
12.2.7	The human supracallosal anterior cingulate cortex, dACC, and action-outcome learning	578
12.2.8	Reward value outputs from the orbitofrontal and pregenual anterior cortex, and vmPFC, to the hippocampal memory system	579
12.2.9	The pregenual anterior cingulate cortex has connectivity with the septal cholinergic system that is involved in memory consolidation	579
12.2.10	Reward value outputs from the orbitofrontal and pregenual anterior cortex, and vmPFC, to the hippocampal system to provide the goals for navigation	580
12.2.11	Subgenual cingulate cortex	581
12.3	Posterior cingulate cortex	581
12.3.1	Introduction and overview	581
12.3.2	Postero-ventral posterior cingulate and medial parietal regions 31pd, 31pv, d23ab, v23ab and 7m, and their relation to episodic memory	582
12.3.3	Antero-dorsal Posterior Cingulate Division regions 23d, 31a, PCV; and RSC, POS2, and POS1; and their relation to navigation and executive function	584
12.3.4	Dorsal Visual Transitional area and ProStriate region: the retrosplenial scene area	587
12.4	Mid-cingulate cortex, the cingulate motor area, and action–outcome learning	588
12.5	How the computations are performed by the cingulate cortex	589
12.5.1	The anterior cingulate cortex and emotion	589
12.5.2	Action-outcome learning in the supracallosal anterior cingulate cortex (dACC)	590
12.5.3	Connectivity of the posterior cingulate cortex with the hippocampal memory system	592
12.6	Synthesis and conclusions	593
13	The prefrontal cortex	596
13.1	Introduction and overview	596
13.2	Divisions of the lateral prefrontal cortex	600
13.2.1	The dorsolateral prefrontal cortex	600
13.2.2	The caudal prefrontal cortex	603
13.2.3	The ventrolateral prefrontal cortex	603
13.3	The connectivity and computational organisation of the human prefrontal cortex	603
13.3.1	Inferior frontal gyrus	604
13.3.2	Dorsolateral prefrontal cortex division	606
13.4	The lateral prefrontal cortex and top-down attention	609
13.5	The frontal pole cortex	612

13.6	How the computations are performed in the prefrontal cortex	613
13.6.1	Cortical short-term memory systems and attractor networks	613
13.6.2	Prefrontal cortex short-term memory networks, and their relation to perceptual networks	615
13.6.3	Mapping from one representation to another in short-term memory	620
13.6.4	The mechanisms of top-down attention	621
13.6.5	Computational necessity for a separate, prefrontal cortex, short-term memory system	622
13.6.6	Synaptic modification is needed to set up but not to reuse short-term memory systems	623
13.6.7	Sequence memory	623
13.6.8	Working memory, and planning	623
14	Language and syntax in the brain	624
14.1	Introduction and overview	624
14.1.1	Introduction	624
14.1.2	Overview	624
14.2	What is computed in different brain systems to implement language	626
14.2.1	The Wernicke-Lichtheim-Geschwind hypothesis	626
14.2.2	The dual-stream hypothesis of speech comprehension	627
14.2.3	Reading requires different brain systems to hearing speech	627
14.2.4	Semantic representations	629
14.2.5	Syntactic processing	630
14.2.6	The parietal cortex: supramarginal and angular gyri	631
14.3	Cortical regions for language and their connectivity in humans	631
14.3.1	A semantic system that includes the inferior bank of the superior temporal sulcus including object representations	632
14.3.2	A semantic system that includes the superior bank of the superior temporal sulcus including visual motion, auditory, somatosensory and social information	634
14.3.3	Multimodal semantic representations	635
14.3.4	Broca's area and related regions (TGv 44 45 47i SFL 55b)	637
14.4	Hypotheses about how semantic representations are computed	640
14.5	A neurodynamical hypothesis about how syntax is computed	641
14.5.1	Binding by synchrony?	641
14.5.2	Syntax using a place code	642
14.5.3	Temporal trajectories through a state space of attractors	642
14.5.4	Hypotheses about the implementation of language in the cerebral cortex	643
14.5.5	Tests of the hypotheses – a model	646
14.5.6	Tests of the hypotheses – findings with the model	651
14.5.7	Evaluation of the hypotheses	654
14.5.8	Further approaches	658
15	The motor cortical areas	660
15.1	Introduction and overview	660
15.2	What is computed in different cortical motor-related areas	661
15.2.1	Ventral parietal and ventral premotor cortex F4	661
15.2.2	Superior parietal areas with activity related to reaching	661
15.2.3	Inferior parietal areas with activity related to grasping, and ventral premotor cortex F5	662
15.3	The mirror neuron system	662
15.4	How the computations are performed in motor cortical and related areas	664
16	The basal ganglia	665
16.1	Introduction and overview	665
16.2	Systems-level architecture of the basal ganglia	666

16.3	What computations are performed by the basal ganglia?	669
16.3.1	Effects of striatal lesions	669
16.3.2	Neuronal activity in different parts of the striatum	670
16.4	How do the basal ganglia perform their computations?	683
16.4.1	Interaction between neurons and selection of output	683
16.4.2	Convergence within the basal ganglia, useful for stimulus-response habit learning	686
16.4.3	Dopamine as a reward prediction error signal for reinforcement learning in the striatum	688
16.5	Comparison of computations for selection in the basal ganglia and cerebral cortex	692

1 Introduction

1.1 What and how the brain computes: introduction

The subject of this book is how the brain works. In order to understand this, it is essential to know **what** is computed by different brain systems; and **how** the computations are performed. The aim of this book is to elucidate what is computed in different brain systems; and to describe current computational approaches and models of how each of these brain systems computes. Understanding the brain in this way has enormous potential for understanding ourselves better in health and in disease. Potential applications of this understanding are to the treatment of the brain in disease; and to artificial intelligence which will benefit from knowledge of how the brain performs many of its extraordinarily impressive functions. This book is pioneering in taking this approach to brain function: to consider **what** is computed by many of our brain systems; and **how** it is computed.

To understand how our brains work, it is essential to know **what** is computed in each part of the brain. That can be addressed by utilising evidence relevant to computation from many areas of neuroscience. Knowledge of the connections between different brain areas is important, for this shows that the brain is organised as systems, with whole series of brain areas devoted for example to visual processing. That provides a foundation for examining the computation performed by each brain area, by comparing what is represented in a brain area with what is represented in the preceding and following brain areas, using techniques of for example neurophysiology and functional neuroimaging. Neurophysiology at the single neuron level is needed because this is the level at which information is transmitted between the computing elements of the brain, the neurons. Evidence from the effects of brain damage, including that available from neuropsychology, is needed to help understand what different parts of the system do, and indeed what each part is necessary for. Functional neuroimaging is useful to indicate where in the human brain different processes take place, and to show which functions can be dissociated from each other. So for each brain system, evidence on what is computed at each stage, and what the system as a whole computes, is essential.

To understand how our brains work, it is also essential to know **how** each part of the brain computes. That requires a knowledge of what is represented and computed by the neurons in each part of the brain, but it also requires knowledge of the network properties of each brain region. This involves knowledge of the connectivity between the neurons in each part of the brain, and knowledge of the synaptic and biophysical properties of the neurons. It also requires knowledge of the theory of what can be computed by networks with defined connectivity.

There are at least three key goals of the approaches described here. One is to understand ourselves better, and how we work and think. A second is to be better able to treat the system when it has problems, for example in mental illnesses. Medical applications are a very important aim of the type of research described here. A third goal, is to be able to emulate and learn from the operation of parts of our brains, which some in the field of artificial intelligence (AI) would like to do to produce more useful computers and machines. All of these goals require, and cannot get off the ground, without a firm foundation in what is computed by brain systems, and theories and models of how it is computed. To understand the operation

of the whole brain, it is necessary to show how the different brain systems operate together: but a necessary foundation for this is to know what is computed in each brain system.

Part of the enterprise here is to stimulate new theories and models of how parts of the brain work. The evidence on what is computed in different brain systems has advanced rapidly in the last 50 years, and provides a reasonable foundation for the enterprise, though there is much that remains to be learned. Theories of how the computation is performed are less advanced, but progress is being made, and current models are described in this book for many brain systems. Before further advances are made, knowledge of the considerable current evidence on how the brain computes provides a useful starting point, especially as current theories do take into account the limitations that are likely to be imposed by the neural architectures present in our brains.

The simplest way to define **brain computation** is to examine what information is represented at each stage of processing, and how this is different from stage to stage. For example in the primary visual cortex (V1), neurons respond to simple stimuli such as bars or edges or gratings and have small receptive fields. Little can be read off about for example whose face is represented from the firing rates of a small number of neurons in V1. On the other hand, after four or five stages of processing, in the inferior temporal visual cortex, information can be read from the firing rates of neurons about whose face is being viewed, and indeed there is remarkable invariance with respect to the position, size, contrast and even in some cases view of the face. That is a major computation, and indicates what can be achieved by biological neuronal network computation.

These approaches can only be taken to understand brain function because there is considerable localization of function in the brain, quite unlike a digital computer. One fundamental reason for localization of function in the brain is that this minimizes the total length of the connections between neurons, and thus brain size. Another is that it simplifies the genetic information that has to be provided in order to build the brain, because the connectivity instructions can refer considerably to local connections. These points are developed in my book *Cerebral Cortex: Principles of Operation* (Rolls, 2016b).

That brings me to what is different about the present book and *Cerebral Cortex: Principles of Operation* (Rolls, 2016b). The previous book took on the enormous task of making progress with understanding how the major part of our brains, the cerebral cortex, works, by understanding its principles of operation. The present book builds on that approach, and uses it as background, but has the different aim of taking each of our brain systems, and describing *what* they compute, and then what is known about *how* each system computes. The issue of how they compute relies for many brain systems on how the cortex operates, so *Cerebral Cortex: Principles of Operation* provides an important complement to the present book.

One of the distinctive properties of this book is that it links the neural computation approach not only firmly to neuronal neurophysiology, which provides much of the primary data about how the brain operates, but also to psychophysical studies (for example of attention); to neuropsychological studies of patients with brain damage; and to functional magnetic resonance imaging (fMRI) (and other neuroimaging) approaches. The empirical evidence that is brought to bear is largely from non-human primates and from humans, because of the considerable similarity of their cortical systems, and the overall aims to understand the human brain, and the disorders that arise after brain damage.

In selecting the research findings on ‘what’ is computed in different brain systems and on ‘how’ it is computed, to include in this book, I have selected pioneering research that has helped to identify key computational principles involved for different brain systems. Discoveries that have laid the foundation for our understanding as research has developed are emphasized. That has meant that much excellent neuroscience research could not be included in this book: but the aim of the book instead is to identify computational principles of op-

eration of brain systems, providing some of the key research discoveries that have helped to identify those principles. I hope that future research will extend this aim further.

1.2 What and how the brain computes: plan of the book

In the rest of Chapter 1, I introduce some of the background for understanding brain computation, such as how single neurons operate, how some of the essential features of this can be captured by simple formalisms, and some of the biological background to what it can be taken happens in the nervous system, such as synaptic modification based on information available locally at each synapse.

Each of the following Chapters has parts concerned with **what** is computed in a brain system, followed with parts concerned with **how** it is computed.

Chapters 2–7 consider the main sensory processing systems of the brain: the ventral visual system with its functions in invariant object recognition (2); the dorsal visual system involved in spatial visual processing, actions in space, and the spatial coordinate transforms that are needed (3); the taste system (4); the olfactory system (5); the somatosensory system (6); and the auditory system (7).

Chapter 8 considers the functions of the temporal lobe, including its functions in semantic representations.

Chapter 9 considers the functions of the hippocampus, which combines neocortical ‘what’, ‘where’ and reward information to implement episodic memory, and its later recall back to the neocortex which is implicated in memory consolidation.

Chapter 10 considers the functions of the parietal cortex, which receives much input from the dorsal processing streams concerned with the location of stimuli and actions in space – the ‘where and action’ processing stream, and which is also involved in navigation.

Chapter 11 describes the functions of the orbitofrontal cortex and amygdala, which compute reward value from inputs received from the ventral processing streams, and are therefore central to understanding the implementation in the brain of emotion and reward-related decision-making. Chapter 12 shows how the anterior cingulate cortex has functions related to the initiation of goal-directed action given its inputs from the orbitofrontal cortex about reward value and its connections with the mid-cingulate motor parts of the cingulate; and how the posterior cingulate cortex has major connections that link ‘what’ and ‘where’ neocortical systems with the hippocampus, making it an important component of the episodic memory system, and perhaps with connected cortical regions involved in navigation.

Chapter 13 describes the prefrontal cortex, which provides off-line short-term and working memory, and the associated functions of planning and top-down attention.

Chapter 14 describes brain systems involved in language and syntax.

Chapter 15 describes motor cortical areas. Chapter 16 describes the basal ganglia, and Chapter 17 the cerebellum, which are both involved in motor function, but which are now also implicated in emotional, social, and cognitive functions.

Chapter 18 describes factors that influence the dynamics and stability of cortical systems, and how these are different in some mental disorders including Schizophrenia, Obsessive-Compulsive Disorder and Depression.

Chapter 19 describes how the functions of each of these systems provide a foundation for understanding functions implemented by the whole brain, including many types of complex and useful behaviors. This Chapter also compares computations in the brain with those performed in digital computers including with machine learning algorithms. This is intended to be a useful guide for engineers and artificial intelligence experts who may wish to learn

from how computations are performed in the brain, and how to emulate the computations performed by the brain. This Chapter also compares the systems-level organisation of computations in rodent brains with those in primate including human brains, and provides evidence that there are many differences in the systems-level computations between rodent and primate including human brains, which is why this book focusses on computations in primate including human brains.

The Appendices are updated somewhat from those in *Cerebral Cortex: Principles of Operation* (Rolls, 2016b), and are provided in this book for those who do not have access to *Cerebral Cortex*. Appendix A provides an introduction to the linear algebra that is useful background for the description of the fundamental operation of key networks found in the brain. Appendix B describes the fundamental operation of key networks of the type that are likely to be the building blocks of brain function. Appendix C shows how information theory can be applied to analyze what is represented by populations of neurons and thus to understand brain function. Appendix D describes Matlab software that has been made available with this book to provide simple demonstrations of the operation of some key neuronal networks related to cortical function; to show how the information represented by neurons can be measured; and to provide a tutorial version of the VisNet program for invariant visual object recognition described in Chapter 2. The neural networks programs are also provided in Python. The programs are available at <https://www.oxcns.org>.

I start the rest of Chapter 1 with some history showing how recently it is that our understanding of the (computational) principles of operation of the brain and cerebral cortex has started to develop.

Before the 1960s there were many and important discoveries about the phenomenology of the cortex, for example that damage in one part would affect vision, and in another part movement, with electrical stimulation often producing the opposite effect. The principles may help us to understand these phenomena, but the phenomena provide limited evidence about how the cortex works, apart from the very important principle of localization of function (see Rolls (2016b)), and the important principle of hierarchical organization (Hughlings Jackson, 1878; Swash, 1989) (see Rolls (2016b)) which has been supported by increasing evidence on the connections between different cortical areas, which is a fundamental building block for understanding brain computations.

In the 1960s David Hubel and Torsten Wiesel made important discoveries about the stimuli that activate primary visual cortex neurons, showing that they respond to bar-like or edge-like visual stimuli (Hubel and Wiesel, 1962, 1968, 1977), instead of the small circular receptive fields in the preceding stage the lateral geniculate nucleus neurons. This led them to suggest the elements of a model of how this might come about, by cortical neurons that respond to elongated lines of lateral geniculate neurons (Fig. 2.5). This led to the concept that hierarchical organization over a series of cortical areas might at each stage form combinations of the features represented in the previous cortical area, in what might be termed feature combination neurons.

However, before 1970 there were few ideas about how the cerebral cortex operates computationally.

David Marr was a pioneer who helped to open the way to an understanding of how the details of cortical anatomy and connectivity help to develop quantitative theories of how cortical areas may compute, including the cerebellar cortex (Marr, 1969), the neocortex (Marr, 1970), and the hippocampal cortex (Marr, 1971). Marr was hampered by some lack in detail of the available anatomical knowledge, and did not for example hypothesize that the hippocampal CA3 network was an autoassociation memory. He attempted to test his theory of

the cerebellum with Sir John (Jack) Eccles by stimulating the climbing fibres in the cerebellum while providing an input from the parallel fibres to a Purkinje cell, but the experiment did not succeed, partly because of a lack of physiological knowledge about the firing rates of climbing fibres, which are low, rarely more than 10 spikes/s, whereas they had stimulated at much higher frequencies. Perhaps in part because David Marr was ahead of the experimental techniques available at the time to test his theories of network operations of cortical systems, he focussed in his later work on more conceptual rather than neural network based approaches, which he applied to understanding vision. This also had only limited success at least in understanding invariant object recognition (Marr, 1982), again related to the lack of available experimental data (Rolls, 2011c).

Very stimulating advances in thinking about cortical function were made in books by Abeles (1991), Braitenberg and Schüz (1991) and Creutzfeldt (1995), but many advances have been made since those books (Rolls, 2016b).

Theories of operation are essential to understanding the brain - e.g. collective computation in attractor networks, and emergent properties. It cannot be done just by molecular biology, though that provides useful tools, and potentially ways to ameliorate brain dysfunction.

I emphasize that to understand brain including cortical function, and processes such as memory, perception, attention, and decision-making in the brain, we are dealing with large-scale computational systems with interactions between the parts, and that this understanding requires analysis at the computational and global level of the operation of many neurons to perform together a useful function. Understanding at the molecular level is important for helping to understand how these large-scale computational processes are implemented in the brain, but will not by itself give any account of what computations are performed to implement these cognitive functions. Instead, understanding cognitive functions such as object recognition, memory recall, attention, and decision-making requires single neuron data to be closely linked to computational models of how the interactions between large numbers of neurons and many networks of neurons allow these cognitive problems to be solved. The single neuron level is important in this approach, for the single neurons can be thought of as the computational units of the system, and is the level at which the information is exchanged by the spiking activity between the computational elements of the brain. The single neuron level is therefore, because it provides the level at which information is communicated between the computing elements of the brain, the fundamental level of information processing, and the level at which the information can be read out (by recording the spiking neuronal activity) in order to understand what information is being represented and processed in each cortical area.

1.3 Neurons in the brain, and their representation in neuronal networks

Neurons in the vertebrate brain typically have, extending from the cell body, large dendrites that receive inputs from other neurons through connections called synapses. The synapses operate by chemical transmission. When a synaptic terminal receives an all-or-nothing action potential from the neuron of which it is a terminal, it releases a transmitter that crosses the synaptic cleft and produces either depolarization or hyperpolarization in the postsynaptic neuron, by opening particular ion channels. (A textbook such as Kandel, Koester, Mack and Siegelbaum (2021) gives further information on this process.) Summation of a number of such depolarizations or excitatory inputs within the time constant of the receiving neuron, which is typically 15–25 ms, produces sufficient depolarization that the neuron fires an action potential. There are often 5,000–20,000 inputs per neuron. Examples of cortical neurons are

Fig. 1.1 Examples of neurons found in the brain. Cell types in the cerebral neocortex are shown. The different laminae of the cortex are designated I–VI, with I at the surface. Cells A–D are pyramidal cells in the different layers. Cell E is a spiny stellate cell, and F is a double bouquet cell.) (From Edward G. Jones and Alan Peters; *Cerebral Cortex, Functional Properties of Cortical Cells* volume 2, published 1984 [Springer Science + Business Media New York], reproduced with permission of SNCSC. Figure 1.1 is copyright protected and excluded from the open access license.)

shown in Figs. 1.1, 1.12, 1.13, and 9.20, further examples are shown in Shepherd (2004), and schematic drawings are shown in Shepherd and Grillner (2010). Once firing is initiated in the cell body (or axon initial segment of the cell body), the action potential is conducted in an all-or-nothing way to reach the synaptic terminals of the neuron, whence it may affect other neurons. Any inputs the neuron receives that cause it to become hyperpolarized make it less likely to fire (because the membrane potential is moved away from the critical threshold at which an action potential is initiated), and are described as inhibitory. The neuron can thus be thought of in a simple way as a computational element that sums its inputs within its time constant and, whenever this sum, minus any inhibitory effects, exceeds a threshold, produces an action potential that propagates to all of its output synaptic terminals. This simple idea is incorporated in many neuronal network models using a formalism of a type described in the next section.

1.4 A formalism for approaching the operation of single neurons in a network

Let us consider a neuron i as shown in Fig. 1.2, which receives inputs from axons that we label j through synapses of strength w_{ij} . The first subscript (i) refers to the output neuron that receives synaptic inputs, and the second subscript (j) to the particular input. j counts from 1 to C , where C is the number of synapses or connections received. The firing rate of the i th neuron is denoted as y_i , and that of the j th input to the neuron as x_j . To express the

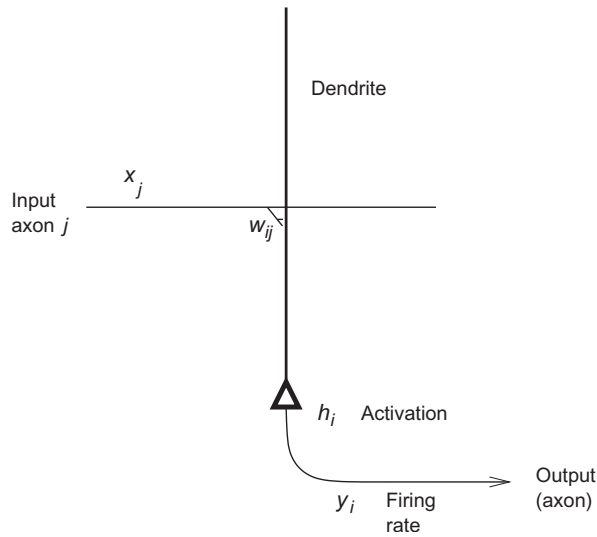

Fig. 1.2 Notation used to describe an individual neuron in a network model. By convention, we generally represent the dendrite as thick, and vertically oriented (as this is the normal way that neuroscientists view cortical pyramidal cells under the microscope); and the axon as thin. The cell body or soma is indicated between them by the triangle, as many cortical neurons have a pyramidal shape. The firing rate we also call the activity of the neuron.

idea that the neuron makes a simple linear summation of the inputs it receives, we can write the activation of neuron i , denoted h_i , as

$$h_i = \sum_j x_j w_{ij} \quad (1.1)$$

where \sum_j indicates that the sum is over the C input axons (or connections) indexed by j to each neuron. The multiplicative form here indicates that activation should be produced by an axon only if it is firing, and depending on the strength of the synapse w_{ij} from input axon j onto the dendrite of the receiving neuron i . Equation 1.1 indicates that the strength of the activation reflects how fast the axon j is firing (that is x_j), and how strong the synapse w_{ij} is. The sum of all such activations expresses the idea that summation (of synaptic currents in real neurons) occurs along the length of the dendrite, to produce activation at the cell body, where the activation h_i is converted into firing y_i . This conversion can be expressed as

$$y_i = f(h_i) \quad (1.2)$$

which indicates that the firing rate is a function (f) of the postsynaptic activation. The function is called the activation function in this case. The function at its simplest could be linear, so that the firing rate would be proportional to the activation (see Fig. 1.3a). Real neurons have thresholds, with firing occurring only if the activation is above the threshold. A threshold linear activation function is shown in Fig. 1.3b. This has been useful in formal analysis of the properties of neural networks. Neurons also have firing rates that become saturated at a maximum rate, and we could express this as the sigmoid activation function shown in Fig. 1.3c. Another simple activation function, used in some models of neural networks, is the binary threshold function (Fig. 1.3d), which indicates that if the activation is below threshold, there is no firing, and that if the activation is above threshold, the neuron fires maximally. Some non-linearity in the activation function is an advantage, for it enables many useful computations to be performed in neuronal networks, including removing interfering effects of similar memories, and enabling neurons to perform logical operations, such as firing only if several inputs are present simultaneously.

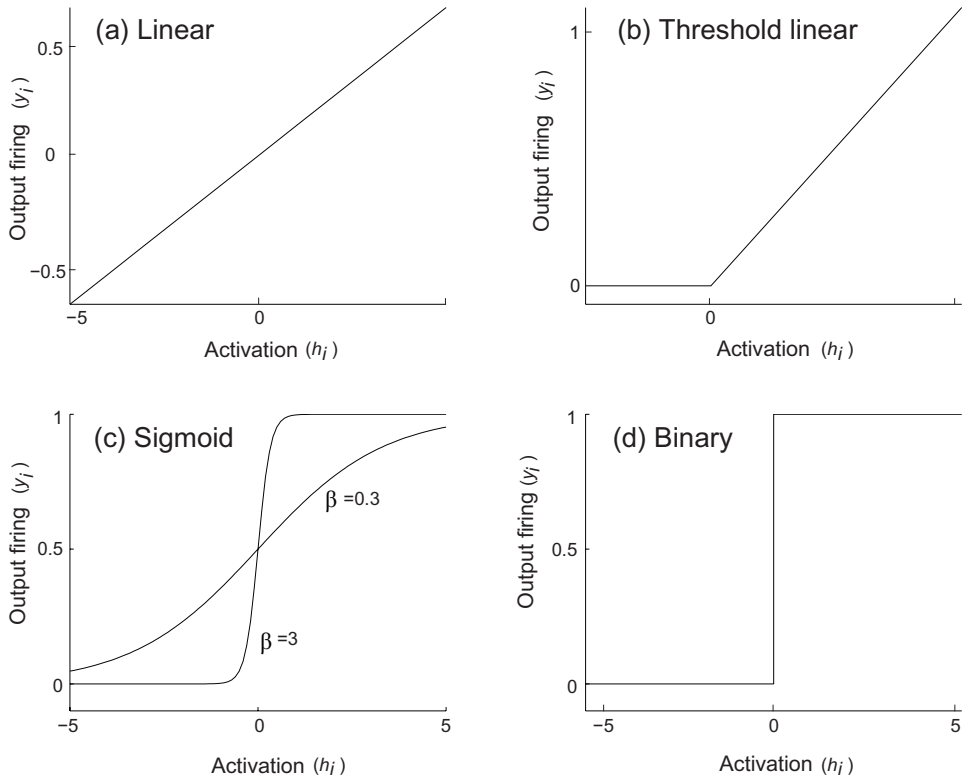

Fig. 1.3 Different types of activation function. The activation function relates the output activity (or firing rate), y_i , of the neuron (i) to its activation, h_i . (a) Linear. (b) Threshold linear. (c) Sigmoid. [One mathematical exemplar of this class of activation function is $y_i = 1/(1 + \exp(-2\beta h_i))$.] The output of this function, also sometimes known as the logistic function, is 0 for an input of $-\infty$, 0.5 for 0, and 1 for $+\infty$. The function incorporates a threshold at the lower end, followed by a linear portion, and then an asymptotic approach to the maximum value at the top end of the function. The parameter β controls the steepness of the almost linear part of the function round $h_i = 0$. If β is small, the output goes smoothly and slowly from 0 to 1 as h_i goes from $-\infty$ to $+\infty$. If β is large, the curve is very steep, and approximates a binary threshold activation function. (d) Binary threshold.

A property implied by Equation 1.1 is that the postsynaptic membrane is electrically short, and so summates its inputs irrespective of where on the dendrite the input is received. In real neurons, the transduction of current into firing frequency (the analogue of the transfer function of Equation 1.2) is generally studied not with synaptic inputs but by applying a steady current through an electrode into the soma. Examples of the resulting curves, which illustrate the additional phenomenon of firing rate adaptation, are shown in Fig. 1.4.

1.5 Synaptic modification

For a neuronal network to perform useful computation, that is to produce a given output when it receives a particular input, the synaptic weights must be set up appropriately. This is often performed by synaptic modification occurring during learning.

A simple learning rule that was originally presaged by Donald Hebb (1949) proposes that synapses increase in strength when there is conjunctive presynaptic and postsynaptic activity. The Hebb rule can be expressed more formally as follows

$$\delta w_{ij} = \alpha y_i x_j \quad (1.3)$$

Fig. 1.4 Activation function of a hippocampal CA1 neuron. Frequency – current plot (the closest experimental analogue of the activation function) for a CA1 pyramidal cell. The firing frequency (in Hz) in response to the injection of 1.5 s long, rectangular depolarizing current pulses has been plotted against the strength of the current pulses (in nA) (abscissa). The first 39 interspike intervals (ISIs) are plotted as instantaneous frequency ($1 / \text{ISI}$), together with the average frequency of the adapted firing during the last part of the current injection (circles and broken line). The plot indicates a current threshold at approximately 0.5 nA, a linear range with a tendency to saturate, for the initial instantaneous rate, above approximately 200 Hz, and the phenomenon of adaptation, which is not reproduced in simple non-dynamical models (see further Appendix A5 of Rolls and Treves 1998). (Reproduced from Lanthorn, T., Storm, J. and Andersen, P. (1984) Current-to-frequency transduction in CA1 hippocampal pyramidal cells: Slow prepotentials dominate the primary range firing. *Experimental Brain Research* 53: 431–443, Copyright © Springer-Verlag.)

where δw_{ij} is the change of the synaptic weight w_{ij} which results from the simultaneous (or conjunctive) presence of presynaptic firing x_j and postsynaptic firing y_i (or strong depolarization), and α is a learning rate constant that specifies how much the synapses alter on any one pairing. The presynaptic and postsynaptic activity must be present approximately simultaneously (to within perhaps 100–500 ms in the real brain).

The Hebb rule is expressed in this multiplicative form to reflect the idea that both presynaptic and postsynaptic activity must be present for the synapses to increase in strength. The multiplicative form also reflects the idea that strong pre- and postsynaptic firing will produce a larger change of synaptic weight than smaller firing rates. The Hebb rule thus captures what is typically found in studies of associative Long-Term Potentiation (LTP) in the brain, described in Section 1.6.

One useful property of large neurons in the brain, such as cortical pyramidal cells, is that with their short electrical length, the postsynaptic term, y_i , is available on much of the dendrite of a cell. The implication of this is that once sufficient postsynaptic activation has been produced, any active presynaptic terminal on the neuron will show synaptic strengthening. This enables associations between coactive inputs, or correlated activity in input axons, to be learned by neurons using this simple associative learning rule.

If, in contrast, a group of coactive axons made synapses close together on a small dendrite, then the local depolarization might be intense, and only these synapses would modify onto the dendrite. (A single distant active synapse might not modify in this type of neuron, because of the long electrotonic length of the dendrite.) The computation in this case is described as Sigma-Pi ($\Sigma\Pi$), to indicate that there is a local product computed during learning; this allows a particular set of locally active synapses to modify together, and then the output of the neuron can reflect the sum of such local multiplications (see Rumelhart and McClelland (1986), Koch (1999)). Sigma-Pi neurons are not used in most of the networks described in this book. There has been some work on how such neurons, if present in the brain, might utilize this functionality in the computation of invariant representations (Mel et al., 1998; Mel and Fiser, 2000) (see Section 2.9).

1.6 Long-term potentiation and long-term depression as models of synaptic modification

In order to understand how the brain computes, it is important to consider the rules that describe how synaptic strengths change during learning and during self-organization of the brain. This section provides an overview of the evidence from long-term potentiation about how associative changes in synaptic strength can occur, and is provided as background reference information. Other mechanisms are considered in Chapters 16 and 17.

1.6.1 Long-Term Potentiation

Long-term potentiation (LTP) and long-term depression (LTD) provide useful models of some of the synaptic modifications that occur in the brain. The synaptic changes found appear to be synapse-specific, and to depend on information available locally at the synapse. LTP and LTD may thus provide a good model of the biological synaptic modifications involved in real neuronal network operations in the brain. Some of the properties of LTP and LTD are described next, together with evidence that implicates them in learning in at least some brain systems. Even if they turn out not to be the basis for the synaptic modifications that occur during learning, they have many of the properties that would be needed by some of the synaptic modification systems used by the brain.

Long-term potentiation is a use-dependent and sustained increase in synaptic strength that can be induced by brief periods of synaptic stimulation (Bliss and Collingridge, 2013; Takeuchi, Duzkiewicz and Morris, 2014; Bliss and Collingridge, 2019; Moser, Moser and Siegelbaum, 2021). It is usually measured as a sustained increase in the amplitude of electrically evoked responses in specific neural pathways following brief trains of high-frequency stimulation. For example, high frequency stimulation of the Schaffer collateral inputs from the CA3 hippocampal cells to the CA1 cells results in a larger response recorded from the CA1 cells to single test pulse stimulation of the pathway. LTP is long-lasting, in that its effect can be measured for hours in hippocampal slices, and in chronic in vivo experiments in some cases it may last for months. LTP becomes evident rapidly, typically in less than 1 minute. LTP is in some brain systems associative. This is illustrated in Fig. 1.5c, in which a weak input to a group of cells (e.g. the commissural input to CA1) does not show LTP unless it is given at the same time as (i.e. associatively with) another input (which could be weak or strong) to the cells. The associativity arises because it is only when sufficient activation of the postsynaptic neuron to exceed the threshold of NMDA receptors (see below) is produced that any learning can occur. The two weak inputs summate to produce sufficient depolarization to exceed the threshold. This associative property is shown very clearly in experiments in which LTP of an input to a single cell only occurs if the cell membrane is depolarized by passing current through it at the same time as the input arrives at the cell. The depolarization alone, or the input alone, is not sufficient to produce the LTP, and the LTP is thus associative. Moreover, in that the presynaptic input and the postsynaptic depolarization must occur at about the same time (within approximately 500 ms), the LTP requires temporal contiguity. LTP is also synapse-specific, in that, for example, an inactive input to a cell does not show LTP even if the cell is strongly activated by other inputs (Fig. 1.5b, input *B*).

These spatiotemporal properties of long term potentiation can be understood in terms of actions of the inputs on the postsynaptic cell, which in the hippocampus has two classes of receptor, NMDA (N-methyl-D-aspartate) and AMPA (alpha-amino-3-hydroxy-5-methylisoxazole-4-propionic acid), activated by the glutamate released by the presynaptic terminals. The NMDA receptor channels are normally blocked by Mg^{2+} , but when the cell is strongly depolarized by strong tetanic stimulation of the type necessary to induce LTP, the Mg^{2+} block

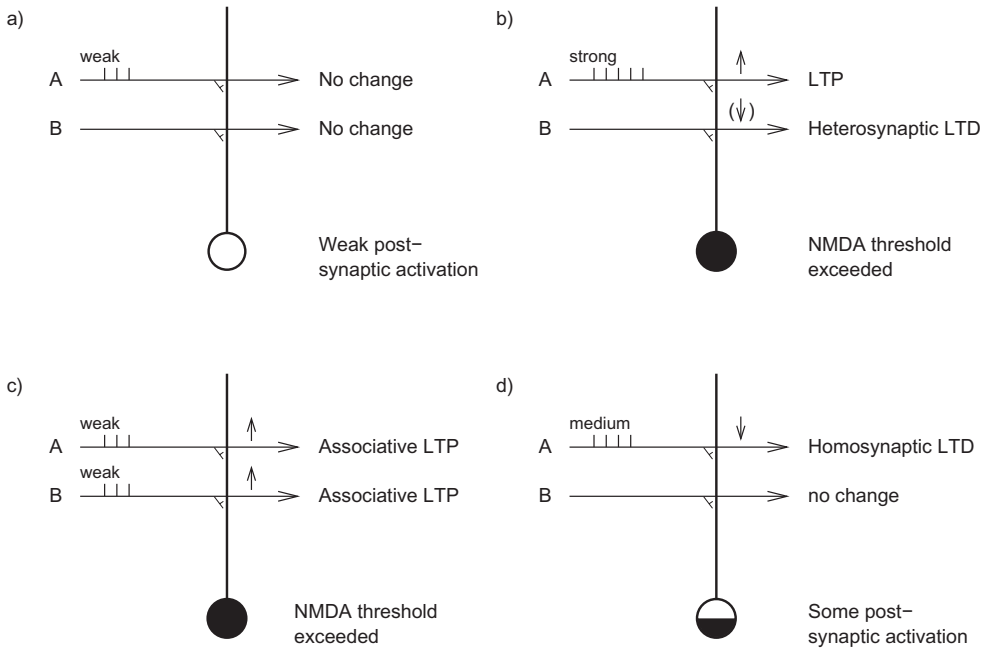

Fig. 1.5 Schematic illustration of synaptic modification rules as revealed by long-term potentiation (LTP) and long-term depression (LTD). The activation of the postsynaptic neuron is indicated by the extent to which its soma is black. There are two sets of inputs to the neuron: A and B . (a) A weak input (indicated by three spikes) on the set A of input axons produces little postsynaptic activation, and there is no change in synaptic strength. (b) A strong input (indicated by five spikes) on the set A of input axons produces strong postsynaptic activation, and the active synapses increase in strength. This is LTP. It is homosynaptic in that the synapses that increase in strength are the same as those through which the neuron is activated. LTP is synapse-specific, in that the inactive axons, B , do not show LTP. They either do not change in strength, or they may weaken. The weakening is called heterosynaptic LTD, because the synapses that weaken are other than those through which the neuron is activated (hetero- is Greek for other). (c) Two weak inputs present simultaneously on A and B summate to produce strong postsynaptic activation, and both sets of active synapses show LTP. (d) Intermediate strength firing on A produces some activation, but not strong activation, of the postsynaptic neuron. The active synapses become weaker. This is homosynaptic LTD, in that the synapses that weaken are the same as those through which the neuron is activated (homo- is Greek for same).

is removed, and Ca^{2+} entering via the NMDA receptor channels triggers events that lead to the potentiated synaptic transmission (see Fig. 1.6 (Horowitz and Horwitz, 2019)). Part of the evidence for this is that NMDA antagonists such as AP5 (D-2-amino-5-phosphonopentanoate) block LTP. Further, if the postsynaptic membrane is voltage clamped to prevent depolarization by a strong input, then LTP does not occur. The voltage-dependence of the NMDA receptor channels introduces a threshold and thus a non-linearity that contributes to a number of the phenomena of some types of LTP, such as cooperativity (many small inputs together produce sufficient depolarization to allow the NMDA receptors to operate); associativity (a weak input alone will not produce sufficient depolarization of the postsynaptic cell to enable the NMDA receptors to be activated, but the depolarization will be sufficient if there is also a strong input); and temporal contiguity between the different inputs that show LTP (in that if inputs occur non-conjunctively, the depolarization shows insufficient summation to reach the required level, or some of the inputs may arrive when the depolarization has decayed). Once the LTP has become established (which can be within one minute of the strong input to the cell), the LTP is expressed through the AMPA receptors, in that the NMDA receptor antagonist AP5 blocks only the establishment of LTP, and not its subsequent expression (Bliss and Collingridge, 2013; Siegelbaum and Kandel, 2013).

There are a number of possibilities about what change is triggered by the entry of Ca^{2+} to the postsynaptic cell to mediate LTP. One possibility is that somehow a messenger (such as

Fig. 1.6 The mechanism of induction of Long-Term Potentiation (LTP) for the CA3 to CA1 synapses in the hippocampus. (A) CA3-CA1 synaptic structure showing glutamate receptors (AMPA receptors AMPARs and an NMDA receptor NMDAR) linked to the post-synaptic density (PSD), a multiprotein assembly that orients receptors to face the presynaptic CA3 terminal. Tau is a structural protein. (B) Electrical circuit for recording CA1 pyramidal neuron-evoked responses. The insert shows the evoked response prior to a tetanizing (high frequency) stimulation (basal state), and an enhanced response following the tetanizing stimulation (LTP-induced). (C) Change in spine head shape before and after the tetanizing stimulation. The latter induces a rapid (within seconds) increase in spine head size, allowing insertion of AMPARs into the PSD. Within minutes, the spine head has slightly shrunken to a long lasting (hours) form with additional AMPARs in the PSD (LTP-induced). In more detail, during normal, low-frequency synaptic transmission glutamate released from the terminals of CA3 Schaffer collateral axons acts on both NMDA and AMPA receptors in the postsynaptic membrane of dendritic spines (the site of excitatory input) of CA1 neurons. Sodium and K⁺ flow through the AMPA receptors but not through the NMDA receptors because their pore is blocked by Mg²⁺ at negative membrane potentials. During a high-frequency tetanus the large depolarization of the postsynaptic membrane (caused by strong activation of the AMPA receptors) relieves the Mg²⁺ blockade of the NMDA receptors, allowing Ca²⁺, Na⁺, and K⁺ to flow through these channels. The resulting increase of Ca²⁺ in the dendritic spine triggers calcium-dependent kinases—calcium/calmodulin-dependent kinase (CaMKII), leading to induction of LTP. (From Horowitz, J.M. and Horowitz, B.A. 2019. Extreme neuroplasticity of hippocampal CA1 pyramidal neurons in hibernating mammalian species. *Frontiers in Neuroanatomy* 13:9. doi: 10.3389/fnana.2019.00009.)

NO) reaches the presynaptic terminals from the postsynaptic membrane and, if the terminals are active, causes them to release more transmitter in future whenever they are activated by an action potential. Consistent with this possibility is the observation that, after LTP has been induced, more transmitter appears to be released from the presynaptic endings. Another possibility is that the postsynaptic membrane changes just where Ca²⁺ has entered, so that AMPA receptors become more responsive to glutamate released in future. Consistent with this possibility is the observation that after LTP, the postsynaptic cell may respond more to locally applied glutamate (using a microiontophoretic technique).

The rule that underlies associative LTP is thus that synapses connecting two neurons become stronger if there is conjunctive presynaptic and (strong) postsynaptic activity. This learning rule for synaptic modification is sometimes called the Hebb rule, after Donald Hebb of McGill University who drew attention to this possibility, and its potential importance in learning (Hebb, 1949).

In that LTP is long-lasting, develops rapidly, is synapse-specific, and is in some cases associative, it is of interest as a potential synaptic mechanism underlying some forms of memory. Evidence linking it directly to some forms of learning comes from experiments in which it has been shown that the drug AP5 infused so that it reaches the hippocampus to block NMDA receptors blocks spatial learning mediated by the hippocampus (Morris, 1989; Martin, Grimwood and Morris, 2000; Takeuchi, Duzskiewicz and Morris, 2014). The task learned by the rats was to find the location relative to cues in a room of a platform submerged in an opaque liquid (milk). Interestingly, if the rats had already learned where the platform was, then the NMDA infusion did not block performance of the task. This is a close parallel to LTP, in that the learning, but not the subsequent expression of what had been learned, was blocked by the NMDA antagonist AP5. Although there is still some uncertainty about the experimental evidence that links LTP to learning (Martin, Grimwood and Morris, 2000; Lynch, 2004; Takeuchi, Duzskiewicz and Morris, 2014), there is a need for a synapse-specific modifiability of synaptic strengths on neurons if neuronal networks are to learn. If LTP is not always an exact model of the synaptic modification that occurs during learning, then something with many of the properties of LTP is nevertheless needed, and is likely to be present in the brain given the functions known to be implemented in many brain regions.

In another model of the role of LTP in memory, Davis (2000) has studied the role of the amygdala in learning associations to fear-inducing stimuli. He has shown that blockade of NMDA synapses in the amygdala interferes with this type of learning, consistent with the idea that LTP also provides a useful model of this type of learning. NMDA receptors in the amygdala are also involved in the extinction of conditioned fear responses (Davis, 2011).

1.6.2 Long-Term Depression

Long-Term Depression (LTD) can also occur. It can in principle be associative or non-associative. In associative LTD, the alteration of synaptic strength depends on the pre- and postsynaptic activities. There are two types. Heterosynaptic LTD occurs when the postsynaptic neuron is strongly activated, and there is low presynaptic activity (see Fig. 1.5b input B, and Table B.1 on page 828). Heterosynaptic LTD is so-called because the synapse that weakens is other than (hetero-) the one through which the postsynaptic neuron is activated. Heterosynaptic LTD is important in associative neuronal networks, and in competitive neuronal networks (see Appendix B). In competitive neural networks it would be helpful if the degree of heterosynaptic LTD depended on the existing strength of the synapse, and there is some evidence that this may be the case (see Appendix B). Homosynaptic LTD occurs when the presynaptic neuron is strongly active, and the postsynaptic neuron has some, but low, activity (see Fig. 1.5d and Table B.1). Homosynaptic LTD is so-called because the synapse that weakens is the same as (homo-) the one that is active. Heterosynaptic and homosynaptic LTD are found in the neocortex (Artola and Singer, 1993; Singer, 1995; Frégnac, 1996) and hippocampus (Christie, 1996), and in many cases are dependent on activation of NMDA receptors (Fazeli and Collingridge, 1996; Bliss and Collingridge, 2013). LTD in the cerebellum is evident as weakening of active parallel fibre to Purkinje cell synapses when the climbing fibre connecting to a Purkinje cell is active (Ito, 1984, 1989, 1993b,a, 2006, 2010).

Neuromodulators such as dopamine and acetylcholine can influence LTP and LTD (Bazari and Parri, 2019; Fremaux and Gerstner, 2015). The ways in which dopamine acts to

modulate learning are described in Chapter 16, and the importance of cholinergic modulation in human memory consolidation (Rolls, 2022b) is described in Chapter 9.

1.6.3 Spike Timing-Dependent Plasticity

An interesting time-dependence of LTP and LTD has been observed, with LTP occurring especially when the presynaptic spikes precede by a few ms the post-synaptic activation, and LTD occurring when the pre-synaptic spikes follow the post-synaptic activation by a few milliseconds (ms) (Markram, Lübke, Frotscher and Sakmann, 1997; Bi and Poo, 1998, 2001; Senn, Markram and Tsodyks, 2001; Dan and Poo, 2004, 2006; Markram, Gerstner and Sjöström, 2012; Fremaux and Gerstner, 2015). This is referred to as spike timing-dependent plasticity, STDP. This type of temporally asymmetric Hebbian learning rule, demonstrated in the hippocampus and neocortex, can induce associations over time, and not just between simultaneous events. Networks of neurons with such synapses can learn sequences (Minai and Levy, 1993), enabling them to predict the future state of the postsynaptic neuron based on past experience (Abbott and Blum, 1996) (see further Koch (1999), Markram, Pikus, Gupta and Tsodyks (1998) and Abbott and Nelson (2000)). This mechanism, because of its apparent time-specificity for periods in the range of ms or tens of ms, could also encourage neurons to learn to respond to temporally synchronous pre-synaptic firing (Gerstner, Kreiter, Markram and Herz, 1997; Gutig and Sompolinsky, 2006), and indeed to decrease the synaptic strengths from neurons that fire at random times with respect to the synchronized group. This mechanism might also play a role in the normalization of the strength of synaptic connection strengths onto a neuron. A version of STDP learning that adjusts the eligibility of synapses for learning provides a more explicit way for controlling the strength of the synaptic weights onto a neuron (El Boustani, Yger, Fregnac and Destexhe, 2012). Further, there is accumulating evidence (Sjöström, Turrigiano and Nelson, 2001) that a more realistic description of the protocols for inducing LTP and LTD probably requires a combination of dependence on spike timing – to take into account the effects of the backpropagating action potential – and dependence on the sub-threshold depolarization of the postsynaptic neuron. However these spike timing-dependent synaptic modifications may be evident primarily at low firing rates rather than those that often occur in the brain (Sjöström, Turrigiano and Nelson, 2001), and may not be especially reproducible in the cerebral neocortex (Fregnac et al., 2010), though interest in STDP, especially from theoretical perspectives, continues (Feldman, 2012, 2009; Fremaux and Gerstner, 2015). Neuromodulators such as dopamine and acetylcholine may also modulate STDP, and modelling approaches show how a delayed modulator such as a reward signal could influence STDP if there is a STDP eligibility trace that lasts until the reward is received (Fremaux and Gerstner, 2015).

However, under the somewhat steady-state conditions of the firing of neurons in the higher parts of the ventral visual system on the 10 ms timescale that are observed not only when single stimuli are presented for 500 ms (see Fig. 2.16), but also when macaques have found a search target and are looking at it (in the experiments described in Sections 2.4.3 and 2.8.9.1), the average of the presynaptic and postsynaptic rates are likely to be the important determinants of synaptic modification. Part of the reason for this is that correlations between the firing of simultaneously recorded inferior temporal cortex neurons are not common, and if present are not very strong or typically restricted to a short time window in the order of 10 ms (Rolls and Treves, 2011; Rolls, 2016b). This point is also made in the context that each neuron has thousands of inputs, several tens of which are normally likely to be active when a cell is firing above its spontaneous firing rate and is strongly depolarized. This may make it unlikely statistically that there will be a strong correlation between a particular presynaptic

spike and postsynaptic firing, and thus that STDP is a main determinant of synaptic strength under these natural conditions.

Synaptic modification for learning is considered further by Rolls (2016b), and some of the implications of different types of synaptic modification are considered in Appendix B.

1.7 Information encoding by neurons, and distributed representations

Most neurons in the cortex respond selectively to different stimuli, and the firing rate increases with the intensity of the stimulus. One example comes from the taste system, where some neurons are tuned to respond best to sweet, others to salt, others to sour, others to bitter, and others to umami (Chapter 4). Their firing rates increase as the intensity of the stimulus increases (in this case, the concentration of the tastant). In the primary visual cortex, some neurons respond to a stimulus at the fovea, and other neurons to a stimulus at a particular retinal position with respect to the fovea. Thus which neurons are active carries or encodes the information. This is called **place coding**, or (firing) **rate encoding** (as it is the number of action potential spikes that is important, and not the detailed timing of the spikes as with temporal encoding). This is also sometimes referred to as **labelled line encoding**, or grandmother cell encoding, if the neurons are very selective, which they are not usually. Indeed, the information is usually distributed across a population of neurons that are each somewhat differently tuned to a small proportion of a stimulus set. This is called distributed encoding, and is considered soon. The term ‘place coding’ probably has its origin in cortical maps, where the stimuli to which a neuron responds depends on the place of the neuron in the map. However, often in the cortex the coding is in high dimensional spaces that do not map easily into a 2D map, but the concept that the stimulus is encoded by which neurons are active still holds very firmly, as described in Appendix C, and we can use the term place coding. We will refer to this type of encoding as place coding or rate coding.

In some parts of the brain, the firing frequency of neurons encodes what the stimulus is, and this happens in the peripheral parts of the auditory system, where some neurons can follow the frequency of auditory stimuli up to about 1,000 Hz (Chapter 7). This is a type of **temporal encoding**, in which timing information can be important. The temporal information in this firing can be important in auditory localisation; but it is notable that the brain recodes this at the first central synapse in the brain into a place code / rate code, in which the particular neurons that are active encode the sound frequency (Chapter 7), because temporal encoding is difficult to maintain accurately when time delays and transmission time differences depend on factors such as the exact diameter of nerve fibres. It is presumably because of the difficulty of maintaining accurate timing in the brain that we have such large transmission lines in the dorsal ‘magnocellular’ visual system, for if the conduction time is fast (as it is with magnocellular neurons), then any absolute differences in transmission times can be minimised. This may be important when motion is being computed in the dorsal visual system. Thus in general temporal encoding is used as little as possible in the brain; and when the time of arrival is important, the brain uses large metabolic resources by employing magnocellular neurons. It has also been argued by some that the timing of spikes within a spike train carries information, but that hypothesis is shown in Appendix C not to apply in several brain systems (Tovee, Rolls, Treves and Bellis, 1993; Rolls, Franco, Aggelopoulos and Jerez, 2006b). At its simplest, such temporal encoding might involve different latencies of neuronal responses for different stimuli, but wherever that has been tested (apart as mentioned in the auditory system), the amount of information encoded by the latencies is small compared to that in the firing rates of neurons; and the information from the latency is redundant with

respect to the rate information, i.e. the latency adds nothing useful to the encoding by firing rate using a place code (Appendix C) (Tovee, Rolls, Treves and Bellis, 1993; Rolls, Franco, Aggelopoulos and Jerez, 2006b; Verhagen, Baker, Vasan, Pieribone and Rolls, 2023).

In the remainder of this section, we consider place / rate coding, and the advantages of using sparse distributed place / rate coding for the representation of information in the brain, and for use in brain computations.

When considering the operation of many neuronal networks in the brain, it is found that many useful properties arise if each input to the network (arriving on the axons as the vector of input firing rates \mathbf{x}) is encoded in the activity of an ensemble or population of the axons or input lines (distributed encoding), and is not signalled by the activity of a single input, which is called local encoding. We start off with some definitions, and then highlight some of the differences, and summarize some evidence that shows the type of encoding used in some brain regions. Then in Appendix B (e.g. Table B.2), I show how many of the useful properties of the neuronal networks described depend on distributed encoding. Evidence on the encoding actually found in visual cortical areas is described in Chapters 2 and 3, in Appendix C, and by Rolls and Treves (2011).

1.7.1 Definitions

All of the following apply to what is termed above ‘place coding’.

A *local representation* is one in which all the information that a particular stimulus or event occurred is provided by the activity of one of the neurons. In a famous example, a single neuron might be active only if one’s grandmother was being seen. An implication is that most neurons in the brain regions where objects or events are represented would fire only very rarely. A problem with this type of encoding is that a new neuron would be needed for every object or event that has to be represented. There are many other disadvantages of this type of encoding, many of which will become apparent in this book. Moreover, there is evidence that objects are represented in the brain by a different type of encoding (sparse distributed encoding, Appendix C; and Rolls and Treves (2011)).

A *fully distributed representation* is one in which all the information that a particular stimulus or event occurred is provided by the activity of the full set of neurons. If the neurons are binary (e.g. either active or not), the most distributed encoding is when half the neurons are active for any one stimulus or event.

A *sparse distributed representation* is a distributed representation in which a small proportion of the neurons is active at any one time. In a sparse representation with binary neurons, less than half of the neurons are active for any one stimulus or event. For binary neurons, we can use as a measure of the sparseness the proportion of neurons in the active state. For neurons with real, continuously variable, values of firing rates, the sparseness a^p of the representation provided by the population can be measured, by extending the binary notion of the proportion of neurons that are firing, as

$$a^p = \frac{(\sum_{i=1}^N y_i / N)^2}{\sum_{i=1}^N y_i^2 / N} \quad (1.4)$$

where y_i is the firing rate of the i th neuron in the set of N neurons (Treves and Rolls, 1991). This is referred to as the population sparseness, and measures of sparseness including that for a single neuron are considered in detail in Section C.3.1 and by Rolls (2016b). A low value of the sparseness a^p indicates that few neurons are firing for any one stimulus.

Coarse coding utilizes overlaps of receptive fields, and can compute positions in the input space using differences between the firing levels of coactive cells (e.g. color-tuned cones in the retina). The representation implied is very distributed. Fine coding (in which, for example, a neuron may be ‘tuned’ to the exact orientation and position of a stimulus) implies more sparse coding.

1.7.2 Advantages of sparse distributed encoding

One advantage of distributed encoding is that the similarity between two representations can be reflected by the correlation between the two patterns of activity that represent the different stimuli. We have already introduced the idea that the input to a neuron is represented by the activity of its set of input axons x_j , where j indexes the axons, numbered from $j = 1, C$ (see Fig. 1.2 and Equation 1.1). Now the set of activities of the input axons is a vector (a vector is an ordered set of numbers; Appendix A provides a summary of some of the concepts involved). We can denote as \mathbf{x}^1 the vector of axonal activity that represents stimulus 1, and \mathbf{x}^2 the vector that represents stimulus 2. Then the similarity between the two vectors, and thus the two stimuli, is reflected by the correlation between the two vectors. The correlation will be high if the activity of each axon in the two representations is similar; and will become more and more different as the activity of more and more of the axons differs in the two representations. Thus the similarity of two inputs can be represented in a graded or continuous way if (this type of) distributed encoding is used. This enables generalization to similar stimuli, or to incomplete versions of a stimulus (if it is, for example, partly seen or partly remembered), to occur. With a local representation, either one stimulus or another is represented, each by its own neuron firing, and similarities between different stimuli are not encoded.

Another advantage of distributed encoding is that the number of different stimuli that can be represented by a set of C components (e.g. the activity of C axons) can be very large. A simple example is provided by the binary encoding of an 8-element vector. One component can code for which of two stimuli has been seen, 2 components (or bits in a computer byte) for 4 stimuli, 3 components for 8 stimuli, 8 components for 256 stimuli, etc. That is, the number of stimuli increases exponentially with the number of components (or, in this case, axons) in the representation. (In this simple binary illustrative case, the number of stimuli that can be encoded is 2^C .) Put the other way round, even if a neuron has only a limited number of inputs (e.g. a few thousand), it can nevertheless receive a great deal of information about which stimulus was present. This ability of a neuron with a limited number of inputs to receive information about which of potentially very many input events is present is probably one factor that makes computation by the brain possible. With local encoding, the number of stimuli that can be encoded increases only linearly with the number C of axons or components (because a different component is needed to represent each new stimulus). (In our example, only 8 stimuli could be represented by 8 axons.)

In the real brain, there is now good evidence that in a number of brain systems, including the high-order visual and olfactory cortices, and the hippocampus, distributed encoding with the above two properties, of representing similarity, and of exponentially increasing encoding capacity as the number of neurons in the representation increases, is found (Rolls and Tovee, 1995b; Abbott, Rolls and Tovee, 1996; Rolls, Treves and Tovee, 1997b; Rolls, Treves, Robertson, Georges-François and Panzeri, 1998b; Rolls, Franco, Aggelopoulos and Reece, 2003b; Rolls, Aggelopoulos, Franco and Treves, 2004; Franco, Rolls, Aggelopoulos and Treves, 2004; Aggelopoulos, Franco and Rolls, 2005; Rolls, Franco, Aggelopoulos and Jerez, 2006b; Rolls and Treves, 2011; Rolls, 2016b) (Appendix C). For example, in the primate inferior temporal visual cortex, the number of faces or objects that can be represented increases approximately exponentially with the number of neurons in the population (Rolls

and Treves, 2011; Rolls, 2016b). If we consider instead the information about which stimulus is seen, we see that this rises approximately linearly with the number of neurons in the representation (Fig. 2.18). This corresponds to an exponential rise in the number of stimuli encoded, because information is a log measure (see Fig. 2.19 and Rolls (2016b)). A similar result has been found for the encoding of position in space by the primate hippocampus (Rolls, Treves, Robertson, Georges-François and Panzeri, 1998b).

It is particularly important that the information can be read from the ensemble of neurons using a simple measure of the similarity of vectors, the correlation (or dot product, see Appendix B) between two vectors (e.g. Fig. 2.18). The importance of this is that it is essentially vector similarity operations that characterize the operation of many neuronal networks (see Appendix B). The neurophysiological results show that both the ability to reflect similarity by vector correlation, and the utilization of exponential coding capacity, are properties of real neuronal networks found in the brain.

To emphasize one of the points being made here, although the binary encoding used in the 8-bit vector described above has optimal capacity for binary encoding, it is not optimal for vector similarity operations. For example, the two very similar numbers 127 and 128 are represented by 01111111 and 10000000 with binary encoding, yet the correlation or bit overlap of these vectors is 0. The brain, in contrast, uses a code that has the attractive property of exponentially increasing capacity with the number of neurons in the representation, though it is different from the simple binary encoding of numbers used in computers; and at the same time the brain codes stimuli in such a way that the code can be read off with simple dot product or correlation-related decoding, which is what is specified for the elementary neuronal network operation shown in Equation 1.2 (see Section 1.7).

1.8 Neuronal network approaches versus connectionism

The approach taken in this book is to introduce how real neuronal networks in the brain may compute, and thus to achieve a fundamental and realistic basis for understanding brain function. This may be contrasted with connectionism, which aims to understand cognitive function by analysing processing in neuron-like computing systems (Rumelhart and McClelland, 1986; McLeod, Plunkett and Rolls, 1998). Connectionist systems are neuron-like in that they analyze computation in systems with large numbers of computing elements in which the information which governs how the network computes is stored in the connection strengths between the nodes (or “neurons”) in the network. However, in many connectionist models the individual units or nodes are not intended to model individual neurons, and the variables that are used in the simulations are not intended to correspond to quantities that can be measured in the real brain. Moreover, connectionist approaches use learning rules in which the synaptic modification (the strength of the connections between the nodes) is determined by algorithms that require information that is not local to the synapse, that is, evident in the pre- and post-synaptic firing rates (see further Appendix B). Instead, in many connectionist systems, information about how to modify synaptic strengths is propagated backwards from the output of the network to affect neurons hidden deep within the network (see Section B.12). Because it is not clear that this is biologically plausible, we have instead in this text concentrated on introducing neuronal network architectures which are more biologically plausible, and which use a local learning rule. Connectionist approaches (see for example McClelland and Rumelhart (1986), McLeod, Plunkett and Rolls (1998)) are very valuable, for they show what can be achieved computationally with networks in which the connection strength determines the computation that the network achieves with quite simple computing elements. However, as models of brain function, many connectionist networks achieve almost too much, by solving

problems with a carefully limited number of “neurons” or nodes, which contributes to the ability of such networks to generalize successfully over the problem space. Connectionist schemes thus make an important start to understanding how complex computations (such as language) could be implemented in brain-like systems. In doing this, connectionist models often use simplified representations of the inputs and outputs, which are often crucial to the way in which the problem is solved. In addition, they may use learning algorithms that are really too powerful for the brain to perform, and therefore they can be taken only as a guide to how cognitive functions might be implemented by neuronal networks in the brain. In this book, we focus on more biologically plausible neuronal networks.

1.9 Introduction to three neuronal network architectures

With neurons of the type outlined in Section 1.4, and an associative learning rule of the type described in Section 1.5, three neuronal network architectures arise that appear to be used in many different brain regions. The three architectures will be described in Appendix B, and a brief introduction is provided here.

In the first architecture (see Fig. 1.7a and b), pattern associations can be learned. The output neurons are driven by an unconditioned stimulus (for example the taste of food). A conditioned stimulus (for example the sight of food) reaches the output neurons by associatively modifiable synapses w_{ij} . If the conditioned stimulus is paired during learning with activation of the output neurons produced by the unconditioned stimulus, then later, after learning, due to the associative synaptic modification, the conditioned stimulus alone will produce the same output as the unconditioned stimulus. **Pattern association networks** are described in Section B.2.

In the second architecture, an **autoassociation or attractor network**, the output neurons have recurrent associatively modifiable synaptic connections w_{ij} to other neurons in the network (see Fig. 1.7c). When an external input causes the output neurons to fire, then associative links are formed through the modifiable synapses that connect the set of neurons that is active. Later, if only a fraction of the original input pattern is presented, then the associative synaptic connections or weights allow the whole of the memory to be retrieved. This is called completion. Because the components of the pattern are associated with each other as a result of the associatively modifiable recurrent connections, this is called an autoassociative memory. It is believed to be used in the cortex for many purposes, including short-term memory; episodic memory, in which the parts of a memory of an episode are associated together; and helping to define the response properties of cortical neurons, which have collaterals between themselves within a limited region. Autoassociation or attractor networks are described in Section B.3.

In the third architecture, a **competitive network**, the main input to the output neurons is received through associatively modifiable synapses w_{ij} (see Fig. 1.7d). Because of the initial values of the synaptic strengths, or because every axon does not contact every output neuron, different patterns tend to activate different output neurons. When one pattern is being presented, the most strongly activated neurons tend via lateral inhibition to inhibit the other neurons. For this reason the network is called competitive. During the presentation of that pattern, associative modification of the active axons onto the active postsynaptic neuron takes place. Later, that or similar patterns will have a greater chance of activating that neuron or set of neurons. Other neurons learn to respond to other input patterns. In this way, a network is built that can categorize patterns, placing similar patterns into the same category. This is useful as a preprocessor for sensory information, self-organizes to produce feature analyzers, and finds uses in many other parts of the brain too. Competitive networks are described in

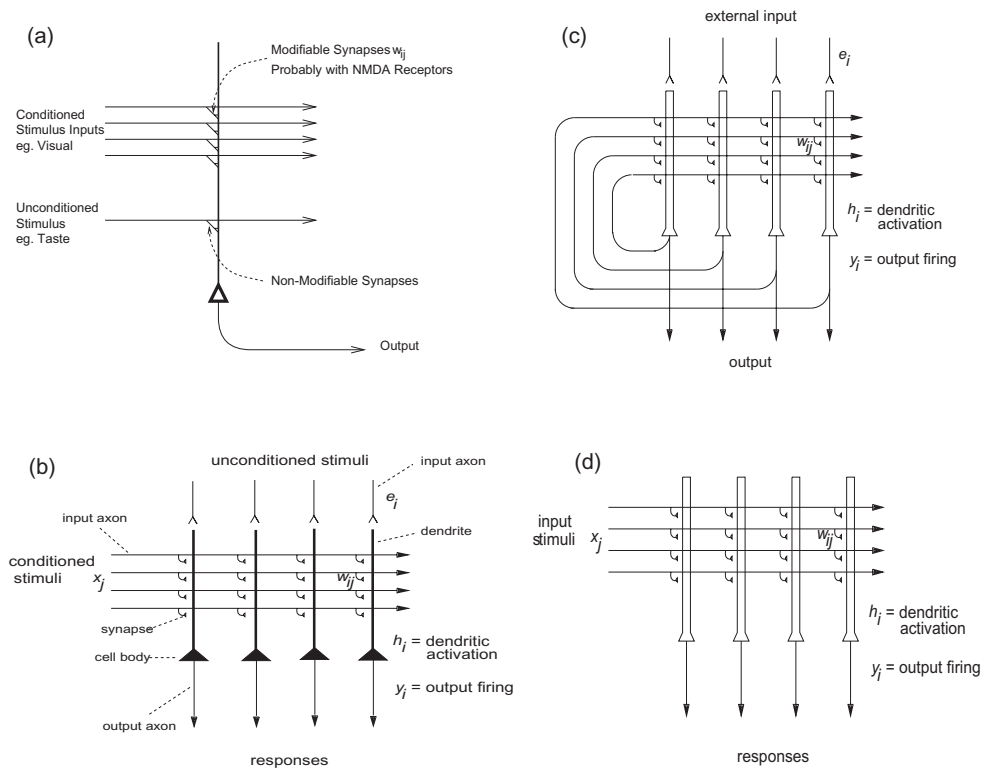

Fig. 1.7 Three network architectures that use local learning rules: (a) pattern association network introduced with a single output neuron; (b) pattern association network; (c) autoassociation network; (d) competitive network. Cortical pyramidal cell bodies are represented by triangular shapes, and the dendrites of each cell are shown above, with the axons shown below. The negative feedback inhibitory neurons are not shown.

Section B.4, and, importantly, perform unsupervised learning in that there is no teacher specifying how each neuron should respond. Instead, the categories are learned from the statistics present in the inputs.

Competitive networks enable new representations in the brain to be formed, by learning to respond to different combinations of inputs. The inputs are sometimes referred to as features. An example in vision might be that a common co-occurrence of two input features, such as a horizontal and vertical line, might enable a ‘T’ junction to be learned. Combinations of just a few features (termed low order combinations) need to be learned at any one stage, otherwise there would be a combinatorial explosion in the number of feature analyzers needed (Feldman, 1985). The building of feature analyzers using competitive learning is a key aspect of the operation of hierarchical networks, as described in Chapter 2.

All three architectures require inhibitory interneurons, which receive inputs from the principal neurons in the network (usually the pyramidal cells shown in Fig. 1.7) and implement feedback inhibition by connections to the pyramidal cells. The inhibition is usually implemented by GABA neurons, and maintains a small proportion of the pyramidal cells active.

These are three fundamental building blocks for neural architectures in the cortex. They are often used in combination with each other. Because they are some of the building blocks of some of the architectures found in the cerebral cortex, they are described in Appendix B.

These three architectures illustrate some of the important types of learning that can be implemented in Neural Networks, as described in more detail in Appendix B. First, competitive learning is an example of **unsupervised learning**, in that the system self-organizes based on the statistics of the inputs being received, without an external teacher to guide its

learning. This is used in the model of invariant visual object recognition, VisNet, described in Chapter 2. This type of learning must be very common in the brain, in that there is often no external teacher to help the system self-organise, let alone an external teacher for every neuron. Unsupervised learning is relatively little used in the machine learning community at present, and there are likely to be important lessons learned from how unsupervised learning is used in the brain.

Pattern association learning is an example of **supervised learning**, in that each output neuron has an external input that specifies the output that each neuron should produce. This external input is e_i in Fig. 1.7b. In the pattern association networks shown in Fig. 1.7b the inputs x_j learn to produce the required outputs just by associative synaptic modification, and this type of learning is common in the brain. In machine learning, the learning rule may be much more powerful, and may involve calculating an error between the output that is required for each neuron, and the actual output that is being produced by the inputs x_j . A one-layer network with such error correction learning is referred to as a one-layer error correction network or one-layer perceptron, and is described in Section B.11. The brain does in general not have the architecture required for this type of learning, as there is no separate teacher for each neuron to specify what its firing should be for every input, and no way to compare the actual firing with the target firing to compute an error to correct the appropriate synaptic weight. The only part of the brain where the architecture might be suitable is the cerebellum, where there is a single climbing fibre for each Purkinje cell, as described in Chapter 17. The error correction type of learning can be implemented in machine learning in a multilayer network, in which inputs are applied to the bottom layer of the network, and every neuron in the output layer has a teacher. In the backpropagation of error algorithm described in Section B.12, the error is backpropagated through all the layers of the network to calculate the error that should be used to correct the firing of every neuron in all the hidden layers not connected to the input or output. This is a non-local type of synaptic modification, and could not easily be implemented in the cortex, partly because there is no teacher for each neuron, and partly because of the implausibility of computing the backpropagated errors through every layer, although attempts have been made (O'Reilly and Munakata, 2000; Guerguiev et al., 2017). Although deep learning trained by error backpropagation is used widely for classifying inputs in machine learning, there is no clear evidence yet that it is or could be implemented in the cortex. The brain may solve similar problems, but in other ways, with one example being invariant visual object recognition as described in Chapter 2.

A third type of learning is **reinforcement learning**, in which there is a single reward signal for the whole network, as described in Sections B.17 and 19.5. This type of learning may be implemented in the brain for the slow learning of stimulus-response habits in the basal ganglia, using dopamine to provide a reward prediction error signal as described in Section 16.4.3.

A fourth learning system is that exemplified by the autoassociation network system illustrated in Fig. 1.7c and described in Section B.3. This is a network that stores information and can retrieve it using a partial cue, and can maintain it using the positive feedback implemented by the recurrent collateral connections. This type of network plays key roles in episodic memory (Chapter 9), short-term memory and attention, and planning (Chapter 13), semantic memory (Chapter 8), and indeed in cortical computation (Rolls, 2016b). This is key to understanding brain function, but is little used in machine learning as other mechanisms can be used in digital computers.

1.10 Systems-level analysis of brain function

To understand the computations in the brain, it is essential to understand the systems-level organization of the brain, in order to understand how the networks in each region provide a particular computational function as part of an overall computational scheme. These systems-level processing streams are described in the different Chapters of this book. The description is based primarily on studies in non-human primates, for they have well-developed cortical areas that in many cases correspond to those found in humans, and it has been possible to analyze their connectivity and their functions by recording the activity of neurons in them.

Some of the processing streams involved in sensory and related memory and emotional functions are shown in Fig. 1.8. Some of these regions are shown in the drawings of the primate brain in Figs. 2.3, 2.1, and 3.1.

The hippocampus receives inputs from both the ‘what’ and the ‘where’ visual systems (Figs. 1.8 and 2.3, and Chapter 9). By rapidly learning associations between conjunctive inputs in these systems, it is able to form memories of particular events occurring in particular places at particular times. To do this, it needs to store whatever is being represented in each of many cortical areas at a given time, and later to recall the whole memory from a part of it. The types of network it contains that are involved in this memory function are described in Chapter 9.

The dorsolateral parts of the prefrontal cortex receive inputs from dorsal stream processing pathways, and the ventrolateral parts from the ventral stream processing pathways, as shown in Figs. 2.4, 2.3 and 3.1. These lateral prefrontal cortical areas, including Brodmann area (BA) 46, provide short-term memory functions, providing the basis for functions such as top-down attention, short-term memory, working memory, and planning (Chapter 13). These lateral prefrontal cortex areas can be thought of as providing processing that need not be dominated by perceptual processing, as must the posterior visual and parietal lobe spatial areas if incoming stimuli are to be perceived, but can instead be devoted to processing recent information that may no longer be present in perceptual areas.

The orbitofrontal cortex, areas BA 11, 12 and 13 (Figs. 1.8, 11.2, 2.3 and 3.1), receives information from the ‘what’ systems for vision, taste, olfaction, touch, and audition), forms multimodal representations, and computes reward value. It is therefore of fundamental importance for emotional, motivational, and social behavior (see Chapter 11).

1.11 Brodmann areas

A very brief outline of some of the connections and functions of different Brodmann areas (Brodmann, 1909, 1925) is provided here, intended mainly for those who are not familiar with them. Brodmann used cytoarchitecture of the cortex studied with a microscope to distinguish different areas, but because function reflects the architecture, different Brodmann areas also to a considerable extent have different functions. Some of these areas are shown by the numbers in Figs. 1.9, 2.3, 2.1, and 3.1. However, a more modern parcellation of the cortex based on function as well as structure produced by the Human Connectome Project and used for the connectivity studies described in this book is described in Section 1.12 and illustrated in Figs. 1.10 and 1.11.

Brodmann areas:

Areas 3, 1 & 2 – Primary somatosensory cortex (in the postcentral gyrus). This is numbered rostral to caudal as 3,1,2. This region is associated with the sense and localization of touch, temperature, vibration, and pain. There is a map or homunculus of different parts of the body.

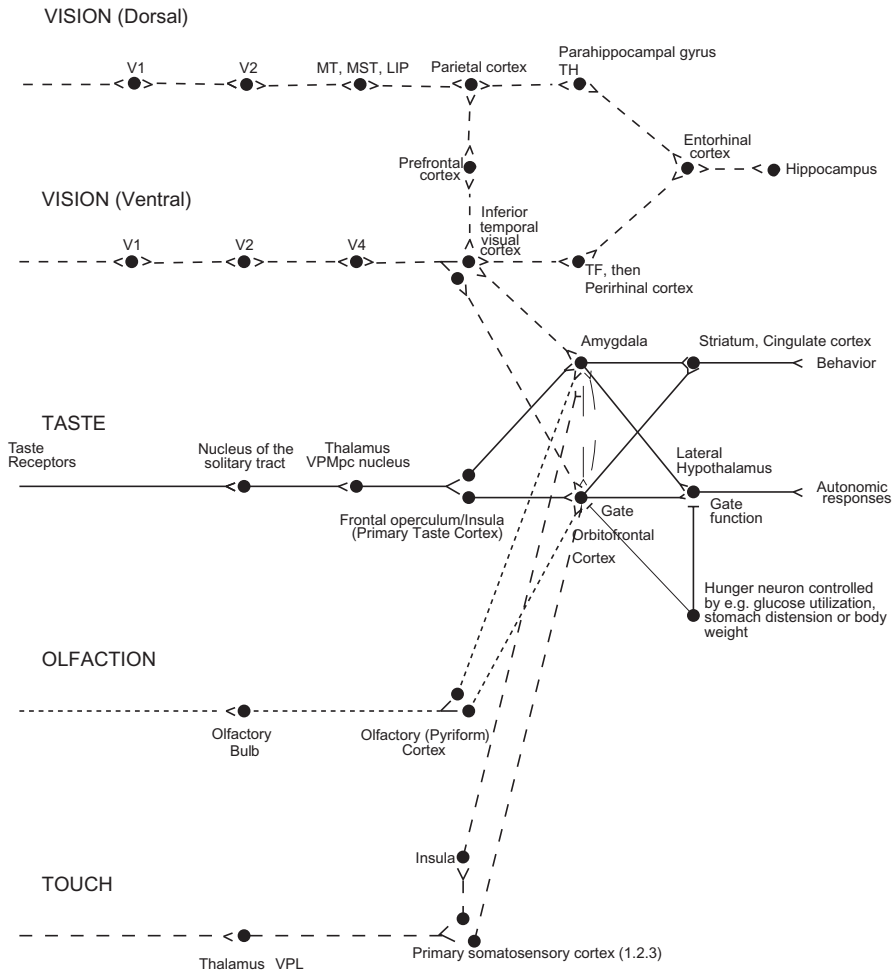

Fig. 1.8 The pathways involved in some different cortical systems described in the text. Forward connections start from early cortical areas on the left. To emphasise that backprojections are important in many memory systems, they are made explicit in the synaptic terminals drawn in the upper part of the diagram, but are a property of most of the connections shown. The top pathway, also shown in Fig. 3.1, shows the connections in the 'dorsal or where visual pathway' from V1 to V2, MT, MST, 7a etc, with some connections reaching the dorsolateral prefrontal cortex and frontal eye fields. The second pathway, also shown in Fig. 2.1, shows the connections in the 'ventral or what visual pathway' from V1 to V2, V4, the inferior temporal visual cortex, etc., with some connections reaching the amygdala and orbitofrontal cortex. The two systems project via the parahippocampal gyrus and perirhinal cortex respectively to the hippocampus, and both systems have projections to the dorsolateral prefrontal cortex. The taste pathways project after the primary taste cortex to the orbitofrontal cortex and amygdala. The olfactory pathways project from the primary olfactory, pyriform, cortex to the orbitofrontal cortex and amygdala. The bottom pathway shows the connections from the primary somatosensory cortex, areas 1, 2 and 3, to the mid-insula, orbitofrontal cortex, and amygdala. Somatosensory areas 1, 2 and 3 also project via area 5 in the parietal cortex, to area 7b.

A lesion in this area may cause agraphesthesia, astereognosia, loss of vibration, proprioception and fine touch, and potentially hemineglect if the non-dominant hemisphere is affected. (Chapter 6).

Area 4 – Primary motor cortex (in the precentral gyrus). This is the area responsible for executing fine motor movements, which includes contralateral finger/hand/wrist or orofacial movements, learned motor sequences, breathing control, and voluntary blinking. There is a motor map in area 4, which approximately corresponds to the map in the primary somatosensory cortex. A lesion in this area may cause paralysis of the contralateral side of the body, including facial palsy, arm or leg monoparesis, and hemiparesis. (Chapter 15.)

Fig. 1.9 Brodmann areas. Upper left: lateral view of the human brain. The front of the brain is on the left. Lower right: Medial view of the human brain. The front of the brain is on the left. (Modified from Purves, D., Augustine, G.J., Fitzpatrick, D. et al., editors (2019) *Neuroscience*. International Edition. © Oxford University Press: Oxford.)

Area 5 – Somatosensory association cortex. Brodmann area 5 is part of the superior parietal cortex, and is a secondary somatosensory area that receives inputs from the primary somatosensory cortex, and projects to parietal area 7b. A lesion in the left superior parietal lobe may cause ideomotor apraxia, which is the loss of ability to produce purposeful, skilled movements as a result of brain pathology not due to physical weakness, paralysis, lack of coordination or sensory loss. Astereognosis (also known as tactile agnosia) is also possible, which would lead to loss of ability to recognize objects by feeling or handling them. (Chapter 6.)

Area 6 – Premotor and Supplementary Motor Cortex (Secondary Motor Cortex). This projects to motor cortex area 4, and can be thought of as a higher order motor cortical area. This region is critical for the sensory guidance of movement and control of proximal and trunk muscles, and contributes to the planning of complex and coordinated motor movements. A lesion here may affect sensory guidance of movement and control of proximal and trunk muscles. Damage to the lateral premotor area 6 may result in kinetic apraxia (which would appear as coarse or unrefined movements that no longer have the appearance of being practiced over time). (Chapter 15.)

Area 7 – 7b: Somatosensory Association Cortex in the anterior part of the superior parietal lobule on the lateral surface. 7a: Visuospatial association cortex in the posterior part of the superior parietal lobule on the lateral surface. The precuneus medially is involved in spatial function including the sense of self (Scott et al., 2005). (Chapter 6.)

Area 8 – A higher order motor cortical area, which projects to area 6. Area 8 includes the frontal eye fields, which are involved in making saccades based on information in short-term memory (Goldberg and Walker, 2013). (Chapter 15.)

Area 9 – is in the dorsolateral/anterior prefrontal cortex (DLPFC). This region is a high order cortical area responsible for motor planning, organization, and regulation, and sustaining attention and working memory. The DLPFC projects to areas such as Area 8. The DLPFC plays an important role in working memory, and hence is important in planning. Area 46 is a part of the dorsolateral prefrontal cortex around and within the principal sulcus, and is involved in spatial working memory (dorsally), and object working memory (ventrally) (Chapter 13.)

Area 10 – Anterior prefrontal cortex (most rostral part of superior and middle frontal gyri). This region is involved in strategic processes of memory retrieval and executive functions (such as reasoning, task flexibility, problem solving, planning, execution, working memory, processing emotional stimuli, inferential reasoning, decision making, calculation of numerical processes, etc.). (Chapter 13.) The ventral medial prefrontal cortex area 10m and the anterior and medial parts of the orbitofrontal cortex are sometimes referred to as the ventromedial prefrontal cortex. (Chapter 11.)

Area 11 – Medial Orbitofrontal cortex, anterior part. (Figs. 11.2 and 11.3. Chapter 11)

Area 12 – Lateral orbitofrontal cortex. (Figs. 11.2 and 11.3. Chapter 11)

Area 13 – Medial orbitofrontal cortex, posterior part (Ongur et al., 2003; Carmichael and Price, 1994; Ongur and Price, 2000; Rolls, 2019e; Rolls et al., 2023c). Areas 11–13 are illustrated in Figs. 11.2 and 11.3, and are involved in reward value, non-reward, and emotion (Rolls, 2019e). (Chapter 11.)

Areas 14–16 Insular cortex. The anterior part contains the taste cortex, and below is visceral / autonomic cortex (Rolls, 2016c). More posteriorly, there are somatotopically organised somatosensory representations. (Chapter 6.)

Area 17 – Primary visual cortex (V1). The primary visual cortex is located in the occipital lobe at the back of the brain, and contains a well-defined map of the visual field. Depending on where and how damage and lesions occur to this region, partial or complete cortical blindness can result; for example, if the upper bank of the calcarine sulcus is damaged, then the lower bank of the visual field is affected. Patients with damage to the striate cortex may show blindsight, in which they deny seeing objects, but can often guess better than chance (Weiskrantz, 1998). (Chapter 2.)

Area 18 – Secondary visual cortex (V2). (Chapter 2.)

Area 19 – Associative visual cortex (V3,V4,V5). (Chapters 2 and 3.)

Area 20 – Inferior temporal gyrus. Includes parts of the inferior temporal visual cortex, which includes area 21 in macaques. (Chapter 2.)

Area 21 – Middle temporal gyrus and part of inferior frontal gyrus. In humans, parts of the middle temporal gyrus may correspond to parts of the cortex in the macaque cortex in the superior temporal sulcus. It contains face expression cells, and is implicated also in humans in theory of mind and autism (Cheng, Rolls, Gu, Zhang and Feng, 2015). (Chapter 2.)

Area 22 – Auditory association cortex (in the Superior Temporal Gyrus, of which the caudal part is usually considered to be within Wernicke's area which is involved in language comprehension). (Chapter 7.)

Area 23 – Ventral posterior cingulate cortex (Rolls, 2019c). (Figs. 12.2 and 12.1). (Chapter 12.)

Area 24 – Part of anterior cingulate cortex and mid-cingulate cortex (Rolls, 2019c; Rolls et

al., 2023c). (Figs. 12.2 and 12.1). (Chapter 12.)

Area 25 – Subgenual cingulate cortex (involved in autonomic function) (Rolls, 2019c). (Figs. 12.2 and 12.1. Chapter 12.)

Area 26 – Ectosplenial portion of the retrosplenial region of the cerebral cortex (Rolls, 2019c; Rolls et al., 2023i). (Figs. 9.1 and 12.1. Chapters 10 and 12.)

Area 27 – Part of the parahippocampal gyrus that may correspond to the presubiculum. (Chapter 9.)

Area 28 – Entorhinal cortex. The gateway to and from the hippocampus (Fig. 9.1). The medial entorhinal cortex contains grid (place) cells in rodents, and grid (spatial view) cells in primates. (Chapter 9.)

Area 29 – Retrosplenial cingulate cortex. Processes spatial information, with connections with the hippocampus. (Figs. 12.2 and 12.1). (Chapter 12.)

Area 30 – Retrosplenial cingulate cortex (Rolls, 2019c; Rolls et al., 2023i). (Figs. 12.2 and 12.1). (Chapter 12.)

Area 31 – Dorsal posterior cingulate cortex (Rolls, 2019c; Rolls et al., 2023i). (Figs. 12.2 and 12.1). (Chapter 12.)

Area 32 – Part of anterior cingulate cortex (Rolls, 2019c). (Figs. 12.2 and 12.1). (Chapter 12.)

Area 33 – Part of anterior cingulate cortex (Rolls, 2019c; Rolls et al., 2023c). (Figs. 12.2 and 12.1). (Chapter 12.)

Area 34 – Part of the parahippocampal gyrus (Fig. 9.1). (Chapter 9.)

Area 35 – Perirhinal cortex (in the rhinal sulcus) (Fig. 9.1). Connects visual and other ventral stream cortical areas to and from the entorhinal cortex and thus hippocampus. (Chapter 9.)

Area 36 – Also perirhinal cortex (in the rhinal sulcus). (Chapter 9.)

Area 37 – Fusiform gyrus. This region is involved in face, object, and scene representation. It receives from earlier cortical visual areas. (Chapter 2.)

Area 38 – Temporopolar area (most rostral part of the superior and middle temporal gyri). Involved in semantic representations. (Chapters 8 and 14.)

Area 39 – Angular gyrus. In the inferior parietal lobule. May be involved in contributions of the dorsal stream to semantic processing. (Sections 14.2.6 and Chapter 14.)

Area 40 – Supramarginal gyrus, in the inferior parietal lobule, is involved in phonological word processing in the left hemisphere of right-handed people. A lesion here causes language disorders characterized by fluent speech paraphasias where words are jumbled and nonsensical sentences are spoken. (Sections 14.2.6 and Chapter 14.)

Areas 41 and 42 – Auditory cortex. (Chapter 7.)

Area 43 – Primary gustatory cortex in the anterior insula. (Chapter 4.)

Areas 44–45 Area 44 (inferior frontal gyrus pars opercularis) and area 45 (inferior frontal gyrus pars triangularis) are together often known as Broca's area in the dominant hemisphere. This region is associated with the praxis of speech (motor speech programming). This includes being able to put together the binding elements of language, selecting information among competing sources, sequencing motor/expressive elements, cognitive control mechanisms for syntactic processing of sentences, and construction of complex sentences and speech patterns. Lesions in this area cause Broca's aphasia: a deficit in the ability to speak and produce the proper words/sounds, even though the person maintains the ability to comprehend language. (Chapter 14.)

Area 45 – Inferior frontal gyrus pars triangularis, and part of Broca's area. (Chapter 14.)

Area 46 – Dorsolateral prefrontal cortex. Area 46 is a part of the dorsolateral prefrontal cortex around and within the principal sulcus, and is involved in spatial working memory (dorsally), and object working memory (ventrally). (Chapter 13.)

Area 47 – Inferior frontal gyrus, pars orbitalis. Often termed 12/47, the lateral orbitofrontal

cortex. (Chapter 11.)

Area 48 – Retrosubicular area (a small part of the medial surface of the temporal lobe).

Area 49 – Parasubicular area in a rodent.

Area 52 – Parainsular area (at the junction of the temporal lobe and the insula).

One atlas that we have found useful for research purposes is the automated anatomical labelling atlas AAL2 and AAL3, which includes detailed divisions of the orbitofrontal cortex (Rolls et al., 2015a, 2020d) (Section D.9).

1.12 Human Connectome Project Multi-Modal Parcellation atlas of the human cortex

The Human Connectome Project multimodal parcellation atlas (HCP-MMP) provides a very useful parcellation of human cerebral cortical areas (Glasser et al., 2016b,a). The atlas is multimodal in that each region is defined by a combination of four criteria, architecture (T1w/T2w myelin content and cortical thickness maps which can be identified with MRI), resting-state functional connectivity, and task-based fMRI activation in seven tasks, using a 3T MRI scanner (Glasser et al., 2016a). The HCP-MMP v1.0 atlas includes 180 cortical areas in each hemisphere, based on analyses in 210 participants. The areas defined include many areas that are of interest because of evidence on their functions, such as parieto-temporal cortex areas LIP, VIP, MT, MST, and occipital areas including V1, V2, V3, V4 etc. The boundaries of each cortical region are defined using this approach based on a combination of the multimodal evidence obtained in all of these ways. This potentially makes this atlas able to discriminate more reliably between different cortical regions with potentially different functions and connectivity than any other atlas based on evidence from a single modality.

Given the usefulness of the parcellation provided in the HCP-MMP atlas (Glasser et al., 2016a), we have provided an extended version of the atlas, HCPex, that extends it with 66 subcortical areas, provides it in volumetric form useful for many types of neuroimaging software (e.g. SPM (Friston et al., 2006) <https://www.fil.ion.ucl.ac.uk/spm/> and FSL (Jenkinson et al., 2012; Smith et al., 2004) <https://fsl.fmrib.ox.ac.uk>), and by providing a reordered version with an option to revert to the original order (Huang et al., 2022). The order of cortical regions defined in HCPex and shown in Tables 1.1–1.6 is used throughout this book. We note that this atlas helps in the analysis of brain structure and function, for many of the cortical areas defined in the HCP-MMP / HCPex atlas are known about functionally, many can be related to corresponding regions in macaques in which much detailed neurophysiology is available, and the atlas helps new investigations of the brain to be related to the known functions of those anatomically defined brain areas.

We note that surface-based registration such as that provided by the HCP-MMP leads to better spatial localization of cortical areas than volumetric methods (Coalson et al., 2018; Glasser et al., 2016b) such as those commonly used and made available in neuroimaging software such as SPM and FSL. However, given that much neuroimaging analysis is performed with software such as SPM and FSL, and that volumetric analysis enables subcortical areas to be easily included straightforwardly in the atlas which is an aim of HCPex, we have provided HCPex which is in volumetric space (Huang, Rolls, Feng and Lin, 2022). At the same time, where better localization is required than may be provided with HCPex, we appreciate and recommend the use of the surface-based version HCP-MMP v1.0 (Glasser et al., 2016a), for the reasons set out by Coalson et al. (2018). In fact, for most of the effective connectivity analyses described in this book, the cortical connectivity was measured with the surface-based parcellation, and the connectivity with subcortical areas was measured with HCPex. We

Fig. 1.10 Anatomical regions in the Human Connectome Project Multimodal Parcellation atlas (HCP-MMP) of the human cortical regions. Cortical regions are shown as defined in the HCP-MMP atlas (Glasser et al., 2016a), and in its extended version HCPex (Huang, Rolls et al. (2022)). The regions are shown on images of the human brain without the sulci expanded to show which cortical HCP-MMP regions are normally visible, for comparison with Fig. 1.11. Abbreviations are provided in Tables 1.1–1.6.

further note that an advantage of the HCP-MMP / HCPex atlas is that the effective connectivity, functional connectivity, and connections measured with diffusion tractography have been measured and described between all 360 cortical regions, and this provides a rich foundation for future studies of the functions and computations of the human cerebral cortex (Rolls et al., 2022a,b, 2023e,h,c,f,i,d,b,a). This is likely to be facilitated when a corresponding atlas for macaques now in development becomes available. These papers also relate the connectivities of each of these HCP-MMP regions to the functions of these cortical regions.

Cortical regions defined in the HCP-MMP / HCPex atlas are shown in Figs. 1.10 and 1.11, with a list of the cortical regions in Tables 1.1–1.6 and of the subcortical regions in HCPex in Table 1.7. Coronal slices to further help visualization of the locations in the brain of these cortical regions are provided by Huang, Rolls, Feng and Lin (2022). Descriptions of most of these cortical regions including their connectivity and functions are provided in the different Chapters of this book. Short summaries of some of the key Divisions in the HCP-MMP and HCPex atlases (Glasser et al., 2016a; Huang et al., 2022) are provided next with reference to Tables 1.1–1.6.

Fig. 1.11 Anatomical regions in the Human Connectome Project Multimodal Parcellation atlas HCP-MMP of the human cortical regions. Cortical Regions are shown as defined in the HCP-MMP atlas (Glasser et al., 2016a), and in its extended version HCPex which includes the thalamus and the other subcortical areas shown (Huang, Rolls et al. (2022)). The regions are shown on images of the human brain with the sulci expanded to show all cortical HCP-MMP regions, for comparison with Fig. 1.12. Abbreviations are provided in Tables 1.1–1.6.

The main visual processing cortical regions are in the Primary Visual, Early Visual, Dorsal Visual Stream, Ventral Visual Stream, and MT+ Complex Divisions in Table 1.1, and in the Lateral Temporal Division in Table 1.3, and their connectivity and functions are described in Chapters 2 and 3, and by Rolls et al. (2023e).

The main somatosensory and motor cortical regions are in the SomatoSensory, ParaCentral and MidCingulate, Premotor, and Posterior Opercular Divisions in Table 1.2, and in the Insula / Frontal Opercular Division in Table 1.3, and their connectivity and functions are described in Chapters 6 and 15, and by Rolls et al. (2023f). Regions 23c, 24dd and 24dv are the midcingulate premotor cortex described by Vogt (2016) and Rolls et al. (2023i).

The main auditory cortical regions are in the Early Auditory, and Auditory Association Divisions in Table 1.2, and their connectivity and functions are described in Chapter 7 and by Rolls et al. (2023h). However some of the regions in the ‘Auditory Association’ Division are in fact multimodal, include visual and auditory responsiveness to social stimuli, and are also

The hippocampal memory system is in the Medial Temporal Division in Table 1.3, with its closely related regions in the Posterior Cingulate Division shown in Table 1.4. Their connectivity and functions are described in Chapters 9 and 10, and by Rolls et al. (2022a), Rolls et al. (2023i), Rolls et al. (2023d), Rolls (2023c), and Rolls (2022b).

The human language-related cortical regions are in the Temporo-Parietal-Occipital TPO Division in Table 1.3, and regions 44, 45 and 471 (Broca's area) in Table 1.6. Their connectivity and functions are described in Chapter 14, and by Rolls et al. (2022b).

The subcortical regions involved in many functions that are in the HCPex atlas (Huang, Rolls, Feng and Lin, 2022) are listed in Table 1.7, and their connectivity and functions are described in Chapter 16 and elsewhere (Rolls et al., 2023b,c; Rolls, 2022b).

1.13 Connectivity of the human brain

To understand what computations are performed by each brain region, and how they are performed, it is very helpful to know the connectivity of different brain regions. The inputs to a brain region for example influence what computations it can perform, and the regions to which it is connected help to define what functions its computations are used for. Brief

descriptions of some methods that are used to investigate the connectivity of the human brain are described next.

1.13.1 Connections analyzed with diffusion tractography

Diffusion tractography uses MRI to measure the diffusion of water in the human brain, and this tends to occur along fibre tracts, so provides some evidence about connections in the brain (Catani and Thiebaut de Schotten, 2008; Lerch et al., 2017; Maier-Hein et al., 2017; Jeurissen et al., 2019).

Diffusion tractography can provide evidence about fibre pathways linking different brain regions. Diffusion tractography shows only direct connections, so comparison with effective connectivity (described below) can help to suggest which effective connectivities may be mediated directly or trans-synaptically. Diffusion tractography does not provide evidence about the direction of connections. The term ‘connections’ is appropriate for use for diffusion tractography, for it provides evidence about anatomical connections.

Diffusion tractography as a method for following connections and measuring their strength is supported by comparisons made in macaques between diffusion tractography and conventional anatomical methods with tracers (van den Heuvel et al., 2015; Donahue et al., 2016).

The methods used in the application of diffusion tractography in the investigations included in this book are described by Huang, Rolls, Hsu, Feng and Lin (2021). Diffusion tractography cannot follow fibres where they become unmyelinated within the cortex, and that is one of its limitations. Another is that it does not work well for long connections across the midline of the human brain (Huang et al., 2021).

1.13.2 Functional connectivity

Functional connectivity is measured by the Pearson correlation between the BOLD (Blood Oxygenation-Level Dependent) fMRI signal in each pair of brain regions, and can provide evidence that may relate to interactions between brain regions, while providing no evidence about causal direction-specific effects. A high functional connectivity may in this scenario thus reflect strong physiological interactions between areas, and provides a different type of evidence to effective connectivity described next. Functional connectivity measured between cortical regions typically ranges continuously between 0.9 and -0.3, so a threshold such as 0.4 is often utilised to view the stronger functional connectivities. No subtraction of the global signal was used in the investigations described here, because this produces many apparently negative functional connectivities that are difficult to interpret, as described in the Supplementary Material of Cheng, Rolls, Qiu, Liu, Tang, Huang, Wang, Zhang, Lin, Zheng, Pu, Tsai, Yang, Lin, Wang, Xie and Feng (2016a).

1.13.3 Effective connectivity

Effective connectivity measures the effect of one brain region on another, and utilizes differences detected at different times in the signals in each connected pair of brain regions to infer effects of one brain region on another. One such approach is dynamic causal modelling, but it applies most easily to activation studies, and is typically limited to measuring the effective connectivity between just a few brain areas (Valdes-Sosa et al., 2011; Bajaj et al., 2016; Friston, 2009), though there have been moves to extend it to resting state studies and more brain areas (Razi et al., 2017; Frassle et al., 2017).

The method used here (Rolls et al., 2023e,h,c, 2022a, 2023i,f,d, 2022b, 2023b) was developed from a Hopf algorithm to enable measurement of effective connectivity between many brain areas, described by Deco et al. (2019). A principle is that the functional connectivity is

measured at time t and time $t + \text{tau}$, where tau is typically 2 s to take into account the time within which a change in the BOLD signal can occur, and then the effective connectivity model is trained by error correction until it can generate the functional connectivity matrices at time t and time $t + \text{tau}$. Full details of the algorithm and its validation are provided elsewhere (Rolls et al., 2022a), and a short description is provided next. The directionality described in these papers has been investigated and validated with analyses using magnetoencephalography (MEG), which operates on a much faster time scale of ms (Rolls et al., 2023a).

To infer the effective connectivity, we use a whole-brain model that allows us to simulate the BOLD activity across all brain regions and time. We use the so-called Hopf computational model, which integrates the dynamics of Stuart-Landau oscillators, expressing the activity of each brain region coupled together by the strength of the connectivity in each direction between every pair of brain regions (Deco et al., 2017b). The local dynamics of each brain area (node) is given by Stuart-Landau oscillators which expresses the normal form of a supercritical Hopf bifurcation, describing the transition from noisy to oscillatory dynamics (Kuznetsov, 2013). It has been shown that the Hopf whole-brain model successfully simulates empirical electrophysiology (Freyer et al., 2011, 2012), MagnetoEncephalography (Deco et al., 2017a) and fMRI (Deco et al., 2017b; Kringelbach et al., 2015; Kringelbach and Deco, 2020). The Hopf whole-brain model can be expressed mathematically as follows:

$$\frac{dx_i}{dt} = \overbrace{[a_i - x_i^2 - y_i^2]x_i - \omega_i y_i}^{\text{LocalDynamics}} + \overbrace{G \sum_{j=1}^N C_{ij}(x_j - x_i)}^{\text{Coupling}} + \overbrace{\beta \eta_i(t)}^{\text{GaussianNoise}} \quad (1.5)$$

$$\frac{dy_i}{dt} = \overbrace{[a_i - x_i^2 - y_i^2]y_i + \omega_i x_i}^{\text{LocalDynamics}} + \overbrace{G \sum_{j=1}^N C_{ij}(y_j - y_i)}^{\text{Coupling}} + \overbrace{\beta \eta_i(t)}^{\text{GaussianNoise}} \quad (1.6)$$

Equations 1.5 and 1.6 describe the coupling of Stuart-Landau oscillators through an effective connectivity matrix C . The $x_i(t)$ term represents the simulated BOLD signal data of brain area i . The values of $y_i(t)$ are relevant to the dynamics of the system but are not part of the information read out from the system. In these equations, $\eta_i(t)$ provides additive Gaussian noise with standard deviation β . The Stuart-Landau oscillators for each brain area i express a Hopf normal form that has a supercritical bifurcation at $a_i = 0$, so that if $a_i > 0$ the system has a stable limit cycle with frequency with frequency $f_i = \omega_i/2$ (where ω_i is the angular velocity); and when $a_i < 0$ the system has a stable fixed point representing a low activity noisy state. The intrinsic frequency f_i of each Stuart-Landau oscillator corresponding to a brain area i is in the 0.008–0.08 Hz band ($i=1, \dots, 360$ cortical regions). The intrinsic frequencies are fitted from the data, provided here by the averaged peak frequency of the narrowband BOLD signals of each brain region. The coupling term representing the input received in node i from every other node j , is weighted by the corresponding effective connectivity C_{ij} . The coupling is the canonical diffusive coupling, which approximates the simplest (linear) part of a general coupling function. G denotes the global coupling weight, scaling equally the total input received in each brain area. While the oscillators are weakly coupled, the periodic orbit of the uncoupled oscillators is preserved.

The effective connectivity matrix can be derived by optimizing the conductivity of each existing anatomical connection as specified by the Structural Connectivity matrix (measured with tractography (Huang et al., 2021)) in order to fit the empirical functional connectivity (FC) pairs and the lagged FC^{tau} pairs. By this, we are able to infer a non-symmetric Effective Connectivity matrix (see Gilson et al. (2016)). Note that FC^{tau} , i.e. the lagged functional connectivity between pairs, lagged at tau s, breaks the symmetry and thus is fundamental for our purpose. Specifically, we compute the distance between the model FC simulated from

the current estimate of the effective connectivity and the empirical data FC^{emp} , as well as the simulated model FC^{tau} and empirical data FC^{tauemp} and adjust each effective connection (entry in the effective connectivity matrix) separately with a gradient-descent approach. The model is run repeatedly with the updated effective connectivity until the fit converges towards a stable value.

We can start with the anatomical connectivity obtained with probabilistic tractography from diffusion MRI (which might help the algorithm by utilising as a constraint connections known to be absent in the brain); or with a C matrix initialized to zero (which has a potential advantage that it is not influenced by possible errors in the diffusion tractography). The latter is implemented in our research for the reason given, but in practice the algorithm produced similar results with either method (Rolls et al., 2022a). The following procedure is used to update each entry C'_{ij} in the effective connectivity matrix

$$C'_{ij} = C_{ij} + \epsilon((FC^{\text{emp}}_{ij} - FC_{ij}) + (FC^{\text{tauemp}}_{ij} - FC^{\text{tau}}_{ij})) \quad (1.7)$$

where ϵ is a learning rate constant, and i and j are the (brain region) nodes. For the implementation, tau was set to 2 s. The maximum effective connectivity was set to a value of 0.2, and was found between V1 and V2.

1.14 Introduction to the fine structure of the cerebral neocortex

An important part of the approach to understanding how the cerebral cortex could implement its computational processes is to take into account as much as possible its fine structure and connectivity, as these provide important indicators of and constraints on how it computes. An introductory description is provided in this section (1.14), and a description that considers the operational / computational principles of neocortex, and compares them to pyriform cortex and hippocampal cortex, is provided by Rolls (2016b). A comparison of the network architecture and computations of the neocortex, cerebellum, and basal ganglia is provided in Section 17.5.5.

1.14.1 The fine structure and connectivity of the neocortex

The neocortex comprises most areas of the cerebral cortex apart from the hippocampal cortex and pyriform cortex, and most of the cortical regions shown in Figs. 1.9, 1.10 and 1.11. Different areas of the neocortex can be distinguished by the appearance of the cells (cytoarchitecture) and fibres or axons (myeloarchitecture), but nevertheless, the basic organization of the different neocortical areas has many similarities, and it is this basic organization that is considered here. Useful sources for more detailed descriptions of neocortical structure and function are the books in the series ‘Cerebral Cortex’ edited by Jones and Peters (Jones and Peters (1984) and Peters and Jones (1984)) and many other resources (Douglas, Markram and Martin, 2004; Shepherd, 2004; Shepherd and Grillner, 2010; da Costa and Martin, 2010; Harris and Mrsic-Flogel, 2013; Kubota, 2014; Harris and Shepherd, 2015; Shepherd and Rowe, 2017). The detailed understanding of the cell types and their patterns of connections is now benefitting from molecular markers (Harris and Shepherd, 2015; Bernard et al., 2012). Approaches to quantitative aspects of the connectivity are provided by Braitenberg and Schüz (1991), Braitenberg and Schüz (1998), Abeles (1991), and by Rolls (2016b). Some of the connections described in Sections 1.14.2 and 1.14.3 are shown schematically in Figs. 1.15 and 1.16. Further analysis of some of the computationally most relevant aspects of neocortical circuitry (see Fig. 1.17) are provided by Rolls (2016b).

Fig. 1.12 Dendritic morphology of excitatory neurons in S1 whisker barrel cortex. L4 IT shows the three morphological classes of L4 intratelencephalic (IT) neurons: pyramidal, star pyramidal and spiny stellate cells. Under IT are other intratelencephalic neurons of L2, L3, 5A/B and 6. PT shows pyramidal tract neurons of L5B. CT shows corticothalamic neurons of L6. (Adapted with permission from Marcel Oberlaender, Christiaan P.J. de Kock, Randy M. Bruno, Alejandro Ramirez, Hanno S. Meyer, Vincent J. Dercksen, Moritz Helmstaedter and Bert Sakmann (2012) Cell type-specific three-dimensional structure of thalamocortical circuits in a column of rat vibrissal cortex. *Cerebral Cortex* 22: 2375–2391. © Oxford University Press.)

1.14.2 Excitatory cells and connections

Some of the cell types found in the neocortex are shown in Fig. 1.1. Cells A–D are pyramidal cells. The dendrites (shown thick in Fig. 1.1) are covered in spines, which receive the excitatory synaptic inputs to the cell. Pyramidal cells with cell bodies in different laminae of the cortex (shown in Fig. 1.1 as I–VI) not only have different distributions of their dendrites, but also different distributions of their axons (shown thin in Fig. 1.1), which connect both within that cortical area and to other brain regions outside that cortical area (see labelling at the bottom of Fig. 1.15). Further examples of cell types, from S1 (somatosensory) rat whisker barrel cortex, are shown in Fig. 1.12 (Harris and Shepherd, 2015).

The main information-bearing afferents to a cortical area have many terminals in layer 4. (By these afferents, we mean primarily those from the thalamus; or for higher cortical regions from the preceding cortical region. We do not mean the cortico-cortical backprojections; nor the subcortical cholinergic, noradrenergic, dopaminergic, and serotonergic inputs, which are numerically minor, although they are important in setting cortical cell thresholds, excitability, and adaptation, see for example Douglas, Markram and Martin (2004).) In primary sensory cortical areas only, there are spiny stellate cells in a rather expanded layer 4, and the thalamic terminals synapse onto these cells (Lund, 1984; Martin, 1984; Douglas and Martin, 1990; Douglas, Markram and Martin, 2004; Levitt, Lund and Yoshioka, 1996; da Costa and Martin, 2013; Harris and Shepherd, 2015). (Primary sensory cortical areas receive their inputs from the primary sensory thalamic nucleus for a sensory modality. An example is the primate striate cortex which receives inputs from the lateral geniculate nucleus, which in turn receives inputs from the retinal ganglion cells. Spiny stellate cells are so-called because they have radially arranged, star-like, dendrites. Their axons usually terminate within the cortical area in which they are located.) Each thalamic axon makes 1,000–10,000 synapses, not more than several (or at most 10) of which are onto any one spiny stellate cell. In addition to these afferent terminals, there are some terminals of the thalamic afferents onto pyramidal cells with cell bodies in layers 6 and 3 (Martin, 1984) (and terminals onto inhibitory interneurons such as basket cells, which thus provide for a feedforward inhibition) (see Fig. 1.13). Even in layer 4, the thalamic axons provide less than 20% of the synapses. The number of thalamo-cortical connections received by a cortical cell is relatively low, in the range 18–191 (da Costa and Martin, 2013). The spiny stellate neurons in layer 4 have axons which terminate in layers 3 and 2, at least partly on dendrites of pyramidal cells with cell bodies in layers 3 and 2. (These synapses are of Type I, that is are asymmetrical and are on spines, so that they are

excitatory. Their transmitter is glutamate.) These layer 3 and 2 pyramidal cells provide the onward cortico-cortical projection with axons which project into layer 4 of the next cortical area. For example, layer 3 and 2 pyramidal cells in the primary visual (striate) cortex of the macaque monkey project into the second visual area (V2), layer 4.

In non-primary sensory areas, important information-bearing afferents from a preceding cortical area terminate in layer 4, but there are no or few spiny stellate cells in this layer (Lund, 1984; Levitt, Lund and Yoshioka, 1996). Layer 4 still looks ‘granular’ (due to the presence of many small cells), but these cells are typically small pyramidal cells (Lund, 1984). (It may be noted here that spiny stellate cells and small pyramidal cells are similar in many ways, with a few main differences including the absence of a major apical dendrite in a spiny stellate which accounts for its non-pyramidal, star-shaped, appearance; and for many spiny stellate cells, the absence of an axon that projects outside its cortical area.) The terminals presumably make synapses with these small pyramidal cells, and also presumably with the dendrites of cells from other layers, including the basal dendrites of deep layer 3 pyramidal cells (see Fig. 1.15).

The axons of the *superficial (layer 2 and 3) pyramidal cells* have collaterals and terminals in layer 5 (see Fig. 1.15), and synapses are made with the dendrites of the layer 5 pyramidal cells (Martin, 1984). The axons also typically project out of that cortical area, and on to the next cortical area in sequence, where they terminate in layer 4, forming the forward cortico-cortical projection. It is also from these pyramidal cells in some sensory regions that are high in the hierarchy that projections to the amygdala arise (Amaral, Price, Pitkanen and Carmichael, 1992).

The axons of the *layer 5 pyramidal cells* have many collaterals in layer 6 (see Fig. 1.1), where synapses could be made with the layer 6 pyramidal cells (based on indirect evidence, see Fig. 13 of Martin (1984)), and axons of these cells typically leave the cortex to project to subcortical sites (such as the striatum), or back to the preceding cortical area to terminate in layer 1. It is remarkable that there are as many of these backprojections as there are forward connections between two sequential cortical areas. The possible computational significance of this connectivity is considered in Chapter 9.

The *layer 6 pyramidal cells* have prolific dendritic arborizations in layer 4 (see Fig. 1.1), and some receive synapses from thalamic afferents (Martin, 1984) (but see Shepherd and Yamawaki (2021)), and also presumably from pyramidal cells in other cortical layers. The axons of these cells form backprojections to the thalamic nucleus which projects into that cortical area, and also axons of cells in layer 6 contribute to the backprojections to layer 1 of the preceding cortical area (see Jones and Peters (1984) and Peters and Jones (1984); see Figs. 1.1 and 1.15). Layer 6 pyramidal cells also project to layer 4, where thalamic afferents terminate. Layer 6 is thus closely related to the thalamus.

Although the pyramidal and spiny stellate cells form the great majority of neocortical neurons with excitatory outputs, there are in addition several further cell types (see Peters and Jones (1984), Chapter 4). Bipolar cells are found in layers 3 and 5, and are characterized by having two dendritic systems, one ascending and the other descending, which, together with the axon distribution, are confined to a narrow vertical column often less than 50 μm in diameter (Peters, 1984a). Bipolar cells form asymmetrical (presumed excitatory) synapses with pyramidal cells, and may serve to emphasize activity within a narrow vertical column.

1.14.3 Inhibitory cells and connections

There are a number of types of neocortical inhibitory neurons. All are described as smooth in that they have few spines, and use GABA (gamma-amino-butyric acid) as a transmitter. (In older terminology they were called Type II.) A number of types of inhibitory neuron

Fig. 1.13 Smooth (inhibitory) cells from cat visual cortex. (A) Chandelier or axoaxonic cell. (B) Large basket cell of layer 3. Basket cells, present in layers 3–6, have few spines on their dendrites so that they are described as smooth, and have an axon which participates in the formation of weaves of preterminal axons which surround the cell bodies of pyramidal cells and form synapses directly onto the cell body. (C) Small basket or clutch cell of layer 3. The major portion of the axonal arbor is confined to layer 4. (D) Double bouquet cell. The axon collaterals run vertically. The cortical layers are as indicated. Bar = 100 μm . (Adapted from Rodney Douglas, Henry Markram and Kevin Martin (2004) *Neocortex*. In Gordon M. Shepherd (ed), *The Synaptic Organization of the Brain* 5e, pp. 499–558. © Oxford University Press.)

can be distinguished, best by their axonal distributions (Szentagothai, 1978; Peters and Regidor, 1981; Douglas, Markram and Martin, 2004; Douglas and Martin, 2004; Shepherd and Grillner, 2010; Harris and Mrsic-Flogel, 2013). One type is the *basket cell*, present in layers 3–6, which has few spines on its dendrites so that it is described as smooth, and has an axon that participates in the formation of weaves of preterminal axons which surround the cell bodies of pyramidal cells and form synapses directly onto the cell body, but also onto the dendritic spines (Somogyi, Kisvarday, Martin and Whitteridge, 1983) (Fig. 1.13). Basket cells comprise 5–7% of the total cortical cell population, compared with approximately 72% for pyramidal cells (Sloper and Powell, 1979b,a). Basket cells receive synapses from the main extrinsic afferents to the neocortex, including thalamic afferents (Fig. 1.13), so that they must contribute to a feedforward type of inhibition of pyramidal cells. The inhibition is feedforward in that the input signal activates the basket cells and the pyramidal cells by independent routes, so that the basket cells can produce inhibition of pyramidal cells that does not depend on whether the pyramidal cells have already fired. Feedforward inhibition of this type not only enhances stability of the system by damping the responsiveness of the pyramidal cell simultaneously with a large new input, but can also be conceived of as a mechanism which normalizes the magnitude of the input vector received by each small region of neocortex (see further Appendix B). In fact, the feedforward inhibitory mechanism allows the pyramidal cells to be set at the appropriate sensitivity for the input they are about to receive. Basket cells can also be polysynaptically activated by an afferent volley in the thalamo-cortical projection (Martin, 1984), so that they may receive inputs from pyramidal cells, and thus participate in feedback inhibition of pyramidal cells.

The transmitter used by the basket cells is gamma-amino-butyric acid (GABA), which

Fig. 1.14 Classes of neocortical inhibitory interneuron.

Parvalbumin-expressing interneurons (PVs) are capable of firing rapidly and with high temporal precision. They consist of two main subgroups: basket cells (BCs) that target the soma and proximal dendrites of principal cells (typically pyramidal cells shown in green), and chandelier cells (ChCs) that target the axon initial segment. PV cells receive strong excitatory inputs from thalamus and cortex, as well as inhibition from other PVs. A key role of these cells is to stabilize the activity of cortical networks using negative feedback: their absence leads to epileptiform activity, whereas more moderate chronic dysfunction of these cells has been implicated in diseases such as schizophrenia.

Somatostatin-expressing interneurons (SOMs) consist largely of Martinotti cells that target the tuft dendrites of principal cells, as well as inhibiting other interneurons. Consistent with their targeting of dendritic tufts, these cells have been implicated in behavior-dependent control of dendritic integration, as well as in more general lateral inhibition. Connections from principal cells to SOMs show facilitating synapses. In contrast to PVs, SOMs receive the majority of their input from local principal cells but little inhibition or thalamic drive.

5HT_{3A}-receptor-expressing interneurons are the most numerous interneuron of the superficial layers. They contain two prominent subgroups: neurogliaform cells (NGs), which are thought to release GABA by volume transmission; and cells that express vasoactive intestinal peptide (VIP) and preferentially target SOMs. Putative 5HT_{3A}-receptor-expressing cells have been implicated in the control of cortical circuits by higher-order cortex and the thalamus. (Reproduced from Harris, K.D. and Mrsic-Flogel, T.D. (2013) Cortical connectivity and sensory coding. *Nature* 503: 51–58, Copyright © Springer Nature Limited.)

opens chloride channels in the postsynaptic membrane. Because the reversal potential for Cl^- is approximately -10 mV relative to rest, opening the Cl^- channels does produce an inhibitory postsynaptic potential (IPSP), which results in some hyperpolarization, especially in the dendrites. This is a subtractive effect, hence it is a linear type of inhibition (Douglas and Martin, 1990; Douglas, Markram and Martin, 2004). However, a major effect of the opening of the Cl^- channels in the cell body is that this decreases the membrane resistance, thus producing a shunting effect. The importance of shunting is that it decreases the magnitude of excitatory postsynaptic potentials (EPSPs) (cf. Andersen, Dingledine, Gjerstad, Langmoen and Laursen (1980) for hippocampal pyramidal cells), so that the effect of shunting is to produce division (i.e. a multiplicative reduction) of the excitatory inputs received by the cell, and not just to act by subtraction (see further Bloomfield (1974), Martin (1984), Douglas and

Martin (1990)). Thus, when modelling the normalization of the activity of cortical pyramidal cells, it is common to include division in the normalization function (cf. Appendix B). It is notable that the dendrites of basket cells can extend laterally 0.5 mm or more (primarily within the layer in which the cell body is located), and that the axons can also extend laterally from the cell body 0.5–1.5 mm. Thus the basket cells produce a form of lateral inhibition which is quite spatially extensive. There is some evidence that each basket cell may make 4–5 synapses with a given pyramidal cell, that each pyramidal cell may receive from 10–30 basket cells, and that each basket cell may inhibit approximately 300 pyramidal cells (Martin, 1984; Douglas and Martin, 1990; Douglas, Markram and Martin, 2004). The basket cells are sometimes called clutch cells.

A second type of GABA-containing inhibitory interneuron is the *axoaxonic* (or ‘*chandelier*’) cell, named because it synapses onto the initial segment of the axon of pyramidal cells. The pyramidal cells receiving this type of inhibition are almost all in layers 2 and 3, and much less in the deep cortical layers. One effect that axoaxonic cells probably produce is thus prevention of outputs from layer 2 and 3 pyramidal cells reaching the pyramidal cells in the deep layers, or from reaching the next cortical area. Up to five axoaxonic cells converge onto a pyramidal cell, and each axoaxonic cell may project to several hundred pyramidal cells scattered in a region that may be several hundred microns in length (Martin, 1984; Peters, 1984b). This implies that axoaxonic cells provide a rather simple device for preventing runaway over-activity of pyramidal cells, but little is known yet about the afferents to axoaxonic cells, so that the functions of these neurons are very incompletely understood.

A third type of (usually smooth and inhibitory) cell is the *double bouquet cell*, which has primarily vertically organized axons. These cells have their cell bodies in layer 2 or 3, and have an axon traversing layers 2–5, usually in a tight bundle consisting of varicose, radially oriented collaterals often confined to a narrow vertical column 50 μm in diameter (Somogyi and Cowey, 1984). Double bouquet cells receive symmetrical, type II (presumed inhibitory) synapses, and also make type II synapses, perhaps onto the apical dendrites of pyramidal cells, so that these neurons may serve, by this double inhibitory effect, to emphasize activity within a narrow vertical column.

An overview of neocortical inhibitory neurons is shown in Fig. 1.14.

1.14.4 Quantitative aspects of cortical architecture

Some quantitative aspects of cortical architecture are described, because, although only preliminary data are available, they are crucial for developing an understanding of how the neocortex could work. Further evidence is provided by Braitenberg and Schüz (1991), and by Abeles (1991). Typical values, many of them after Abeles (1991), are shown in Table 1.8. The figures given are for a rather generalized case, and indicate the order of magnitude. The number of synapses per neuron (20,000) is an estimate for monkeys; those for humans may be closer to 40,000, and for the mouse, closer to 8,000. The number of 18,000 excitatory synapses made by a pyramidal cell is set to match the number of excitatory synapses received by pyramidal cells, for the great majority of cortical excitatory synapses are made from axons of cortical, principally pyramidal, cells.

Microanatomical studies show that pyramidal cells rarely make more than one connection with any other pyramidal cell, even when they are adjacent in the same area of the cerebral cortex. An interesting calculation takes the number of local connections made by a pyramidal cell within the approximately 1 mm of its local axonal arborization (say 9,000), and the number of pyramidal cells with dendrites in the same region, and suggests that the probability that a pyramidal cell makes a synapse with its neighbour is low, approximately 0.1 (Braitenberg and Schüz, 1991; Abeles, 1991) (see further Hill et al. (2012) and Markram et al.

Table 1.8 Typical quantitative estimates for neocortex reflecting estimates in macaques. (Some of the information in this Table is adapted from M. Abeles, *Corticonics, Neural Circuits of the Cerebral Cortex*, p. 59, Table 1.5.4, Copyright © 1991, Cambridge University Press. Human data from Bethlehem et al. (2022)).

Neuronal density	20,000–40,000/mm ³
Neuronal composition:	
Pyramidal	75%
Spiny stellate	10%
Inhibitory neurons, for example smooth stellate, chandelier	15%
Synaptic density	8 x 10 ⁸ /mm ³
Numbers of synapses on pyramidal cells:	
Excitatory synapses from remote sources onto each neuron	9,000
Excitatory synapses from local sources onto each neuron	9,000
Inhibitory synapses onto each neuron	2,000
Pyramidal cell dendritic length	10 mm
Number of synapses made by axons of pyramidal cells	18,000
Number of synapses on inhibitory neurons	2,000
Number of synapses made by inhibitory neurons	300
Dendritic length density	400 m/mm ³
Axonal length density	3,200 m/mm ³
Typical cortical thickness	2 mm (3 mm in humans)
Cortical area	
human	150,000 mm ²
macaque (assuming 2 mm for cortical thickness)	30,000 mm ²
rat (assuming 2 mm for cortical thickness)	300 mm ²

(2015)). This fits with the estimate from simultaneous recording of nearby pyramidal cells using spike-triggered averaging to monitor time-locked EPSPs (Abeles, 1991; Thomson and Deuchars, 1994).

Now the implication of the pyramidal cell to pyramidal cell connectivity just described is that within a cortical area of perhaps 1 mm², the region within which typical pyramidal cells have dendritic trees and their local axonal arborization, there is a probability of excitatory-to-excitatory cell connection of 0.1. Moreover, this population of mutually interconnected neurons is served by ‘its own’ population of inhibitory interneurons (which have a spatial receiving and sending zone in the order of 1 mm²), enabling local threshold setting and optimization of the set of neurons with ‘high’ (0.1) connection probability in that region. Such an architecture is effectively recurrent or re-entrant. It may be expected to show some of the properties of recurrent networks, including the fast dynamics described in Appendix B. Such fast dynamics may be facilitated by the fact that cortical neurons in the awake behaving monkey generally have a low spontaneous rate of firing of a few spikes/s (personal observations; see for example Rolls and Tovee (1995b), Rolls, Treves, Tovee and Panzeri (1997d), and Franco, Rolls, Aggelopoulos and Jerez (2007)), which means that even any small additional input may produce some spikes sooner than would otherwise have occurred, because some of the neurons may be very close to a threshold for firing. It might also show some of the autoassociative retrieval of information typical of autoassociation networks, if the synapses between the nearby pyramidal cells have the appropriate (Hebbian) modifiability. In this context, the value of 0.1 for the probability of a connection between nearby neocortical pyramidal cells is of interest, for the connection probability between hippocampal CA3 pyramidal is approximately 0.02–0.04, and this is thought to be sufficient to sustain associative retrieval (see

Appendix B, Rolls and Treves (1998), and Rolls (2012b)). The role of this diluted connectivity of the recurrent excitatory synapses between nearby neocortical pyramidal cells and between hippocampal CA3 cells as underlying a principle of operation of the cerebral cortex is considered by Rolls (2016b).

In the neocortex, each 1 mm² region within which there is a relatively high density of recurrent collateral connections between pyramidal cells probably overlaps somewhat continuously with the next. This raises the issue of modules in the cortex, described by many authors as regions of the order of 1 mm² (with different authors giving different sizes), in which there are vertically oriented columns of neurons that may share some property (for example, responding to the same orientation of a visual stimulus), and that may be anatomically marked (for example (Powell, 1981; Mountcastle, 1984; Douglas et al., 1996; da Costa and Martin, 2010)). The anatomy just described, with the local connections between nearby (1 mm) pyramidal cells, and the local inhibitory neurons, may provide a network basis for starting to understand the columnar architecture of the neocortex, for it implies that local recurrent connectivity on this scale implementing local re-entrancy is a feature of cortical computation. We can note that the neocortex could not be a single, global, autoassociation network, because the number of memories that could be stored in an autoassociation network, rather than increasing with the number of neurons in the network, is limited by the number of recurrent connections per neuron, which is in the order of 10,000 (see Table 1.8), or less, depending on the species, as pointed out by O’Kane and Treves (1992). This would be an impossibly small capacity for the whole cortex. It is suggested that instead a principle of cortical design is that it does have in part local connectivity, so that each part can have its own processing and storage, which may be triggered by other modules, but is a distinct operation from that which occurs simultaneously in other modules Rolls (2016b).

An interesting parallel between the hippocampus and any small patch of neocortex is the allocation of a set of many small excitatory (usually non-pyramidal, spiny stellate or granular) cells at the input side. In the neocortex this is layer 4, in the hippocampus the dentate gyrus Rolls (2016b). In both cases, these cells receive the feedforward inputs and relay them to a population of pyramidal cells (in layers 2–3 of the neocortex and in the CA3 field of the hippocampus) which have extensive recurrent collateral connections. In both cases, the pyramidal cells receive inputs both as relayed by the preprocessing array and directly. Such analogies might indicate that the functional roles of neocortical layer 4 cells and of dentate granule cells could be partially the same Rolls (2016b).

The short-range high density of connectivity may also contribute to the formation of cortical topographic maps, as described in Section B.4.6. This may help to ensure that different parameters of the input space are represented in a nearly continuous fashion across the cortex, to the extent that the reduction in dimensionality allows it; or when preserving strict continuity is not possible, to produce the clustering of cells with similar response properties, as illustrated for example by color ‘blobs’ in striate cortex, or by the local clustering of face cells in the temporal cortical visual areas (Rolls, 2007e, 2008b, 2011d, 2012d).

1.14.5 Functional pathways through the cortical layers

Because of the complexity of the circuitry of the cerebral cortex, some of which is summarized in Figs. 1.15, 1.16 and 1.17, there are only preliminary indications available now of how information is processed through cortical layers and between cortical areas (da Costa and Martin, 2010; Harris and Mrsic-Flogel, 2013; Harris and Shepherd, 2015; Rolls, 2016b). For the following description, reference should be made to Figs. 1.15, 1.16 and 1.17.

In primary sensory cortical areas, the main extrinsic ‘forward’ input is from the thalamus, and ends in layer 4, where synapses are formed onto spiny stellate cells. These in turn project

Fig. 1.15 Basic circuit for visual cortex. Excitatory neurons, which are spiny and use glutamate as a transmitter, and include the pyramidal and spiny stellate cells, are indicated by open somata; their axons are indicated by solid lines, and their synaptic boutons by open symbols. Inhibitory (smooth, GABAergic) neurons are indicated by black (filled) somata; their axons are indicated by dotted lines, and their synaptic boutons by solid symbols. thal, thalamus; cx, cortex; sub-cx, subcortex. Cortical layers 1–6 are as indicated. (Adapted from Rodney Douglas, Henry Markram and Kevin Martin (2004) Neocortex. In Gordon M. Shepherd (ed), *The Synaptic Organization of the Brain* 5e, pp. 499–558. © Oxford University Press.)

heavily onto pyramidal cells in layers 3 and 2, which in turn send projections forward to the next cortical area. The situation is made more complex than this by the fact that the thalamic afferents also synapse onto the basal dendrites in or close to the layer 2 pyramidal cells, as well as onto layer 6 pyramidal cells and inhibitory interneurons. Given that the functional implications of this particular architecture are not fully clear, it would be of interest to examine the strength of the functional links between thalamic afferents and different classes of cortical cell using cross-correlation techniques, to determine which neurons are strongly activated by thalamic afferents with monosynaptic or polysynaptic delays. Given that this is technically difficult, an alternative approach has been to use electrical stimulation of the thalamic afferents to classify cortical neurons as mono- or poly-synaptically driven, then to examine the response properties of the neuron to physiological (visual) inputs, and finally to fill the cell with horseradish peroxidase so that its full structure can be studied (see for example Martin (1984)). Using these techniques, it has been shown in the cat visual cortex that spiny stellate cells can indeed be driven monosynaptically by thalamic afferents to the cortex. Further, many of these neurons have S-type receptive fields, that is they have distinct on and off regions of the receptive field, and respond with orientation tuning to elongated visual stimuli (Martin, 1984) (see Rolls and Deco (2002)). Further, consistent with the anatomy just described, pyramidal cells in the deep part of layer 3, and in layer 6, could also be monosynaptically activated by thalamic afferents, and had S-type receptive fields (Martin, 1984). Also consistent with the anatomy just described, pyramidal cells in layer 2 were di- (or poly-) synaptically activated by stimulation of the afferents from the thalamus, but also had S-type receptive fields.

In contrast to these ‘core’ thalamo-cortical inputs to primary sensory cortical areas which

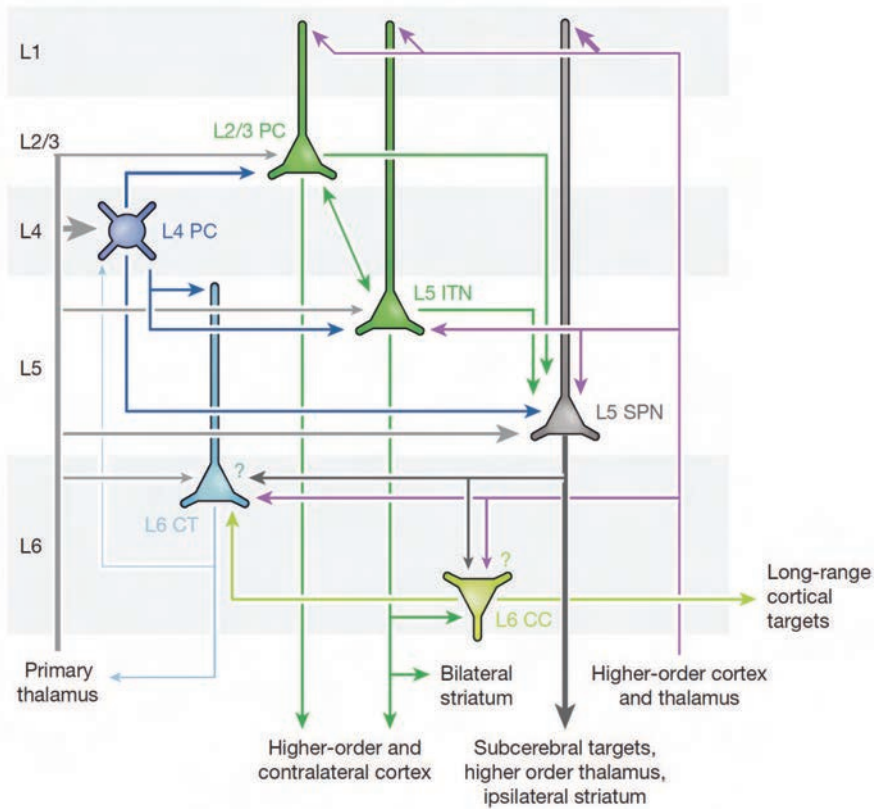

Fig. 1.16 Canonical connectivity of cortical principal cells. Line thickness represents the strength of a pathway. Sensory information arrives from primary thalamus into all cortical layers, but most densely into L4 and the L5–L6 border. Contextual inputs from higher-order cortex and thalamus most densely target L1, L5 and L6, but avoid L4. L4 principal cells comprise two morphological classes, pyramidal and spiny stellate cells. L4 principal cells project to all layers, but most strongly L2/3. However they receive little intracolumnar input in return. L2/3 principal cells send outputs L5, and to the next cortical area in the hierarchy L4. Upper L5 (L5A) ‘Intratelencephalic neurons’ project locally upward to L2/3 and to the striatum and send backprojections to the preceding cortical area in the hierarchy. They show firing rate adaptation. Lower L5 (L5B) ‘Subcerebral projection neurons’ (SPNs) are larger cells with prominent dendritic tufts in L1. They project to subcerebral motor centres for example via the pyramidal tract, and send collaterals to the striatum and higher-order thalamus with large, strong ‘driver’ synapses. They show little adaptation, and may fire in bursts. L6 Corticothalamic cells (CTs) send projections to the thalamus which, unlike those of L5 SPNs, are weak, and target the reticular and specific thalamic nuclei. Corticothalamic cells also project to cortical layer 4, where they strongly target interneurons, as well as hyperpolarizing principal cells via group II mGluRs (metabotropic glutamate receptors). Consistent with this connectivity, optogenetic stimulation of L6 *in vivo* suppresses cortical activity, suggesting a role of this layer in gain control or translaminar inhibition. (Reproduced from Harris, K.D. and Mrsic-Flogel, T.D. (2013). Cortical connectivity and sensory coding. *Nature* 503: 51–58. Copyright © Springer Nature.)

carry the main input to such cortical areas, ‘matrix’ thalamo-cortical connections from higher-order thalamic nuclei project to non-primary cortical areas, further up in the hierarchy (Harris and Shepherd, 2015). In higher cortical areas, the main inputs that drive the cortex come instead from the preceding cortical area in a hierarchy, and not from the ‘matrix’ thalamic nucleus (Harris and Shepherd, 2015; Shepherd and Yamawaki, 2021).

Inputs could reach the layer 5 pyramidal cells from the pyramidal cells in layers 2 and 3, the axons of which ramify extensively in layer 5, in which the layer 5 pyramidal cells have widespread basal dendrites (see Fig. 1.1), and also perhaps from thalamic afferents. Many layer 5 pyramidal cells are di- or trisynaptically activated by stimulation of the thalamic af-

ferents, consistent with them receiving inputs from monosynaptically activated deep layer 3 pyramidal cells, or from disynaptically activated pyramidal cells in layer 2 and upper layer 3 (Martin, 1984). Upper L5 (L5A) ‘Intratelencephalic neurons’ project locally upward to L2/3 and to the striatum and send backprojections to the preceding cortical area in the hierarchy. They show firing rate adaptation (i.e. their firing rates gradually decrease over short time periods). Lower L5 (L5B) ‘Subcerebral projection neurons’ (SPNs) are larger cells with prominent dendritic tufts in L1. They project to subcerebral motor centres for example via the pyramidal tract, and send collaterals to the striatum and higher-order thalamus with large, strong ‘driver’ synapses (Harris and Mrsic-Flogel, 2013; Harris and Shepherd, 2015). They may also provide some cortico-cortical backprojections, which terminate in superficial layers of the cerebral cortex, including layer 1 (see Rolls (2016b)). They show little adaptation, and may fire in bursts. These neurons may have a less sparse representation than those in L2/3, with this representation being useful for high information transmission. (In contrast, the more sparse representation in L2/L3 pyramidal cells may be useful when information is being stored in the recurrent collaterals, for this maximizes the number of patterns that can be stored and correctly retrieved. This may be one reason why the cerebral neocortex has superficial pyramidal cell layers (L2/L3) which are separate from the deep pyramidal cell layers (L5/L6) (see further Rolls (2016b) and Rolls and Mills (2017)).

L6 Corticocortical cells (CCs) have small dendritic trees, and long-range horizontal axons. L6 Corticothalamic cells (CTs) send projections to the thalamus which, unlike those of L5 Subcerebral projection neurons (typically pyramidal tract neurons), are weak, and target the reticular nucleus, and a particular thalamic nucleus which then sends thalamo-cortical connections back to the cortical region that connects to that part of the thalamus. Some of these are pyramidal tract neurons. One type of thalamo-cortical neuron described as ‘matrix’ type (found typically in thalamic regions that project to non-primary sensory / association cortical areas (Harris and Shepherd, 2015)) sends connections to L2/3 and L5A pyramidal cells, which then connect to cortico-thalamic cells (Shepherd and Yamawaki, 2021). This thus forms a loop with excitatory synapses throughout, so control by inhibitory neurons is needed, but the CT influence on thalamic cells is weak, so this may not be a strong positive feedback loop (Shepherd and Yamawaki, 2021). Corticothalamic cells have low conduction speed, so their effect is slow. Matrix type thalamocortical cells also project to cortical layer 1 (Harris and Shepherd, 2015). Corticothalamic cells also project to cortical layer 4, where they strongly target interneurons, as well as hyperpolarizing principal cells via group II mGluRs. Consistent with this connectivity, optogenetic stimulation of L6 *in vivo* suppresses cortical activity, suggesting a role of this layer in gain control or translaminar inhibition (Harris and Mrsic-Flogel, 2013). The cortico-thalamic connections involving CT cells may accordingly be for some type of control function, rather than performing any new computation (by which I mean for example autoassociation, pattern association, or competitive learning). In many types of behavior, CT cells are rather silent, so their function is a mystery (Harris and Shepherd, 2015; Shepherd and Yamawaki, 2021).

What Fig. 1.16 does not bring out is what I consider to be the key anatomical and computational feature of the cortex, excitatory connections between pyramidal cells implemented by the recurrent collateral connections (Rolls, 2016b, 2021c). These are shown for neocortex in the canonical neocortical circuit of Rolls (2016b) (Fig. 1.17). The recurrent collateral connections are associatively modifiable. The concept is that this anatomy and physiology provides for what computationally are attractor networks (Section B.3), which provide the neocortex with its key computational properties of implementing a local short-term memory that can be implemented by ongoing firing, providing the basis for planning; and semantic networks, which enable attributes of individual objects or people to be associated with the individual. In neocortex, the anatomical evidence suggests that there are separate attractor networks in

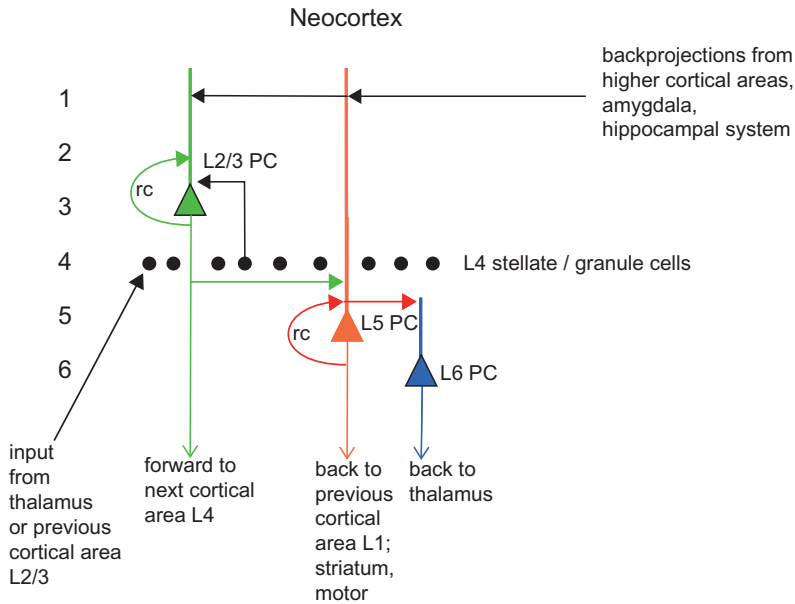

Fig. 1.17 Functional canonical microcircuit of the neocortex (see text). The cortical layers are numbered 1–6, with layer 1 at the surface of the cortex, and layer 6 adjacent to the white matter consisting of axonal connections to other brain areas. Recurrent collateral connections (rc) are shown as a loop back to a particular population of cells, of which just one neuron is shown in this and Figs. 5.7 and 9.22. In primates the feedforward projection neurons are concentrated in L3B; and the main feedback projection neurons are in L6 and Lower L5 (L5B), but some L2 and L3A neurons do send backprojections (Markov et al 2014b). Some L6 cortico-thalamic neurons send a projection to L4 (see text). (From Rolls, E. T. (2016) *Cerebral Cortex: Principles of Operation*. Oxford University Press: Oxford.)

the superficial layers (2 and 3), and in the deep layers (layer 5) (Rolls, 2016b). These may be specialised for somewhat different functions, with the superficial attractor networks involved in the main feedforward computations from area to area of the cerebral cortex; and the deep layer specialised for outputs to motor and related structures such as the striatum, and for backprojections to the preceding cortical area (Rolls and Mills, 2017), consistent with what is shown in Fig. 1.17.

A key feature of the neocortical recurrent collateral system is that it is local, extending just several mm from any given neuron. This provides a basis for separate attractor networks in nearby cortical regions spaced only several mm apart, and this is necessary to provide for high memory capacity of the whole neocortex, made possible by the partial independence of the local attractors. Without this relative independence of nearby attractors, the total memory capacity of the cortex would be determined by the leading term of the number of recurrent collateral synapses onto any one neuron, as described in Section B.3 (O’Kane and Treves, 1992). Because the recurrent collaterals are local, the total memory capacity of the cortex is the number of memories that could be stored in any one local attractor network (of order 10,000, if the number C of recurrent collaterals onto each pyramidal cell is 10,000), multiplied by the number of local attractor networks in the cortex, divided by a factor of 2–3 due to interference between nearby attractors with some overlap of anatomical connectivity as one moves across the cortical sheet (Roudi and Treves, 2006, 2008). If the human neocortical surface area is of order 1,900 cm², and each local neocortical attractor has a diameter of 3 mm (and thus an area of approximately 7 mm²), then the number of independent attractor networks would be approximately 27,000, each with a memory capacity of at least several thousand items. The locality of the recurrent collaterals in the neocortex also means that it tends to support topological maps (Section B.4.6), with this locality of neocortical processing

in turn contributing to the convergence from area to area as one moves up a cortical hierarchy (Rolls, 2016b).

This fundamental aspect of neocortical architecture and principle of operation, its locality, is in complete contrast to the hippocampus as described in Chapter 9 in which the CA3 cells provide a single attractor network so that any item can be associated with any other item to form an episodic memory (Fig. 9.22); and with the olfactory pyriform cortex as described in Section 5.3.2 (see Fig. 5.7) in which there is no topology in the input space of odors as represented in the glomeruli of the olfactory bulb, so that associations may need to be found throughout the olfactory space. The locality of the dense recurrent collateral excitatory connections between pyramidal cells is a fundamental principle of the evolution and operation of the neocortex.

Further consideration of how computations are performed by cortical circuitry are provided in Section B.18, and by Rolls (2016b), Rolls and Mills (2017), and Rolls (2021c).

Studies on the function of inhibitory pathways in the cortex are also beginning. The fact that basket cells often receive strong thalamic inputs, and that they terminate on pyramidal cell bodies where part of their action is to shunt the membrane, suggests that they act in part as a feedforward inhibitory system that normalizes the thalamic influence on pyramidal cells by dividing their response in proportion to the average of the thalamic input received (see Appendix B). The smaller and numerous smooth (or sparsely spiny) non-pyramidal cells that are inhibitory may receive inputs from pyramidal cells as well as inhibit them, so that these neurons could perform the very important function of recurrent or feedback inhibition (see Appendix B). It is only feedback inhibition that can take into account not only the inputs received by an area of cortex, but also the effects that these inputs have, once multiplied by the synaptic weight vector on each neuron, so that recurrent inhibition is necessary for competition and contrast enhancement (see Appendix B).

Another way in which the role of inhibition in the cortex can be analyzed is by applying a drug such as bicuculline using iontophoresis (which blocks GABA receptors to a single neuron), while examining the response properties of the neuron (see Sillito (1984)). With this technique, it has been shown that in the visual cortex of the cat, layer 4 simple cells lose their orientation and directional selectivity. Similar effects are observed in some complex cells, but the selectivity of other complex cells may be less affected by blocking the effect of endogenously released GABA in this way (Sillito, 1984). One possible reason for this is that the inputs to complex cells must often synapse onto the dendrites far from the cell body, and distant synapses will probably be unaffected by the GABA receptor blocker released near the cell body. The experiments reveal that inhibition is very important for the normal selectivity of many visual cortex neurons for orientation and the direction of movement. Many of the cells displayed almost no orientation selectivity without inhibition. This implies that not only is the inhibition important for maintaining the neuron on an appropriate part of its activation function, but also that lateral inhibition between neurons is important because it allows the responses of a single neuron (which need not be markedly biased by its excitatory input) to have its responsiveness set by the activity of neighbouring neurons (see Appendix B).

1.14.6 The scale of lateral excitatory and inhibitory effects, and the concept of modules

The forward cortico-cortical afferents to a cortical area sometimes have a columnar pattern to their distribution, with the column width 200–300 μm in diameter (see Eccles (1984)). Similarly, individual thalamo-cortical axons often end in patches in layer 4 which are 200–300 μm in diameter (Martin, 1984). The dendrites of spiny stellate cells are in the region of 500 μm in diameter, and their axons can distribute in patches 200–300 μm across, separated by distances

of up to 1 mm (Martin, 1984). The dendrites of layer 2 and 3 pyramidal cells can be approximately $300\ \mu\text{m}$ in diameter, but after this the relatively narrow column appears to become less important, for the axons of the superficial pyramidal cells can distribute over 1 mm or more, both in layers 2 and 3, and in layer 5 (Martin, 1984). Other neurons that may contribute to the maintenance of processing in relatively narrow columns are the double bouquet cells, which because they receive inhibitory inputs, and themselves produce inhibition, all within a column perhaps $50\ \mu\text{m}$ across (see above), would tend to enhance local excitation. The bipolar cells, which form excitatory synapses with pyramidal cells, may also serve to emphasize activity within a narrow vertical column approximately $50\ \mu\text{m}$ across. These two mechanisms for enhancing local excitation operate against a much broader-ranging set of lateral inhibitory processes, and could it is suggested have the effect of increasing contrast between the firing rates of pyramidal cells $50\ \mu\text{m}$ apart, and thus be very important in competitive interactions between pyramidal cells. Indeed, the lateral inhibitory effects are broader than the excitatory effects described so far, in that for example the axons of basket cells spread laterally $500\ \mu\text{m}$ or more (see above) (although those of the small, smooth non-pyramidal cells are closer to $300\ \mu\text{m}$ – see Peters and Saint Marie (1984)). Such short-range local excitatory interactions with longer range inhibition not only provide for contrast enhancement and for competitive interactions, but also can result in the formation of maps in which neurons with similar responses are grouped together and neurons with dissimilar response are more widely separated (see Appendix B). Thus these local interactions are consistent with the possibilities that cortical pyramidal cells form a competitive network (see Appendix B and below), and that cortical maps are formed at least partly as a result of local interactions of this kind in a competitive network (see Section B.4.6).

The type of genetic specification that could provide the fundamental connectivity rules between cortical areas, which would then self-organize the details of the exact synaptic connectivity, have been considered by Rolls and Stringer (2000). They compared the connectivity of different cortical areas, thereby suggested a set of rules that the genes might be specifying, and then simulated using genetic algorithms the selection of the appropriate rules for solving particular types of computational problem, including pattern association memory, autoassociation memory, and competitive learning (see Rolls (2016b) and Section B.20). Although molecular studies are making progress in studying categories of cortical neurons based on their genetic signature (Zeisel et al., 2018), these approaches have not yet focussed on the key question of the few genes that specify the connections of each cortical area that enable the classes of neuron in one cortical area to recognise the classes of neuron in other cortical areas with which they should make connections (Rolls and Stringer, 2000).

In contrast to the relatively localized terminal distributions of forward cortico-cortical and thalamo-cortical afferents, the cortico-cortical backward projections that end in layer 1 have a much wider horizontal distribution, of up to several millimetres (mm). It is suggested that this enables the backward-projecting neurons to search over a larger number of pyramidal cells in the preceding cortical area for activity that is conjunctive with their own (Rolls, 2016b, 2021c).

2 The ventral visual system

2.1 Introduction and overview

2.1.1 Introduction

Information in the ‘*ventral or what*’ visual cortical processing stream projects after the primary visual cortex, area V1, to the secondary visual cortex (V2), and then via area V4 to the posterior and then to the anterior inferior temporal visual cortex (see Figs. 1.8, 2.1, and 2.3). The ventral visual system performs invariant visual object recognition, that is, it encodes objects by the level of the anterior inferior temporal cortex, and the representation is relatively invariant with respect to where for example the object is on the retina, its size, and even for some neurons its view. That makes the output of this system ideal as an input to memory systems and for systems that learn the reward value of visual stimuli, for if the output system learns something about the object when one transform is shown (e.g. one view), then the learning automatically generalizes to other transforms. That is a key computation performed by this system. We start with overviews: first about what is computed, and then about how it is computed.

2.1.2 Overview of what is computed in the ventral visual system

What is computed in the ventral visual system is described in Sections 2.1.4 to 2.4 with an overview here.

1. The primate retina has a fovea with closely packed cones and ganglion cells that provide for high visual acuity at the fovea (Rolls and Cowey, 1970). This shapes the computations performed in the ventral visual system, and indeed in systems such as the hippocampus and orbitofrontal cortex that receive from the ventral visual system. Object recognition of typically one or a very few objects is performed primarily with the high resolution fovea when an object is being fixated. This greatly simplifies visual object recognition, because the whole scene does not have to be processed simultaneously, as occurs in some artificial vision systems. The extrafoveal retina is used more to attract attention, so that the eyes move to foveate the stimulus in order to identify it. Foveal vision thus requires mechanisms to saccade to fixate on objects, and to track moving objects to keep them on the fovea, and these mechanisms are implemented in the dorsal visual system and superior colliculus.
2. The retina provides a pixel-based representation in retinal coordinates, which has no transform invariances, and moreover which changes greatly whenever an object moves even a small amount on the retina, and when the eyes move even a little. That means that a major computation is needed in the ventral visual system, to produce a transform-invariant representation of objects, faces, etc that can be read off easily by other brain systems.
3. The retinal pixel-level representation is passed by the lateral geniculate nucleus of the thalamus, which provides some further lateral inhibition to that already implemented between the retinal ganglion cells for high-pass spatial frequency filtering, useful for contrast enhancement of boundaries and contrast equalization over different parts of retinal space.

Fig. 2.1 Lateral view of the macaque brain showing the connections in the ‘ventral or what visual pathway’ from V1 to V2, V4, the inferior temporal visual cortex, etc., with some connections reaching the amygdala and orbitofrontal cortex. as, arcuate sulcus; cal, calcarine sulcus; cs, central sulcus; lf, lateral (or Sylvian) fissure; lun, lunale sulcus; ps, principal sulcus; io, inferior occipital sulcus; ip, intraparietal sulcus (which has been opened to reveal some of the areas it contains); sts, superior temporal sulcus (which has been opened to reveal some of the areas it contains). AIT, anterior inferior temporal cortex; FST, visual motion processing area; LIP, lateral intraparietal area; MST, visual motion processing area (also called V5); OFC, orbitofrontal cortex; PIT, posterior inferior temporal cortex; STP, superior temporal plane; TA, architectonic area including auditory association cortex; TE, architectonic area including high order visual association cortex, and some of its subareas TEa and TEb; TG, architectonic area in the temporal pole; V1–V4, visual areas 1–4; VIP, ventral intraparietal area; TEO, architectonic area including posterior visual association cortex. The numbers refer to architectonic areas, and have the following approximate functional equivalence: 1, 2, 3, somatosensory cortex (posterior to the central sulcus); 4, motor cortex; 5, superior parietal lobule; 7a, inferior parietal lobule, visual part; 7b, inferior parietal lobule, somatosensory part; 6, lateral premotor cortex; 8, frontal eye field; 12, inferior convexity prefrontal cortex; 46, dorsolateral prefrontal cortex.

4. The primary visual cortex converts the circular centre-surround receptive field representation received from the lateral geniculate nucleus into a massively expanded new representation in which the receptive fields are elongated so that the neurons respond to bars or edges with a given orientation and size / spatial frequency. The expansion of neuron numbers helps to decorrelate the representation provided across neurons of retinal inputs, which in turn helps in the process of forming neurons that respond to low-order combinations of features (such as a horizontal and vertical edge that join) at subsequent levels of visual processing. Binocular neurons are formed.
5. V2 neurons have larger receptive fields (typically 2 deg) than those in V1 (typically 1 deg), and V4 neurons have large receptive fields (typically 4 deg). Neurons in V2 and V4 respond to more complex shapes than those in V1. Some respond to visual texture, and some respond to both shape and texture, which may be useful for segregating objects from their background. V2 and V4 neurons are often tuned to stereoscopic depth, and/or to color.
6. Posterior inferior temporal visual cortex neurons (BA 20, TEO) have larger receptive fields, but are still not very translation invariant, in that small eye movements to a different position result in different sets of neurons being active.
7. Rolls and colleagues discovered many of the key properties of anterior inferior temporal (AIT) visual cortex neurons, as described in this Chapter and summarized elsewhere (Rolls, 2021d). These macaque anterior inferior temporal cortex neurons have large re-

ceptive fields often with a diameter of 70 degrees when an object is seen against a blank background. This means that their responses do not depend on completely precise fixation of an object, and indeed, their response can be translation (shift) invariant over tens of degrees. Their responses can be relatively selective for objects or faces: by which I mean that they can be selective for some and not other objects, or some but not other faces. Their responses to objects are often quite invariant with respect to changes of not only position, but also of object size, spatial frequency, contrast, and even in some cases of the view of an object or face. In other cases, the neurons are view-specific, encoding for example a view of the right but not the left profile of a particular person.

8. The responses of AIT neurons thus provide a basis for object and face recognition, and indeed which object or face was presented can be read out from the responses of small numbers of these selective neurons, as shown by information theoretic analyses (Appendix C). Moreover, their responses are relatively uncorrelated with each other, so that over tens of neurons the information from a population of these neurons increases approximately linearly. Put another way, the number of objects or faces that can be encoded by these neurons increases approximately exponentially with the number of neurons (as information is a logarithmic measure) (with populations of tens of neurons). The tuning of these neurons is sparse distributed, with the distributed property allowing useful generalization, and the sparseness providing high capacity in terms of the number of objects that can be encoded. Each neuron has an approximately exponential probability distribution of firing rates, with most objects producing low firing rates, and high firing rates to a few objects or faces. The code can be read out by dot (or inner) product decoding, which is highly biologically plausible, because receiving neurons then only need to sum the firing rates of their inputs weighted by their synaptic strengths to correctly decode the stimulus. Most of the information is present in the firing rates, with a little in the response latencies, and rather little in any stimulus-dependent cross-correlations between the firing of different neurons.
9. The response fields of AIT neurons shrink to a few degrees in complex visual scenes. This enables neurons to be selective for an object being fixated, so that information can be passed to brain regions such as the hippocampus and orbitofrontal cortex that enable the learning that is implemented in these brain regions to be selective for the object being fixated, which is what is needed biologically, and not for the whole scene. AIT neurons in such crowded scenes even have some asymmetry around the fovea, so that different neurons can encode not only what object is present, but where it is relative to the fovea if it is close to the fovea.
10. The responses of AIT neurons, and thereby V4 neurons by backprojections, can also be influenced by top-down attention. For example, if a stimulus at one position in a receptive field is relevant to a task, the response to a stimulus in that position can be enhanced relative to a stimulus in another part of the receptive field. Similar top-down attention can also operate for objects. These effects can be modelled by top-down biased competition using cortico-cortical backprojections. The origins of these top-down influences include the prefrontal cortex.
11. There is some evidence that IT neurons can modify their responses over the first few presentations of objects or faces to learn how to best categorize the new objects or faces, without disrupting existing representations.
12. In primates, the reward vs punishment value of stimuli are not represented in the inferior temporal visual cortex, as shown by visual discrimination reversal experiments, and by devaluation experiments in which the reward value is reduced to zero by feeding to satiety. The reward value of visual stimuli is learned in the orbitofrontal cortex and amygdala. This

clear separation of reward value from perceptual representations is a key feature of the organisation of primate perceptual systems, and ensures that we do not go blind to objects when their reward value is decreased to zero; and that we can learn about for example the location of objects even when their reward value is currently zero.

13. In addition to this inferior temporal cortex system, in which we are speaking primarily about the cortex that forms the inferior temporal gyrus (area 21, TE), there is also a whole set of visual areas in the cortex in the superior temporal sulcus (STS), running from posterior to anterior. Many of these neurons require movement in order to respond, but are nevertheless often object or face selective. Such neurons may respond for example to a head turning towards the viewer, or for other neurons away from the viewer. These neurons may be useful for encoding gesture with social significance, for some of these neurons may respond to the head turning away from the viewer, or to the eyes closing, both of which indicate breaking of social contact, and which co-occur so could arise by learned association. Some of these neurons code in object-based coordinates, in that they may respond to a head performing ventral flexion with respect to the body, independently of whether the head is the correct way up or inverted (which of course reverses the optic flow but not the object-based description). These neurons provide very clear evidence for object-based descriptions of objects in the temporal lobe cortical visual areas.
14. Some temporal lobe neurons, especially in the cortex in the STS or close to this, encode face expression, and some of these respond to face gesture (movement), such as lip-smacking, which is an affiliative / social gesture in macaques.
15. Although processing in the temporal cortical visual areas is primarily unimodal (visual) as far as AIT, there are neurons in the cortex in the STS that respond to auditory stimuli, including the sounds of macaque vocalizations and humans speaking (Baylis et al., 1987). It is likely that some neurons in these areas in macaques learn to respond by association to corresponding visual and auditory stimuli, such as the sight and sound of a macaque lip-smacking, and single neurons with auditory as well as visual responses have now been described in macaques (Khandhadia et al., 2021). In humans in temporal lobe areas, such multimodal neurons have been recorded, and have been termed ‘concept cells’ (Quiari Quiroga, 2012), and neurons with some similar properties are found in macaques (Rolls, 2023d).
16. Although much of what we know about what is computed in the ventral visual stream can be best established by neuronal recording in macaques, the results of fMRI investigations in humans, in which the activity of tens of thousands of neurons is averaged, is at least consistent. The point here is that because the code used by these neurons is often independent, the details of what is being computed can be most clearly established by recording the activity of neurons and populations of neurons, with some of the examples provided above and in the rest of this Chapter providing evidence on the richness of what is represented.
17. In humans, effective connectivity analyses and the use of the Human Connectome Project HCP-MMP atlas show how the ventral visual stream visual pathways connect via the fusiform face cortex FFC to the inferior temporal visual cortex, and then via the lateral parahippocampal gyrus TF to provide ‘what’ inputs to the hippocampal ventral visual system (Rolls et al., 2023e) (Section 2.5). The inferior temporal cortex in humans has connectivity to the semantic systems in the banks of the superior temporal sulcus that extend up into the inferior parietal cortex region PGi (Section 2.5.2).

Many of these neurophysiological discoveries were made by Rolls and colleagues, and are described below and elsewhere (Rolls, 1984, 2000a, 2011d, 2012d, 2016b, 2021d), where citations are provided. These discoveries have been confirmed and extended, for example

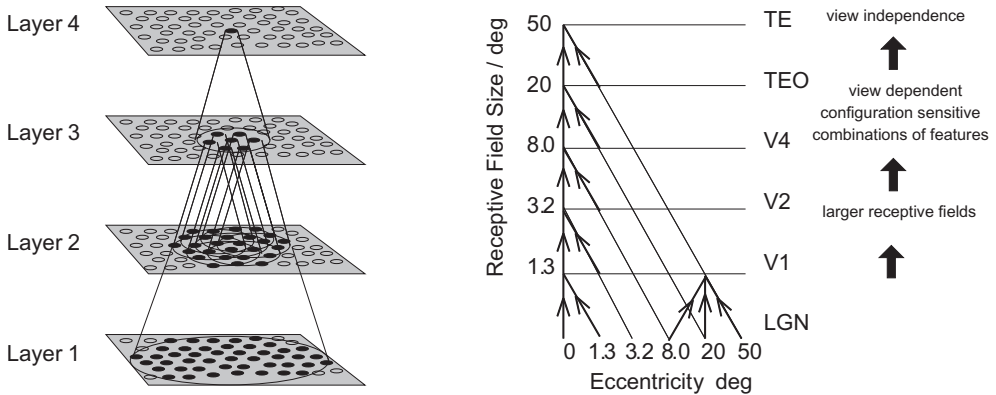

Fig. 2.2 Convergence in the visual system. Right – as it occurs in the brain. V1, visual cortex area V1; TEO, posterior inferior temporal cortex; TE, anterior inferior temporal cortex (IT). Left – as implemented in VisNet, a model of invariant visual object recognition. Convergence through the network is designed to provide fourth layer neurons with information from across the entire input retina, by providing an increase of receptive field size of 2.5 times at each stage. Layer 1 of the model corresponds to V2 in the brain.

by showing that the clustering of face cells appears as face patches with fMRI (Freiwald, Tsao and Livingstone, 2009; Rust and DiCarlo, 2010; Freiwald, 2020; Tsao, 2014; Freedman, 2015; Aparicio, Issa and DiCarlo, 2016; Arcaro and Livingstone, 2021).

2.1.3 Overview of how computations are performed in the ventral visual system

How the computations are performed in the ventral visual system is described in Sections 2.6–2.9 with an overview here.

1. Invariant visual object recognition is implemented in the ventral visual system using only about 5 stages of hierarchical processing, V1, V2, V4, posterior inferior temporal cortex, and anterior inferior temporal cortex. This allows approximately 15 ms of processing time for each stage. That is just sufficient for processes implemented by recurrent collaterals such as attractor network computations to be involved.
2. Although there are as many backprojections as forward projections between each pair of stages of the hierarchy, these are used for memory recall and top-down attention, and probably not for backpropagation of error learning, which is *prima facie* biologically implausible.
3. A biologically plausible form of learning to categorize new stimuli is competitive learning, and this is at present the most plausible candidate mechanism for how object and face representations are learned over successive stages of the hierarchy, with convergence from stage to stage consistent with the increase of receptive field size from stage to stage (Fig. 2.2).
4. Because different views of an object can be quite different, a mechanism is needed to associate together different transforms of the same object. An associative synaptic learning rule that incorporates a short-term trace of previous neuronal activity is proposed in the VisNet model to enable these associations to be learned, utilising the property of the natural world that temporally close visual stimuli are statistically likely to be different transforms of the same object (Rolls, 1992a, 2012d, 2016b, 2021d). Systems (such as HMAX) without this ‘slow learning’ capability fail in this key aspect of visual object recognition, transform-invariant representations of objects.

5. Training a system such as VisNet therefore benefits from the types of transforms of objects as they are found in the natural world, to facilitate this type of learning about the statistics of the environment that utilises time, but also spatial continuity. The types of transform over which VisNet can produce transform-invariant representations of objects include position on the retina, size, spatial frequency, lighting, deformation, and view.
6. A key feature of the type of computation implemented in VisNet is that it is unsupervised, performed without a teacher. Instead, VisNet uses the temporal statistics present in the natural environment to learn the transforms that correspond to a particular object or face.
7. In contrast, AI approaches such as deep learning using backpropagation of errors typically require prespecification of the object categories that should be learned (that is, the use of a teacher for each output neuron, which is biologically implausible). In practice these deep learning systems are trained with very large numbers of exemplars of a class, typically without systematic use of close transforms of the same object. This requires very large numbers of training trials. Deep learning networks may have up to 100 layers, again biologically implausible. Moreover, little is learned from these deep learning models about how the brain solves complex problems such as invariant visual object and face recognition, because deep convolutional learning does not use biological constraints such as local learning rules, and when mappings from images to categories are found, clear computational principles of how the mapping is achieved are largely not understood (Plebe and Grasso, 2019). VisNet is the most biologically plausible approach to how computations in the ventral visual system for invariant object and face recognition are performed using unsupervised ‘slow’, memory trace-based, learning (Rolls, 2021d).
8. Other proposals such as feature spaces are too simple to implement object recognition for the reasons give above, though features such as texture, and color may be usefully combined with shape information to help invariant visual object recognition in a VisNet-like system. Object-based systems that utilise connections between parts also seem implausible, because of the requirement of powerful syntax to describe how all the parts are joined together.
9. VisNet implements a feature hierarchy approach to object recognition. Feature hierarchy networks are biologically plausible in that they can be implemented with local synaptic learning rules (needing only the activity in the pre-synaptic and post-synaptic neurons), implemented in competitive networks (described in Section B.4). They are evolutionarily economical in that the same type of competitive network can be utilised in each stage of the hierarchy, without the need for evolution to optimise many different types of network and the genetic specification for them; and in that they can be used in every sensory system.
10. Invariant visual object recognition is one of the major and difficult computations performed by the primate (including of course human) brain, and developments in this field of current or new approaches will be important.

2.1.4 What is computed in the ventral visual system is unimodal, and is related to other ‘what’ systems after the inferior temporal visual cortex

The ventral visual system systems-level organization is illustrated in Figs. 1.8, 2.1, 2.3, and 2.4, and these Figures show that anatomically the ventral visual system receives inputs from the retina, and not from other modalities (such as taste or smell). The unimodal nature of the processing is also shown by the fact that neurons in the inferior temporal cortex respond primarily to visual stimuli, and not to taste or olfactory stimuli, etc. (Rolls, 2000a; Baylis, Rolls and Leonard, 1987; Rolls, 2012d, 2016b). The computation that must be performed along

Fig. 2.3 Visual processing pathways in monkeys. Solid lines indicate connections arising from both central and peripheral visual field representations; dotted lines indicate connections restricted to peripheral visual field representations. Shaded boxes in the 'ventral (lower) or what' stream indicate visual areas related primarily to object vision; shaded boxes in the 'dorsal or where' stream indicate areas related primarily to spatial vision; and white boxes indicate areas not clearly allied with only one stream. Abbreviations: DP, dorsal prelunate area; FST, fundus of the superior temporal area; HIPP, hippocampus; LIP, lateral intraparietal area; MSTc, medial superior temporal area, central visual field representation; MSTp, medial superior temporal area, peripheral visual field representation; MT, middle temporal area; MTp, middle temporal area, peripheral visual field representation; PO, parieto-occipital area; PP, posterior parietal sulcal zone; STP, superior temporal polysensory area; V1, primary visual cortex; V2, visual area 2; V3, visual area 3; V3A, visual area 3, part A; V4, visual area 4; and VIP, ventral intraparietal area. Inferior parietal area 7a; prefrontal areas 8, 11 to 13, 45 and 46 are from Brodmann (1925). Inferior temporal areas TE and TEO, parahippocampal area TF, temporal pole area TG, and inferior parietal area PG are from Von Bonin and Bailey (1947). Rostral superior temporal sulcal (STS) areas are from Seltzer and Pandya (1978) and VTF is the visually responsive portion of area TF (Boussaoud, Desimone and Ungerleider 1991). Area 46 in the dorsolateral prefrontal cortex is involved in short-term memory. (Modified from Ungerleider, L. G. (1995) Functional brain imaging studies of cortical mechanisms for memory. *Science* 270: 769-775. Copyright © The American Association for the Advancement of Science.)

this stream is primarily to build a representation of objects that shows invariance. After this processing, the visual representation is interfaced to other sensory systems in areas in which simple associations must be learned between stimuli in different modalities (see Chapters 9 and 11). The representation must thus be in a form in which the simple generalization properties of associative networks can be useful. Given that the association is about what object is present (and not where it is on the retina), the representation computed in sensory systems must be in a form that allows the simple correlations computed by associative networks to reflect similarities between objects, and not between their positions on the retina.

The ventral visual stream converges with other 'what' and mainly unimodal information

processing streams for taste, olfaction, touch, and hearing in a number of areas, particularly the amygdala and orbitofrontal cortex (see Figs. 1.8, 2.1, and 2.3). These areas appear to be necessary for learning to associate sensory stimuli with reinforcing (rewarding or punishing) stimuli. For example, the amygdala is involved in learning associations between the sight of food and its taste. (The taste is a primary or innate reinforcer.) The orbitofrontal cortex is especially involved in rapidly relearning these associations, when environmental contingencies change (Rolls, 2014a; Rolls and Grabenhorst, 2008; Rolls, 2000d, 2019e) (Chapter 11). They thus are brain regions in which the computation at least includes simple pattern association (e.g. between the sight of an object and its taste). In the orbitofrontal cortex, this association learning is also used to produce a representation of flavor, in that neurons are found in the orbitofrontal cortex that are activated by both olfactory and taste stimuli (Rolls and Baylis, 1994), and in that the neuronal responses in this region reflect in some cases olfactory to taste association learning (Rolls, Critchley, Mason and Wakeman, 1996b; Critchley and Rolls, 1996b). In these regions too, the representation is concerned not only with what sensory stimulus is present, but for some neurons, with its hedonic or reward-related properties, which are often computed by association with stimuli in other modalities. For example, many of the visual neurons in the orbitofrontal cortex respond to the sight of food only when hunger is present. This probably occurs because the visual inputs here have been associated with a taste input to this region, with the taste response only occurring when the food is rewarding because hunger is present (Chapter 11) (Rolls, 2014a, 2015d; Rolls and Grabenhorst, 2008; Rolls, 2000d, 2016b). The outputs from these associative memory systems, the amygdala and orbitofrontal cortex, project onwards (Fig. 1.8) to structures such as the hypothalamus, through which they control autonomic and endocrine responses such as salivation and insulin release to the sight of food; to the cingulate cortex for actions to be learned to lead to the reward outcomes signalled by the orbitofrontal cortex (Rolls, 2019c) (Chapter 12); and to the striatum, including the ventral striatum, through which behavioral responses to learned reinforcing stimuli are produced (Chapter 16).

What is computed in the ventral visual system can best be appreciated by considering the properties of anterior inferior temporal cortex (AIT) neurons, as this can be considered as the end of the primate ventral visual system, and this is described in Section 2.4. The next two sections provide some background on the stages of visual processing that lead to the inferior temporal visual cortex.

2.2 What: V1 – primary visual cortex

In V1, concentric center-antagonistic surround receptive fields (RF) become a minority, while orientation selectivity emerges, as discovered by Hubel and Wiesel (1962) and illustrated in Fig. 2.5. Second, many neurons become selective for motion direction. Third, many cells have ‘complex’ RFs, that is, they respond to both light increments and decrements in their RFs, compared to ‘simple’ cells which do not. Fourth, most cells become driven by both eyes and many are tuned to stereoscopic depth. Fifth, V1 cells become more selective for spatial frequency. In addition, some cells show double color opponency (Vanni, Hokkanen, Werner and Angelucci, 2020). The receptive field diameters are typically 1–2 degrees in the foveal region. A Difference of Gaussian function fits the centre-surround organization (Vanni et al., 2020), but an alternative formulation which fits essentially as well is that the receptive fields of simple cells can be modelled by 2D-Gabor functions (Daugman, 1988) as described in Section 2.8.1.4. Further descriptions of V1 are provided in Kandel et al. (2021), and in Chapter 2 of Rolls and Deco (2002).

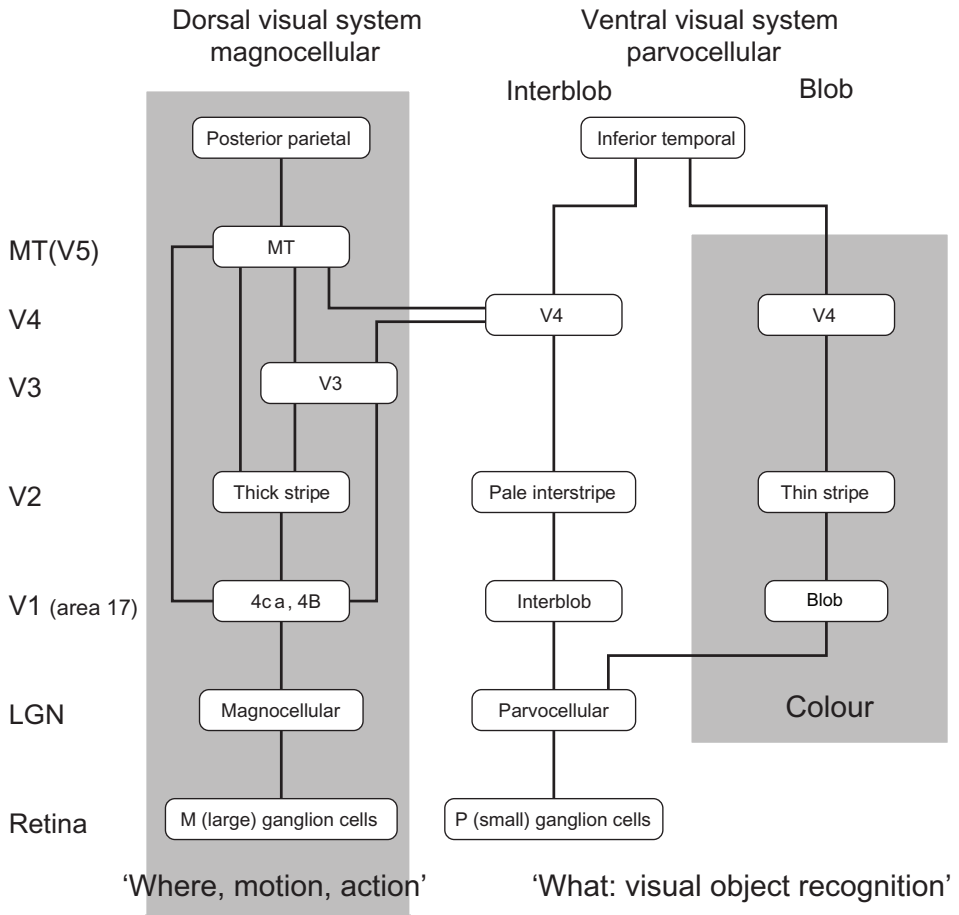

Fig. 2.4 A schematic diagram of the visual pathways from the retina to visual cortical areas. LGN, lateral geniculate nucleus; V1, primary visual cortex; V2, V3, V4, and MT, other visual cortical areas; M, magnocellular; P, parvocellular.

2.3 What: V2 and V4 – intermediate processing areas in the ventral visual system

In V2, latencies of early neuronal responses are approximately 60–70 ms, compared to 30–50 ms in V1 (Vanni et al., 2020). Many V2 cells assign contrast edges to particular objects, that is, encode border ownership (Vanni et al., 2020). This may be useful for separating objects from their background.

Some neurons in V4 code jointly for object shape and for object texture/color (Pasupathy et al., 2019; Kim et al., 2019), while others code for these separately. The combination of shape with texture may facilitate the segmentation of objects from their background. The corresponding area in humans is V4 and the lateral occipital cortex (LOC).

The size of the receptive fields in V4 is intermediate between that of V1 and the inferior temporal visual cortex, and has a diameter in degrees of approximately $1.0 + 0.625 \times$ receptive field eccentricity (and is thus approximately 4 degrees at 5 degrees of eccentricity, the edge of the fovea) (Kim et al., 2019). Because the receptive fields are larger in V4 than V1, V4 neurons can respond to extended combinations of features in the correct relative positions to form for example curves or corners (Roe et al., 2012; Jiang et al., 2021).

Some neurons in V2 and V4 respond to end-stopped lines, to tongues flanked by inhibitory subregions, to combinations of lines, or to combinations of colors (Rolls and Deco,

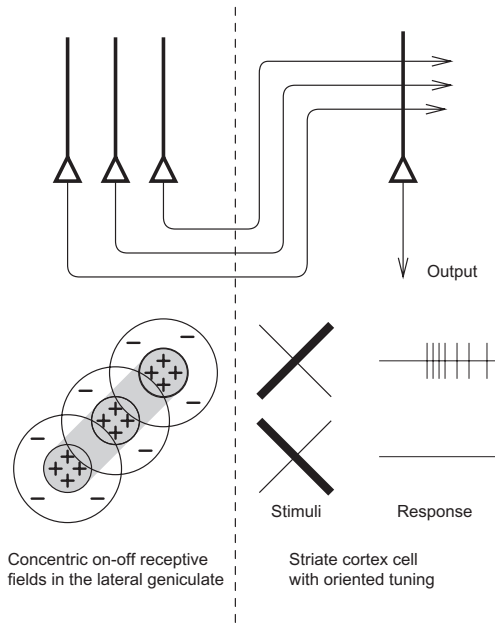

Fig. 2.5 Receptive fields in the lateral geniculate have concentric on-centre off-surround (or vice versa) receptive fields (left). Neurons in the striate cortex, such as the simple cell illustrated on the right, respond to elongated lines or edges at certain orientations. A suggestion that the lateral geniculate neurons might combine their responses in the way shown to produce orientation-selective simple cells was made by Hubel and Wiesel (1962).

2002; Hegde and Van Essen, 2000; Ito and Komatsu, 2004; Roe et al., 2012; Jiang et al., 2021)). *What* is computed here is useful as part of a feature hierarchy system for object recognition, as described below.

2.4 What: Invariant representations of faces and objects in the inferior temporal visual cortex

2.4.1 Reward value is not represented in the primate ventral visual system

The representation in the inferior temporal cortex is independent of whether the object is associated with reward or punishment, that is the representation is about objects per se (Rolls, Judge and Sanghera, 1977; Rolls, Aggelopoulos and Zheng, 2003a). This was shown in visual discrimination reversal experiments in which inferior temporal cortex neurons respond to an object independently of its association with reward vs punishment value, as illustrated in Fig. 2.6. It was also shown that IT neurons do not alter their responses after the reward value of a food-related visual stimulus is reduced to zero, by feeding to satiety (Rolls et al., 1977). Importantly, this is in contrast to what happens one synapse further on, in the orbitofrontal cortex, in the same test situations (Thorpe, Rolls and Maddison, 1983; Rolls, Critchley, Mason and Wakeman, 1996b; Critchley and Rolls, 1996a). As noted above, this clear separation of perceptual representations in the inferior temporal visual cortex from reward value (see Chapter 11) is a key feature of the organisation of primate perceptual systems (it is found in the taste and olfactory systems too, see Chapters 4 and 5), and ensures that we do not go blind to objects when their reward value is decreased to zero; and that we can learn about for example the location of objects even when their reward value is currently zero.

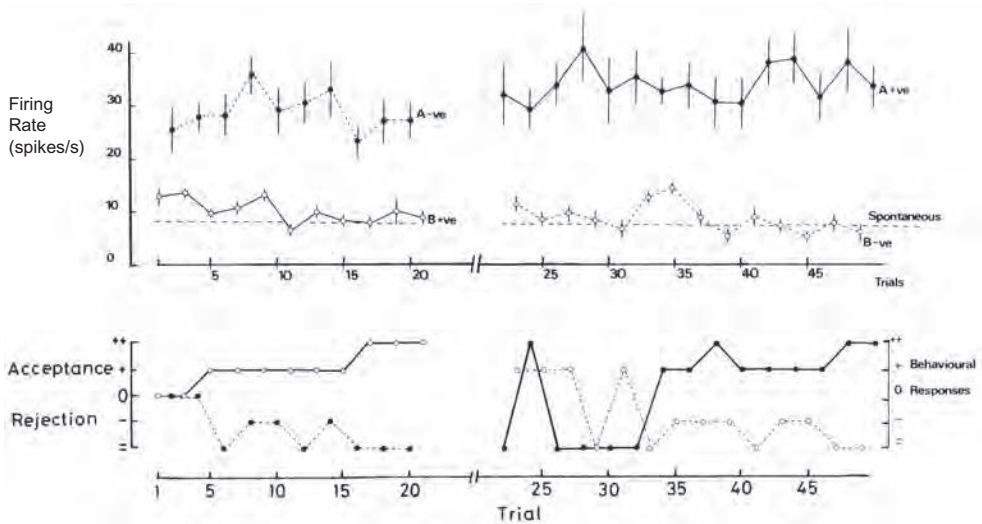

Fig. 2.6 Examples of the responses of a neuron in the inferior temporal visual cortex, showing that its responses (firing rate in spikes/s, upper panel) do not reverse when the reward association of the visual stimuli reverses. For the first 21 trials of the visual discrimination task, visual stimulus A was aversive (–ve, because if the monkey licked he obtained saline), and visual stimulus B was associated with reward (+ve, because if the monkey licked when he saw this stimulus, he obtained fruit juice). The neuron responded more to stimulus A than to stimulus B. After trial 21, the contingencies reversed (so that A was now +ve, and B –ve). The monkey learned the reversal correctly by about trial 35 (lower panel). However, the inferior temporal cortex neuron did not reverse when the reinforcement contingency reversed – it continued to respond to stimulus A after the reversal, even though the stimulus was now +ve. Thus this, and other inferior temporal cortex neurons, respond to the physical aspects of visual stimuli, and not to the stimuli based on their reinforcement association or the reinforcement contingency. (Reprinted from E. T. Rolls, S. J. Judge, and M. K. Sanghera (1977) Activity of neurones in the inferotemporal cortex of the alert monkey. *Brain Research* 130: 229–238. Copyright © Elsevier Ltd.)

2.4.2 Translation invariant representations

There is convergence from each small part of a region to the succeeding region (or layer in the hierarchy) in such a way that the receptive field sizes of neurons (for example 1 degree near the fovea in V1) become larger by a factor of approximately 2.5 with each succeeding stage (see Fig. 2.2). [The typical parafoveal receptive field sizes found would not be inconsistent with the calculated approximations of, for example, 8 degrees in V4, 20 degrees in TEO, and 50 degrees in anterior inferior temporal cortex (Boussaoud et al., 1991) (see Fig. 2.2).] Such zones of convergence would overlap continuously with each other (Fig. 2.2). This convergent connectivity provides part of the basis for the fact that many neurons in the temporal cortical visual areas respond to a stimulus relatively independently of where it is in their receptive field, and moreover maintain their stimulus selectivity when the stimulus appears in different parts of their large visual receptive field (Gross, Desimone, Albright and Schwartz, 1985; Tovee, Rolls and Azzopardi, 1994; Rolls, Aggelopoulos and Zheng, 2003a). This is called translation or shift invariance. In addition to having topologically appropriate connections, it is necessary for the connections to have the appropriate synaptic weights to perform the mapping of each set of features, or object, to the same set of neurons in IT. How this could be achieved is addressed in the computational neuroscience models described later in this Chapter and elsewhere (Wallis and Rolls, 1997; Rolls and Deco, 2002; Rolls and Stringer, 2006b; Stringer, Perry, Rolls and Proske, 2006; Rolls, 2012d, 2016b, 2021d).

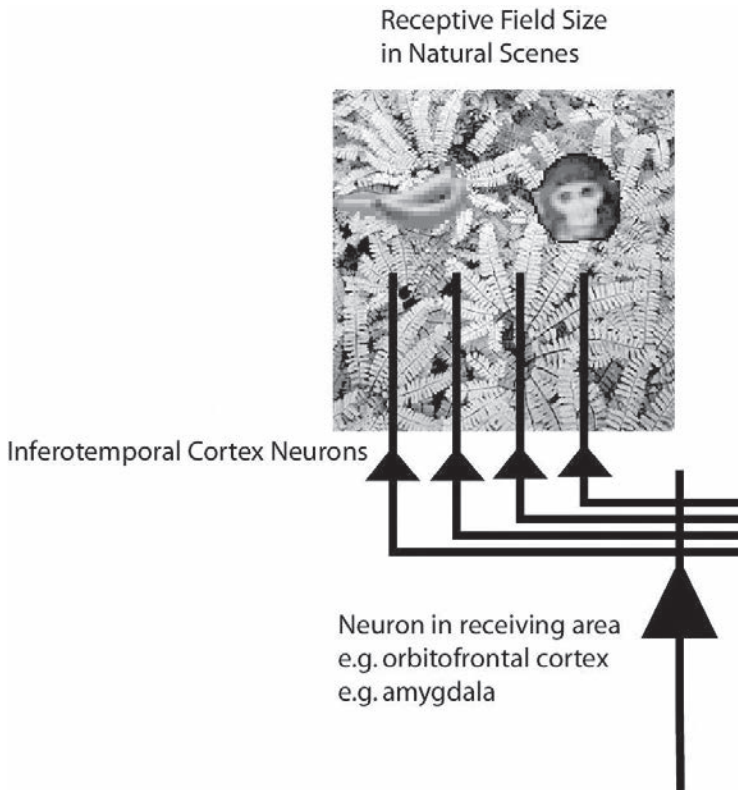

Fig. 2.7 Objects shown in a natural scene, in which the task was to search for and touch one of the stimuli. The objects in the task as run were smaller. The diagram shows that if the receptive fields of inferior temporal cortex neurons are large in natural scenes with multiple objects (in this scene, bananas and a face), then any receiving neuron in structures such as the orbitofrontal cortex and amygdala would receive information from many stimuli in the field of view, and would not be able to provide evidence about each of the stimuli separately.

2.4.3 Reduced translation invariance in natural scenes, and the selection of a rewarded object

Until recently, research on translation invariance considered the case in which there is only one object in the visual field. What happens in a cluttered, natural, environment? Do all objects that can activate an inferior temporal neuron do so whenever they are anywhere within the large receptive fields of inferior temporal neurons? If so, the output of the visual system might be confusing for structures that receive inputs from the temporal cortical visual areas. If one of the objects in the visual field was associated with reward, and another with punishment, would the output of the inferior temporal visual cortex to reward / emotion-related brain systems be an amalgam of both stimuli? If so, how would we be able to choose between the stimuli, and have an emotional response to one but not perhaps the other, and select one for action and not the other (see Fig. 2.7)?

In an investigation of this, it was found that even if an effective face was present in the parafovea, an IT neuron represented correctly (by a low firing rate) a non-effective face at the fovea (Rolls and Tovee, 1995a). This provides evidence that in situations with more than one stimulus present, IT neurons still represent what is at the fovea. This makes the interface to action simpler, in that what is at the fovea can be interpreted (e.g. by an associative memory) partly independently of the surroundings, and choices and actions can be directed if appropriate to what is at the fovea (cf. Ballard (1993)). These findings are a step towards understanding how the visual system functions in a normal environment (see also Gallant,

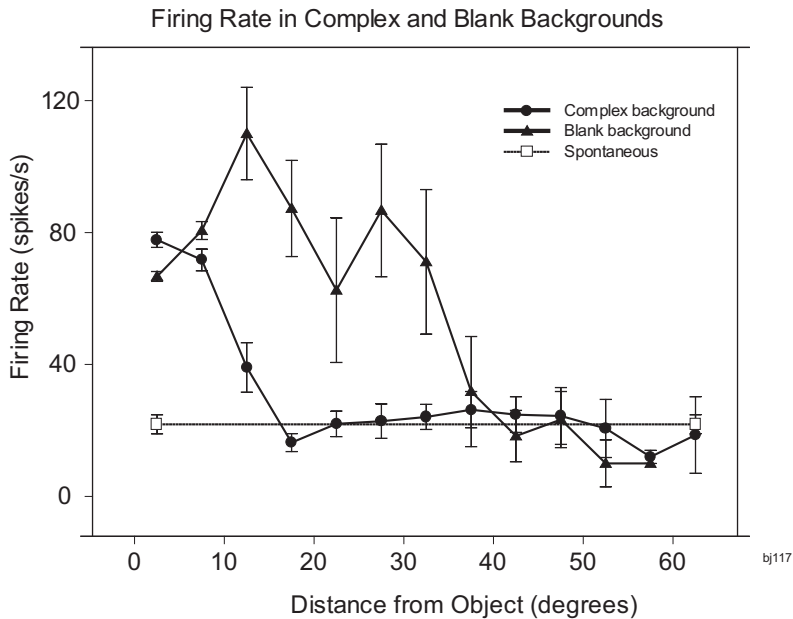

Fig. 2.8 Firing of a temporal cortex cell to an effective visual stimulus presented either in a blank background or in a natural scene, as a function of the angle in degrees at which the monkey was fixating away from the effective stimulus. The task was to search for and touch the stimulus. (After Rolls, E. T., Aggelopoulos, N.C. and Zheng, F. 2003 The receptive fields of inferior temporal cortex neurons in natural scenes. *Journal of Neuroscience* 23: 339–348.)

Connor and Van-Essen (1998), Stringer and Rolls (2000), Sheinberg and Logothetis (2001), and Rolls and Deco (2006).

To investigate further how information is passed from the inferior temporal cortex (IT) to other brain regions to enable stimuli to be selected from natural scenes for action, Rolls, Aggelopoulos and Zheng (2003a) analyzed the responses of single and simultaneously recorded IT neurons to stimuli presented in complex natural backgrounds. In one situation, a visual fixation task was performed in which the monkey fixated at different distances from the effective stimulus. In another situation the monkey had to search for two objects on a screen, and a touch of one object was rewarded with juice, and of another object was punished with saline (see Fig. 2.7 for a schematic overview, and Fig. 2.69 on page 162 for the actual display). In both situations neuronal responses to the effective stimuli for the neurons were compared when the objects were presented in the natural scene or on a plain background. It was found that the overall response of the neuron to objects was sometimes somewhat reduced when they were presented in natural scenes, though the selectivity of the neurons remained. However, the main finding was that the magnitudes of the responses of the neurons typically became much less in the real scene the further the monkey fixated in the scene away from the object (see Figs. 2.8 and 2.70, and Section 2.8.9.1).

It is proposed that this reduced translation invariance in natural scenes helps an unambiguous representation of an object that may be the target for action to be passed to the brain regions that receive from the primate inferior temporal visual cortex. It helps with the binding problem, by reducing in natural scenes the effective receptive field of inferior temporal cortex neurons to approximately the size of an object in the scene. The computational utility and basis for this is considered in Section 2.8.9 and by Rolls and Deco (2002), Trappenberg, Rolls and Stringer (2002), Deco and Rolls (2004), Aggelopoulos and Rolls (2005), and Rolls and Deco (2006), and includes an advantage for what is at the fovea because of the large cortical

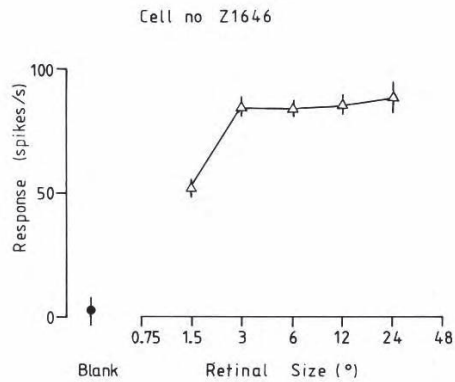

Fig. 2.9 Typical response of an inferior temporal cortex face-selective neuron to faces of different sizes. The size subtended at the retina in degrees is shown. (From Rolls, E.T. and Baylis, G.C. (1986) Size and contrast have only small effects on the responses to faces of neurons in the cortex of the superior temporal sulcus of the monkey. *Experimental Brain Research* 65: 38–48. Copyright © Springer Nature.)

magnification of the fovea, and shunting interactions between representations weighted by how far they are from the fovea.

These discoveries indicate that the principle of *what* is computed in the ventral visual system is to provide strong weight to whatever is close to the fovea in natural environments. This principle of operation is very important in interfacing the visual system to action systems, because the effective stimulus in making inferior temporal cortex neurons fire is in natural scenes usually on or close to the fovea. This means that the spatial coordinates of where the object is in the scene do not have to be represented in the inferior temporal visual cortex, nor passed from it to the action selection system, as the latter can assume that the object making IT neurons fire is close to the fovea in natural scenes. Thus the position in visual space being fixated provides part of the interface between sensory representations of objects and their coordinates as targets for actions in the world. The small receptive fields that include the fovea of IT neurons in natural scenes make this possible. After this, local, egocentric, processing implemented in the dorsal visual processing stream using e.g. stereodisparity may be used to guide action towards objects being fixated (Rolls and Deco, 2002; Rolls, 2016b) (see Section 3.4).

The reduced receptive field size in complex natural scenes also enables emotions to be selective to just what is being fixated, because this is the information that is transmitted by the firing of IT neurons to structures such as the orbitofrontal cortex and amygdala that are involved in emotion as described in Chapter 11.

Another principle of *what* is computed is that the whole scene is not processed simultaneously by the ventral visual system, as that greatly simplifies the process of object recognition. Successive fixations to different parts of the scene then enable a representation of a whole scene to be built up, over time, and to be held effectively in memory.

Interestingly, although the size of the receptive fields of inferior temporal cortex neurons become reduced in natural scenes so that neurons in IT respond primarily to the object being fixated, there is nevertheless frequently some asymmetry in the receptive fields (see Section 2.8.10 and Fig. 2.74). This provides a partial solution to how multiple objects and their position close to the fovea in a scene can be captured with a single glance (Aggelopoulos and Rolls, 2005), and is another principle of *what* is computed in the ventral visual system.

2.4.4 Size and spatial frequency invariance

It was discovered that some neurons in the inferior temporal visual cortex and cortex in the anterior part of the superior temporal sulcus (IT/STS) respond relatively independently of the size of an effective face stimulus, with a mean size invariance (to a half maximal response) of 12 times (3.5 octaves) (Rolls and Baylis, 1986). An example of the responses of an inferior temporal cortex face-selective neuron to faces of different sizes is shown in Fig. 2.9. This is not a property of a simple single-layer network (see Fig. 2.26), nor of neurons in V1, which respond best to small stimuli, with a typical size-invariance of 1.5 octaves. Also, the neurons typically continued to respond to a face when the information in it had been reduced from 3D to a 2D representation in grey on a monitor, with a response that was on average 0.5 of that to a real face.

Another transform over which recognition is relatively invariant is spatial frequency. For example, a face can be identified when it is blurred (when it contains only low spatial frequencies), and when it is high-pass spatial frequency filtered (when it looks like a line drawing). If the face images to which these neurons respond are low-pass filtered in the spatial frequency domain (so that they are blurred), then many of the neurons still respond when the images contain frequencies only up to 8 cycles per face. Similarly, the neurons still respond to high-pass filtered images (with only high spatial frequency edge information) when frequencies down to only 8 cycles per face are included (Rolls, Baylis and Leonard, 1985). Face recognition shows similar invariance with respect to spatial frequency (see Rolls, Baylis and Leonard (1985)). Further analysis of these neurons with narrow (octave) bandpass spatial frequency filtered face stimuli shows that the responses of these neurons to an unfiltered face can not be predicted from a linear combination of their responses to the narrow band stimuli (Rolls, Baylis and Hasselmo, 1987). This lack of linearity of these neurons, and their responsiveness to a wide range of spatial frequencies (see also their broad critical band masking (Rolls, 2008b)), indicate that in at least this part of the primate visual system recognition does not occur using Fourier analysis of the spatial frequency components of images.

The utility of *what* is computed in this representation for memory systems in the brain is that the output of the visual system will represent an object invariantly with respect to position on the retina, size, etc, and this simplifies the functionality required of the (multiple) memory systems, which need then to simply associate the object representation with reward (orbitofrontal cortex and amygdala), associate it with position in the environment (hippocampus), recognise it as familiar (perirhinal cortex), associate it with a motor response in a habit memory (basal ganglia), etc. (Rolls, 2007d, 2016b, 2012d, 2014a). The associations can be relatively simple, involving for example Hebbian associativity (see chapters throughout this book, and Appendix B).

It has been discovered that some neurons in the temporal cortical visual areas actually represent the absolute size of objects such as faces independently of viewing distance (Rolls and Baylis, 1986). This could be called neurophysiological size constancy. The utility of *what* is computed by this small population of neurons is that the absolute size of an object is a useful feature to use as an input to neurons that perform object recognition. Faces only come in certain sizes.

2.4.5 Combinations of features in the correct spatial configuration

Many neurons in this processing stream respond to combinations of features (including objects), but not to single features presented alone, and the features must have the correct spatial arrangement. This has been shown, for example, with faces, for which it was discovered by masking out or presenting parts of the face (for example eyes, mouth, or hair) in isolation, or by jumbling the features in faces, that some cells in the cortex in IT/STS respond only if two

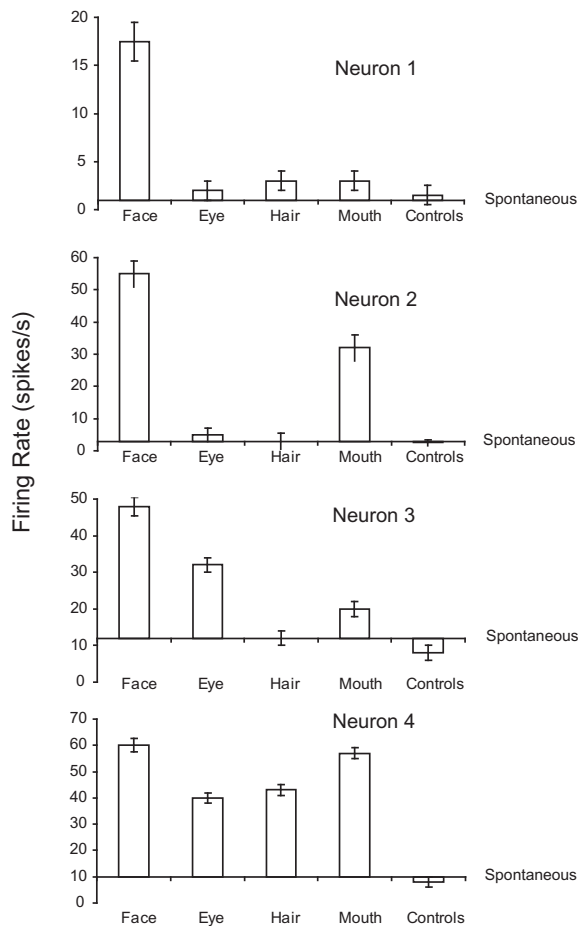

Fig. 2.10 Responses of four temporal cortex neurons to whole faces and to parts of faces. The mean firing rate \pm sem are shown. The responses are shown as changes from the spontaneous firing rate of each neuron. Some neurons respond to one or several parts of faces presented alone. Other neurons (of which the top one is an example) respond only to the combination of the parts (and only if they are in the correct spatial configuration with respect to each other as shown by Rolls et al 1994b). The control stimuli were non-face objects. (After Perrett, D.I., Rolls, E. T. and Caan, W. (1982) Visual neurons responsive to faces in the monkey temporal cortex. *Experimental Brain Research* 47: 329–342.)

or more features are present, and are in the correct spatial arrangement (Perrett, Rolls and Caan, 1982; Rolls, Tovee, Purcell, Stewart and Azzopardi, 1994b). Fig. 2.10 shows examples of four neurons, the top one of which responds only if all the features are present, and the others of which respond not only to the full face, but also to one or more features. Corresponding evidence has been found for non-face cells. For example, Tanaka et al. (1990) showed that some posterior inferior temporal cortex neurons might only respond to the combination of an edge and a small circle if they were in the correct spatial relationship to each other.

Evidence consistent with the suggestion that neurons are responding to combinations of a few variables represented at the preceding stage of cortical processing is that some neurons in V2 and V4 respond to end-stopped lines, to tongues flanked by inhibitory subregions, to combinations of lines, or to combinations of colors (see Rolls and Deco (2002), Hegde and Van Essen (2000) and Ito and Komatsu (2004)). Neurons that respond to combinations of features but not to single features contained in those combinations indicate that the system is non-linear (Elliffe, Rolls and Stringer, 2002).

The fact that some temporal cortex neurons respond to objects or faces consisting of a set

of features only if the whole combination of features is present and they are in the correct spatial arrangement with respect to each other (not jumbled) is part of the evidence that some inferior temporal cortex neurons are tuned to respond to objects or faces, and are part of a feature hierarchy system as described in Section 2.6.6.

If a task requires in addition to the normal representation of objects by the inferior temporal cortex, the ability to discriminate between stimuli composed of highly overlapping feature conjunctions in a low-dimensional feature space, then the perirhinal cortex may contribute to this type of discrimination, as described in Section 9.2.7.

2.4.6 A view-invariant representation

For recognizing and learning about objects (including faces), it is important that an output of the visual system should be not only translation- and size-invariant, but also relatively view-invariant. In an investigation of whether there are such neurons, we discovered that some temporal cortical neurons reliably responded differently to the faces of two different individuals independently of viewing angle (Hasselmo, Rolls, Baylis and Nalwa, 1989b) (see example in Fig. 2.11 upper), although in most cases (16/18 neurons) the response was not perfectly view-independent. Mixed together in the same cortical regions there are neurons with view-dependent responses (Hasselmo, Rolls, Baylis and Nalwa, 1989b; Rolls and Tovee, 1995b; Chang and Tsao, 2017) (see example in Fig. 2.11 lower)). Such neurons might respond, for example, to a view of a profile of a monkey but not to a full-face view of the same monkey (Perrett, Smith, Potter, Mistlin, Head, Milner and Jeeves, 1985b; Hasselmo, Rolls, Baylis and Nalwa, 1989b).

These discoveries of view-dependent, partially view-independent, and view-independent representations in the same cortical regions are consistent with the hypothesis discussed below that view-independent representations are being built in these regions by associating together the outputs of neurons that have different view-dependent responses to the same individual. These findings also provide evidence that one output of the visual system includes representations of what is being seen, in a view-independent way that would be useful for object recognition and for learning associations about objects; and that another output is a view-based representation that would be useful in social interactions to determine whether another individual is looking at one, and for selecting details of motor responses, for which the orientation of the object with respect to the viewer is required (Rolls and Deco, 2002; Rolls, 2016b).

Further evidence that some neurons in the temporal cortical visual areas have object-based rather than view-based responses comes from a study of a population of neurons that responds to moving faces (Hasselmo, Rolls, Baylis and Nalwa, 1989b). For example, four neurons responded vigorously to a head undergoing ventral flexion, irrespective of whether the view of the head was full face, of either profile, or even of the back of the head. These different views could only be specified as equivalent in object-based coordinates. Further, the movement specificity was maintained across inversion, with neurons responding for example to ventral flexion of the head irrespective of whether the head was upright or inverted (see example in Fig. 2.12). In this procedure, retinally encoded or viewer-centered movement vectors are reversed, but the object-based description remains the same.

Also consistent with object-based encoding is the discovery of a small number of neurons that respond to images of faces of a given absolute size, irrespective of the retinal image size or distance (Rolls and Baylis, 1986).

Neurons with view invariant responses to objects seen naturally in their home cages by macaques have also been discovered (Booth and Rolls, 1998). The stimuli were presented for 0.5 s on a color video monitor while the monkey performed a visual fixation task. The

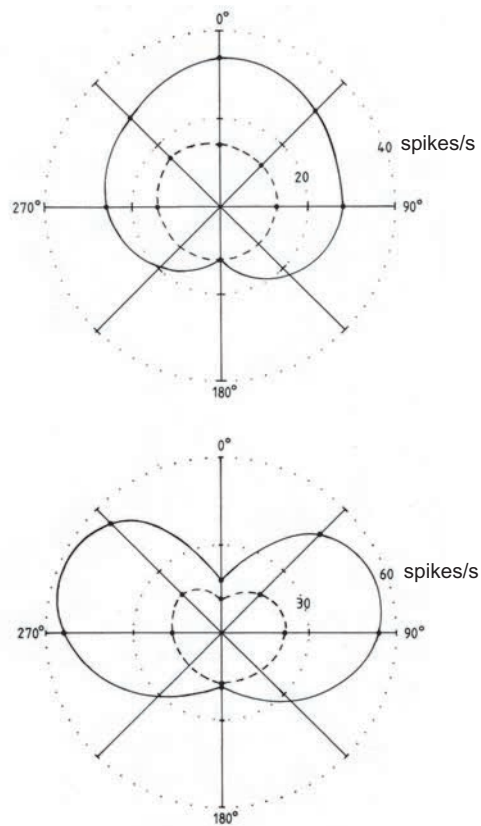

Fig. 2.11 Upper: View invariant response of an inferior temporal cortex neuron to two faces. In the polar response plot, 0° is the front of the face, and 90° the right profile. The firing rate in spikes/s is shown by the distance from the centre of the plot. The responses to two different faces are shown by the solid and dashed lines. The neuron discriminated between the faces, apart from the view of the back of the head. Lower: View dependent response of an inferior temporal cortex neuron to two faces. The neuron responded best to the left and right profiles. Some neurons respond to only one of the profiles, and this neuron had a small preference for the left profile. (After Hasselmo, M.E., Rolls, E. T., Baylis, G.C. and Nalwa, V. (1989) Object-centered encoding by face-selective neurons in the cortex in the superior temporal sulcus of the monkey. *Experimental Brain Research* 75: 417–429.)

stimuli were images of 10 real plastic objects that had been in the monkey's cage for several weeks, to enable him to build view invariant representations of the objects. Control stimuli were views of objects that had never been seen as real objects. The neurons analyzed were in the TE cortex in and close to the ventral lip of the anterior part of the superior temporal sulcus. Many neurons were found that responded to some views of some objects. However, for a smaller number of neurons, the responses occurred only to a subset of the objects (using ensemble encoding), irrespective of the viewing angle. Moreover, the firing of a neuron on any one trial, taken at random and irrespective of the particular view of any one object, provided information about which object had been seen, and this information increased approximately linearly with the number of neurons in the sample (see Fig. 2.13). This is strong quantitative evidence that some neurons in the inferior temporal cortex provide an invariant representation of objects. Moreover, the results of Booth and Rolls (1998) show that the information is available in the firing rates, and has all the desirable properties of distributed representations described above, including exponentially high coding capacity, and rapid speed of readout of the information.

Further evidence consistent with these findings is that some studies have shown that the responses of some visual neurons in the inferior temporal cortex do not depend on the pres-

Fig. 2.12 Object-centred encoding: Neuron responding to ventral flexion (V) of the head independently of view even when the head was inverted. Ventral flexion is tilting the head from the full frontal view forwards to face down at 45 degrees. Dorsal flexion is tilting the head until it is looking 45 degrees up. The response is shown as a change in firing rate in spikes/s \pm sem from the spontaneous firing rate. (After Hasselmo, M.E., Rolls, E. T., Baylis, G.C. and Nalwa, V. (1989) Object-centered encoding by face-selective neurons in the cortex in the superior temporal sulcus of the monkey. *Experimental Brain Research* 75: 417–429.)

ence or absence of critical features for maximal activation (Perrett, Rolls and Caan, 1982; Tanaka, 1993, 1996). For example, the responses of neuron 4 in Fig. 2.10 responded to several of the features in a face when these features were presented alone (Perrett, Rolls and Caan, 1982). In another example, Mikami, Nakamura and Kubota (1994) showed that some TE cells respond to partial views of the same laboratory instrument(s), even when these partial views contain different features. Such functionality is important for object recognition when part of an object is occluded, by for example another object. In a different approach, Logothetis, Pauls, Bulthoff and Poggio (1994) have reported that in monkeys extensively trained (over thousands of trials) to treat different views of computer generated wire-frame 'objects' as the same, a small population of neurons in the inferior temporal cortex did respond to different views of the same wire-frame object (see also Logothetis and Sheinberg (1996)). However, extensive training is not necessary for invariant representations to be formed, and indeed no explicit training in invariant object recognition was given in the experiment by Booth and Rolls (1998), as Rolls' hypothesis (1992a) is that view invariant representations can be learned by associating together the different views of objects as they are moved and inspected naturally in a period that may be in the order of a few seconds. Evidence for this is described in Section 2.4.7.

2.4.7 Learning of new representations in the temporal cortical visual areas

To investigate the idea that visual experience might guide the formation of the responsiveness of neurons so that they provide an economical and ensemble-encoded representation of items actually present in the environment, the responses of inferior temporal cortex face-selective neurons have been analyzed while a set of new faces were shown. Some of the neurons studied in this way altered the relative degree to which they responded to the different members of the set of novel faces over the first few (1–2) presentations of the set (Rolls, Baylis, Hasselmo and Nalwa, 1989a) (see examples in Fig. 2.14). If in a different experiment a single novel face

Fig. 2.13 View-independent object encoding: information in a population of different numbers of inferior temporal cortex cells available from a single trial, in which one view was shown, about which of 10 objects each with 4 different views in the stimulus set had been seen. The solid symbols show the information decoded with a Bayesian probability estimator algorithm, and the open symbols with dot product decoding. (After Booth, M.C.A. and Rolls, E. T. (1998) View-invariant representations of familiar objects by neurons in the inferior temporal visual cortex. *Cerebral Cortex* 8: 510–523.)

was introduced when the responses of a neuron to a set of familiar faces were being recorded, the responses to the set of familiar faces were not disrupted, while the responses to the novel face became stable within a few presentations. Alteration of the tuning of individual neurons in this way may result in a good discrimination over the population as a whole of the faces known to the monkey. This evidence is consistent with the categorization being performed by self-organizing competitive neuronal networks, as described in Section B.4. Consistent findings have been described more recently (Freedman, 2015).

Further evidence that these neurons can learn new representations very rapidly comes from an experiment in which binarized black and white (two-tone) images of faces that blended with the background were used (see Fig. 2.15, left). These did not activate face-selective neurons. Full grey-scale images of the same photographs were then shown for ten 0.5 s presentations (Fig. 2.15, middle). In a number of cases, if the neuron happened to be responsive to that face, when the binarized version of the same face was shown next (Fig. 2.15, right), the neurons responded to it (Tovee, Rolls and Ramachandran, 1996). This is a direct parallel to the same phenomenon that is observed psychophysically, and provides dramatic evidence that these neurons are influenced by only a very few seconds (in this case 5 s) of experience with a visual stimulus (Tovee et al., 1996). We have shown a neural correlate of this effect using similar stimuli and a similar paradigm in a PET (positron emission tomography) neuroimaging study in humans, with a region showing an effect of the learning found for faces in the right temporal lobe, and for objects in the left temporal lobe (Dolan, Fink, Rolls, Booth, Holmes, Frackowiak and Friston, 1997).

The discovery that inferior temporal visual cortex neurons can learn rapidly in an unsupervised way to categorise new objects or faces (Rolls, Baylis, Hasselmo and Nalwa, 1989a) has been confirmed, with size invariance requiring temporal contiguity (Li and DiCarlo, 2010) as predicted by the VisNet model of memory trace rule dependent learning and related psychophysics (Perry, Rolls and Stringer, 2006), and it has been confirmed that reward is not necessary for this type of self-organising learning of invariant representations (Li and DiCarlo, 2012). The psychophysical discovery of the importance in humans of associations over time

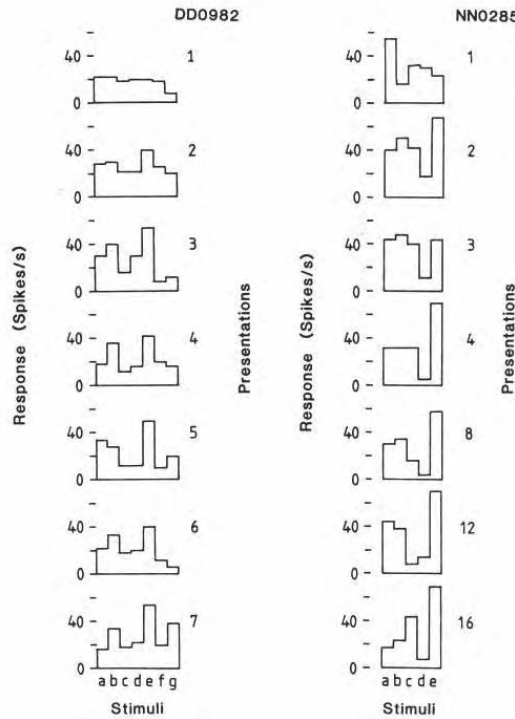

Fig. 2.14 Learning in the responses of inferior temporal cortex neurons. Results for two face-selective neurons are shown. On presentation 1 a set of 7 completely novel faces was shown when recording from neuron DD0982. The firing rates elicited on 1-sec presentations of each stimulus (a-g) are shown. After the first presentation, the set of stimuli was repeated in random sequence for a total of 7 iterations. After the first two presentations, the relative responses of the neuron to the different stimuli settled down to a fairly reliable response profile to the set of stimuli (as shown by statistical analysis). NN0285 – data from a similar experiment with another neuron, and another completely new set of face stimuli. (After Rolls, E. T., Baylis, G.C. Hasselmo, M.E. and Nalwa, V. (1989) The effect of learning on the face-selective responses of neurons in the cortex in the superior temporal sulcus of the monkey. *Experimental Brain Research* 76: 153–164.)

for helping to build invariant object representations (Perry, Rolls and Stringer, 2006) has been confirmed in further psychophysical investigations in humans (Jia, Hong and DiCarlo, 2021).

Such rapid learning of representations of new objects appears to be a major type of learning in which the temporal cortical areas are involved. Ways in which this learning could occur are considered later in this Chapter. In addition, some of these neurons may be involved in a short term memory for whether a particular familiar visual stimulus (such as a face) has been seen recently. The evidence for this is that some of these neurons respond differently to recently seen stimuli in visual memory tasks (Baylis and Rolls, 1987; Miller and Desimone, 1994; Xiang and Brown, 1998). In the inferior temporal visual cortex proper, neurons respond more to novel than to familiar stimuli, but treat the stimuli as novel if one or more other stimuli intervene between the first (novel) and second (familiar) presentations of a particular stimulus (Baylis and Rolls, 1987). More ventrally, in what is in or close to the perirhinal cortex, these memory spans may hold for several intervening stimuli in the same task (Xiang and Brown, 1998) (see Section 9.2.7). Some neurons in these areas respond more when a sample stimulus reappears in a delayed match to sample task with intervening stimuli (Miller and Desimone, 1994), and the basis for this using a short term memory implemented in the prefrontal cortex is described in Section 13.6.1. Neurons in the more ventral (perirhinal) cortical area respond

Objects

Faces

Fig. 2.15 Images of the type used to investigate rapid learning in the neurophysiological experiments of Tovee, Rolls and Ramachandran (1996) and the PET imaging study of Dolan, Fink, Rolls et al. (1997). When the black and white (two-tone) images at the left are shown, the objects or faces are not generally recognized. After the full grey scale images (middle) have been shown for a few seconds, humans and inferior temporal cortex neurons respond to the faces or objects in the black and white images (right).

during the delay in a match to sample task with a delay between the sample stimulus and the to-be-matched stimulus (Miyashita, 1993; Renart, Parga and Rolls, 2000) (see Section 9.2.7).

2.4.8 A sparse distributed representation is what is computed in the ventral visual system

An important question for understanding brain function is whether a particular object (or face) is represented in the brain by the firing of one or a few gnostic (or ‘grandmother’) cells (see Barlow (1972)), or whether instead the firing of a group or ensemble of cells each with somewhat different responsiveness provides the representation. We tested this experimentally, and discovered that *what* is computed in the ventral visual system is a sparse distributed representation of objects and faces of a type that can easily be read by neurons in the next brain areas, as described next. Advantages of distributed codes include generalization and graceful degradation (fault tolerance), and a potentially very high capacity in the number of stimuli that can be represented (that is exponential growth of capacity with the number of neurons in the representation) (see Appendix B, Rolls and Treves (1998), Rolls (2016b), and Rolls and Treves (2011)). If the ensemble encoding is sparse, this provides a good input to an associative memory, for then large numbers of stimuli can be stored (see Appendix B, Chapters 2 and 3 of Rolls and Treves (1998), and Rolls (2016b)). A quantitative analysis of information encoding by inferior temporal cortex neurons and by neurons in other brain areas is provided in Appendix B.

We discovered that in the inferior temporal visual cortex and cortex in the anterior part of the superior temporal sulcus (IT/STS), responses of a group of neurons, but not of a single neuron, provide evidence about which face was shown. We showed, for example, that these neurons typically respond with a graded set of firing rates to different faces, with firing rates from 120 spikes/s to the most effective face, to no response at all to a number of the least effective faces (Baylis, Rolls and Leonard, 1985; Rolls and Tovee, 1995b; Rolls, 2016b). In

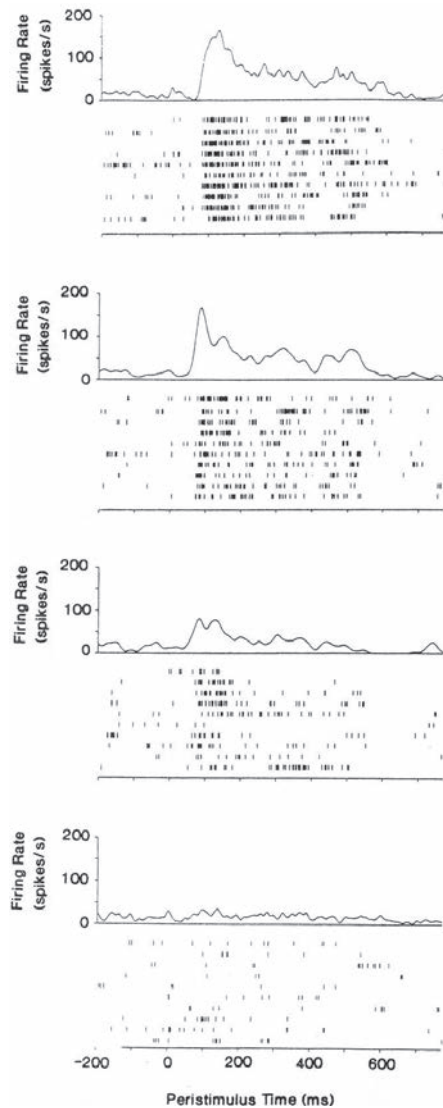

Fig. 2.16 Peristimulus time histograms and rastergrams showing the responses on different trials (originally in random order) of a face-selective neuron in the inferior temporal visual cortex to four different faces. (In the rastergrams each vertical line represents one spike from the neuron, and each row is a separate trial. Each block of the Figure is for a different face.) (Reproduced from M. J. Tovee, E. T. Rolls, A. Treves, and R. P. Bellis. (1993) Information encoding and the responses of single neurons in the primate temporal visual cortex. *Journal of Neurophysiology* 70: 640–654. © The American Physiological Society.)

fact, the firing rate probability distribution of a single neuron to a set of stimuli is approximately exponential (Rolls and Tovee, 1995b; Treves, Panzeri, Rolls, Booth and Waksman, 1999; Rolls, 2016b; Baddeley, Abbott, Booth, Sengpiel, Freeman, Waksman and Rolls, 1997; Franco, Rolls, Aggelopoulos and Jerez, 2007). To provide examples, Fig. 2.16 shows typical firing rate changes of a single neuron on different trials to each of several different faces. This makes it clear that from the firing rate on any one trial, information is available about which stimulus was shown, and that the firing rate is graded, with a different firing rate response of the neuron to each stimulus.

The distributed nature of the encoding typical for neurons in the inferior temporal visual cortex is illustrated in Fig. 2.17, which shows that temporal cortical neurons typically re-

Fig. 2.17 Responses of four different temporal cortex visual neurons to a set of five faces (A–E), and, for comparison, to a wide range of non-face objects and foods. F–J are non-face stimuli. The means and standard errors of the responses computed over 8–10 trials are shown. (Reprinted from G.C. Baylis, E.T. Rolls, C.M. Leonard. (1985) Selectivity between faces in the responses of a population of neurons in the cortex in the superior temporal sulcus of the monkey. *Brain Research* 342: 91–102. Copyright © Elsevier Ltd.)

sponded to several members of a set of five faces, with each neuron having a different profile of responses to each face (Baylis, Rolls and Leonard, 1985). It would be difficult for most of these single cells to tell which of even five faces, let alone which of hundreds of faces, had been seen. Yet across a population of such neurons, much information about the particular face that has been seen is provided, as shown below.

The single neuron selectivity or sparseness a^s of the activity of inferior temporal cortex neurons was 0.65 over a set of 68 stimuli including 23 faces and 45 non-face natural scenes, and a measure called the response sparseness a_r^s of the representation, in which the spon-

Fig. 2.18 (a) The values for the average information available in the responses of different numbers of inferior temporal visual cortex neurons on each trial, about which one of a set of 20 face stimuli has been shown. The decoding method was Dot Product (DP, \times) or Probability Estimation (PE, $+$). The full line indicates the amount of information expected from populations of increasing size, when assuming random correlations within the constraint given by the ceiling (the information in the stimulus set, $I = 4.32$ bits). (b) The percent correct for the corresponding data to those shown in (a). The measurement period was 500 ms. (After Rolls, E. T., Treves, A. and Tovee, M. J. (1997) The representational capacity of the distributed encoding of information provided by populations of neurons in the primate temporal visual cortex. *Experimental Brain Research* 114: 149–162.)

taneous rate was subtracted from the firing rate to each stimulus so that the responses of the neuron were being assessed, was 0.38 across the same set of stimuli (Rolls and Tovee, 1995b). [For the definition of sparseness see Section C.3.1, and Appendix B. For binary neurons (firing for example either at a high rate or not at all), the single neuron sparseness is the proportion of stimuli that a single neuron responds to. These definitions, and what is found in cortical neuronal representations, are described further elsewhere (Franco, Rolls, Aggelopoulos and Jerez, 2007; Rolls and Treves, 2011; Rolls, 2016b).]

It has been possible to apply information theory (see Appendix C) to show that each neuron conveys on average approximately 0.4 bits of information about which face in a set of 20 faces has been seen (Tovee and Rolls, 1995; Tovee, Rolls, Treves and Bellis, 1993; Rolls, Treves, Tovee and Panzeri, 1997d). If a neuron responded to only one of the faces in the set of 20, then it could convey (if noiseless) 4.6 bits of (stimulus-specific) information about one of the faces (when that face was shown). If, at the other extreme, it responded to half the faces in the set, it would convey 1 bit of information about which face had been seen on any one trial. In fact, the average maximum (stimulus-specific) information about the best stimulus was 1.8 bits of information. This provides good evidence not only that the representation is distributed, but also that it is a sufficiently reliable representation that useful information can be obtained from it.

An important discovery is that when the information available from a population of neurons about which of 20 faces has been seen is considered, the information increases approximately linearly as the number of neurons in the population increases from 1 to 14 (Rolls,

Fig. 2.19 The number of stimuli (in this case from a set of 20 faces) that are encoded in the responses of different numbers of neurons in the temporal lobe visual cortex, based on the results shown in Fig. 2.18. The solid circles are the result of the raw calculation, and the open circles correspond to the cross-validated case. (After Rolls, E. T., Treves, A. and Tovee, M.J. (1997) The representational capacity of the distributed encoding of information provided by populations of neurons in the primate temporal visual cortex. *Experimental Brain Research* 114: 149–162; and Abbott, L.F., Rolls, E. T. and Tovee, M.J. (1996) Representational capacity of face coding in monkeys. *Cerebral Cortex* 6: 498–505.)

Treves and Tovee, 1997b; Abbott, Rolls and Tovee, 1996) (see Fig. 2.18 and Section C.3.5). Remembering that the information in bits is a logarithmic measure, this shows that the representational capacity of this population of cells increases exponentially (see Fig. 2.19). This is the case both when an optimal, probability estimation, form of decoding of the activity of the neuronal population is used, and also when the neurally plausible dot product type of decoding is used (Fig. 2.18). (The dot product decoding assumes that what reads out the information from the population activity vector is a neuron or a set of neurons that operates just by forming the dot product of the input population vector and its synaptic weight vector – see Rolls, Treves and Tovee (1997b), and Appendix B.) By simulation of further neurons and further stimuli, we have shown that the capacity grows very impressively, approximately as shown in Fig. 2.19 (Abbott, Rolls and Tovee, 1996). The result has been replicated with simultaneously recorded neurons (Rolls, Franco, Aggelopoulos and Reece, 2003b; Rolls, Aggelopoulos, Franco and Treves, 2004; Rolls, 2016b). This result is exactly what would be hoped for from a distributed representation. This result is not what would be expected for local encoding, for which the number of stimuli that could be encoded would increase linearly with the number of cells. (Even if the grandmother cells were noisy, adding more replicates to increase reliability would not lead to more than a linear increase in the number of stimuli that can be encoded as a function of the number of cells.) Moreover, the encoding in the inferior temporal visual cortex about objects remains based on the spike count from each neuron, and not on the relative time of firing of each neuron or stimulus-dependent synchronization, when analyzed with simultaneous single neuron recording (Rolls, Franco, Aggelopoulos and Reece, 2003b; Rolls, Aggelopoulos, Franco and Treves, 2004; Franco, Rolls, Aggelopoulos and Treves, 2004) even in natural scenes when an attentional task is being performed (Aggelopoulos, Franco and Rolls, 2005). Further, we discovered that much of the information is available in short times of e.g. 20 or 50 ms (Tovee and Rolls, 1995; Rolls, Franco, Aggelopoulos and Jerez, 2006b), so that the receiving neuron does not need to integrate over a long time period to estimate a firing rate.

These findings, provided more fully and with equations in Appendix C, provide very firm evidence that the encoding built at the end of the visual system is distributed, and that part of the power of this representation is that by receiving inputs from relatively small numbers

Fig. 2.20 Some examples of the objects and faces encoded by anterior inferior temporal cortex neurons (see text, and further examples in Fig. C.7).

of such neurons, neurons at the next stage of processing (for example in memory structures such as the hippocampus, amygdala, and orbitofrontal cortex) would obtain information about which of a very great number of objects or faces had been shown (Rolls and Treves, 2011).

In this sense, the inferior temporal visual cortex provides a representation of objects and faces, in which information about which object or face is shown is made explicit in the firing of the neurons in such a way that the information can be read off very simply by memory systems such as the orbitofrontal cortex, amygdala, and perirhinal cortex / hippocampal systems. The information can be read off using dot product decoding, that is by using a synaptically weighted sum of inputs from inferior temporal cortex neurons (see further Rolls (2016b) and Section 9.2.7). Examples of some of the types of objects and faces that are encoded in this way by anterior inferior temporal cortex neurons are shown in Fig. 2.20.

This representational capacity of neuronal populations has fundamental implications for the connectivity of the brain, for it shows that neurons need not have hundreds of thousands or millions of inputs to have available to them information about what is represented in another population of cells, but that instead the real numbers of perhaps 8,000–10,000 synapses per neuron would be adequate for them to receive considerable information from the several different sources between which this set of synapses is allocated.

It may be noted that it is unlikely that there are further processing areas beyond those described where ensemble coding changes into grandmother cell encoding. Anatomically, there does not appear to be a whole further set of visual processing areas present in the brain; and outputs from the temporal lobe visual areas such as those described are taken directly to limbic and related regions such as the amygdala and orbitofrontal cortex, and via the perirhinal and entorhinal cortex to the hippocampus (see Chapter 9, Rolls (2000a), Rolls (2016b), and Rolls (2011d)). Indeed, tracing this pathway onwards, we have found a population of neurons with face-selective responses in the amygdala, and in the majority of these neurons, different responses occur to different faces, with ensemble (not local) coding still being present (Leonard, Rolls, Wilson and Baylis, 1985). The amygdala, in turn, projects to another structure that may be important in other behavioral responses to faces, the ventral striatum, and comparable neurons have also been found in the ventral striatum (Williams, Rolls, Leonard and Stern, 1993). We have also recorded from face-responding neurons in the part of the orbitofrontal cortex that receives from the IT/STS cortex, and discovered that the encoding there is also not local but is distributed (Rolls, Critchley, Browning and Inoue, 2006a).

2.4.9 Face expression, gesture, and view represented in a population of neurons in the cortex in the superior temporal sulcus

In addition to the population of neurons that code for face identity, which tend to have object-based representations and are in areas TEa and TEM on the ventral bank of the superior temporal sulcus, there is a separate population in the cortex in the anterior part of the superior temporal sulcus (e.g. area TPO) that conveys information about facial expression (Hasselmo, Rolls and Baylis, 1989a) (see e.g. Fig. 2.21). Some of the neurons in this region tend to have view-based representations (so that information is conveyed for example about whether the face is looking at one, or is looking away), and might respond to moving faces, and to facial gesture (Hasselmo, Rolls, Baylis and Nalwa, 1989b).

The discovery of neurons in the cortex in the superior temporal sulcus (STS) that respond to face expression, face and head movement, and social signals such as breaking eye contact by closing the eyes or by turning the head to break eye contact (Baylis, Rolls and Leonard, 1987; Hasselmo, Rolls and Baylis, 1989a; Hasselmo, Rolls, Baylis and Nalwa, 1989b) led to the proposal that these cortical regions are involved in social behavior. That proposal has now been accepted (Pitcher and Ungerleider, 2021). The discoveries also led to the proposal that this visual cortical stream involved a combination of information from the ventral and dorsal visual streams (Hasselmo, Rolls and Baylis, 1989a; Hasselmo, Rolls, Baylis and Nalwa, 1989b), and that also has been accepted (Pitcher and Ungerleider, 2021). The connectivity that underlies this convergence in humans (Rolls et al., 2023e) is described in Section 2.5. This STS system has been proposed to be the source of the inputs to neurons in the primate orbitofrontal cortex that have similar responses to socially relevant face expression and gesture (Rolls, Critchley, Browning and Inoue, 2006a). These neurons in the orbitofrontal cortex are likely to be important in social and emotional responses to faces, in that face and voice expression processing is impaired by damage to the human orbitofrontal cortex (Hornak, Rolls and Wade, 1996; Hornak, Bramham, Rolls, Morris, O'Doherty, Bullock and Polkey, 2003). Impairments of processing in this STS visual stream have been implicated in autism by the lower functional connectivity of these STS cortical regions in people with autism spectrum disorder (Cheng, Rolls, Gu, Zhang and Feng, 2015; Cheng, Rolls, Zhang, Sheng, Ma, Wan, Luo and Feng, 2016b; Rolls, Zhou, Cheng, Gilson, Deco and Feng, 2020f).

Thus information in cortical areas that project to the amygdala and orbitofrontal cortex includes information about face identity, and about face expression and gesture (Rolls, Critchley, Browning and Inoue, 2006a; Leonard, Rolls, Wilson and Baylis, 1985; Rolls, 2011d). Both types of information are important in social and emotional responses to other primates (including humans), which must be based on who the individual is as well as on the face expression or gesture being made (Rolls, 2014a). One output from the amygdala for this information is probably via the ventral striatum, for a small population of neurons has been found in the ventral striatum with responses selective for faces (Rolls and Williams, 1987a; Williams, Rolls, Leonard and Stern, 1993).

2.4.10 Specialized regions in the temporal cortical visual areas

As we have just seen, some neurons respond to face identity, and others to face expression (Hasselmo, Rolls and Baylis, 1989a; Rolls, 2011d, 2014a). The neurons responsive to expression were found primarily in the cortex in the superior temporal sulcus, while the neurons responsive to identity were found in the inferior temporal gyrus. In more detail, the face-selective neurons described in this book are found mainly between 7 mm and 3 mm posterior to the sphenoid reference, which in a 3–4 kg macaque corresponds to approximately 11 to 15 mm anterior to the interaural plane (Baylis, Rolls and Leonard, 1987; Rolls, 2007e,c, 2011d,

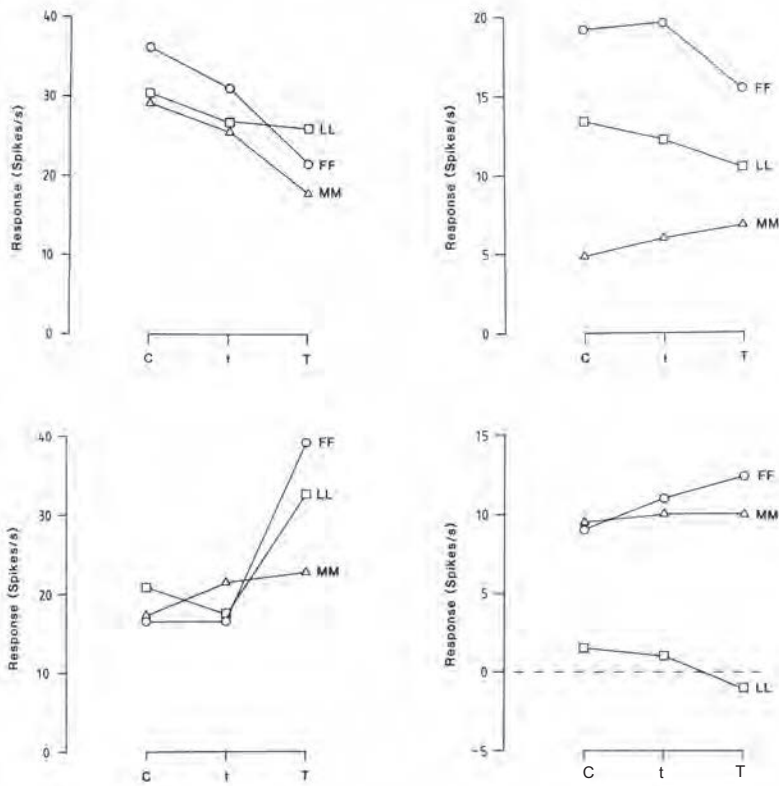

Fig. 2.21 There is a population of neurons in the cortex in the superior temporal sulcus (STS) with responses tuned to respond differently to different face expressions. The cells in the two left panels did not discriminate between individuals (faces MM, FF, and LL), but did discriminate between different expressions on the faces of those individuals (C, calm expression; t, mild threat; T, strong threat). In contrast, the cells in the right two panels responded differently to different individuals, and did not discriminate between different expressions. The neurons that discriminated between expressions were found mainly in the cortex in the fundus of the superior temporal sulcus; the neurons that discriminated between identity were in contrast found mainly in the cortex in the lateral part of the ventral lip of the superior temporal sulcus (areas TEa and TE_m). (Reproduced with permission from Michael E. Hasselmo, Edmund T. Rolls and Gordon C. Baylis (1989) *The role of expression and identity in the face-selective responses of neurons in the temporal visual cortex of the monkey*. Copyright © 1989 Elsevier Ltd.)

2012d). The ‘middle face patch’ of Tsao, Freiwald, Tootell and Livingstone (2006) was at A6, which is probably part of the posterior inferior temporal cortex. In the anterior inferior temporal cortex areas we have investigated, there are separate regions specialized for face identity in areas TEa and TE_m on the ventral lip of the superior temporal sulcus and the adjacent gyrus, and for face expression and movement in the cortex deep in the superior temporal sulcus (Hasselmo, Rolls and Baylis, 1989a; Baylis, Rolls and Leonard, 1987; Rolls, 2007e, 2011d, 2012d) (see Sections 2.4.9 and 2.4.10).

A further way in which some of these neurons in the cortex in the superior temporal sulcus may be involved in social interactions is that some of them respond to gestures, for example to a face undergoing ventral flexion (i.e. the head bending at the neck forwards and down) (Perrett, Smith, Potter, Mistlin, Head, Milner and Jeeves, 1985b; Hasselmo, Rolls, Baylis and Nalwa, 1989b). The interpretation of these neurons as being useful for social interactions is that in some cases these neurons respond not only to ventral head flexion, but also to the eyes lowering and the eyelids closing (Hasselmo, Rolls, Baylis and Nalwa, 1989b). These movements (turning the head away, breaking eye contact, and eyelid lowering) often occur

Fig. 2.22 Lateral view of the macaque brain (left hemisphere) showing the different architectonic areas (e.g. TEm, TEa) in and bordering the anterior part of the superior temporal sulcus (STS) of the macaque (see text). The STS has been drawn opened to reveal the cortical areas inside it, and is circumscribed by a thick line. (From Seltzer, B. and Pandya, D.N. (1978) Afferent cortical connections and architectonics of the superior temporal sulcus and surrounding cortex in the rhesus monkey. *Brain Research* 149: 1–24. Copyright © Elsevier Ltd.)

together when a monkey is breaking social contact with another, and neurons that respond to these components could be built by associative synaptic modification. It is also important when decoding facial expression to retain some information about the direction of the head relative to the observer, for this is very important in determining whether a threat is being made in your direction. The presence of view-dependent, head and body gesture (Hasselmo, Rolls, Baylis and Nalwa, 1989b), and eye gaze (Perrett, Smith, Potter, Mistlin, Head, Milner and Jeeves, 1985b), representations in some of these cortical regions where face expression is represented is consistent with this requirement. In contrast, the TE areas (more ventral, mainly in the macaque inferior temporal gyrus), in which neurons tuned to face identity (Hasselmo, Rolls and Baylis, 1989a) and with view-independent responses (Hasselmo, Rolls, Baylis and Nalwa, 1989b) are more likely to be found, may be more related to an object-based representation of identity. Of course, for appropriate social and emotional responses, both types of subsystem would be important, for it is necessary to know both the direction of a social gesture, and the identity of the individual, in order to make the correct social or emotional response (Rolls, 2014a).

Further evidence for specialization of function in the different architectonically defined areas of the temporal cortex (Seltzer and Pandya, 1978) (see Fig. 2.22) was found by Baylis, Rolls and Leonard (1987). Areas TPO, PGa and IPa are multimodal, with neurons that respond to visual, auditory and/or somatosensory inputs. The more ventral areas in the inferior temporal gyrus (areas TE3, TE2, TE1, TEa and TEm) are primarily unimodal visual areas. Areas in the cortex in the anterior and dorsal part of the superior temporal sulcus (e.g. TPO, IPa and IPg) have neurons specialized for the analysis of moving visual stimuli. Neurons responsive primarily to faces are found more frequently in areas TPO, TEa and TEm, where they comprise approximately 20% of the visual neurons responsive to stationary stimuli, in

contrast to the other temporal cortical areas in which they comprise 4–10%. The stimuli that activate other cells in these TE regions include simple visual patterns such as gratings, and combinations of simple stimulus features (Gross, Desimone, Albright and Schwartz, 1985; Baylis, Rolls and Leonard, 1987; Tanaka, Saito, Fukada and Moriya, 1990). If patches are identified by fMRI, the proportion of neurons tuned to for example faces may be high (Tsao, Freiwald, Tootell and Livingstone, 2006; Freiwald, Tsao and Livingstone, 2009; Tsao, 2014; Freiwald, 2020; Arcaro and Livingstone, 2021). Due to the fact that face-selective neurons have a wide distribution (Baylis, Rolls and Leonard, 1987), and also occur in different patches (Tsao et al., 2006; Tsao, 2014), it might be expected that only large lesions, or lesions that interrupt outputs of these visual areas, would produce readily apparent face-processing deficits.

Another specialization is that areas TEa and TEM, which receive inter alia from the cortex in the intraparietal sulcus, have neurons that are tuned to binocular disparity, so that information derived from stereopsis about the 3D structure of objects is represented in the inferior temporal cortical visual areas (Janssen, Vogels and Orban, 1999, 2000). Interestingly, these neurons respond only when the black and white regions in the two eyes are correlated (that is, when a white patch in one eye corresponds to a white patch in the other eye) (Janssen et al., 2003). This corresponds to what we see perceptually and consciously. In contrast, in V1, MT and MST, depth-tuned neurons can respond to anticorrelated depth images, that is where white in one eye corresponds to black in the other (Parker, Cumming and Dodd, 2000; DeAngelis, Cumming and Newsome, 2000; Parker, 2007), and this may be suitable for eye movement control, but much less for shape and object discrimination and identification. It may be expected that other depth cues, such as perspective, surface shading, and occlusion, affect the response properties of some neurons in inferior temporal cortex visual areas. Binocular disparity, and information from these other depth cues, may be used to compute the absolute size of objects, which is represented independently of the distance of the object for a small proportion of inferior temporal cortex neurons (Rolls and Baylis, 1986). Knowing the absolute size of an object is useful evidence to include in the identification of an object. Although cues from binocular disparity can thus drive some temporal cortex visual neurons, and there is a small proportion of inferior temporal neurons that respond better to real faces and objects than to 2D representations on a monitor, it is found that the majority of TE neurons respond as well or almost as well to 2D images on a video monitor as to real faces or objects (Perrett, Rolls and Caan, 1982). Moreover, the tuning of inferior temporal cortex neurons to images of faces or objects on a video monitor is similar to that to real objects (personal observations of E. T. Rolls).

Neuroimaging data in humans, while not being able to address the details of what is encoded in a brain area or of how it is encoded, does provide evidence consistent with the neurophysiology that there are different face processing systems in the human brain, and different processing subsystems for faces, objects, moving objects, scenes, and agents performing actions (Spiridon, Fischl and Kanwisher, 2006; Grill-Spector and Malach, 2004; Epstein and Kanwisher, 1998; Morin, Hadj-Bouziane, Stokes, Ungerleider and Bell, 2015; Nasr, Liu, Devaney, Yue, Rajimehr, Ungerleider and Tootell, 2011; Weiner and Grill-Spector, 2015; Deen, Koldewyn, Kanwisher and Saxe, 2015; Pitcher, Ianni and Ungerleider, 2019; Zhang, Japee, Stacy, Flessert and Ungerleider, 2020; Haxby, Gobbini and Nastase, 2020; Pitcher and Ungerleider, 2021). For example, Kanwisher, McDermott and Chun (1997) and Ishai, Ungerleider, Martin, Schouten and Haxby (1999) have shown activation by faces of an area in the fusiform gyrus; Hoffman and Haxby (2000) have shown that distinct areas are activated by eye gaze and face identity; Dolan, Fink, Rolls, Booth, Holmes, Frackowiak and Friston (1997) have shown that a fusiform gyrus area becomes activated after humans learn to identify faces in complex scenes; and the amygdala (Morris, Fritch, Perrett, Rowland, Young, Calder and Dolan, 1996) and orbitofrontal cortex (Blair, Morris, Frith, Perrett and Dolan, 1999; Rolls,

2014a) may become activated particularly by certain face expressions. Cortical regions in humans that respond to faces, body parts, objects, scenes (Pitcher et al., 2019; Vogels, 2022) and word form (Vinckier et al., 2007; Dehaene and Cohen, 2011) and the connectivity between them (Rolls et al., 2023e) are considered further in Section 2.5. Consistent with the neurophysiology described below and by Baylis, Rolls and Leonard (1987), human fMRI studies are able to detect small patches of non-face and other types of responsiveness in areas that appeared to respond primarily to one category such as faces (Grill-Spector, Sayres and Ress, 2006; Haxby, 2006).

Different inferior temporal cortex neurons in macaques not only provide different types of information about different aspects of faces, as described above, but also respond differently to different *categories* of visual stimuli, with for example some neurons conveying information primarily about faces, and others about objects (Rolls and Tovee, 1995b; Rolls, Treves, Tovee and Panzeri, 1997d; Booth and Rolls, 1998; Rolls and Treves, 2011; Rolls, 2012d, 2016b). In fact, when recording in the inferior temporal cortex, one finds small clustered groups of neurons, with neurons within a cluster responding to somewhat similar attributes of stimuli, and different clusters responding to different categories or types of visual stimuli. For example, within the set of neurons responding to moving faces, there are some neuronal clusters that respond to for example ventral and dorsal flexion of the head on the body; others that respond to axial rotation of the head; others that respond to the sight of mouth movements; and others that respond to the gaze direction in a face being viewed (Hasselmo, Rolls, Baylis and Nalwa, 1989b; Perrett, Smith, Potter, Mistlin, Head, Milner and Jeeves, 1985b). The parts of the body to which neurons in the cortex in the superior temporal sulcus respond include not only to heads, moving for example with respect to the body (Hasselmo, Rolls, Baylis and Nalwa, 1989b) (e.g. Fig. 2.12), but also to body parts, and to images of bodies walking (Perrett, Smith, Mistlin, Chitty, Head, Potter, Broennimann, Milner and Jeeves, 1985a; Pitcher, Ianni and Ungerleider, 2019; Vogels, 2022), both of which may be important in social behavior.

Within the domain of objects, some neuronal clusters respond based on the shapes of the object (e.g. responding to elongated and not round objects), others respond based on the texture of the object being viewed, and others are sensitive to what the object is doing (Hasselmo, Rolls, Baylis and Nalwa, 1989b; Perrett, Smith, Mistlin, Chitty, Head, Potter, Broennimann, Milner and Jeeves, 1985a). Within a cluster, each neuron is tuned differently, and may combine at least partly with information predominant in other clusters, so that at least some of the neurons in a cluster can become quite selective between different objects, with the preference for individual objects showing the usual exponential firing rate distribution (Rolls, 2016b). Using optical imaging in macaques, Tanaka and colleagues (Tanaka, 1996) have seen comparable evidence for different localized clusters of neuronal activation produced by different types or categories of stimuli.

The principle that Rolls proposes underlies this local clustering is the representation of the high dimensional space of objects and their features into a two-dimensional cortical sheet using the local self-organizing mapping principles described in Section B.4.6 and illustrated in a Matlab program described in Appendix D. In this situation, these principles produce maps that have many fractures, but nevertheless include local clusters of similar neurons. Exactly this clustering can be produced in the model of visual object recognition, VisNet, described in Section 2.8 by replacing the lateral inhibition filter shown in Fig. 2.29 with a difference of Gaussians filter of the type illustrated in Fig. B.21. Such a difference of Gaussians filter would reflect the effects of short range excitatory (recurrent collateral) connections between cortical pyramidal cells, and slightly longer range inhibition produced through inhibitory interneurons. These local clusters minimize the wiring length between neurons, if the computations involve exchange of information within neurons of a similar general type, as will usually be

the case (see Section B.4.6). Minimizing wiring length is crucial in keeping brain size relatively low (see Section B.4.6). Another useful property of such self-organizing maps is that they encourage distributed representations in which semi-continuous similarity functions are mapped. This is potentially useful in building representations that then generalize usefully when new stimuli are shown between representations that are already set up continuously in the map.

Another fundamental contribution and key aspect of neocortical design facilitated by the short-range recurrent excitatory connections is that the attractors that are formed are local. This is fundamentally important, for if the neocortex had long-range connectivity, it would tend to be able to form only as many attractor states as there are connections per neocortical neuron, which would be a severe limit on cortical memory capacity (O’Kane and Treves, 1992) (see further Sections 1.14.4, B.9, Rolls (2016b), and Spalla et al. (2021)).

It is consistent with this general conceptual background that Kreiman, Koch and Fried (2000) and others ((De Falco et al., 2016; Ison et al., 2015; Quian Quiroga, 2012) see Fried, Rutishauser, Cerf and Kreiman (2014) and Rolls (2015c)) have described some neurons in the human temporal lobe that seem to respond to categories of object or to concepts of people. This is consistent with the principles just described, although in humans backprojections from language or other cognitive areas concerned for example with tool use might also influence the categories represented in high order cortical areas, as described in Section B.4.5, and by Farah, Meyer and McMullen (1996), Farah (2000) and Rolls (2016b). In fact, neurons recorded in the macaque inferior temporal visual cortex predict by a weighted sum the recognition of objects by human observers (Majaj, Hong, Solomon and DiCarlo, 2015), providing evidence that what has been discovered in the inferior temporal cortex is relevant to understanding human visual object recognition. Moreover, this also indicates that inferior temporal cortex neurons provide a useful goal for what the models of object recognition described in Section 2.6 must account for, in order to provide a basis for understanding human visual object recognition.

2.5 The connectivity of the ventral visual pathways in humans

It is now possible to consider how the ventral stream visual pathways are organised in humans by considering the connectivity between ventral stream visual regions in the human brain. This approach builds on the Human Connectome Project Multimodal Parcellation atlas (HCP-MMP) (Glasser et al., 2016a; Huang et al., 2022) introduced in Section 1.12, and measures diffusion tractography, functional connectivity, and effective connectivity as described in Sections 1.13.1 - 1.13.3. The connectivities described here were measured in 171 participants imaged at 7T in the Human Connectome Project (Glasser et al., 2016b). By using this high resolution atlas, and by measuring effective connectivity between the regions defined in it to help identify the flow of information, and adding what has been discovered from neurophysiology in macaques and from activation studies in humans, a framework is provided for understanding *what* computations are performed at different stages of processing in the human brain, and that in turn has implications for *how* the computations are performed. Several visual streams have been identified in humans (Rolls et al., 2023e), and are described next.

2.5.1 A Ventrolateral Visual Cortical Stream to the inferior temporal visual cortex for object and face representations

The Ventrolateral Visual Cortical Stream is characterized by effective connectivities that lead towards the inferior temporal visual cortex. After a progression from $V1 > V2 > V3 > V4$ (where $>$ indicates the general progression but does not exclude some connectivity that is more than between strictly adjacent levels in the hierarchy), $V4$ (and to some extent $V3$) have effective connectivity to HCP-MMP ventral visual division regions such as PIT (a posterior inferior temporal cortex region identified in humans) and $V8$. PIT, and to some extent $V8$, then have connectivity to FFC, the ‘fusiform face cortex’ (Fig. 2.23), which is in the fusiform gyrus in which scenes are represented medially (Sulpizio et al., 2020), then objects and faces, and next moving laterally, words in a visual word form area (Dehaene and Cohen, 2011). This can be considered as a series of representations each at a different spatial scale of size from medial to lateral. FFC in turn has connectivity to posterior inferior temporal cortex regions TE2p and PH (and PH also connects to TE2p). PH and TE2p project to PHT, which in turn projects to TE1p, and to an anterior inferior temporal cortex region TE2a. The posterior inferior temporal cortex regions TE1p and TE2p project to anterior inferior temporal cortex regions TE2a, TE1m and TE1a (Fig. 2.23).

TE1a then projects anteriorly to temporal pole region TGd which is involved in semantic representations for language (Rolls et al., 2022b) (Chapter 8). Other regions related to language, temporo-parieto-occipital regions TPOJ1, TPOJ2 and TPOJ3 (Rolls et al., 2022b), also receive effective connectivity from ventrolateral visual cortical stream regions including the FFC, providing a route for face and word form inputs to reach language-related regions (Figs. 2.24 and 2.25). We therefore have a route through the ventrolateral visual stream as shown schematically in Fig. 2.23 which can now be shown to reach human language-related cortical regions. This ventrolateral cortical visual stream also provides ‘what’ visual outputs (Rolls et al., 2023e) to the orbitofrontal cortex / vmPFC reward/punishment emotion-related system (Rolls et al., 2023c); to the hippocampal memory system as a ‘what’ component of episodic memory (Rolls et al., 2022a); and to the prefrontal cortex for short-term memory and planning (Rolls et al., 2023f); and to the cortex in the superior temporal sulcus (STS) involved in multimodal representations relevant to social behavior and to semantics, which is described next.

These findings are supported by tract-tracing studies in macaques (Kravitz et al., 2013, 2011), though more cortical regions are distinguished in the human brain, and the advantage of studying the connectivity in humans with a parcellation such as the HCP-multimodal parcellation (Glasser et al., 2016a; Huang et al., 2022) is that we are now dealing with identifiable systems in humans that other studies (fMRI, lesion etc) in humans can directly relate to by reference to the HCP-multimodal parcellation, and that the connectivity in humans relates to the strength of connections in both directions between every pair of cortical regions, not only to whether anatomical connections can be traced.

Key discoveries that we made with neuronal recordings in macaques as described in Section 2.4 about this ventrolateral visual cortical stream leading to the anterior inferior temporal visual cortex (IT) are that IT neurons code for objects and not their reward value (Rolls et al., 1977); that some neurons code for faces (Perrett et al., 1979, 1982); that IT neurons use sparse distributed encoding for face identity (Baylis, Rolls and Leonard, 1985; Rolls, Treves, Tovee and Panzeri, 1997d) with relatively independent information provided by populations of neurons (Treves, Panzeri, Rolls, Booth and Wakeman, 1999; Rolls, Treves and Tovee, 1997b; Rolls and Treves, 2011); that feature combinations in the correct spatial position encode faces and objects (Perrett, Rolls and Caan, 1982; Desimone, Albright, Gross and Bruce, 1984); and that IT neurons have representations of objects that are invariant with respect to

Fig. 2.23 Effective connectivity of the Ventrolateral Visual Cortical Stream which reaches inferior temporal cortex TE regions in which objects and faces are represented: schematic overview. A green arrow shows how the Ventrolateral Visual Stream provides ‘what’ input to the hippocampal memory system via parahippocampal gyrus TF to perirhinal PeEc connectivity from FFC, PH, TE1p, TE2a and TE2p. The Ventrolateral Visual Stream also provides input to the semantic language system via TGd. The Ventrolateral Visual Stream also has connectivity to the inferior parietal visual area PFm, PGs and PGI as indicated by 2 green arrows. The widths of the lines and the size of the arrowheads indicate the magnitude and direction of the effective connectivity. (From Rolls,E.T., Deco,G., Huang,C.-C. and Feng,J. (2023) Multiple cortical visual streams in humans. *Cerebral Cortex* 33: 3319-3349. doi: 10.1093/cercor/bhac276. Copyright © Oxford University Press.)

transforms including retinal position (Tovee, Rolls and Azzopardi, 1994; Gross, Desimone, Albright and Schwartz, 1985), size and contrast (Rolls and Baylis, 1986), spatial frequency (Rolls et al., 1985, 1987), and in some cases to view (Booth and Rolls, 1998; Hasselmo, Rolls, Baylis and Nalwa, 1989b). For natural vision, we discovered in complex natural scenes that IT neurons respond primarily to the object being fixated (Sheinberg and Logothetis, 2001; Rolls et al., 2003a; Aggelopoulos and Rolls, 2005) by reducing their receptive field size (Rolls et al., 2003a) which simplifies the interpretation of the output of IT by structures such as the orbitofrontal cortex which implements object-reward association learning (Rolls, Critchley, Mason and Wakeman, 1996b; Thorpe, Rolls and Maddison, 1983; Rolls, 2019e,f) and the hippocampal system which implements object-scene location learning (Rolls, Xiang and Franco, 2005c; Rolls and Xiang, 2006; Rolls, 2023c). The ‘what’ information to the hippocampal

memory system (via TF the lateral parahippocampal cortex and in some cases perirhinal or entorhinal cortex) is tapped from this ventrolateral object/face system from FFC, PH, PHT, TE2p, TE1p, TE2a and TGd (Rolls et al., 2023e) (Fig. 2.23). Moreover, we discovered that IT neurons can learn rapidly to represent new objects without disturbing representations of previously learned objects (Rolls et al., 1989b). Results consistent with these discoveries and principles of operation have been reported (Freiwald, Tsao and Livingstone, 2009; Rust and DiCarlo, 2010; Freiwald, 2020; Tsao, 2014; Freedman, 2015; Aparicio, Issa and DiCarlo, 2016; Arcaro and Livingstone, 2021).

The hierarchical organisation of the connectivity of the Ventrolateral Visual Stream shown schematically in Fig. 2.23 provides an architecture that with convergence from stage to stage allows features to be combined across larger receptive fields from stage to stage to produce, using competitive learning, neurons that become specialised with sparse distributed encoding to represent different objects and faces (Rolls, 1992a, 2021b), as described in Sections 2.6.6–2.13. Invariances such as position, size and view can be built into the neuronal responses by using a local synaptic learning rule in the competitive network that enables these properties of objects, which tend to be invariant over short time epochs of 1 - several s, to be learned by the neurons (Rolls, 1992a, 2021b). This unsupervised self-organising learning system with only local synaptic learning rules has been built into a model, VisNet, that shows how this learning can take place (Rolls, 1992a; Wallis and Rolls, 1997; Rolls, 2021d,b; Stringer et al., 2007b; Perry et al., 2006; Stringer and Rolls, 2002; Elliffe et al., 2002). A similar approach has been developed by others (Franzius et al., 2007; Wiskott and Sejnowski, 2002; Wyss et al., 2006). This biologically plausible approach to invariant visual object recognition is described in the rest of this Chapter.

A very different approach to object recognition using deep convolutional networks (Rajalingham et al., 2018; Yamins et al., 2014; Cadieu et al., 2014; Yamins and DiCarlo, 2016; Rajalingham et al., 2018) is biologically implausible, because in the brain there is no teacher for each output neuron, and errors between the firing rate of each output neuron and a putative teacher's instruction cannot be used to calculate for every synapse at every earlier stage of the hierarchy and then backpropagated back to correct every one of those synaptic strengths (Rolls, 2021b,d) (see Sections B.12 B.14 and 2.9.4). Further, top-down processes such as memory recall (Treves and Rolls, 1994; Rolls and Treves, 1994; Rolls, 2021b) and top-down attention (Deco and Rolls, 2005a, 2004; Rolls, 2021b) can be implemented biologically plausibly by the cortico-cortical backprojection effective connectivities found in the real brain (Fig. 2.23), and that associative memory recall / top-down attention functionality is likely to be inconsistent with error backpropagation. Moreover most of the deep learning approaches to vision utilise convolutional deep learning (see Sections 2.9.4, 19.4, and B.14), with the convolution part also being biologically implausible. Comparing neurons recorded in the brain with the units found in deep learning algorithms tuned to produce neurons that resemble those in the brain (Cadieu, Hong, Yamins, Pinto, Ardila, Solomon, Majaj and DiCarlo, 2014; Yamins, Hong, Cadieu, Solomon, Seibert and DiCarlo, 2014; Yamins and DiCarlo, 2016; Rajalingham, Issa, Bashivan, Kar, Schmidt and DiCarlo, 2018; Jia, Hong and DiCarlo, 2021; Zhuang, Yan, Nayebi, Schrimpf, Frank, DiCarlo and Yamins, 2021) seems like a poorly founded exercise, for two reasons. First, the solutions found by deep convolution networks and other machine learning algorithms for image to category mapping may be very different to those found in a system such as the brain that uses only local learning rules and is restricted to only 4–5 layers in the hierarchy. Second, it is difficult to know what can be learned about how primate including human vision works computationally from deep learning and related machine learning algorithms, given that the understanding of exactly how these machine learning algorithms reach their mapping is almost un-understood, apart from the recipe that makes them work (Plebe and Grasso, 2019; Bowers et al., 2023).

2.5.2 A Visual Cortical Stream to the cortex in the inferior bank of the superior temporal sulcus involved in semantic representations

One output of the Ventrolateral Visual Cortical Stream for object and face information is to the cortex in the inferior parts of the Superior Temporal Sulcus (STS), regions STSva and STSvp (Rolls et al., 2022b). These inferior cortical regions in the STS have been identified by a community analysis as part of a ventral temporal lobe semantic system involved in language (Rolls et al., 2022b). The visual inputs to regions STSva and STSvp in this ventral STS semantic system are described here. The visual inputs to these inferior STS regions STSva and STSvp are shown in Fig. 2.24, and come from inferior temporal visual cortex (TE1a, TE1m and TE2a), temporal pole (TGd and TGv), and parietal PGi. Other connectivities shown with green arrows in Fig. 2.24 are with the memory-related parts of the posterior cingulate cortex (31pd and 31pv) (Rolls et al., 2023i); and from the ventromedial prefrontal cortex (vmPFC, in particular 10v and 10r) (Rolls et al., 2023c). STSva and STSvp have connectivity directed towards Broca's area 44 and 45, and related areas (47s, 47l), and to the Superior Frontal Language region SFL (Rolls et al., 2022b). This 'inferior STS cortex semantic network', for which the visual input is described here, is described in more detail for the same participants elsewhere (Rolls et al., 2022b) (see Chapter 8).

This inferior (/ventral) STS cortex network that includes STSva and STSvp is considered to be separate from the superior (/dorsal) STS cortex network described below that includes STSda and STSdp because these regions fall into different semantic connectivity networks as shown by a community analysis (Rolls et al., 2022b). The inferior network is likely to be more involved in invariant object and face identity representations for static visual stimuli of the type represented in the inferior temporal visual cortex, whereas the superior (/dorsal) regions are more likely to be involved in responses to face expression and visual motion including that which can be combined with auditory stimuli such as the sight and sound of a vocalization (Baylis, Rolls and Leonard, 1987; Hasselmo, Rolls, Baylis and Nalwa, 1989b; Hasselmo, Rolls and Baylis, 1989a; Rolls, 2021b; Rolls, Deco, Huang and Feng, 2022b; Rolls, Rauschecker, Deco, Huang and Feng, 2023h) (see Section 2.4).

2.5.3 A Visual Cortical Stream to the cortex in the superior bank of the superior temporal sulcus involved in multimodal semantic representations including visual motion, auditory, somatosensory and social information

In the superior bank of the cortex in the Superior Temporal Sulcus (STS), regions STSda and STSdp have been identified by a community analysis as part of a superior temporal lobe semantic system involved in language (Rolls et al., 2022b). The visual inputs to regions STSda and STSdp in this superior STS semantic system are described here. Visual inputs reach STSdp from PGi (Rolls et al., 2023e) (Fig. 2.25), and provide a route for moving visual stimuli / objects analyzed in the parietal cortex to reach STS regions (Rolls et al., 2023d). Visual inputs also reach STSdp from the Superior Temporal Visual (STV) region which receives from both MT and FFC (Fig. 2.25), and which as described below could contribute to the neuronal activity in the cortex in the STS which has been shown to respond to moving heads, faces and objects in macaques (Hasselmo et al., 1989b,a). STSda and STSdp also have connectivity from STSva and STSvp which have strong connectivity with the Ventrolateral Visual Stream (Figs. 2.23 and 2.25). STSda and STSdp also receive auditory effective connectivity from A5 (Fig. 2.25) (Rolls et al., 2023h). STSdp has connectivity directed towards Broca's area 44 and 45, and related areas (47l), and to the PeriSylvian Language region PSL and to the Superior Frontal Language region SFL (Rolls et al., 2022b).

Fig. 2.24 Inferior bank of the STS cortex semantic system in STSva and STSvp: schematic overview. An output of the Ventrolateral Visual System for object and face information is to the cortex in the inferior parts of the Superior Temporal Sulcus, STSva and STSvp. The visual inputs to these inferior STS cortex regions are shown with green arrows, and come from TE1a, TE1m, TE2a, TGd, TGv, and PGI. Other connectivities are with the memory-related parts of the posterior cingulate cortex (31pd and 31pv); and from the vmPFC (10v and 10r). STSva and STSvp have connectivity directed towards Broca’s area 44 and 45, and related areas (47s), and to the Superior Frontal Language region (SFL). (From Rolls, E.T., Deco, G., Huang, C.-C. and Feng, J. (2023) Multiple cortical visual streams in humans. *Cerebral Cortex* 33: 3319-3349. doi: 10.1093/cercor/bhac276. Copyright © Oxford University Press.)

This ‘superior STS cortex semantic system’ thus enables multimodal representations including visual, auditory, and probably also somatosensory via PGI, to gain access to the language system. This is a major output of cortical visual processing for use in language, described in more detail elsewhere (Rolls et al., 2022b). There is also a link via TF to the hippocampal memory system (Fig. 2.25) (Rolls et al., 2022a).

Discoveries in macaques provide an indication for what is represented in these STS regions. It was discovered that single neurons in the macaque STS respond to face expression and also to face and head movement to encode the social relevance of stimuli (Hasselmo, Rolls, Baylis and Nalwa, 1989b; Hasselmo, Rolls and Baylis, 1989a). For example, a neuron might respond to closing of the eyes, or to turning of the head away from facing the viewer, both of which break social contact (Hasselmo et al., 1989b,a). Some neurons respond to the direction of gaze (Perrett et al., 1987). It was found that many of the neurons in the STS respond only or

Fig. 2.25 Superior bank of the STS semantic system in STSda and STSdp: schematic overview. Visual inputs for moving visual stimuli / objects reach STSdp from PGi. Visual inputs also reach STSdp from the Superior Temporal Visual area which receives from FFC. STSda and STSdp also have connectivity from STSva and STSvp which have strong connectivity with the Ventrolateral Visual Stream (Fig. 2.23). STSda and STSdp also receive auditory effective connectivity from A5. STSdp has connectivity directed towards Broca's area 44 and 45, and related areas (47l), and to the PeriSylvian Language region PSL and to the Superior Frontal Language region SFL. (From Rolls, E.T., Deco, G., Huang, C.-C. and Feng, J. (2023) Multiple cortical visual streams in humans. *Cerebral Cortex* 33: 3319-3349. doi: 10.1093/cercor/bhac276. Copyright © Oxford University Press.)

much better to moving faces or objects (Hasselmo et al., 1989a), whereas in the anterior inferior temporal cortex neurons were discovered that respond well to static visual stimuli, and are tuned for face identity (Perrett, Rolls and Caan, 1982; Rolls, 1984, 2000a; Rolls and Treves, 2011; Rolls, Treves, Tovee and Panzeri, 1997d; Rolls, Treves and Tovee, 1997b; Hasselmo, Rolls and Baylis, 1989a). It has been proposed that PGi, with its inputs from PGs which has connectivity with superior parietal and intraparietal regions that encode visual motion, is part of this processing stream for socially relevant face-related information (Rolls et al., 2023d). Consistent with this, the effective connectivity is stronger from PGi to STS regions (Rolls et al., 2023e). In humans, representations of this type could provide part of the basis for the development of systems to interpret the significance of such stimuli, including theory of mind. Consistent with this proposal, activations in the temporo-parietal junction region are related to theory of mind (DiNicola et al., 2020; Buckner and DiNicola, 2019; Schurz et

al., 2017). Signals of this type are important in understanding the meaning of seen faces and objects. Indeed evidence about moving objects present in the STS cortex may reach it from PGs and PGI, which in turn receive connectivity from the intraparietal sulcus regions (Rolls et al., 2023d) in which neurons respond to visual motion and to grasping objects which are important in tool use (Maravita and Romano, 2018), which is another fundamental aspect of the meaning or semantics of stimuli. We proposed that the cortex in the STS in which neurons respond to moving faces, eyes, etc and to changing facial expression enables ventral stream ‘what’ information to be combined with dorsal stream motion information to form a third visual stream, and that this could be useful for social functions (Hasselmo et al., 1989b,a), especially as this system projects to the orbitofrontal cortex / vmPFC where similar types of neuronal response are found (Rolls et al., 2006a). The concept that this STS cortical system is important in social behavior has recently gained support (Pitcher and Ungerleider, 2021; Pitcher et al., 2019). Moreover, neurons in macaques can respond to auditory stimuli such as vocalisation both in the STS regions (Baylis, Rolls and Leonard, 1987) and in the orbitofrontal cortex (Rolls, Critchley, Browning and Inoue, 2006a). The connectivity described here helps to provide a functional framework for the processing streams involved in these types of function.

The connectivity of a ventromedial visual cortical stream leading to the parahippocampal scene area and hippocampus as a ‘where’ input for episodic memory is described in Section 9.2.8.1 (Rolls et al., 2023e, 2022a; Rolls, 2023c), and of the dorsal visual stream to the parietal cortex in Section 3.6 (Rolls et al., 2023e,d). The parietal cortex visual inputs to the parahippocampal scene area to provide for idiothetic update of ‘where’ inputs to the hippocampus for episodic memory are described in Section 9.2.8.2 (Rolls et al., 2023e,d, 2022a; Rolls, 2023c). Visual inputs to the semantic systems in the ventral and dorsal banks of the cortex in the superior temporal sulcus are described in Chapter 8 (Rolls et al., 2023e, 2022b).

That completes the elaboration of the points made in Section 2.1.2 about *what* is computed in the ventral visual system. We now turn to consider hypotheses about *how* these computations are performed in the ventral visual system.

2.6 How the computations are performed: approaches to invariant object recognition

Given that a key computation performed in the ventral visual system is invariant visual object recognition, we now consider several approaches to **how** this computation is performed in the brain. In this section, a number of approaches are briefly reviewed. Then we turn to the most biologically plausible approach so far, a feature hierarchy system, and then in Section 2.8 we consider developments of this that enable the object recognition to be transform invariant, in the VisNet model.

We start by emphasizing that generalization to different positions, sizes, views etc. of an object is not a simple property of one-layer neural networks. Although neural networks do generalize well, the type of generalization they show naturally is to vectors which have a high dot product or correlation with what they have already learned. To make this clear, Fig. 2.26 is a reminder that the activation h_i of each neuron is computed as

$$h_i = \sum_j x_j w_{ij} \quad (2.1)$$

where the sum is over the C input axons, indexed by j . Now consider translation (or shift) of

Fig. 2.26 A neuron that computes a dot product of the input pattern with its synaptic weight vector generalizes well to other patterns based on their similarity measured in terms of dot product or correlation, but shows no translation (or size, etc.) invariance.

the input pattern vector by one position. The dot product will now drop to a low level, and the neuron will not respond, even though it is the same pattern, just shifted by one location. This makes the point that special processes are needed to compute invariant representations. Network approaches to such invariant pattern recognition are described in this chapter, and the nature of the problem to be solved is described further in Section B.4.7 and Fig. B.24 on page 871. Once an invariant representation has been computed by a sensory system, it is in a form that is suitable for presentation to a pattern association or autoassociation neural network (see Appendix B). This is key to understanding computationally how the inferior temporal visual cortex interfaces to be associated with reward value in the orbitofrontal cortex, and how IT interface to the episodic memory system in the hippocampus.

A number of different computational approaches that have been taken both in artificial vision systems and as suggestions for how the brain performs invariant object recognition are described in the following parts of this section (2.6). This places in context the approach that appears to be taken in the brain and that forms the basis for VisNet described in Section 2.8.

2.6.1 Feature spaces

One very simple possibility for performing object classification is based on feature spaces, which amount to lists of the features that are present in a particular object. The features might consist of textures, colors, areas, ratios of length to width, etc. The spatial arrangement of the features is not taken into account. If n different properties are used to characterize an object, each viewed object is represented by a set of n real numbers. It then becomes possible to represent an object by a point R^n in an n -dimensional space (where R is the resolution of the real numbers used). Such schemes have been investigated (Tou and Gonzalez, 1974; Gibson, 1950, 1979; Bolles and Cain, 1982; Mundy and Zisserman, 1992; Selfridge, 1959; Mel, 1997), but, because the relative positions of the different parts are not implemented in the object recognition scheme, are not sensitive to spatial jumbling of the features. For example, if the features consisted of nose, mouth, and eyes, such a system would respond to faces with jumbled arrangements of the eyes, nose, and mouth, which does not match human vision, nor the responses of macaque inferior temporal cortex neurons, which are sensitive to the spatial arrangement of the features in a face (Rolls, Tovee, Purcell, Stewart and Azzopardi, 1994b). Similarly, such an object recognition system might not distinguish a normal car from

a car with the back wheels removed and placed on the roof. Such systems do not therefore perform shape recognition (where shape implies something about the spatial arrangement of features within an object, see further Ullman (1996)), and something more is needed, and is implemented in the primate visual system.

However, I note that the features that are present in objects, e.g. a furry texture, are useful to incorporate in object recognition systems, and the brain may well use, and the model VisNet in principle can use, evidence from which features are present in an object as part of the evidence for identification of a particular object. I note that the features might consist also of for example the pattern of movement that is characteristic of a particular object (such as a buzzing fly), and might use this as part of the input to final object identification.

The capacity to use shape in invariant object recognition is fundamental to primate vision, but may not be used or fully implemented in the visual systems of some other animals with less developed visual systems. For example, pigeons may correctly identify pictures containing people, a particular person, trees, pigeons etc, but may fail to distinguish a figure from a scrambled version of a figure (Herrnstein, 1984; Cerella, 1986). Thus their object recognition may be based more on a collection of parts than on a direct comparison of complete figures in which the relative positions of the parts are important. Even if the details of the conclusions reached from that research are revised (Wasserman, Kirkpatrick-Steger and Biederman, 1998), it nevertheless does appear that at least some birds may use computationally simpler methods than those needed for invariant shape recognition. For example, it may be that when some birds are trained to discriminate between images in a large set of pictures, they tend to rely on some chance detail of each picture (such as a spot appearing by mistake on the picture), rather than on recognition of the shapes of the object in the picture (Watanabe, Lea and Dittrich, 1993).

2.6.2 Structural descriptions and syntactic pattern recognition

A second approach to object recognition is to decompose the object or image into parts, and to then produce a structural description of the relations between the parts. The underlying assumption is that it is easier to capture object invariances at a level where parts have been identified. This is the type of scheme for which Marr and Nishihara (1978) and Marr (1982) opted. The particular scheme (Binford, 1981) they adopted consists of generalized cones, series of which can be linked together to form structural descriptions of some, especially animate, stimuli (see Fig. 2.27). Such schemes assume that there is a 3D internal model (structural description) of each object. Perception of the object consists of parsing or segmenting the scene into objects, and then into parts, then producing a structural description of the object, and then testing whether this structural description matches that of any known object stored in the system. Other examples of structural description schemes include those of Winston (1975), Sutherland (1968), and Milner (1974). The relations in the structural description may need to be quite complicated, for example ‘connected together’, ‘inside of’, ‘larger than’ etc.

Perhaps the most developed model of this type is the recognition by components (RBC) model of Biederman (1987), implemented in a computational model by Hummel and Biederman (1992). His small set (less than 50) of primitive parts named ‘geons’ include simple 3D shapes such as boxes, cylinders and wedges. Objects are described by a syntactically linked list of the relations between each of the geons of which they are composed. Describing a table in this way (as a flat top supported by three or four legs) seems quite economical. The emphasis more recently has been on the non-accidental properties of objects, which are maintained when objects transform (Kim and Biederman, 2012). Other schemes use 2D surface patches as their primitives (Dane and Bajcsy, 1982; Brady, Ponce, Yuille and Asada, 1985; Faugeras

Fig. 2.27 A 3D structural description of an object based on generalized cone parts. Each box corresponds to a 3D model, with its model axis on the left side of the box and the arrangement of its component axes on the right. In addition, some component axes have 3D models associated with them, as indicated by the way the boxes overlap. (Reproduced from Marr, D. and Nishihara, H.K. (1978) Representation and recognition of the spatial organization of three dimensional structure. *Proceedings of the Royal Society of London B* 200: 269–294. © Royal Society.)

and Hebert, 1986; Faugeras, 1993). When 3D objects are being recognized, the implication is that the structural description is a 3D description. This is in contrast to feature hierarchical systems, in which recognition of a 3D object from any view might be accomplished by storing a set of associated 2D views (see below, Section 2.6.6).

There are a number of difficulties with schemes based on structural descriptions, some general, and some with particular reference to the potential difficulty of their implementation in the brain. First, it is not always easy to decompose the object into its separate parts, which must be performed before the structural description can be produced. For example, it may be difficult to produce a structural description of a cat curled up asleep from separately identifiable parts. Identification of each of the parts is also frequently very difficult when 3D objects are seen from different viewing angles, as key parts may be invisible, occluded, or highly distorted. This is particularly likely to be difficult in 3D shape perception. It appears that being committed to producing a correct description of the parts before other processes can operate is making too strong a commitment early on in the recognition process.

A second difficulty is that many objects or animals that can be correctly recognized have rather similar structural descriptions. For example, the structural descriptions of many four-legged animals are rather similar. Rather more than a structural description seems necessary to identify many objects and animals.

A third difficulty, which applies especially to biological systems, is the difficulty of implementing the syntax needed to hold the structural description as a 3D model of the object, of producing a syntactic structural description on the fly (in real time, and with potentially great flexibility of the possible arrangement of the parts), and of matching the syntactic description of the object in the image to all the stored representations in order to find a match. An example of a structural description for a limb might be body > thigh > shin > foot > toes. In this description > means 'is linked to', and this link must be between the correct pair of descriptors. If we had just a set of parts, without the syntactic or relational linking, then there would be no way of knowing whether the toes are attached to the foot or to the body. In fact, worse than this, there would be no evidence about what was related to what, just a set of parts. Such syntactical relations are difficult to implement in neuronal networks,

because if the representations of all the features or parts just mentioned were active simultaneously, how would the spatial relations between the features also be encoded? (How would it be apparent just from the firing of neurons that the toes were linked to the rest of the foot but not to the body?) It would be extremely difficult to implement this ‘on the fly’ syntactic binding in a biologically plausible network (though cf. Hummel and Biederman (1992)), and the only suggested mechanism for flexible syntactic binding, temporal synchronization of the firing of different neurons, is not well supported as a quantitatively important mechanism for information encoding in the ventral visual system (Sections C.2.5 and C.3.7), and would have major difficulties in implementing correct, relational, syntactic binding (see Section 2.8.5.1).

A fourth difficulty of the structural description approach is that segmentation into objects must occur effectively before object recognition, so that the linked structural description list can be of one object. Given the difficulty of segmenting objects in typical natural cluttered scenes (Ullman, 1996), and the compounding problem of overlap of parts of objects by other objects, segmentation as a first necessary stage of object recognition adds another major difficulty for structural description approaches.

A fifth difficulty is that metric information, such as the relative size of the parts that are linked syntactically, needs to be specified in the structural description (Stankiewicz and Hummel, 1994), which complicates the parts that have to be syntactically linked.

It is because of these difficulties that even in artificial vision systems implemented on computers, where almost unlimited syntactic binding can easily be implemented, the structural description approach to object recognition has not yet succeeded in producing a scheme which actually works in more than an environment in which the types of objects are limited, and the world is far from the natural world, consisting for example of 2D scenes (Mundy and Zisserman, 1992).

Although object recognition in the brain is unlikely to be based on the structural description approach, for the reasons given above, and the fact that the evidence described in this chapter supports a feature hierarchy rather than the structural description implementation in the brain, it is certainly the case that humans can provide verbal, syntactic, descriptions of objects in terms of the relations of their parts, and that this is often a useful type of description. Humans may therefore it is suggested supplement a feature hierarchical object recognition system built into their ventral visual system with the additional ability to use the type of syntax that is necessary for language to provide another level of description of objects. This is of course useful in, for example, engineering applications.

2.6.3 Template matching and the alignment approach

Another approach to object recognition is template matching, comparing the image on the retina with a stored image or picture of an object. This is conceptually simple, but there are in practice major problems. One major problem is how to align the image on the retina with the stored images, so that all possible images on the retina can be compared with the stored template or templates of each object.

The basic idea of the alignment approach (Ullman, 1996) is to compensate for the transformations separating the viewed object and the corresponding stored model, and then compare them. For example, the image and the stored model may be similar, except for a difference in size. Scaling one of them will remove this discrepancy and improve the match between them. For a 2D world, the possible transforms are translation (shift), scaling, and rotation. Given for example an input letter of the alphabet to recognize, the system might, after segmentation (itself a very difficult process if performed independently of (prior to) object recognition), compensate for translation by computing the centre of mass of the object, and shifting the character to a ‘canonical location’. Scale might be compensated for by

calculating the convex hull (the smallest envelope surrounding the object), and then scaling the image. Of course how the shift and scaling would be accomplished is itself a difficult point – easy to perform on a computer using matrix multiplication as in simple computer graphics, but not the sort of computation that could be performed easily or accurately by any biologically plausible network. Compensating for rotation is even more difficult (Ullman, 1996). All this has to happen before the segmented canonical representation of the object is compared to the stored object templates with the same canonical representation. The system of course becomes vastly more complicated when the recognition must be performed of 3D objects seen in a 3D world, for now the particular view of an object after segmentation must be placed into a canonical form, regardless of which view, or how much of any view, may be seen in a natural scene with occluding contours. However, this process is helped, at least in computers that can perform high precision matrix multiplication, by the fact that (for many continuous transforms such as 3D rotation, translation, and scaling) all the possible views of an object transforming in 3D space can be expressed as the linear combination of other views of the same object (see Chapter 5 of Ullman (1996); Koenderink and van Doorn (1991); and Koenderink (1990)).

This alignment approach is the main theme of the book by Ullman (1996), and there are a number of computer implementations (Lowe, 1985; Grimson, 1990; Huttenlocher and Ullman, 1990; Sashua, 1995). However, as noted above, it seems unlikely that the brain is able to perform the high precision calculations needed to perform the transforms required to align any view of a 3D object with some canonical template representation. For this reason, and because the approach also relies on segmentation of the object in the scene before the template alignment algorithms can start, and because key features may need to be correctly identified to be used in the alignment (Edelman, 1999), this approach is not considered further here.

However, it is certainly the case that humans are very sensitive to precise feature configurations (Ullman et al., 2016).

We may note here in passing that some animals with a less computationally developed visual system appear to attempt to solve the alignment problem by actively moving their heads or eyes to see what template fits, rather than starting with an image on the eye and attempting to transform it into canonical coordinates. This ‘active vision’ approach used for example by some invertebrates has been described by Land (1999) and Land and Collett (1997).

2.6.4 Invertible networks that can reconstruct their inputs

Hinton, Dayan, Frey and Neal (1995) and Hinton and Ghahramani (1997) (see Section B.15) have argued that cortical computation is invertible, so that for example the forward transform of visual information from V1 to higher areas loses no information, and there can be a backward transform from the higher areas to V1. A comparison of the reconstructed representation in V1 with the actual image from the world might in principle be used to correct all the synaptic weights between the two (in both the forward and the reverse directions), in such a way that there are no errors in the transform. This suggested reconstruction scheme would seem to involve non-local synaptic weight correction (though see Section B.15 for a suggested, although still biologically implausible, neural implementation), or other biologically implausible operations. The scheme also does not seem to provide an account for why or how the responses of inferior temporal cortex neurons become the way they are (providing information about which object is seen relatively independently of position on the retina, size, or view). The whole forward transform performed in the brain seems to lose much of the information about the size, position and view of the object, as it is evidence about which object is present invariant of its size, view, etc. that is useful to the stages of processing about

objects that follow. Because of these difficulties, and because the backprojections are needed for processes such as recall (see Rolls (2016b) and Section 9.3.8), this invertible network approach is not considered further in this book.

In the context of recall, if the visual system were to perform a reconstruction in V1 of a visual scene from what is represented in the inferior temporal visual cortex, then it might be supposed that remembered visual scenes might be as information-rich (and subjectively as full of rich detail) as seeing the real thing. This is not the case for most humans, and indeed this point suggests that at least what reaches consciousness from the inferior temporal visual cortex (which is activated during the recall of visual memories) is the identity of the object (as made explicit in the firing rate of the neurons), and not the low-level details of the exact place, size, and view of the object in the recalled scene, even though, according to the reconstruction argument, that information should be present in the inferior temporal visual cortex.

Another difficulty is that if the backprojections are used for top-down attention and recall, as seems to be the case (Rolls, 2016b), then associative modifiability of the top-down backprojections is appropriate, and may not be compatible with invertible networks.

2.6.5 Deep learning

Another approach, from the machine learning area, is that of deep convolutional networks (LeCun, Kavukcuoglu and Farabet, 2010; LeCun, Bengio and Hinton, 2015), which are described in Sections B.14 and 2.9.4. Convolutional networks are a biologically-inspired trainable architecture that can learn invariant features. Each stage in a ConvNet is composed of a filter bank, some non-linearities, and feature pooling layers. With multiple stages, a ConvNet can learn multi-level hierarchies of features (LeCun et al., 2010, 2015). Non-linearities that include rectification and local contrast normalization are important in such systems (Jarrett et al., 2009) (and are of course properties of VisNet).

Convolutional networks are very biologically implausible, in that each unit (or ‘neuron’) receives from only typically a 3×3 or 2×2 unit patch of the preceding area; by using lateral weight copying within a layer; by having up to 140 or more layers stacked on top of each other in the hierarchy; by using the non-biologically plausible backpropagation of error training algorithm; and by using a teacher for every neuron in the output layer. Interestingly, unlike VisNet, there is no attempt in general to teach the network transform invariance by presenting images with spatial continuity, and no attempt to take advantage of the statistics of the world to help it learn which transforms are probably of the same object by capitalising on temporal continuity (Rolls, 2021d). Further, convolutional networks cannot explain the sensitivity of humans to precise feature configurations (Ullman et al., 2016). Although the computations involved are very different, comparisons of neurons in the brain with the neurons found in deep learning networks have been made (Yamins and DiCarlo, 2016; Rajalingham, Issa, Bashivan, Kar, Schmidt and DiCarlo, 2018), and are evaluated in Section 2.9.4.

2.6.6 Feature hierarchies and 2D view-based object recognition

The hierarchical organisation of the ventral visual system is illustrated in Fig. 2.2. This lends itself as a suitable framework for a *feature hierarchy* approach to 2D shape and object encoding and recognition, which is illustrated in Fig. 2.28.

2.6.6.1 The feature hierarchy approach to object recognition

In the feature hierarchy approach, the system starts with some low-level description of the visual scene, in terms for example of oriented straight line segments of the type that are rep-

Fig. 2.28 The feature hierarchy approach to object recognition. The inputs may be neurons tuned to oriented straight line segments. In early intermediate levels neurons respond to a combination of these inputs in the correct spatial position with respect to each other. In further intermediate levels, of which there may be several, neurons respond with some invariance to the feature combinations represented early, and form higher order feature combinations. Finally, in the top level, neurons respond to combinations of what is represented in the preceding intermediate level, and thus provide evidence about objects in a position (and scale and even view) invariant way. Convergence through the network is designed to provide top level neurons with information from across the entire input retina, as part of the solution to translation invariance, and other types of invariance are treated similarly.

resented in the responses of primary visual cortex (V1) neurons (Hubel and Wiesel, 1962; Miller, 2016) (Fig. 2.5), and then builds, in repeated hierarchical levels, features based on what is represented in previous levels. A feature may thus be defined as a combination of what is represented in the previous level. For example, after V1, features might consist of combinations of straight lines, which might represent longer curved lines (Zucker, Dobbins and Iverson, 1989), or terminated lines (in fact represented in V1 as end-stopped cells), corners, ‘T’ junctions which are characteristic of obscuring edges, and (at least in humans) the arrow and ‘Y’ vertices that are characteristic properties of human environments such as the corners of a building or room. Evidence that such feature combination neurons are present in V2 is that some neurons respond to combinations of line elements that join at different angles (Hegde and Van Essen, 2000; Ito and Komatsu, 2004). (An example of this might be a neuron responding to a ‘V’ shape at a particular orientation.) As one ascends the hierarchy, neurons might respond to more complex trigger features (such as two parts of a complex figure in the correct spatial arrangement with respect to each other, as shown by Tanaka (1996) for V4 and posterior inferior temporal cortex neurons). In the (anterior) inferior temporal visual cortex, we showed that some face-selective neurons respond to combinations of features such as eyes, mouth, and hair, but not to these components presented individually, or in a configuration with the parts rearranged (Perrett, Rolls and Caan, 1982; Rolls, Tovee, Purcell, Stewart and Azzopardi, 1994b), and this is captured by hierarchical competitive networks (Robinson and Rolls, 2015). Further on, neurons might respond to combinations of several such intermediate-level feature combination neurons, and thus come to respond systematically differently to different objects, and thus to convey information about which object is present. This approach received neurophysiological support early on from the results of Hubel and Wiesel (1962; 1968) in the cat and monkey, and much of the data described in Chapter 5 of Rolls and Deco (2002) (available at <https://www.oxcns.org> as a .pdf) are consistent with this scheme.

One advantage of feature hierarchy systems is that they can map the whole of an input

space (in this case the retina) to the whole of the output space (in this case anterior inferior temporal visual cortex) without needing neurons with millions and millions of synaptic inputs. Consider the problem that needs to be solved. A particular face seen over a wide range of positions on the retina will activate the same neuron in the anterior inferior temporal cortex. If this were to be achieved in a one-level system, without a hierarchy, then a neuron in the second level would need to have connections to every neuron in level 1 that might be involved in the representation of that particular face image at every possible position at which the face might be placed on level 1. That involves a combinatorial explosion in the number of connections that every neuron in level 2 would need to the enormous numbers of neurons in level 1. Instead, a hierarchical approach divides the problem into several stages, in which any one neuron at a given stage responds to just a limited set of combinations of neuronal firing over a small region of the previous level. This enables a single neuron in the top level to respond to a combination of inputs from any part of the input space, as illustrated in Fig. 2.2. Moreover, if the neurons at any one level self-organize by a process such as competitive learning (Section B.4), then each neuron needs to connect to only a limited number of neurons in the preceding level (e.g. 10,000), and the competition helps to ensure that different neurons within a local cortical region within which lateral inhibition operates through the inhibitory interneurons learn to respond to different combinations of features in the input space. Moreover, not every combination of inputs needs to be encoded by neurons, but only those that occur during self-organization given the statistics of the world. For example, natural image statistics reflect the presence of structure in the input space, in for example edges in a scene, so that not every possible combination of pixels in the input space need to be encoded, for vision in a world with natural image statistics.

A second advantage is that the feature analyzers can be built out of the rather simple competitive networks described in Section B.4 that use a local learning rule, and have no external teacher, so that they are rather biologically plausible. Another advantage is that, once trained at lower levels on sets of features common to most objects, the system can then learn new objects quickly using only its higher levels (Elliott, Rolls and Stringer, 2002).

A related third advantage is that, if implemented with competitive nets as in the case of VisNet (see Section 2.8), then neurons are allocated by self-organization to represent just the features present in the natural statistics of real images (cf. Field (1994)), and not every possible feature that could be constructed by random combinations of pixels on the retina.

A related fourth advantage of feature hierarchy networks is that because they can utilize competitive networks, they can still produce a good estimate of what is in the image under non-ideal conditions, when only parts of objects are visible because for example of occlusion by other objects, etc. The reasons for this are that competitive networks assess the evidence for the presence of certain ‘features’ to which they are tuned using a dot product operation on their inputs, so that they are inherently tolerant of missing input evidence; and reach a state that reflects the best hypothesis or hypotheses (with soft competition) given the whole set of inputs, because there are competitive interactions between the different neurons (see Section B.4).

A fifth advantage of a feature hierarchy system is that, as shown in Section 2.8.6, the system does not need to perform segmentation into objects as part of pre-processing, nor does it need to be able to identify parts of an object, and can also operate in cluttered scenes in which the object may be partially obscured. The reason for this is that once trained on objects, the system then operates somewhat like an associative memory, mapping the image properties forward onto whatever it has learned about before, and then by competition selecting just the most likely output to be activated. Indeed, the feature hierarchy approach provides a mechanism by which processing at the object recognition level could feed back using back-projections to early cortical areas to provide top-down guidance to assist segmentation Rolls

(2016b). Although backprojections are not built into VisNet2 (Rolls and Milward, 2000), they have been added when attentional top-down processing must be incorporated (Deco and Rolls, 2004).

A sixth advantage of feature hierarchy systems is that they can naturally utilize features in the images of objects that are not strictly part of a shape description scheme, such as the fact that different objects have different textures, colors etc. Feature hierarchy systems, because they utilize whatever is represented at earlier stages in forming feature combination neurons at the next stage, naturally incorporate such ‘feature list’ evidence into their analysis, and have the advantages of that approach (see Section 2.6.1 and also Mel (1997)). Indeed, the feature space approach can utilize a hybrid representation, some of whose dimensions may be discrete and defined in structural terms, while other dimensions may be continuous and defined in terms of metric details (Biederman, 1987), and others may be concerned with non-shape properties such as texture and color (cf. Edelman (1999)).

A seventh advantage of feature hierarchy systems is that they do not need to utilize ‘on the fly’ or run-time arbitrary binding of features. Instead, the spatial syntax is effectively hardwired into the system when it is trained, in that the feature combination neurons have learned to respond to their set of features when they are in a given spatial arrangement on the retina.

An eighth advantage of feature hierarchy systems is that they can self-organize (given the right functional architecture, trace synaptic learning rule, and the temporal statistics of the normal visual input from the world), with no need for an external teacher to specify for each output neuron what it must respond to. The need for a teacher is a major argument against the biological plausibility of deep learning approaches such as convolution nets to visual object recognition (see Sections 2.6.5 and 2.9.4). In a feature hierarchy network the correct, object, representation can self-organize itself given rather economically specified genetic rules for building the network (Rolls and Stringer, 2000). Artificial neuronal network approaches to invariant object recognition could have major benefits if they could self-organize like the brain without pre-specification of what should be learned, and indeed what each output neuron should learn (see Sections 2.6.5 and 2.9.4).

Ninth, hierarchical visual systems may recognize 3D objects based on a limited set of 2D views of objects, and the same architectural rules just stated and implemented in VisNet will correctly associate together the different views of an object. It is part of the concept, and consistent with neurophysiological data (Tanaka, 1996), that the neurons in the upper levels will generalize correctly within a view (see Section 2.8.7).

Tenth, another advantage of cortical feature hierarchy systems is that they can operate fast, in approximately 20 ms per level (see Sections B.4 and B.6.5).

Eleventh, although hierarchical cortical systems so far have been described in a feed-forward mode of operation, they are completely compatible with backprojections, again connected mainly between adjacent levels, to implement top-down effects of attention and cognition, and to implement memory recall (Rolls, 2016b). The connectivity requirements in terms of the number of input and output connections of each neuron are met best by having back-projection connections mainly between adjacent levels of the backprojection hierarchy. As described by Rolls (2016b), the backprojections must not dominate the bottom-up (feedforward) connections, and therefore are relatively weak, which is facilitated by their termination in layer 1 of the cortex, well away from the cell body, and where the effects can be shunted if there are strong bottom-up inputs.

Twelfth, hierarchical cortical systems are also consistent with local recurrent collateral connections within a small region within a level of the hierarchy, to implement memory and constraint satisfaction functions as described by Rolls (2016b).

Thirteenth, some artificial neural networks are invertible (Hinton et al., 1995; Hinton and

Ghahramani, 1997), and operate by minimizing an error between an input representation and a reconstructed input representation based on a forward pass to the top of the hierarchy, and a backward pass down the hierarchy. There are a number of reasons why this seems implausible for cortical architecture. One is that information appears to be lost in the forward pass in the neocortex, for example in computing position and view invariant representations at the top of the network, for use in subsequent stages of processing. That makes it unlikely that what is represented at the top of a cortical network could be used to reconstruct the input. Another problem is how an error-correction synaptic modification rule might be computed and applied to the appropriate synapses of the neurons at every stage of the cortical architecture. A third difficulty is that if the backprojections are used for top-down attention and recall, as seems to be the case (Rolls, 2016b), then associative modifiability of the top-down backprojections is appropriate, and may not be compatible with invertible networks.

Fourteenth, feature hierarchies are biologically plausible, and evolutionarily economical. They are biologically plausible in that they can be implemented with local synaptic learning rules (needing only the activity in the pre-synaptic and post-synaptic neurons), in competitive networks (described in Section B.4). They are evolutionarily economical in that the same type of competitive network can be utilised in each stage of the hierarchy, without the need for evolution to optimise many different types of network and the genetic specification for them; and can be used in every sensory system.

A number of problems need to be solved for such feature hierarchy systems to provide a useful model of, for example, object recognition in the primate visual system.

First, some way needs to be found to keep the number of feature combination neurons realistic at each stage, without undergoing a combinatorial explosion. If a separate feature combination neuron was needed to code for every possible combination of n types of feature each with a resolution of 2 levels (binary encoding) in the preceding stage, then 2^n neurons would be needed. The suggestion that is made in Section 2.7 is that by forming neurons that respond to low-order combinations of features (neurons that respond to a combination of only say 2–4 features from the preceding stage), the number of actual feature analyzing neurons can be kept within reasonable numbers. By reasonable I mean the number of neurons actually found at any one stage of the visual system, which, for V4 might be in the order of 60×10^6 neurons (assuming a volume for macaque V4 of approximately $2,000 \text{ mm}^3$, and a cell density of 20,000–40,000 neurons per mm^3 , see Table 1.8). This is certainly a large number; but the fact that a large number of neurons is present at each stage of the primate visual system is in fact consistent with the hypothesis that feature combination neurons are part of the way in which the brain solves object recognition.

Another factor that also helps to keep the number of neurons under control is the statistics of the visual world, which contain great redundancies. The world is not random, and indeed the statistics of natural images are such that many regularities are present (Field, 1994), and not every possible combination of pixels on the retina needs to be separately encoded.

A third factor that helps to keep the number of connections required onto each neuron under control is that in a multilevel hierarchy each neuron can be set up to receive connections from only a small region of the preceding level. Thus an individual neuron does not need to have connections from all the neurons in the preceding level. Over multiple levels, the required convergence can be produced so that the same neurons in the top level can be activated by an image of an effective object anywhere on the retina (see Fig. 2.2).

A second problem of feature hierarchy approaches is how to map all the different possible images of an individual object through to the same set of neurons in the top level by modifying the synaptic connections (see Fig. 2.2). The solution discussed in Sections 2.7, 2.8.1.1 and 2.8.4 is the use of a synaptic modification rule with a short-term memory trace of the previous

activity of the neuron, to enable it to learn to respond to the now transformed version of what was seen very recently, which, given the statistics of looking at the visual world, will probably be an input from the same object.

A third problem of feature hierarchy approaches is how they can learn in just a few seconds of inspection of an object to recognize it in different transforms, for example in different positions on the retina in which it may never have been presented during training. A solution to this problem is provided in Section 2.8.5, in which it is shown that this can be a natural property of feature hierarchy object recognition systems, if they are trained first for all locations on the intermediate level feature combinations of which new objects will simply be a new combination, and therefore require learning only in the upper levels of the hierarchy.

A fourth potential problem of feature hierarchy systems is that when solving translation invariance they need to respond to the same local spatial arrangement of features (which are needed to specify the object), but to ignore the global position of the whole object. It is shown in Section 2.8.5 that feature hierarchy systems can solve this problem by forming feature combination neurons at an early stage of processing (e.g. V1 or V2 in the brain) that respond with high spatial precision to the local arrangement of features. Such neurons would respond differently for example to L, +, and T if they receive inputs from two line-responding neurons. It is shown in Section 2.8.5 that at later levels of the hierarchy, where some of the intermediate level feature combination neurons are starting to show translation invariance, then correct object recognition may still occur because only one object contains just those sets of intermediate level neurons in which the spatial representation of the features is inherent in the encoding.

After the immediately following description of early models of a feature hierarchy approach implemented in the Cognitron and Neocognitron, we turn in Section 2.7 to hypotheses of *how* the key computations could be performed in the ventral visual system. These are developed in the context of a feature hierarchy approach to invariant visual object recognition. Then in Section 2.8, the VisNet model of *how* these computations are implemented in the ventral visual system is described.

2.6.6.2 The Cognitron and Neocognitron

An early computational model of a hierarchical feature-based approach to object recognition, joining other early discussions of this approach (Selfridge, 1959; Sutherland, 1968; Barlow, 1972; Milner, 1974), was proposed by Fukushima (1975; 1980; 1989; 1989; 1991). His model used two types of cell within each layer to approach the problem of invariant representations. In each layer, a set of ‘simple cells’, with defined position, orientation, etc. sensitivity for the stimuli to which they responded, was followed by a set of ‘complex cells’, which generalized a little over position, orientation, etc. This simple cell – complex cell pairing within each layer provided some invariance. When a neuron in the network using competitive learning with its stimulus set, which was typically letters on a 16×16 pixel array, learned that a particular feature combination had occurred, that type of feature analyzer was replicated in a non-local manner throughout the layer, to provide further translation invariance. Invariant representations were thus learned by using a convolution (and this was the forerunner of deep convolutional networks (Section B.14), but is biologically implausible). This is this very different to VisNet. Up to eight layers were used. The network could learn to differentiate letters, even with some translation, scaling, or distortion. Although internally it is organized and learns very differently to VisNet, it is an independent example of the fact that useful invariant pattern recognition can be performed by multilayer hierarchical networks. A major biological implausibility of the system is that once one neuron within a layer learned, other similar neurons were set up throughout the layer by a non-local process. A second biological limitation was that no learning rule or self-organizing process was specified as to how the

complex cells can provide translation invariant representations of simple cell responses – this was simply hardwired. Solutions to both these issues are provided by VisNet.

2.7 Hypotheses about how the computations are performed in a feature hierarchy approach to for invariant object recognition

The neurophysiological findings described in Section 2.4, and wider considerations on the possible computational properties of the cerebral cortex (Rolls, 1990b, 1989f, 1992a, 1994a, 1995a, 1997c, 2000a; Rolls and Treves, 1998; Rolls and Deco, 2002; Rolls, 2016b), led to the following outline working hypotheses on object recognition by visual cortical mechanisms (see Rolls (1992a) which is a paper delivered to the Royal Society on 8-9 July 1991, Rolls (2012d), and Rolls (2021d)). The principles underlying the processing of faces and other objects may be similar, but more neurons may become allocated to represent different aspects of faces because of the need to recognize the faces of many different individuals, that is to identify many individuals within the category faces.

Cortical visual processing for object recognition is considered to be organized as a set of hierarchically connected cortical regions consisting at least of V1, V2, V4, posterior inferior temporal cortex (TEO), inferior temporal cortex (e.g. TE3, TEa and TEM), and anterior temporal cortical areas (e.g. TE2 and TE1) (in macaques). (This stream of processing has many connections with a set of cortical areas in the anterior part of the superior temporal sulcus, including area TPO.) There is convergence from each small part of a region to the succeeding region (or layer in the hierarchy) in such a way that the receptive field sizes of neurons (e.g. 1 degree near the fovea in V1) become larger by a factor of approximately 2.5 with each succeeding stage (and the typical parafoveal receptive field sizes found would not be inconsistent with the calculated approximations of e.g. 8 degrees in V4, 20 degrees in TEO, and 50 degrees in the inferior temporal cortex (Boussaoud, Desimone and Ungerleider, 1991)) (see Fig. 2.2 on page 57). Such zones of convergence would overlap continuously with each other (see Fig. 2.2). This connectivity would be part of the architecture by which translation invariant representations are computed.

Each layer is considered to act partly as a set of local self-organizing competitive neuronal networks with overlapping inputs. (The region within which competition would be implemented would depend on the spatial properties of inhibitory interneurons, and might operate over distances of 1–2 mm in the cortex.) These competitive nets operate by a single set of forward inputs leading to (typically non-linear, e.g. sigmoid) activation of output neurons; of competition between the output neurons mediated by a set of feedback inhibitory interneurons which receive from many of the principal (in the cortex, pyramidal) cells in the net and project back (via inhibitory interneurons) to many of the principal cells and serve to decrease the firing rates of the less active neurons relative to the rates of the more active neurons; and then of synaptic modification by a modified Hebb rule, such that synapses to strongly activated output neurons from active input axons strengthen, and from inactive input axons weaken (see Section B.4). A biologically plausible form of this learning rule that operates well in such networks is

$$\delta w_{ij} = \alpha y_i (x_j - w_{ij}) \quad (2.2)$$

where α is a learning rate constant, and x_j and w_{ij} are in appropriate units (see Section B.4). Such competitive networks operate to detect correlations between the activity of the input neurons, and to allocate output neurons to respond to each cluster of such correlated inputs. These networks thus act as categorizers. In relation to visual information processing, they

would remove redundancy from the input representation, and would develop low entropy representations of the information (cf. Barlow (1985), Barlow, Kaushal and Mitchison (1989)). Such competitive nets are biologically plausible, in that they utilize Hebb-modifiable forward excitatory connections, with competitive inhibition mediated by cortical inhibitory neurons. The competitive scheme I suggest would not result in the formation of ‘winner-take-all’ or ‘grandmother’ cells, but would instead result in a small ensemble of active neurons representing each input with a sparse distributed representation (Rolls, 1990b, 1989f; Rolls and Treves, 1998; Rolls, 2012d) (see Section B.4). The scheme has the advantages that the output neurons learn better to distribute themselves between the input patterns (cf. Bennett (1990)), and that the sparse representations formed have utility in maximizing the number of memories that can be stored when, towards the end of the visual system, the visual representation of objects is interfaced to associative memory (Rolls, 1990b, 1989f; Rolls and Treves, 1998)¹.

Translation invariance would be computed in such a system by utilizing competitive learning to detect regularities in inputs when real objects are translated in the physical world. The hypothesis is that because objects have continuous properties in space and time in the world, an object at one place on the retina might activate feature analyzers at the next stage of cortical processing, and when the object was translated to a nearby position, because this would occur in a short period (e.g. 0.5 s), the membrane of the postsynaptic neuron would still be in its ‘Hebb-modifiable’ state (caused for example by calcium entry as a result of the voltage-dependent activation of NMDA receptors), and the presynaptic afferents activated with the object in its new position would thus become strengthened on the still-activated postsynaptic neuron. It is suggested that the short temporal window (e.g. 0.5 s) of Hebb-modifiability helps neurons to learn the statistics of objects moving and more generally transforming in the physical world, and at the same time to form different representations of different feature combinations or objects, as these are physically discontinuous and present less regular correlations to the visual system (Rolls, 1992a, 2021d). Földiák (1991) has proposed computing an average activation of the postsynaptic neuron to assist with the same problem. One idea here is that the temporal properties of the biologically implemented synaptic learning mechanism are such that it is well suited to detecting the relevant continuities in the world of real objects (Rolls, 1992a, 2021d). Another suggestion (Rolls, 1992a, 2021d) is that a memory trace for what has been seen in the last 300 ms appears to be implemented by a mechanism as simple as continued firing of inferior temporal neurons after the stimulus has disappeared, as has been found in masking experiments (Rolls and Tovee, 1994; Rolls, Tovee, Purcell, Stewart and Azzopardi, 1994b; Rolls, Tovee and Panzeri, 1999b; Rolls, 2003, 2016b).

I also proposed (Rolls, 1992a) that other invariances, for example size, spatial frequency, and rotation invariance, could be learned by a comparable process. (Early processing in V1 that enables different neurons to represent inputs at different spatial scales would allow combinations of the outputs of such neurons to be formed at later stages. Scale invariance would then result from detecting at a later stage which neurons are almost conjunctively active as the size of an object alters.) It is proposed that this process takes place at each stage of the

¹ In that each neuron has graded responses centred about an optimal input, the proposal has some of the advantages with respect to hypersurface reconstruction described by Poggio and Girosi (1990a). However, the system I propose learns differently, in that instead of using perhaps non-biologically plausible algorithms to optimally locate the centres of the receptive fields of the neurons, the neurons use graded competition to spread themselves throughout the input space, depending on the statistics of the inputs received, and perhaps with some guidance from backprojections (see below). In addition, the competitive nets I propose use as a distance function the dot product between the input vector to a neuron and its synaptic weight vector, whereas radial basis function networks use a Gaussian measure of distance (see Section B.4.8). Both systems benefit from the finite width of the response region of each neuron which tapers from a maximum, and is important for enabling the system to generalize smoothly from the examples with which it has learned (cf. Poggio and Girosi (1990b), Poggio and Girosi (1990a)), to help the system to respond for example with the correct invariances as described below.

multiple-layer cortical processing hierarchy, so that invariances are learned first over small regions of space, and then over successively larger regions. This limits the size of the connection space within which correlations must be sought.

Increasing complexity of representations could also be built in such a multiple layer hierarchy by similar mechanisms. At each stage or layer the self-organizing competitive nets would result in combinations of inputs becoming the effective stimuli for neurons. In order to avoid the combinatorial explosion, it is proposed, following Feldman (1985), that low-order combinations of inputs would be what is learned by each neuron. (Each input would not be represented by activity in a single input axon, but instead by activity in a set of active input axons.) Evidence consistent with this suggestion that neurons are responding to combinations of a few variables represented at the preceding stage of cortical processing is that some neurons in V1 respond to combinations of bars or edges (see Section 2.5 of Rolls and Deco (2002); Sillito et al. (1995); and Shevelev et al. (1995)); V2 and V4 respond to end-stopped lines, to angles formed by a combination of lines, to acute curvature, to tongues flanked by inhibitory subregions, and to combinations of colors (Hegde and Van Essen, 2000; Rolls and Deco, 2002; Ito and Komatsu, 2004; Carlson et al., 2011; Kourtzi and Connor, 2011; Roe et al., 2012; Nandy et al., 2013; Kim et al., 2019; Jiang et al., 2021); in posterior inferior temporal cortex to stimuli which may require two or more simple features to be present (Tanaka, Saito, Fukada and Moriya, 1990); and in the temporal cortical face processing areas to images that require the presence of several features in a face (such as eyes, hair, and mouth) in order to respond (Perrett, Rolls and Caan, 1982; Yamane, Kaji and Kawano, 1988) (see Chapter 5 of Rolls and Deco (2002), Rolls (2007e), Rolls (2016b), Rolls (2011d), and Fig. 2.10). (Precursor cells to face-responsive neurons might, it is suggested, respond to combinations of the outputs of the neurons in V1 that are activated by faces, and might be found in areas such as V4.)

It is an important part of this proposal that some local spatial information would be inherent in the features that were being combined. For example, cells might not respond to the combination of an edge and a small circle unless they were in the correct spatial relation to each other. (This is in fact consistent with the data of Tanaka, Saito, Fukada and Moriya (1990), and with our data on face neurons, in that some faces neurons require the face features to be in the correct spatial configuration, and not jumbled (Rolls, Tovee, Purcell, Stewart and Azzopardi, 1994b).) The local spatial information in the features being combined would ensure that the representation at the next level would contain some information about the (local) arrangement of features. Further low-order combinations of such neurons at the next stage would include sufficient local spatial information so that an arbitrary spatial arrangement of the same features would not activate the same neuron, and this is the proposed, and limited, solution that this mechanism would provide for the feature binding problem (Elliffe, Rolls and Stringer, 2002). By this stage of processing a view-dependent representation of objects suitable for view-dependent processes such as behavioral responses to face expression and gesture would be available.

It is also proposed that view-independent representations could be formed by the same type of computation, operating to combine a limited set of views of objects (Rolls, 1992a, 2021d). The plausibility of providing view-independent recognition of objects by combining a set of different views of objects has been proposed by a number of investigators (Koenderink and Van Doorn, 1979; Poggio and Edelman, 1990; Logothetis, Pauls, Bulthoff and Poggio, 1994; Ullman, 1996). Consistent with the suggestion that the view-independent representations are formed by combining view-dependent representations in the primate visual system, is the fact that in the temporal cortical areas, neurons with view-independent representations of faces are present in the same cortical areas as neurons with view-dependent representations (from which the view-independent neurons could receive inputs) (Hasselmo,

Rolls, Baylis and Nalwa, 1989b; Perrett, Smith, Potter, Mistlin, Head, Milner and Jeeves, 1985b; Booth and Rolls, 1998). This solution to ‘object-based’ representations is very different from that traditionally proposed for artificial vision systems, in which the coordinates in 3D space of objects are stored in a database, and general-purpose algorithms operate on these to perform transforms such as translation, rotation, and scale change in 3D space (e.g. Marr (1982)). In the present, much more limited but more biologically plausible scheme, the representation would be suitable for recognition of an object, and for linking associative memories to objects, but would be less good for making actions in 3D space to particular parts of, or inside, objects, as the 3D coordinates of each part of the object would not be explicitly available. It is therefore proposed that visual fixation is used to locate in foveal vision part of an object to which movements must be made, and that local disparity and other measurements of depth then provide sufficient information for the motor system to make actions relative to the small part of space in which a local, view-dependent, representation of depth would be provided (using computations of the type described in Section 3.4 and by Rolls (2020b)).

The computational processes proposed above operate by an unsupervised learning mechanism, which utilizes statistical regularities in the physical environment to enable representations to be built (Rolls, 2021d). In some cases it may be advantageous to utilize some form of mild teaching input to the visual system, to enable it to learn for example that rather similar visual inputs have very different consequences in the world, so that different representations of them should be built. In other cases, it might be helpful to bring representations together, if they have identical consequences, in order to use storage capacity efficiently. It is proposed elsewhere (Rolls, 1990b, 1989f; Rolls and Treves, 1998; Rolls, 2016b) (as described in Section B.4.5) that the backprojections from each adjacent cortical region in the hierarchy (and from the amygdala and hippocampus to higher regions of the visual system) play such a role by providing guidance to the competitive networks suggested above to be important in each cortical area. This guidance, and also the capability for recall, are it is suggested implemented by Hebb-modifiable connections from the backprojecting neurons to the principal (pyramidal) neurons of the competitive networks in the preceding stages (Rolls, 1990b, 1989f; Rolls and Treves, 1998; Rolls, 2016b) (see Section B.4).

The computational processes outlined above use sparse distributed coding with relatively finely tuned neurons with a graded response region centred about an optimal response achieved when the input stimulus matches the synaptic weight vector on a neuron. The distributed nature of the coding but with fine tuning would help to limit the combinatorial explosion, to keep the number of neurons within the biological range. The graded response region would be crucial in enabling the system to generalize correctly to solve for example the invariances. However, such a system would need many neurons, each with considerable learning capacity, to solve visual perception in this way. This is fully consistent with the large number of neurons in the visual system, and with the large number of, probably modifiable, synapses on each neuron (e.g. 10,000). Further, the fact that many neurons are tuned in different ways to faces is consistent with the fact that in such a computational system, many neurons would need to be sensitive (in different ways) to faces, in order to allow recognition of many individual faces when all share a number of common properties.

2.8 VisNet: a model of how the computations are performed in the ventral visual system

The feature hierarchy approach to invariant object recognition was introduced in Sections 2.6.6 and 2.7, and advantages and disadvantages of it were discussed. Hypotheses about how object recognition could be implemented in the brain that are consistent with much of the

neurophysiology discussed in Section 2.4 and elsewhere (Rolls and Deco, 2002; Rolls, 2007e, 2016b, 2011d, 2012d) were set out in Section 2.7. These hypotheses effectively incorporate a feature hierarchy system while encompassing much of the neurophysiological evidence. In this Section (2.8), we consider the computational issues that arise in such feature hierarchy systems, and in the brain systems that implement visual object recognition. The issues are considered with the help of a particular model, VisNet, which requires precise specification of the hypotheses, and at the same time enables them to be explored and tested numerically and quantitatively. However, we emphasize that the issues to be covered in Section 2.8 are key and major computational issues for architectures of this feature hierarchical type (Rolls and Stringer, 2006b), and are very relevant to understanding how any mechanism for invariant object recognition is implemented in the cerebral cortex.

*It is worth emphasising that each of the investigations described in this section (2.8) with VisNet address issues that need to be accounted for by any theory and model of **how** the computations are performed in the ventral visual system.*

A feature of the research with VisNet is that most of the investigations have been performed to account for particular neurophysiological findings, and the results obtained with VisNet have then been compared with the neuronal responses found in the cerebral cortex, in particular in the inferior temporal visual cortex (Rolls, 2012d; Rolls and Webb, 2014; Webb and Rolls, 2014; Robinson and Rolls, 2015; Rolls and Mills, 2018; Rolls, 2021d).

VisNet is a model of invariant object recognition based on Rolls' (1992a) hypotheses (Section 2.7). It is a computer simulation that allows hypotheses to be tested and developed about how multilayer hierarchical networks of the type proposed to be implemented in the visual cortical pathways operate (Rolls, 2016b, 2012d, 2021d). The architecture captures a number of aspects of the architecture of the visual cortical pathways, and is described next. The model of course, as with all models, requires precise specification of what is to be implemented, and at the same time involves specified simplifications of the real architecture, as investigations of the fundamental aspects of the information processing being performed are more tractable in a simplified and at the same time quantitatively specified model. First the architecture of the model is described, and this is followed by descriptions of key issues in such multilayer feature hierarchical models, such as the issue of feature binding, the optimal form of training rule for the whole system to self-organize, the operation of the network in natural environments and when objects are partly occluded, how outputs about individual objects can be read out from the network, and the capacity of the system.

A version of VisNet written entirely in Matlab for simplicity is made available in connection with the publication of this book (Rolls, 2023a) at <https://www.oxcns.org> (see Appendix D). Although it is not the full version of VisNet with which the research described next has been performed which is written in C, and will not perform identically to the full version, the Matlab version may be useful for tutorial use to help make explicit how the computations are performed in this example of a network that can learn invariant representations with unsupervised learning.

2.8.1 The architecture of VisNet

Fundamental elements of Rolls' (1992a) theory for how cortical networks might implement invariant object recognition are described in Section 2.7. They provide the basis for the design of VisNet, and can be summarized as:

- A series of competitive networks, organized in hierarchical layers, exhibiting mutual inhibition over a short range within each layer. These networks allow combinations of features or inputs occurring in a given spatial arrangement to be learned by neurons, ensuring that higher order spatial properties of the input stimuli are represented in the network.

- A convergent series of connections from a localized population of cells in preceding layers to each cell of the following layer, thus allowing the receptive field size of cells to increase through the visual processing areas or layers.
- A modified Hebb-like learning rule incorporating a temporal trace of each cell's previous activity, which, it is suggested, will enable the neurons to learn transform invariances.

The first two elements of Rolls' theory are used to constrain the general architecture of a network model, VisNet, of the processes just described that is intended to learn invariant representations of objects. The simulation results described in this chapter using VisNet show that invariant representations can be learned by the architecture. It is moreover shown that successful learning depends crucially on the use of the modified Hebb rule. The general architecture simulated in VisNet, and the way in which it allows natural images to be used as stimuli, has been chosen to enable some comparisons of neuronal responses in the network and in the brain to similar stimuli to be made.

2.8.1.1 The memory trace learning rule

The synaptic learning rule implemented in the VisNet simulations utilizes the spatio-temporal constraints placed upon the behavior of 'real-world' objects to learn about natural object transformations. By presenting consistent sequences of transforming objects the cells in the network can learn to respond to the same object through all of its naturally transformed states, as described by Földiák (1991), Rolls (1992a), Wallis, Rolls and Földiák (1993), Wallis and Rolls (1997) and Rolls (2021d). The learning rule incorporates a decaying trace of previous cell activity and is henceforth referred to simply as the 'trace' learning rule. The learning paradigm described here is intended in principle to enable learning of any of the transforms tolerated by inferior temporal cortex neurons, including position, size, view, lighting, and spatial frequency (Rolls, 1992a, 1994a, 1995a, 1997c, 2000a; Rolls and Deco, 2002; Rolls, 2007e,c, 2008b, 2016b, 2012d; Rolls and Webb, 2014; Webb and Rolls, 2014; Robinson and Rolls, 2015; Rolls and Mills, 2018; Rolls, 2021d).

To clarify the reasoning behind this point, consider the situation in which a single neuron is strongly activated by a stimulus forming part of a real world object. The trace of this neuron's activation will then gradually decay over a time period in the order of 0.5 s. If, during this limited time window, the net is presented with a transformed version of the original stimulus then not only will the initially active afferent synapses modify onto the neuron, but so also will the synapses activated by the transformed version of this stimulus. In this way the cell will learn to respond to either appearance of the original stimulus. Making such associations works in practice because it is very likely that within short time periods different aspects of the same object will be being inspected. The cell will not, however, tend to make spurious links across stimuli that are part of different objects because of the unlikelihood in the real world of one object consistently following another.

Various biological bases for this temporal trace have been advanced:

- The persistent firing of neurons for as long as 100–400 ms observed after presentations of stimuli for 16 ms (Rolls and Tovee, 1994) could provide a time window within which to associate subsequent images. Maintained activity may potentially be implemented by recurrent connections between as well as within cortical areas (Rolls and Treves, 1998; Rolls, 2016b) (see Section 13.6.1)².

²The prolonged firing of inferior temporal cortex neurons during memory delay periods of several seconds, and associative links reported to develop between stimuli presented several seconds apart (Miyashita, 1988) are on too long a time scale to be immediately relevant to the present theory. In fact, associations between visual events occurring several seconds apart would, under *normal* environmental conditions, be detrimental to the operation of a

- The binding period of glutamate in the NMDA channels, which may last for 100 ms or more, may implement a trace rule by producing a narrow time window over which the *average* activity at each presynaptic site affects learning (Rolls, 1992a; Rhodes, 1992; Földiák, 1991; Spruston, Jonas and Sakmann, 1995; Hestrin, Sah and Nicoll, 1990).
- Chemicals such as nitric oxide may be released during high neural activity and gradually decay in concentration over a short time window during which learning could be enhanced (Földiák, 1991; Montague, Gally and Edelman, 1991).

The trace update rule used in the baseline simulations of VisNet (Wallis and Rolls, 1997) is equivalent to both Földiák's used in the context of translation invariance and to the earlier rule of Sutton and Barto (1981) explored in the context of modelling the temporal properties of classical conditioning, and can be summarized as follows:

$$\delta w_j = \alpha \bar{y}^\tau x_j \quad (2.3)$$

where

$$\bar{y}^\tau = (1 - \eta)y^\tau + \eta\bar{y}^{\tau-1} \quad (2.4)$$

and

x_j :	j^{th} input to the neuron.	y :	Output from the neuron.
\bar{y}^τ :	Trace value of the output of the neuron at time step τ .	α :	Learning rate. Annealed between unity and zero.
w_j :	Synaptic weight between j^{th} input and the neuron.	η :	Trace value. The optimal value varies with presentation sequence length.

To bound the growth of each neuron's synaptic weight vector, \mathbf{w}_i for the i th neuron, its length is explicitly normalized (a method similarly employed by von der Malsburg (1973) which is commonly used in competitive networks, see Section B.4). An alternative, more biologically relevant implementation, using a local weight bounding operation which utilizes a form of heterosynaptic long-term depression (see Section 1.6), has in part been explored using a version of the Oja (1982) rule (see Wallis and Rolls (1997)).

Learning for layer 1 of VisNet (corresponding to V2) uses purely Hebbian training, without a temporal trace (Rolls and Milward, 2000). The reason for this is that it is essential to form feature combination neurons that respond for example to combinations of edges before any invariance learning is introduced, because the spatial structure of objects can only be specified if the relative positions of features is defined by feature combination neurons.

2.8.1.2 The network implemented in VisNet

The network itself is designed as a series of hierarchical, convergent, competitive networks, in accordance with the hypotheses advanced above. The actual network consists of a series of four layers, constructed such that the convergence of information from the most disparate parts of the network's input layer can potentially influence firing in a single neuron in the final layer – see Fig. 2.2. This corresponds to the scheme described by many researchers (Van Essen et al., 1992; Rolls, 1992a, for example) as present in the primate visual system – see Fig. 2.2. The forward connections to a cell in one layer are derived from a topologically related and confined region of the preceding layer. The choice of whether a connection between neurons in adjacent layers exists or not is based upon a Gaussian distribution of connection probabilities which roll off radially from the focal point of connections for each neuron. (A

network of the type described here, because they would probably arise from different objects. In contrast, the system described benefits from associations between visual events which occur close in time (typically within 1 s), as they are likely to be from the same object.

minor extra constraint precludes the repeated connection of any pair of cells.) In particular, the forward connections to a cell in one layer come from a small region of the preceding layer defined by the radius in Table 2.1 which will contain approximately 67% of the connections from the preceding layer. Table 2.1 shows the dimensions for VisNetL, the system we have been using since 2008, which is a (16x) larger version of the version of VisNet than used in most of our earlier investigations, which utilized 32x32 neurons per layer.

Table 2.1 VisNet dimensions. Dimensions shows the number of neurons in each of the 4 layers. # Connections shows the number of synaptic connections onto each neuron. Radius shows the radius of the connectivity from the previous layer of a single neuron (see text).

	Dimensions	# Connections	Radius
Layer 4	128x128	100	48
Layer 3	128x128	100	36
Layer 2	128x128	100	24
Layer 1	128x128	272	24
Input layer	256x256x32	–	–

Figure 2.2 shows the general convergent network architecture used. Localization and limitation of connectivity in the network is intended to mimic cortical connectivity, partially because of the clear retention of retinal topology through regions of visual cortex. This architecture also encourages the gradual combination of features from layer to layer which has relevance to the binding problem, as described in Section 2.8.5³.

2.8.1.3 Competition and lateral inhibition

In order to act as a competitive network some form of mutual inhibition is required within each layer, which should help to ensure that all stimuli presented are evenly represented by the neurons in each layer. This is implemented in VisNet by a form of lateral inhibition. The idea behind the lateral inhibition, apart from this being a property of cortical architecture in the brain, was to prevent too many neurons that received inputs from a similar part of the preceding layer responding to the same activity patterns. The purpose of the lateral inhibition was to ensure that different receiving neurons coded for different inputs. This is important in reducing redundancy (see Section B.4). The lateral inhibition is conceived as operating within a radius that was similar to that of the region within which a neuron received converging inputs from the preceding layer (because activity in one zone of topologically organized

³Modelling topological constraints in connectivity leads to an issue concerning neurons at the edges of the network layers. In principle these neurons may either receive no input from beyond the edge of the preceding layer, or have their connections repeatedly sample neurons at the edge of the previous layer. In practice either solution is liable to introduce artificial weighting on the few active inputs at the edge and hence cause the edge to have unwanted influence over the development of the network as a whole. In the real brain such edge-effects would be naturally smoothed by the transition of the locus of cellular input from the fovea to the lower acuity periphery of the visual field. However, it poses a problem here because we are in effect only simulating the small high acuity foveal portion of the visual field in our simulations. As an alternative to the former solutions Wallis and Rolls (1997) elected to form the connections into a toroid, such that connections wrap back onto the network from opposite sides. This wrapping happens at all four layers of the network, and in the way an image on the ‘retina’ is mapped to the input filters. This solution has the advantage of making all of the boundaries effectively invisible to the network. Further, this procedure does not itself introduce problems into evaluation of the network for the problems set, as many of the critical comparisons in VisNet involve comparisons between a network with the same architecture trained with the trace rule, or with the Hebb rule, or not trained at all. In practice, it is shown below that only the network trained with the trace rule solves the problem of forming invariant representations.

Fig. 2.29 Contrast-enhancing filter, which has the effect of local lateral inhibition. The parameters δ and σ in Equation 2.5 modify the amount and extent of inhibition respectively.

processing within a layer should not inhibit processing in another zone in the same layer, concerned perhaps with another part of the image)⁴.

The lateral inhibition and contrast enhancement just described is actually implemented in VisNet2 (Rolls and Milward, 2000) in two stages, to produce filtering of the type illustrated in Fig. 2.29. This lateral inhibition is implemented by convolving the activation of the neurons in a layer with a spatial filter, I , where δ controls the contrast and σ controls the width, and a and b index the distance away from the centre of the filter

$$I_{a,b} = \begin{cases} -\delta e^{-\frac{a^2+b^2}{\sigma^2}} & \text{if } a \neq 0 \text{ or } b \neq 0, \\ 1 - \sum_{a \neq 0, b \neq 0} I_{a,b} & \text{if } a = 0 \text{ and } b = 0. \end{cases} \quad (2.5)$$

This is a filter that leaves the average activity unchanged. A modified version of this filter designed as a difference of Gaussians with the same inhibition but shorter range local excitation is being tested to investigate whether the self-organizing maps that this promotes (Section B.4.6) help the system to provide some continuity in the representations formed. The concept is that this may help the system to code efficiently for large numbers of untrained stimuli that fall between trained stimuli in similarity space.

The second stage involves contrast enhancement. In VisNet (Wallis and Rolls, 1997), this was implemented by raising the neuronal activations to a fixed power and normalizing the resulting firing within a layer to have an average firing rate equal to 1.0. In VisNet2 (Rolls and Milward, 2000) and in subsequent simulations a more biologically plausible form of the activation function, a sigmoid, is used:

$$y = f^{\text{sigmoid}}(r) = \frac{1}{1 + e^{-2\beta(r-\alpha)}} \quad (2.6)$$

where r is the activation (or firing rate) of the neuron after the lateral inhibition, y is the firing rate after the contrast enhancement produced by the activation function, and β is the slope or gain and α is the threshold or bias of the activation function. The sigmoid bounds the firing rate between 0 and 1 so global normalization is not required. The slope and threshold are held constant within each layer. The slope is constant throughout training, whereas the threshold

⁴Although the extent of the lateral inhibition actually investigated by Wallis and Rolls (1997) in VisNet operated over adjacent pixels, the lateral inhibition introduced by Rolls and Milward (2000) in what they named VisNet2 and which has been used in subsequent simulations operates over a larger region, set within a layer to approximately half of the radius of convergence from the preceding layer. Indeed, Rolls and Milward (2000) showed in a problem in which invariant representations over 49 locations were being used with a 17 face test set, that the best performance was with intermediate range lateral inhibition, using the parameters for σ shown in Table 2.3. These values of σ set the lateral inhibition radius within a layer to be approximately half that of the spread of the excitatory connections from the preceding layer.

is used to control the sparseness of firing rates within each layer. The (population) sparseness of the firing within a layer is defined (Rolls and Treves, 1998) as:

$$a = \frac{(\sum_i y_i/n)^2}{\sum_i y_i^2/n} \quad (2.7)$$

where n is the number of neurons in the layer. To set the sparseness to a given value, e.g. 5%, the threshold is set to the value of the 95th percentile point of the activations within the layer. (Unless otherwise stated here, the neurons used the sigmoid activation function as just described.)

In most simulations with VisNet2 and later (Rolls, 2021d), the sigmoid activation function was used with parameters (selected after a number of optimization runs) similar to those shown in Table 2.2.

Table 2.2 Sigmoid parameters and sparseness in the tutorial version of VisNet (Section D.6)

Layer	1	2	3	4
Sparseness	0.01	0.01	0.01	0.01
Slope β	10	10	10	10

In addition, the lateral inhibition parameters normally used in VisNet2 simulations are similar to those shown in Table 2.3 but scaled to reflect the size of the network.

Table 2.3 Lateral inhibition parameters for the 25-location runs in the 32x32 version of VisNet used by Rolls and Milward (2000).

Layer	1	2	3	4
Radius, σ	1.38	2.7	4.0	6.0
Contrast, δ	1.5	1.5	1.6	1.4

2.8.1.4 The input to VisNet

VisNet is provided with a set of input filters which can be applied to an image to produce inputs to the network that correspond to those provided by simple cells in visual cortical area 1 (V1). The purpose of this is to enable within VisNet the more complicated response properties of cells between V1 and the inferior temporal cortex (IT) to be investigated, using as inputs natural stimuli such as those that could be applied to the retina of the real visual system. This is to facilitate comparisons between the activity of neurons in VisNet and those in the real visual system, to the same stimuli. In VisNet no attempt is made to train the response properties of simple cells, but instead we start with a defined series of filters to perform fixed feature extraction to a level equivalent to that of simple cells in V1, as have other researchers in the field (Hummel and Biederman, 1992; Buhmann, Lange, von der Malsburg, Vorbrüggen and Würtz, 1991; Fukushima, 1980), because we wish to simulate the more complicated response properties of cells between V1 and the inferior temporal cortex (IT). In many papers before 2012 we used difference of Gaussian filters, but more recently we have used Gabor filters to simulate V1 similar to those described and used by Deco and Rolls (2004).

The Gabor filters are described next. Following Daugman (1988) the receptive fields of the simple cell-like input neurons are modelled by 2D-Gabor functions. The Gabor receptive fields have five degrees of freedom given essentially by the product of an elliptical Gaussian

and a complex plane wave. The first two degrees of freedom are the 2D-locations of the receptive field's centre; the third is the size of the receptive field; the fourth is the orientation of the boundaries separating excitatory and inhibitory regions; and the fifth is the symmetry. This fifth degree of freedom is given in the standard Gabor transform by the real and imaginary part, i.e. by the phase of the complex function representing it, whereas in a biological context this can be done by combining pairs of neurons with even and odd receptive fields. This design is supported by the experimental work of Pollen and Ronner (1981), who found simple cells in quadrature-phase pairs. Even more, Daugman (1988) proposed that an ensemble of simple cells is best modelled as a family of 2D-Gabor wavelets sampling the frequency domain in a log-polar manner as a function of eccentricity. Experimental neurophysiological evidence constrains the relation between the free parameters that define a 2D-Gabor receptive field (De Valois and De Valois, 1988). There are three constraints fixing the relation between the width, height, orientation, and spatial frequency (Lee, 1996). The first constraint posits that the aspect ratio of the elliptical Gaussian envelope is 2:1. The second constraint postulates that the plane wave tends to have its propagating direction along the short axis of the elliptical Gaussian. The third constraint assumes that the half-amplitude bandwidth of the frequency response is about 1 to 1.5 octaves along the optimal orientation. Further, we assume that the mean is zero in order to have an admissible wavelet basis (Lee, 1996).

In more detail, the Gabor filters are constructed as follows (Deco and Rolls, 2004). We consider a pixelized grey-scale image given by a $N \times N$ matrix $\Gamma_{ij}^{\text{orig}}$. The subindices ij denote the spatial position of the pixel. Each pixel value is given a grey level brightness value coded in a scale between 0 (black) and 255 (white). The first step in the preprocessing consists of removing the DC component of the image (i.e. the mean value of the grey-scale intensity of the pixels). (The equivalent in the brain is the low-pass filtering performed by the retinal ganglion cells and lateral geniculate cells. The visual representation in the LGN is essentially a contrast invariant pixel representation of the image, i.e. each neuron encodes the relative brightness value at one location in visual space referred to the mean value of the image brightness.) We denote this contrast-invariant LGN representation by the $N \times N$ matrix Γ_{ij} defined by the Equation

$$\Gamma_{ij} = \Gamma_{ij}^{\text{orig}} - \frac{1}{N^2} \sum_{i=1}^N \sum_{j=1}^N \Gamma_{ij}^{\text{orig}}. \quad (2.8)$$

Feedforward connections to a layer of V1 neurons perform the extraction of simple features like bars at different locations, orientations and sizes. Realistic receptive fields for V1 neurons that extract these simple features can be represented by 2D-Gabor wavelets. Lee (1996) derived a family of discretized 2D-Gabor wavelets that satisfy the wavelet theory and the neurophysiological constraints for simple cells mentioned above. They are given by an expression of the form

$$G_{pqkl}(x, y) = a^{-k} \Psi_{\Theta_l}(a^{-k}(x - 2p), a^{-k}(y - 2q)) \quad (2.9)$$

where

$$\Psi_{\Theta_l} = \Psi(x \cos(l\Theta_0) + y \sin(l\Theta_0), -x \sin(l\Theta_0) + y \cos(l\Theta_0)), \quad (2.10)$$

and the mother wavelet is given by

$$\Psi(x, y) = \frac{1}{\sqrt{2\pi}} e^{-\frac{1}{8}(4x^2 + y^2)} [e^{i\kappa x} - e^{-\frac{\kappa^2}{2}}]. \quad (2.11)$$

In the above equations $\Theta_0 = \pi/L$ denotes the step size of each angular rotation; l the index of rotation corresponding to the preferred orientation $\Theta_l = l\pi/L$; k denotes the octave;

Fig. 2.30 The filter sampling paradigm. Here each square represents the retinal image presented to the network after being filtered by a difference of gaussian filter of the appropriate orientation sign and frequency. The circles represent the consistent retinotopic coordinates used to provide input to a layer 1 cell. The filters double in spatial frequency towards the reader. Left to right the orientation tuning increases from 0° in steps of 45° , with segregated pairs of positive (P) and negative (N) filter responses. (Reprinted from Wallis, G. and Rolls, E. T. (1997) Invariant face and object recognition in the visual system. *Progress in Neurobiology* 51: 167–194. Copyright © Elsevier Ltd.)

and the indices pq the position of the receptive field centre at $c_x = p$ and $c_y = q$. In this form, the receptive fields at all levels cover the spatial domain in the same way, i.e. by always overlapping the receptive fields in the same fashion. In the model we use $a = 2$, $b = 1$ and $\kappa = \pi$ corresponding to a spatial frequency bandwidth of one octave. We used symmetric filters with the angular spacing between the different orientations set to 45 degrees; and with 4 filter frequencies spaced one octave apart starting with 0.5 cycles per pixel, and with the sampling from the spatial frequencies set as shown in Table 2.4. Each individual filter is tuned to spatial frequency (0.0625 to 0.5 cycles / pixel over four octaves); orientation (0° to 135° in steps of 45°); and sign (± 1) (Rolls, 2021d).

Table 2.4 VisNet layer 1 connectivity. The frequency is in cycles per pixel

Frequency	0.5	0.25	0.125	0.0625
# Connections	201	50	13	8

Of the 272 layer 1 connections, the number for each group is as shown in Table 2.4.

Cells of layer 1 of VisNet receive a topologically consistent, localized, random selection of the filter responses in the input layer, under the constraint that each cell samples every filter spatial frequency and receives a constant number of inputs. Figure 2.30 shows pictorially the general filter sampling paradigm, and Fig. 2.31 the typical connectivity to a layer 1 cell from the filters of the input layer. The blank squares indicate that no connection exists between the layer 1 cell chosen and the filters of that particular orientation, sign, and spatial frequency.

2.8.1.5 Measures for network performance

A neuron can be said to have learnt an invariant representation if it discriminates one set of stimuli from another set, across all transformations. For example, a neuron’s response is translation invariant if its response to one set of stimuli irrespective of presentation is consistently higher than for all other stimuli irrespective of presentation location. Note that we state ‘set of stimuli’ since neurons in the inferior temporal cortex are not generally selective for a single stimulus but rather a subpopulation of stimuli (Baylis, Rolls and Leonard, 1985; Abbott, Rolls and Tovee, 1996; Rolls, Treves and Tovee, 1997b; Rolls and Treves, 1998; Rolls and Deco, 2002; Rolls, 2007e; Franco, Rolls, Aggelopoulos and Jerez, 2007; Rolls and Treves, 2011) (see Appendix C). The measure of network performance used in VisNet1 (Wallis and Rolls, 1997), the ‘Fisher metric’ (referred to in some figure labels as the Discrim-

Fig. 2.31 Typical connectivity before training between a single cell in the first layer of the network and the input layer, represented by plotting the receptive fields of every input layer cell connected to the particular layer 1 cell. Separate input layer cells have activity that represents a positive (P) or negative (N) output from the bank of filters which have different orientations in degrees (the columns) and different spatial frequencies (the rows). Here the overall receptive field of the layer 1 cell is centred just below the centre-point of the retina. The connection scheme allows for relatively fewer connections to lower frequency cells than to high frequency cells in order to cover a similar region of the input at each frequency. A blank square indicates that there is no connection to the layer 1 neuron from an input neuron with that particular filter type. (After Wallis, G. and Rolls, E. T. (1997) Invariant face and object recognition in the visual system. *Progress in Neurobiology* 51: 167–194. Copyright © Elsevier Ltd.)

ination Factor), reflects how well a neuron discriminates between stimuli, compared to how well it discriminates between different locations (or more generally the images used rather than the objects, each of which is represented by a set of images, over which invariant stimulus or object representations must be learned). The Fisher measure is very similar to taking the ratio of the two F values in a two-way ANOVA, where one factor is the stimulus shown, and the other factor is the position in which a stimulus is shown. The measure takes a value greater than 1.0 if a neuron has more different responses to the stimuli than to the locations. That is, values greater than 1 indicate invariant representations when this measure is used in the following figures. Further details of how the measure is calculated are given by Wallis and Rolls (1997).

Measures of network performance based on information theory and similar to those used in the analysis of the firing of real neurons in the brain (see Appendix C) were introduced by Rolls and Milward (2000) for VisNet2, and are used in later papers (Rolls, 2021d). A single cell information measure was introduced which is the maximum amount of information the cell has about any one stimulus / object independently of which transform (e.g. position on the retina) is shown. Because the competitive algorithm used in VisNet tends to produce local representations (in which single cells become tuned to one stimulus or object), this information measure can approach $\log_2 N_S$ bits, where N_S is the number of different stimuli. Indeed, it is an advantage of this measure that it has a defined maximal value, which enables how well the network is performing to be quantified. Rolls and Milward (2000) showed that the Fisher and single cell information measures were highly correlated, and given the advantage just noted of the information measure, it was adopted in Rolls and Milward (2000) and subsequent papers. Rolls and Milward (2000) also introduced a multiple cell information measure, which has the advantage that it provides a measure of whether all stimuli are encoded by different neurons in the network. Again, a high value of this measure indicates good performance.

For completeness, further specification is provided next of the two information theoretic measures, which are described in detail by Rolls and Milward (2000) (see Appendix C for

introduction of the concepts, and Appendix D for availability of a Matlab version of the code). The measures assess the extent to which either a single cell, or a population of cells, responds to the same stimulus invariantly with respect to its location, yet responds differently to different stimuli. The measures effectively show what one learns about which stimulus was presented from a single presentation of the stimulus at any randomly chosen location. Results for top (4th) layer cells are shown. High information measures thus show that cells fire similarly to the different transforms of a given stimulus (object), and differently to the other stimuli. The single cell stimulus-specific information, $I(s, R)$, is the amount of information the set of responses, R , has about a specific stimulus, s (see Rolls, Treves, Tovee and Panzeri (1997d) and Rolls and Milward (2000)). $I(s, R)$ is given by

$$I(s, R) = \sum_{r \in R} P(r|s) \log_2 \frac{P(r|s)}{P(r)} \quad (2.12)$$

where r is an individual response from the set of responses R of the neuron. For each cell the performance measure used was the maximum amount of information a cell conveyed about any one stimulus. This (rather than the mutual information, $I(S, R)$ where S is the whole set of stimuli s), is appropriate for a competitive network in which the cells tend to become tuned to one stimulus⁵.

If all the output cells of VisNet learned to respond to the same stimulus, then the information about the set of stimuli S would be very poor, and would not reach its maximal value of \log_2 of the number of stimuli (in bits). The second measure that is used here is the information provided by a set of cells about the stimulus set, using the procedures described by Rolls, Treves and Tovee (1997b) and Rolls and Milward (2000). The multiple cell information is the mutual information between the whole set of stimuli S and of responses R calculated using a decoding procedure in which the stimulus s' that gave rise to the particular firing rate response vector on each trial is estimated. (The decoding step is needed because the high dimensionality of the response space would lead to an inaccurate estimate of the information if the responses were used directly, as described by Rolls, Treves and Tovee (1997b) and Rolls and Treves (1998).) A probability table is then constructed of the real stimuli s and the decoded stimuli s' . From this probability table, the mutual information between the set of actual stimuli S and the decoded estimates S' is calculated as

$$I(S, S') = \sum_{s, s'} P(s, s') \log_2 \frac{P(s, s')}{P(s)P(s')} \quad (2.13)$$

This was calculated for the subset of cells which had as single cells the most information about which stimulus was shown. In particular, in Rolls and Milward (2000) and subsequent papers, the multiple cell information was calculated from the first five cells for each stimulus that had maximal single cell information about that stimulus, that is from a population of 35 cells if there were seven stimuli (each of which might have been shown in for example 9 or 25 positions on the retina, or other types of transform).

2.8.2 Initial experiments with VisNet

Having established a network model, Wallis and Rolls (1997) (following a first report by Wallis, Rolls and Földiák (1993)) described four experiments in which the theory of how invariant representations could be formed was tested using a variety of stimuli undergoing a number of

⁵ $I(s, R)$ has also been termed the stimulus-specific surprise, see DeWeese and Meister (1999). Its average across stimuli is the mutual information $I(S, R)$.

Fig. 2.32 The three stimuli used in the first two VisNet experiments. (After Wallis, G. and Rolls, E. T. (1997) Invariant face and object recognition in the visual system. *Progress in Neurobiology* 51: 167–194. Copyright © Elsevier Ltd.)

natural transformations. In each case the network produced neurons in the final layer whose responses were largely invariant across a transformation and highly discriminating between stimuli or sets of stimuli.

2.8.2.1 ‘T’, ‘L’ and ‘+’ as stimuli: learning translation invariance

One of the classical properties of inferior temporal cortex face cells is their invariant response to face stimuli translated across the visual field (Tovee, Rolls and Azzopardi, 1994). In this first experiment, the learning of translation invariant representations by VisNet was investigated.

In order to test the network a set of three stimuli, based upon probable 3D edge cues – consisting of a ‘T’, ‘L’ and ‘+’ shape – was constructed⁶. The actual stimuli used are shown in Fig. 2.32. These stimuli were chosen partly because of their significance as form cues, but on a more practical note because they each contain the same fundamental features – namely a horizontal bar conjoined with a vertical bar. In practice this means that the oriented simple cell filters of the input layer cannot distinguish these stimuli on the basis of which features are present. As a consequence of this, the representation of the stimuli received by the network is non-orthogonal and hence considerably more difficult to classify than was the case in earlier experiments involving the trace rule (Földiák, 1991). The expectation is that layer 1 neurons would learn to respond to spatially selective combinations of the basic features thereby helping to distinguish these non-orthogonal stimuli. The trajectory followed by each stimulus consisted of sweeping left to right horizontally across three locations in the top row, and then sweeping back, right to left across the middle row, before returning to the right hand side across the bottom row – tracing out a ‘Z’ shape path across the retina. Unless stated otherwise this pattern of nine presentation locations was adopted in all image translation experiments described by Wallis and Rolls (1997).

Training was carried out by permutatively presenting all stimuli in each location a total of 800 times. The sequence described above was followed for each stimulus, with the sequence start point and direction of sweep being chosen at random for each of the 800 training trials.

Figures 2.33 and 2.34 show the response after training of a first layer neuron selective for the ‘T’ stimulus. The weighted sum of all filter inputs reveals the combination of horizontally and vertically tuned filters in identifying the stimulus. In this case many connections to the lower frequency filters have been reduced to zero by the learning process, except at the relevant orientations. This contrasts strongly with the random wiring present before training, as seen previously in Fig. 2.31. It is important that neurons at early stages of feature hierarchy networks respond to combinations of features in defined relative spatial positions, before invariance is built into the system, as this is part of the way that the binding problem is solved, as described in more detail in Section 2.8.5 and by Elliffe, Rolls and Stringer (2002). The feature combination tuning is illustrated by the VisNet layer 1 neuron shown in Figs. 2.33 and 2.34.

Likewise, Fig. 2.35 depicts two neural responses, but now from the two intermediate layers of the network, taken from the top 30 most highly invariant cells, not merely the top

⁶Chakravarty (1979) described the application of these shapes as cues for the 3D interpretation of edge junctions, and Tanaka et al. (1991) have demonstrated the existence of cells responsive to such stimuli in IT.

Fig. 2.33 The left graph shows the response of a VisNet layer 1 neuron to the three training stimuli for the nine training locations. Alongside this are the results of summing all the filter inputs to the neuron. The discrimination factor for this cell was 1.04.

Fig. 2.34 The same cell as in the previous figure and the same input reconstruction results but separated into four rows of differing spatial frequency, and eight columns representing the four filter tuning orientations in positive and negative complementary pairs.

two or three. The gradual increase in the discrimination indicates that the tolerance to shifts of the preferred stimulus gradually builds up through the layers.

The results for layer 4 neurons are illustrated in Fig. 2.36. By this stage translation-invariant, stimulus-identifying, cells have emerged. The response profiles confirm the high level of neural selectivity for a particular stimulus irrespective of location.

Figure 2.37 contrasts the measure of invariance, or discrimination factor, achieved by cells in the four layers, averaged over five separate runs of the network. Translation invariance clearly increases through the layers, with a considerable increase in translation invariance between layers 3 and 4. This sudden increase may well be a result of the geometry of the network, which enables cells in layer 4 to receive inputs from any part of the input layer.

Having established that invariant cells have emerged in the final layer, we now consider the role of the trace rule, by assessing the network tested under two new conditions. Firstly, the performance of the network was measured before learning occurs, that is with its initially random connection weights. Secondly, the network was trained with η in the trace rule set to 0, which causes learning to proceed in a traceless, standard Hebbian, fashion. (Hebbian learning is purely associative, as shown for example in Equation B.29.)

Fig. 2.35 Response profiles for two intermediate layer neurons – discrimination factors 1.34 and 1.64 – in the L, T, and + experiment. (After Wallis, G. and Rolls, E. T. (1997) Invariant face and object recognition in the visual system. Progress in Neurobiology 51: 167–194. Copyright © Elsevier Ltd.)

Fig. 2.36 Response profiles for two fourth layer VisNet neurons – discrimination factors 4.07 and 3.62 – in the L, T, and + experiment. (After Wallis, G. and Rolls, E. T. (1997) Invariant face and object recognition in the visual system. Progress in Neurobiology 51: 167–194.)

Figure 2.38 shows the results under the three training conditions. The results show that the trace rule is the decisive factor in establishing the invariant responses in the layer 4 neurons. It is interesting to note that the Hebbian learning results are actually *worse* than those achieved by chance in the untrained net. In general, with Hebbian learning, the most highly discriminating cells barely rate higher than 1. This value of discrimination corresponds to the case in which a cell responds to only one stimulus and in only one location. The poor performance with the Hebb rule comes as a direct consequence of the presentation paradigm being employed. If we consider an image as representing a vector in multidimensional space, a particular image in the top left-hand corner of the input retina will tend to look more like any other image in that same location than the same image presented elsewhere. A simple competitive network using just Hebbian learning will thus tend to categorize images by *where* they are rather than what they are – the exact opposite of what the net was intended to learn. This comparison thus indicates that a small memory trace acting in the standard Hebbian learning paradigm can radically alter the normal vector averaging, image classification, performed by a Hebbian-based competitive network.

One question that emerges about the representation in the final layer of the network relates to how evenly the network divides up its resources to represent the learnt stimuli. It is conceivable that one stimulus stands out among the set of stimuli by containing very distinc-

Fig. 2.37 Variation in VisNet neural discrimination factors as a measure of performance for the top 30 most highly discriminating cells through the four layers of the network, averaged over five runs of the network in the L, T, and + experiment. (After Wallis, G. and Rolls, E. T. (1997) Invariant face and object recognition in the visual system. *Progress in Neurobiology* 51: 167–194.)

Fig. 2.38 Variation in neural discrimination factors as a measure of performance for the top 30 most highly discriminating cells in the fourth layer for the three training regimes, averaged over five runs of the network. (After Wallis, G. and Rolls, E. T. (1997) Invariant face and object recognition in the visual system. *Progress in Neurobiology* 51: 167–194. Copyright © Elsevier Ltd.)

tive features which would make it easier to categorize. This may produce an unrepresentative number of neurons with high discrimination factors which are in fact all responding to the same stimulus. It is important that at least some cells code for (or provide information about) each of the stimuli. As a simple check on this, the preferred stimulus of each cell was found and the associated measure of discrimination added to a total for each stimulus. This measure in practice never varied by more than a factor of 1.3:1 for all stimuli. The multiple cell information measure used in some later figures addresses the same issue, with similar results.

2.8.2.2 ‘T’, ‘L’, and ‘+’ as stimuli: Optimal network parameters

The second series of investigations described by Wallis and Rolls (1997) using the ‘T’, ‘L’ and ‘+’ stimuli, centred upon finding optimal parameters for elements of the network, such as the optimal trace time constant η , which controls the relative effect of previous activities on current learning as described above. The network performance was gauged using a single 800 epoch training run of the network with the median discrimination factor (with the upper and lower quartile values) for the top sixteen cells of the fourth layer being displayed at each parameter value.

Figure 2.39 displays the effect of varying the value of η for the nine standard presentation locations. The optimal value of η might conceivably change with the alteration of the number of training locations, and indeed one might predict that it would be smaller if the number of presentation locations was reduced. To confirm this, network performance was also measured for presentation sweeps over only five locations. Figure 2.40 shows the results of this experiment, which confirm the expected shift in the general profile of the curve towards shorter time constant values. Of course, the optimal value of η derived is in effect a compromise between optimal values for the three layers in which the trace operates. Since neurons in each layer have different effective receptive field sizes, one would expect each layer’s neurons to be exposed to different portions of the full sweep of a particular stimulus. This would in turn suggest that the optimal value of η will grow through the layers.

2.8.2.3 Faces as stimuli: translation invariance

The aim of the next set of experiments described by Wallis and Rolls (1997) was to start to address the issues of how the network operates when invariant representations must be learned for a larger number of stimuli, and whether the network can learn when much more complicated, real biological stimuli (faces) are used. The set of face images used appears in Fig. 2.41. In practice, to equalize luminance the D.C. component of the images was removed.

Fig. 2.39 Variation in VisNet network performance as a function of the trace rule parameter η in neurons of layers 2 to 4 – over nine locations in the L, T and + experiment. In addition, so as to minimize the effect of cast shadows, an oval Hamming window was applied to the face image which also served to remove any hard edges of the image relative to the plain background upon which they were set.

The results of training in the translation invariance paradigm with 7 faces each in 9 locations are shown in Figs. 2.42, 2.43 and 2.44. The network produces neurons with high discrimination factors, and this only occurs if it is trained with the trace rule. Some layer 4 neurons showed a somewhat distributed representation, as illustrated in the examples of layer 4 neurons shown in Fig. 2.42. The more recent Matlab version of VisNet available from 2022 (Section D.6) would obtain perfect performance on this type of problem, with layer 4 neurons responding to only one object or face with complete invariance, that is a high response to one face invariantly of the transform, with no response to any other face or object.

In order to check that there was an invariant representation in layer 4 of VisNet that could be read by a receiving population of neurons, a fifth layer was added to the net which fully sampled the fourth layer cells. This layer was in turn trained in a supervised manner using gradient descent or with a Hebbian associative learning rule. Wallis and Rolls (1997) showed that the object classification performed by the layer 5 network was better if the network had been trained with the trace rule than when it was untrained or was trained with a Hebb rule.

2.8.2.4 Faces as stimuli: view invariance

Given that the network had been shown to be able to operate usefully with a more difficult translation invariance problem, we next addressed the question of whether the network can

Fig. 2.42 Response profiles for two VisNet neurons in the fourth layer – discrimination factors 2.64 and 2.10. The net was trained on 7 faces each in 9 locations. (After Wallis,G. and Rolls, E. T. solve other types of transform invariance, as we had intended. The next experiment addressed this question, by training the network on the problem of 3D stimulus rotation, which produces non-isomorphic transforms, to determine whether the network can build a view-invariant categorization of the stimuli (Wallis and Rolls, 1997). The trace rule learning paradigm should, in conjunction with the architecture described here, prove capable of learning any of the transforms tolerated by IT neurons, so long as each stimulus is presented in short sequences during which the transformation occurs and can be learned. This experiment continued with the use of faces but now presented them centrally in the retina in a sequence of different views of a face. The images used are shown in Fig. 2.45. The faces were again smoothed at the edges to erase the harsh image boundaries, and the D.C. term was removed. During the 800 epochs of learning, each stimulus was chosen at random, and a sequence of preset views of it was shown, rotating the face either to the left or to the right.

Although the actual number of images being presented is smaller, some 21 views in all, there is good reason to think that this problem may be harder to solve than the previous translation experiments. This is simply due to the fact that all 21 views exactly overlap with

Fig. 2.45 Three faces in seven different views used as stimuli in an experiment in view-invariant recognition by VisNet. (After Wallis, G. and Rolls, E. T. (1997) Invariant face and object recognition in the visual system. *Progress in Neurobiology* 51: 167–194. Copyright © Elsevier Ltd.)

one another. The net was indeed able to solve the invariance problem, with examples of invariant layer 4 neuron response profiles appearing in Fig. 2.46.

Figure 2.47 confirms the improvement in invariant stimulus representation found through the layers, and that layer 4 provides a considerable improvement in performance over the previous layers. Figure 2.48 shows the Hebb trained and untrained nets performing equally poorly, whilst the trace trained net shows good invariance across the entire 30 cells selected.

2.8.3 The optimal parameters for the temporal trace used in the learning rule

The trace used in VisNet enables successive features that, based on the natural statistics of the visual input, are likely to be from the same object or feature complex to be associated together. For good performance, the temporal trace needs to be sufficiently long that it covers the period in which features seen by a particular neuron in the hierarchy are likely to come from the same object. On the other hand, the trace should not be so long that it produces associations between features that are parts of different objects, seen when for example the eyes move to another object. One possibility is to reset the trace during saccades between different objects. If explicit trace resetting is not implemented, then the trace should, to opti-

Fig. 2.47 Variation in VisNet network performance for the top 30 most highly discriminating cells through the four layers of the network, averaged over five runs of the network in the experiment with seven different views of each of three faces. mize the compromise implied by the above, lead to strong associations between temporally close stimuli, and increasingly weaker associations between temporally more distant stimuli. In fact, the trace implemented in VisNet has an exponential decay, and it has been shown that this form is optimal in the situation where the exact duration over which the same object is being viewed varies, and where the natural statistics of the visual input happen also to show a decreasing probability that the same object is being viewed as the time period in question increases (Wallis and Baddeley, 1997). Moreover, as is made evident in Figs. 2.40 and 2.39, performance can be enhanced if the duration of the trace does at the same time approximately match the period over which the input stimuli are likely to come from the same object or feature complex. Nevertheless, good performance can be obtained in conditions under which the trace rule allows associations to be formed only between successive items in the visual stream (Rolls and Milward, 2000; Rolls and Stringer, 2001a).

It is also the case that the optimal value of η in the trace rule is likely to be different for different layers of VisNet, and for cortical processing in the ‘what’ visual stream. For early layers of the system, small movements of the eyes might lead to different feature combinations providing the input to cells (which at early stages have small receptive fields), and a short duration of the trace would be optimal. However, these small eye movements might be around the same object, and later layers of the architecture would benefit from being able to associate together their inputs over longer times, in order to learn about the larger scale properties that characterize individual objects, including for example different views of objects observed as an object turns or is turned. Thus the suggestion is made that the temporal trace could be effectively longer at later stages (e.g. inferior temporal visual cortex) compared to early stages (e.g. V4 and posterior inferior temporal cortex) of processing in the visual system. In addition, as will be shown in Section 2.8.5, it is important to form feature combinations with high spatial precision before invariance learning supported by a temporal trace starts, in order that the feature combinations and not the individual features have invariant representations. This leads to the suggestion that the trace rule should either not operate, or be short, at early stages of cortical visual processing such as V1. This is reflected in the operation of VisNet2, which does not use a temporal trace in layer 1 (Rolls and Milward, 2000).

2.8.4 Different forms of the trace learning rule, and their relation to error correction and temporal difference learning

The original trace learning rule used in the simulations of Wallis and Rolls (1997) took the form

$$\delta w_j = \alpha \bar{y}^\tau x_j^\tau \quad (2.14)$$

where the trace \bar{y}^τ is updated according to

$$\bar{y}^\tau = (1 - \eta)y^\tau + \eta\bar{y}^{\tau-1}. \quad (2.15)$$

The parameter $\eta \in [0, 1]$ controls the relative contributions to the trace \bar{y}^τ from the instantaneous firing rate y^τ and the trace at the previous time step $\bar{y}^{\tau-1}$, where for $\eta = 0$ we have $\bar{y}^\tau = y^\tau$ and equation 2.14 becomes the standard Hebb rule

$$\delta w_j = \alpha y^\tau x_j^\tau. \quad (2.16)$$

At the start of a series of investigations of different forms of the trace learning rule, Rolls and Milward (2000) demonstrated that VisNet's performance could be greatly enhanced with a modified Hebbian learning rule that incorporated a trace of activity from the preceding time steps, with no contribution from the activity being produced by the stimulus at the current time step. This rule took the form

$$\delta w_j = \alpha \bar{y}^{\tau-1} x_j^\tau. \quad (2.17)$$

The trace shown in Equation 2.17 is in the postsynaptic term, and similar effects were found if the trace was in the presynaptic term, or in both the pre- and the postsynaptic terms. The crucial difference from the earlier rule (see Equation 2.14) was that the trace should be calculated up to only the preceding timestep, with no contribution to the trace from the firing on the current trial to the current stimulus. How might this be understood?

One way to understand this is to note that the trace rule is trying to set up the synaptic weight on trial τ based on whether the neuron, based on its previous history, is responding to that stimulus (in other transforms, e.g. position). Use of the trace rule at $\tau - 1$ does this, that is it takes into account the firing of the neuron on previous trials, with no contribution from the firing being produced by the stimulus on the current trial. On the other hand, use of the trace at time τ in the update takes into account the current firing of the neuron to the stimulus in that particular position, which is not a good estimate of whether that neuron should be allocated to invariantly represent that stimulus. Effectively, using the trace at time τ introduces a Hebbian element into the update, which tends to build position-encoded analyzers, rather than stimulus-encoded analyzers. (The argument has been phrased for a system learning translation invariance, but applies to the learning of all types of invariance.) A particular advantage of using the trace at $\tau - 1$ is that the trace will then on different occasions (due to the randomness in the location sequences used) reflect previous histories with different sets of positions, enabling the learning of the neuron to be based on evidence from the stimulus present in many different positions. Using a term from the current firing in the trace (i.e. the trace calculated at time τ) results in this desirable effect always having an undesirable element from the current firing of the neuron to the stimulus in its current position (or any other transform).

2.8.4.1 The modified Hebbian trace rule and its relation to error correction

The rule of Equation 2.17 corrects the weights using a postsynaptic trace obtained from the previous firing (produced by other transforms of the same stimulus), with no contribution

to the trace from the current postsynaptic firing (produced by the current transform of the stimulus). Indeed, insofar as the current firing y^τ is not the same as $\bar{y}^{\tau-1}$, this difference can be thought of as an error. This leads to a conceptualization of using the difference between the current firing and the preceding trace as an error correction term, as noted in the context of modelling the temporal properties of classical conditioning by Sutton and Barto (1981), and developed next in the context of invariance learning (see Rolls and Stringer (2001a)).

First, we re-express the rule of Equation 2.17 in an alternative form as follows. Suppose we are at timestep τ and have just calculated a neuronal firing rate y^τ and the corresponding trace \bar{y}^τ from the trace update Equation 2.15. If we assume $\eta \in (0, 1)$, then rearranging Equation 2.15 gives

$$\bar{y}^{\tau-1} = \frac{1}{\eta}(\bar{y}^\tau - (1 - \eta)y^\tau), \quad (2.18)$$

and substituting Equation 2.18 into Equation 2.17 gives

$$\begin{aligned} \delta w_j &= \alpha \frac{1}{\eta} (\bar{y}^\tau - (1 - \eta)y^\tau) x_j^\tau \\ &= \alpha \frac{1 - \eta}{\eta} \left(\frac{1}{1 - \eta} \bar{y}^\tau - y^\tau \right) x_j^\tau \\ &= \hat{\alpha} (\hat{\beta} \bar{y}^\tau - y^\tau) x_j^\tau \end{aligned} \quad (2.19)$$

where $\hat{\alpha} = \alpha \frac{1 - \eta}{\eta}$ and $\hat{\beta} = \frac{1}{1 - \eta}$. The modified Hebbian trace learning rule (2.17) is thus equivalent to Equation 2.19 which is in the general form of an error correction rule (Hertz, Krogh and Palmer, 1991). That is, rule (2.19) involves the subtraction of the current firing rate y^τ from a target value, in this case $\hat{\beta} \bar{y}^\tau$.

Although above we have referred to rule (2.17) as a modified Hebbian rule, I note that it is only associative in the sense of associating *previous* cell firing with the current cell inputs. In the next section we continue to explore the error correction paradigm, examining five alternative examples of this sort of learning rule.

2.8.4.2 Five forms of error correction learning rule

Error correction learning rules are derived from gradient descent minimization (Hertz, Krogh and Palmer, 1991), and continually compare the current neuronal output to a target value t and adjust the synaptic weights according to the following Equation at a particular timestep τ

$$\delta w_j = \alpha (t - y^\tau) x_j^\tau. \quad (2.20)$$

In this usual form of gradient descent by error correction, the target t is fixed. However, in keeping with our aim of encouraging neurons to respond similarly to images that occur close together in time it seems reasonable to set the target at a particular timestep, t^τ , to be some function of cell activity occurring close in time, because encouraging neurons to respond to temporal classes will tend to make them respond to the different variants of a given stimulus (Földiák, 1991; Rolls, 1992a; Wallis and Rolls, 1997). For this reason, Rolls and Stringer (2001a) explored a range of error correction rules where the targets t^τ are based on the trace of neuronal activity calculated according to Equation 2.15. I note that although the target is not a fixed value as in standard error correction learning, nevertheless the new learning rules perform gradient descent on each timestep, as elaborated below. Although the target may be varying early on in learning, as learning proceeds the target is expected to become more and more constant, as neurons settle to respond invariantly to particular stimuli. The first set of five error correction rules we discuss are as follows.

$$\delta w_j = \alpha (\beta \bar{y}^{\tau-1} - y^\tau) x_j^\tau, \quad (2.21)$$

Fig. 2.49 Numerical results for VisNet with the five error correction rules (2.21), (2.22), (2.23), (2.24), (2.25) (with positive clipping of synaptic weights) trained on 7 faces in 9 locations. On the left are single cell information measures, and on the right are multiple cell information measures. (After Rolls, E. T. and Stringer, S.M. (2001) Invariant object recognition in the visual system with error correction and temporal difference learning. *Network: Computation in Neural Systems* 12: 111–129.)

$$\delta w_j = \alpha(\beta y^{\tau-1} - y^\tau) x_j^\tau, \quad (2.22)$$

$$\delta w_j = \alpha(\beta \bar{y}^\tau - y^\tau) x_j^\tau, \quad (2.23)$$

$$\delta w_j = \alpha(\beta \bar{y}^{\tau+1} - y^\tau) x_j^\tau, \quad (2.24)$$

$$\delta w_j = \alpha(\beta y^{\tau+1} - y^\tau) x_j^\tau, \quad (2.25)$$

where updates (2.21), (2.22) and (2.23) are performed at timestep τ , and updates (2.24) and (2.25) are performed at timestep $\tau + 1$. (The reason for adopting this convention is that the basic form of the error correction rule (2.20) is kept, with the five different rules simply replacing the term t .) It may be readily seen that Equations (2.22) and (2.25) are special cases of Equations (2.21) and (2.24) respectively, with $\eta = 0$.

These rules are all similar except for their targets t^τ , which are all functions of a temporally nearby value of cell activity. In particular, rule (2.23) is directly related to rule (2.19), but is more general in that the parameter $\hat{\beta} = \frac{1}{1-\eta}$ is replaced by an unconstrained parameter β . In addition, we also note that rule (2.21) is closely related to a rule developed in Peng, Sha, Gan and Wei (1998) for view invariance learning. The above five error correction rules are biologically plausible in that the targets t^τ are all local cell variables (see Appendix B and Rolls and Treves (1998)). In particular, rule (2.23) uses the trace \bar{y}^τ from the current time level τ , and rules (2.22) and (2.25) do not need exponential trace values \bar{y} , instead relying only on the instantaneous firing rates at the current and immediately preceding timesteps. However, all five error correction rules involve decrementing of synaptic weights according to an error which is calculated by subtracting the current activity from a target.

Numerical results with the error correction rules trained on 7 faces in 9 locations are presented in Fig. 2.49. For all the results shown the synaptic weights were clipped to be positive during the simulation, because it is important to test that decrementing synaptic weights purely within the positive interval $w \in [0, \infty]$ will provide significantly enhanced performance. That is, it is important to show that error correction rules do not necessarily require possibly biologically implausible modifiable negative weights. For each of the rules (2.21), (2.22), (2.23), (2.24), (2.25), the parameter β has been individually optimized to the following respective values: 4.9, 2.2, 2.2, 3.8, 2.2. On the left and right are results with the single and multiple cell information measures, respectively. Comparing Fig. 2.49 with Fig. 2.50 shows that all five error correction rules offer considerably improved performance over both the standard trace rule (2.14) and rule (2.17). From the left-hand side of Fig. 2.49 it can be seen that rule (2.21) performs best, and this is probably due to two reasons. Firstly, rule (2.21)

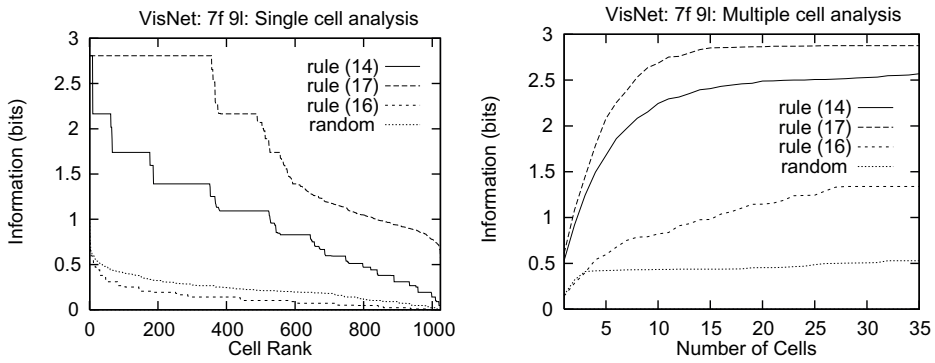

Fig. 2.50 Numerical results for VisNet with the standard trace rule (2.14), learning rule (2.17), the Hebb rule (2.16), and random weights, trained on 7 faces in 9 locations: single cell information measure (left), multiple cell information measure (right). (After Rolls, E. T. and Stringer, S.M. (2001) Invariant object recognition in the visual system with error correction and temporal difference learning. *Network: Computation in Neural Systems* 12: 111–129.)

incorporates an exponential trace $\bar{y}^{\tau-1}$ in its target t^τ , and we would expect this to help neurons to learn more quickly to respond invariantly to a class of inputs that occur close together in time. Hence, setting $\eta = 0$ as in rule (2.22) results in reduced performance. Secondly, unlike rules (2.23) and (2.24), rule (2.21) does not contain any component of y^τ in its target. If we examine rules (2.23), (2.24), we see that their respective targets $\beta\bar{y}^\tau$, $\beta\bar{y}^{\tau+1}$ contain significant components of y^τ .

2.8.4.3 Relationship to temporal difference learning

Rolls and Stringer (2001a) not only considered the relationship of rule (2.17) to error correction, but also considered how the error correction rules shown in Equations (2.21), (2.22), (2.23), (2.24) and (2.25) are related to temporal difference learning (Sutton, 1988; Sutton and Barto, 1998). Sutton (1988) described temporal difference methods in the context of prediction learning. These methods are a class of incremental learning techniques that can learn to predict final outcomes through comparison of successive predictions from the preceding time steps (Section B.17.3). This is in contrast to traditional supervised learning, which involves the comparison of predictions only with the final outcome. Consider a series of multistep prediction problems in which for each problem there is a sequence of observation vectors, \mathbf{x}^1 , \mathbf{x}^2 , ..., \mathbf{x}^m , at successive timesteps, followed by a final scalar outcome z . For each sequence of observations temporal difference methods form a sequence of predictions y^1 , y^2 , ..., y^m , each of which is a prediction of z . These predictions are based on the observation vectors \mathbf{x}^τ and a vector of modifiable weights \mathbf{w} ; i.e. the prediction at time step τ is given by $y^\tau(\mathbf{x}^\tau, \mathbf{w})$, and for a linear dependency the prediction is given by $y^\tau = \mathbf{w}^T \mathbf{x}^\tau$. (Note here that \mathbf{w}^T is the transpose of the weight vector \mathbf{w} .) The problem of prediction is to calculate the weight vector \mathbf{w} such that the predictions y^τ are good estimates of the outcome z .

The supervised learning approach to the prediction problem is to form pairs of observation vectors \mathbf{x}^τ and outcome z for all time steps, and compute an update to the weights according to the gradient descent equation

$$\delta \mathbf{w} = \alpha(z - y^\tau) \nabla_{\mathbf{w}} y^\tau \quad (2.26)$$

where α is a learning rate parameter and $\nabla_{\mathbf{w}}$ indicates the gradient with respect to the weight vector \mathbf{w} . However, this learning procedure requires all calculation to be done at the end of the sequence, once z is known. To remedy this, it is possible to replace method (2.26) with a temporal difference algorithm that is mathematically equivalent but allows the computational workload to be spread out over the entire sequence of observations. Temporal difference methods are a particular approach to updating the weights based on the values of successive

predictions, $y^\tau, y^{\tau+1}$. Sutton (1988) showed that the following temporal difference algorithm is equivalent to method (2.26)

$$\delta \mathbf{w} = \alpha(y^{\tau+1} - y^\tau) \sum_{k=1}^{\tau} \nabla_{\mathbf{w}} y^k, \quad (2.27)$$

where $y^{m+1} \equiv z$. However, unlike method (2.26) this can be computed incrementally at each successive time step since each update depends only on $y^{\tau+1}, y^\tau$ and the sum of $\nabla_{\mathbf{w}} y^k$ over previous time steps k . The next step taken in Sutton (1988) is to generalize equation (2.27) to the following final form of temporal difference algorithm, known as ‘TD(λ)’

$$\delta \mathbf{w} = \alpha(y^{\tau+1} - y^\tau) \sum_{k=1}^{\tau} \lambda^{\tau-k} \nabla_{\mathbf{w}} y^k \quad (2.28)$$

where $\lambda \in [0, 1]$ is an adjustable parameter that controls the weighting on the vectors $\nabla_{\mathbf{w}} y^k$. Equation (2.28) represents a much broader class of learning rules than the more usual gradient descent-based rule (2.27), which is in fact the special case TD(1).

A further special case of Equation (2.28) is for $\lambda = 0$, i.e. TD(0), as follows

$$\delta \mathbf{w} = \alpha(y^{\tau+1} - y^\tau) \nabla_{\mathbf{w}} y^\tau. \quad (2.29)$$

But for problems where y^τ is a linear function of \mathbf{x}^τ and \mathbf{w} , we have $\nabla_{\mathbf{w}} y^\tau = \mathbf{x}^\tau$, and so Equation (2.29) becomes

$$\delta \mathbf{w} = \alpha(y^{\tau+1} - y^\tau) \mathbf{x}^\tau. \quad (2.30)$$

If we assume the prediction process is being performed by a neuron with a vector of inputs \mathbf{x}^τ , synaptic weight vector \mathbf{w} , and output $y^\tau = \mathbf{w}^T \mathbf{x}^\tau$, then we see that the TD(0) algorithm (2.30) is identical to the error correction rule (2.25) with $\beta = 1$. In understanding this comparison with temporal difference learning, it may be useful to note that the firing at the end of a sequence of the transformed exemplars of a stimulus is effectively the temporal difference target z . This establishes a link to temporal difference learning (described further in Section B.17.3). Further, I note that from learning epoch to learning epoch, the target z for a given neuron will gradually settle down to be more and more fixed as learning proceeds.

We now explore in more detail the relation between the error correction rules described above and temporal difference learning. For each sequence of observations with a single outcome the temporal difference method (2.30), when viewed as an error correction rule, is attempting to adapt the weights such that $y^{\tau+1} = y^\tau$ for all successive pairs of time steps – the same general idea underlying the error correction rules (2.21), (2.22), (2.23), (2.24), (2.25). Furthermore, in Sutton and Barto (1998), where temporal difference methods are applied to reinforcement learning, the TD(λ) approach is again further generalized by replacing the target $y^{\tau+1}$ by any weighted average of predictions y from arbitrary future timesteps, e.g. $t^\tau = \frac{1}{2}y^{\tau+3} + \frac{1}{2}y^{\tau+7}$, including an exponentially weighted average extending forward in time. So a more general form of the temporal difference algorithm has the form

$$\delta \mathbf{w} = \alpha(t^\tau - y^\tau) \mathbf{x}^\tau, \quad (2.31)$$

where here the target t^τ is an arbitrary weighted average of the predictions y over future timesteps. Of course, with standard temporal difference methods the target t^τ is always an average over *future* timesteps $k = \tau + 1, \tau + 2$, etc. But in the five error correction rules this is only true for the last exemplar (2.25). This is because with the problem of prediction, for example, the ultimate target of the predictions y^1, \dots, y^m is a final outcome $y^{m+1} \equiv z$.

However, this restriction does not apply to our particular application of neurons trained to respond to temporal classes of inputs within VisNet. Here we only wish to set the firing rates y^1, \dots, y^m to the same value, not some final given value z . However, the more general error correction rules clearly have a close relationship to standard temporal difference algorithms. For example, it can be seen that Equation (2.22) with $\beta = 1$ is in some sense a temporal mirror image of Equation (2.30), particularly if the updates δw_j are added to the weights w_j only at the end of a sequence. That is, rule (2.22) will attempt to set y^1, \dots, y^m to an *initial* value $y^0 \equiv z$. This relationship to temporal difference algorithms allowed us to begin to exploit established temporal difference analyses to investigate the convergence properties of the error correction methods (Rolls and Stringer, 2001a).

Although the main aim of Rolls and Stringer (2001a) in relating error correction rules to temporal difference learning was to begin to exploit established temporal difference analyses, they observed that the most general form of temporal difference learning, TD(λ), in fact suggests an interesting generalization to the existing error correction learning rules for which we currently have $\lambda = 0$. Assuming $y^\tau = \mathbf{w}^T \mathbf{x}^\tau$ and $\nabla_{\mathbf{w}} y^\tau = \mathbf{x}^\tau$, the general Equation (2.28) for TD(λ) becomes

$$\delta \mathbf{w} = \alpha (y^{\tau+1} - y^\tau) \sum_{k=1}^{\tau} \lambda^{\tau-k} \mathbf{x}^k \quad (2.32)$$

where the term $\sum_{k=1}^{\tau} \lambda^{\tau-k} \mathbf{x}^k$ is a weighted sum of the vectors \mathbf{x}^k . This suggests generalizing the original five error correction rules (2.21), (2.22), (2.23), (2.24), (2.25) by replacing the term x_j^τ by a weighted sum $\hat{x}_j^\tau = \sum_{k=1}^{\tau} \lambda^{\tau-k} x_j^k$ with $\lambda \in [0, 1]$. In Sutton (1988) \hat{x}_j^τ is calculated according to

$$\hat{x}_j^\tau = x_j^\tau + \lambda \hat{x}_j^{\tau-1} \quad (2.33)$$

with $\hat{x}_j^0 \equiv 0$. This gives the following five temporal difference-inspired error correction rules

$$\delta w_j = \alpha (\beta \bar{y}^{\tau-1} - y^\tau) \hat{x}_j^\tau, \quad (2.34)$$

$$\delta w_j = \alpha (\beta y^{\tau-1} - y^\tau) \hat{x}_j^\tau, \quad (2.35)$$

$$\delta w_j = \alpha (\beta \bar{y}^\tau - y^\tau) \hat{x}_j^\tau, \quad (2.36)$$

$$\delta w_j = \alpha (\beta \bar{y}^{\tau+1} - y^\tau) \hat{x}_j^\tau, \quad (2.37)$$

$$\delta w_j = \alpha (\beta y^{\tau+1} - y^\tau) \hat{x}_j^\tau, \quad (2.38)$$

where it may be readily seen that Equations (2.35) and (2.38) are special cases of equations (2.34) and (2.37) respectively, with $\eta = 0$. As with the trace \bar{y}^τ , the term \hat{x}_j^τ is reset to zero when a new stimulus is presented. These five rules can be related to the more general TD(λ) algorithm, but continue to be biologically plausible using only local cell variables. Setting $\lambda = 0$ in rules (2.34), (2.35), (2.36), (2.37), (2.38), gives us back the original error correction rules (2.21), (2.22), (2.23), (2.24), (2.25) which may now be related to TD(0).

Numerical results with error correction rules (2.34), (2.35), (2.36), (2.37), (2.38), and \hat{x}_j^τ calculated according to equation (2.33) with $\lambda = 1$, with positive clipping of weights, trained on 7 faces in 9 locations are presented in Fig. 2.51. For each of the rules (2.34), (2.35), (2.36), (2.37), (2.38), the parameter β has been individually optimized to the following respective values: 1.7, 1.8, 1.5, 1.6, 1.8. On the left and right are results with the single and multiple cell information measures, respectively. Comparing these five temporal difference-inspired rules it can be seen that the best performance is obtained with rule (2.38) where many more cells reach the maximum level of performance possible with respect to the single cell information measure. In fact, this rule offered the best such results. This may well be due to the fact that

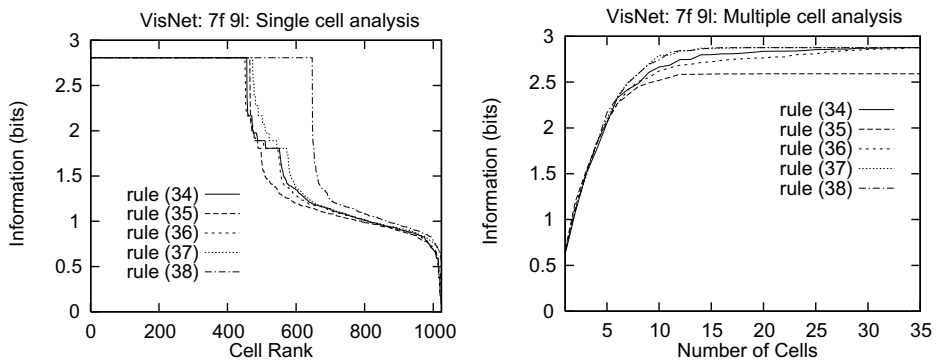

Fig. 2.51 Numerical results for VisNet with the five temporal difference-inspired error correction rules (2.34), (2.35), (2.36), (2.37), (2.38), and \hat{x}_j^τ calculated according to Equation (2.33) (with positive clipping of synaptic weights) trained on 7 faces in 9 locations. On the left are single cell information measures, and on the right are multiple cell information measures. (After Rolls, E. T. and Stringer, S.M. (2001) Invariant object recognition in the visual system with error correction and temporal difference learning. *Network: Computation in Neural Systems* 12: 111–129.)

this rule may be directly compared to the standard TD(1) learning rule, which itself may be related to classical supervised learning for which there are well known optimality results, as discussed further by Rolls and Stringer (2001a).

From the simulations described by Rolls and Stringer (2001a) it appears that the form of optimization described above associated with TD(1) rather than TD(0) leads to better performance within VisNet. Comparing Figs. 2.49 and 2.51 shows that the TD(1)-like rule (2.38) with $\lambda = 1.0$ and $\beta = 1.8$ gives considerably superior results to the TD(0)-like rule (2.25) with $\beta = 2.2$. In fact, the former of these two rules provided the best single cell information results in these studies. It is hypothesized that these results are related to the fact that only a finite set of image sequences is presented to VisNet, and so the type of optimization performed by TD(1) for repeated presentations of a finite data set is more appropriate for this problem than the form of optimization performed by TD(0).

2.8.4.4 Evaluation of the different training rules

In terms of biological plausibility, I note the following. First, all the learning rules investigated by Rolls and Stringer (2001a) are local learning rules, and in this sense are biologically plausible (see Appendix B). (The rules are local in that the terms used to modify the synaptic weights are potentially available in the pre- and post-synaptic elements.)

Second I note that all the rules do require some evidence of the activity on one or more previous stimulus presentations to be available when the synaptic weights are updated. Some of the rules, e.g. learning rule (2.23), use the trace \bar{y}^τ from the current time level, while rules (2.22) and (2.25) do not need to use an exponential trace of the neuronal firing rate, but only the instantaneous firing rates y at two successive time steps. It is known that synaptic plasticity does involve a combination of separate processes each with potentially differing time courses (Koch, 1999), and these different processes could contribute to trace rule learning. Another mechanism suggested for implementing a trace of previous neuronal activity is the continuing firing for often 300 ms produced by a short (16 ms) presentation of a visual stimulus (Rolls and Tovee, 1994) that is suggested to be implemented by local cortical recurrent attractor networks (Rolls and Treves, 1998; Rolls, 2016b) (Section 13.6).

Third, I note that in utilizing the trace in the targets t^τ , the error correction (or temporal difference inspired) rules perform a comparison of the instantaneous firing y^τ with a temporally nearby value of the activity, and this comparison involves a subtraction. The subtraction provides an error, which is then used to increase or decrease the synaptic weights. This is a somewhat different operation from long-term depression (LTD) as well as long term pot-

entiation (LTP), which are *associative* changes which depend on the pre- and post-synaptic activity. However, it is interesting to note that an error correction rule which appears to involve a subtraction of current firing from a target might be implemented by a combination of an associative process operating with the trace, and an anti-Hebbian process operating to remove the effects of the current firing. For example, the synaptic updates $\delta w_j = \alpha(t^\tau - y^\tau)x_j^\tau$ can be decomposed into two separate associative processes $\alpha t^\tau x_j^\tau$ and $-\alpha y^\tau x_j^\tau$, that may occur independently. (The target, t^τ , could in this case be just the trace of previous neural activity from the preceding trials, excluding any contribution from the current firing.) Another way to implement an error correction rule using associative synaptic modification would be to force the post-synaptic neuron to respond to the error term. Although this has been postulated to be an effect that could be implemented by the climbing fibre system in the cerebellum (Ito, 1989, 1984, 2013) (Chapter 17), there is no similar system known for the neocortex, and it is not clear how this particular implementation of error correction might operate in the neocortex.

In Section 2.8.4.2 we describe five learning rules as error correction rules. We now discuss an interesting difference of these error correction rules from error correction rules as conventionally applied. It is usual to derive the general form of error correction learning rule from gradient descent minimization in the following way (Hertz, Krogh and Palmer, 1991). Consider the idealized situation of a single neuron with a number of inputs x_j and output $y = \sum_j w_j x_j$, where w_j are the synaptic weights. We assume that there are a number of input patterns and that for the k th input pattern, $\mathbf{x}^k = [x_1^k, x_2^k, \dots]^T$, the output y^k has a target value t^k . Hence an error measure or cost function can be defined as

$$e(\mathbf{w}) = \frac{1}{2} \sum_k (t^k - y^k)^2 = \frac{1}{2} \sum_k (t^k - \sum_j w_j x_j^k)^2. \quad (2.39)$$

This cost function is a function of the input patterns \mathbf{x}^k and the synaptic weight vector $\mathbf{w} = [w_1, w_2, \dots]^T$. With a fixed set of input patterns, we can reduce the error measure by employing a gradient descent algorithm to calculate an improved set of synaptic weights. Gradient descent achieves this by moving downhill on the error surface defined in \mathbf{w} space using the update

$$\delta w_j = -\alpha \frac{\partial e}{\partial w_j} = \alpha \sum_k (t^k - y^k) x_j^k. \quad (2.40)$$

If we update the weights after each pattern k , then the update takes the form of an error correction rule

$$\delta w_j = \alpha (t^k - y^k) x_j^k, \quad (2.41)$$

which is also commonly referred to as the delta rule or Widrow–Hoff rule (see Widrow and Hoff (1960) and Widrow and Stearns (1985)). Error correction rules continually compare the neuronal output with its pre-specified target value and adjust the synaptic weights accordingly. In contrast, the way Rolls and Stringer (2001a) introduced of utilizing error correction is to specify the target as the activity trace based on the firing rate at nearby timesteps. Now the actual firing at those nearby time steps is not a pre-determined fixed target, but instead depends on how the network has actually evolved. This effectively means the cost function $e(\mathbf{w})$ that is being minimized changes from timestep to timestep. Nevertheless, the concept of calculating an error, and using the magnitude and direction of the error to update the synaptic weights, is the similarity Rolls and Stringer (2001a) made to gradient descent learning.

To conclude this evaluation, the error correction and temporal difference rules explored by Rolls and Stringer (2001a) provide interesting approaches to help understand invariant pattern recognition learning. Although we do not know whether the full power of these rules

is expressed in the brain, we provided suggestions about how they might be implemented. At the same time, I note that the original trace rule used by Földiák (1991), Rolls (1992a), Wallis, Rolls and Földiák (1993), and Wallis and Rolls (1997) is a simple associative rule, is therefore biologically very plausible, and, while not as powerful as many of the other rules introduced by Rolls and Stringer (2001a), can nevertheless solve the same class of problem. Rolls and Stringer (2001a) also emphasized that although they demonstrated how a number of new error correction and temporal difference rules might play a role in the context of view invariant object recognition, they may also operate elsewhere where it is important for neurons to learn to respond similarly to temporal classes of inputs that tend to occur close together in time.

2.8.5 The issue of feature binding, and a solution

In this section we investigate two key issues that arise in hierarchical layered network architectures, such as VisNet, other examples of which have been described and analyzed by Fukushima (1980), Ackley, Hinton and Sejnowski (1985), Rosenblatt (1961), Riesenhuber and Poggio (1999b) and Serre, Oliva and Poggio (2007b) (see also Section 2.9.2). One issue is whether the network can discriminate between stimuli that are composed of the same basic alphabet of features. The second issue is whether such network architectures can find solutions to the spatial binding problem. These issues are addressed next and by Elliffe, Rolls and Stringer (2002).

The first issue investigated is whether a hierarchical layered network architecture of the type exemplified by VisNet can discriminate stimuli that are composed of a limited set of features and where the different stimuli include cases where the feature sets are subsets and supersets of those in the other stimuli. A question is whether if the network has learned representations of both the parts and the wholes, will the network identify that the whole is present when it is shown, and not just that one or more parts is present? (In many investigations with VisNet, complex stimuli (such as faces) were used where each stimulus might contain unique features not present in the other stimuli.) To address this issue, Elliffe, Rolls and Stringer (2002) used stimuli that are composed from a set of four features which are designed so that each feature is spatially separate from the other features, and no unique combination of firing caused for example by overlap of horizontal and vertical filter outputs in the input representation distinguishes any one stimulus from the others. The results described in Section 2.8.5.4 show that VisNet can indeed learn correct invariant representations of stimuli that do consist of feature sets where individual features do not overlap spatially with each other and where the stimuli can be composed of sets of features which are supersets or subsets of those in other stimuli. Fukushima and Miyake (1982) did not address this crucial issue where different stimuli might be composed of subsets or supersets of the same set of features, although they did show that stimuli with partly overlapping features could be discriminated by the Neocognitron.

In Section 2.8.5.6 we address the spatial binding problem in architectures such as VisNet. This computational problem that needs to be addressed in hierarchical networks such as the primate visual system and VisNet is how representations of features can be (e.g. translation) invariant, yet can specify stimuli or objects in which the features must be specified in the correct spatial arrangement. This is the feature binding problem, discussed for example by von der Malsburg (1990), and arising in the context of hierarchical layered systems (Ackley, Hinton and Sejnowski, 1985; Fukushima, 1980; Rosenblatt, 1961). The issue is whether or not features are bound into the correct combinations in the correct relative spatial positions, or if alternative combinations of known features or the same features in different relative spatial positions would elicit the same responses. All this has to be achieved while at the same time

producing position invariant recognition of the whole combination of features, that is, the object. This is a major computational issue that needs to be solved for memory systems in the brain to operate correctly. This can be achieved by what is effectively a learning process that builds into the system a set of neurons in the hierarchical network that enables the recognition process to operate correctly with the appropriate position, size, view etc. invariances.

2.8.5.1 Syntactic binding of separate neuronal ensembles by synchronization

The problem of syntactic binding of neuronal representations, in which some features must be bound together to form one object, and other simultaneously active features must be bound together to represent another object, has been addressed by von der Malsburg (see von der Malsburg (1990)). He has proposed that this could be performed by temporal synchronization of those neurons that were temporarily part of one representation in a different time slot from other neurons that were temporarily part of another representation. The idea is attractive in allowing arbitrary relinking of features in different combinations. Singer, Engel, Konig, and colleagues (Singer, Gray, Engel, Konig, Artola and Brocher, 1990; Engel, Konig, Kreiter, Schillen and Singer, 1992; Singer and Gray, 1995; Singer, 1999; Fries, 2015; Uran, Peter, Lazar, Barnes, Klon-Lipok, Shapcott, Roese, Fries, Singer and Vinck, 2022), and others (Abeles, 1991) have obtained some evidence that when features must be bound, synchronization of neuronal populations can occur (but see Shadlen and Movshon (1999)), and this has been modelled (Hummel and Biederman, 1992).

Synchronization to implement syntactic binding has a number of disadvantages and limitations (see also Rolls (2016b), and Riesenhuber and Poggio (1999a)). The greatest computational problem is that synchronization does not by itself define the spatial relations between the features being bound, so is not just as a binding mechanism adequate for shape recognition. For example, temporal binding might enable features 1, 2 and 3, which might define one stimulus to be bound together and kept separate from for example another stimulus consisting of features 2, 3 and 4, but would require a further temporal binding (leading in the end potentially to a combinatorial explosion) to indicate the relative spatial positions of the 1, 2 and 3 in the 123 stimulus, so that it can be discriminated from e.g. 312.

A second problem with the synchronization approach to the spatial binding of features is that, when stimulus-dependent temporal synchronization has been rigorously tested with information theoretic approaches, it has so far been found that most of the information available is in the number of spikes, with rather little, less than 5% of the total information, in stimulus-dependent synchronization (Aggelopoulos, Franco and Rolls, 2005; Franco, Rolls, Aggelopoulos and Treves, 2004; Rolls, Aggelopoulos, Franco and Treves, 2004) (see Section C.3.7). For example, Aggelopoulos, Franco and Rolls (2005) showed that when macaques used object-based attention to search for one of two objects to touch in a complex natural scene, between 99% and 94% of the information was present in the firing rates of inferior temporal cortex neurons, and less than 5% in any stimulus-dependent synchrony that was present between the simultaneously recorded inferior temporal cortex neurons. The implication of these results is that any stimulus-dependent synchrony that is present is not quantitatively important as measured by information theoretic analyses under natural scene conditions when feature binding, segmentation of objects from the background, and attention are required (Rolls and Treves, 2011). This has been found for the inferior temporal cortex, a brain region where features are put together to form representations of objects (Rolls and Deco, 2002), and where attention has strong effects, at least in scenes with blank backgrounds (Rolls, Aggelopoulos and Zheng, 2003a). It would of course also be of interest to test the same hypothesis in earlier visual areas, such as V4, with quantitative, information theoretic, techniques. However, it is found that stimulus-dependent correlations between the firing of

neurons far from increasing the information available from a population of neurons, in fact typically limits the amount of information that can be extracted from a neuronal population (Panzeri et al., 2022), providing further evidence against the binding by neuronal temporal synchronisation hypothesis.

In connection with rate codes, it should be noted that a rate code implies using the number of spikes that arrive in a given time, and that this time can be very short, as little as 20–50 ms, for very useful amounts of information to be made available from a population of neurons (Tovee, Rolls, Treves and Bellis, 1993; Rolls and Tovee, 1994; Rolls, Tovee, Purcell, Stewart and Azzopardi, 1994b; Tovee and Rolls, 1995; Rolls, Tovee and Panzeri, 1999b; Rolls, 2003; Rolls, Franco, Aggelopoulos and Jerez, 2006b) (see Section C.3.4).

A third problem with the ‘Communication Through Coherence’ hypothesis (Fries, 2015; Uran et al., 2022) whereby synchrony of oscillations between coupled cortical areas enhances communication between those areas is that in a formal model of coupled attractor networks, the strength of the coupling between the networks that was sufficient for information transfer was far lower than that required to force oscillations in each of the two networks to become coherent, that is, phase coupled (Rolls, Webb and Deco, 2012). Our investigation provides evidence that gamma oscillations can arise in strongly activated networks with high firing rates, and that communication between networks can occur perfectly well at much lower connectivities between the networks that is required for coherence. Our evidence is for ‘*Communication Before Coherence*’ (Rolls, Webb and Deco, 2012). It could be that these phenomena of gamma oscillations and coherence arise as spandrels—as effects of over-stimulation of neuronal populations that do not serve a useful computational function (Rolls, 2016b).

In the context of VisNet, and how the real visual system may operate to implement object recognition, the use of synchronization does not appear to match the way in which the visual system is organized. For example, von der Malsburg’s argument would indicate that, using only a two-layer network, synchronization could provide the necessary feature linking to perform object recognition with relatively few neurons, because they can be reused again and again, linked differently for different objects. In contrast, the primate uses a considerable part of its cortex, perhaps 50% in monkeys, for visual processing, with therefore what could be in the order of 6×10^8 neurons and 6×10^{12} synapses involved (estimating from the values given in Table 1.8), so that the solution adopted by the real visual system may be one that relies on many neurons with simpler processing than arbitrary syntax implemented by synchronous firing of separate assemblies suggests. On the other hand, a solution such as that investigated by VisNet, which forms low-order combinations of what is represented in previous layers, is very demanding in terms of the number of neurons required, and this matches what is found in the primate visual system.

2.8.5.2 Sigma-Pi neurons

Another approach to a binding mechanism is to group spatial features based on local mechanisms that might operate for closely adjacent synapses on a dendrite (in what is a Sigma-Pi type of neuron, see Sections 2.9 and A.2.3) (Finkel and Edelman, 1987; Mel, Ruderman and Archie, 1998; Mel, Schiller and Poirazi, 2017). A problem for such architectures is how to force one particular neuron to respond to the same feature combination invariantly with respect to all the ways in which that feature combination might occur in a scene.

2.8.5.3 Binding of features and their relative spatial position by feature combination neurons

The approach to the spatial binding problem that is proposed for VisNet is that individual neurons at an early stage of processing are set up (by learning without a temporal trace learning rule) to respond to low order combinations of input features occurring in a given relative

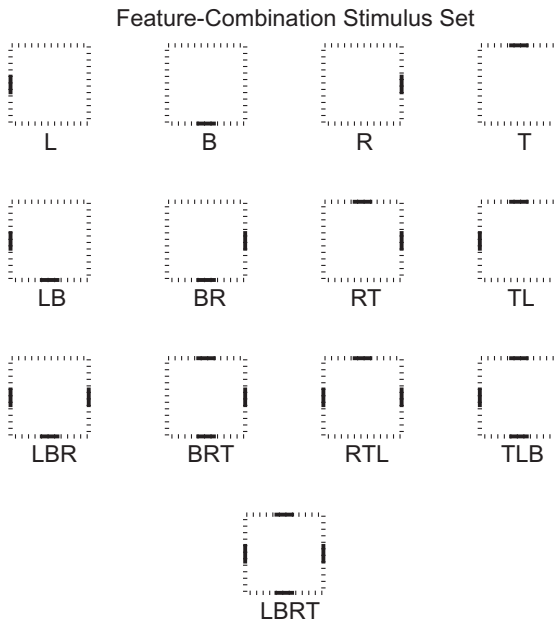

Fig. 2.52 Demonstration that VisNet can form separate representations of stimuli that are subsets or supersets of each other. All members of the full object set are shown, using a dotted line to represent the central 32×32 square on which the individual features are positioned, with the features themselves shown as dark line segments. Nomenclature is by acronym of the features present. (After Elliffe, M.C.M., Rolls, E. T. and Stringer, S.M. (2002) Invariant recognition of feature combinations in the visual system. *Biological Cybernetics* 86: 59–71. Copyright © Springer Nature.)

spatial arrangement and position on the retina (Rolls, 1992a, 1994a, 1995a; Wallis and Rolls, 1997; Rolls and Treves, 1998; Elliffe, Rolls and Stringer, 2002; Rolls and Deco, 2002; Rolls, 2016b) (cf. Feldman (1985)). (By low order combinations of input features we mean combinations of a few input features. By forming neurons that respond to combinations of a few features in the correct spatial arrangement the advantages of the scheme for syntactic binding are obtained, yet without the combinatorial explosion that would result if the feature combination neurons responded to combinations of many input features so producing potentially very specifically tuned neurons which very rarely responded.) Then invariant representations are developed in the next layer from these feature combination neurons which already contain evidence on the local spatial arrangement of features. Finally, in later layers, only one stimulus would be specified by the particular set of low order feature combination neurons present, even though each feature combination neuron would itself be somewhat invariant. The overall design of the scheme is shown in Fig. 2.28. Evidence that many neurons in V1 respond to combinations of spatial features with the correct spatial configuration is now starting to appear (see Section 2.7), and neurons that respond to feature combinations (such as two lines with a defined angle between them, and overall orientation) are found in V2 (Hegde and Van Essen, 2000; Ito and Komatsu, 2004). The tuning of a VisNet layer 1 neuron to a combination of features in the correct relative spatial position is illustrated in Figs. 2.33 and 2.34.

2.8.5.4 Discrimination between stimuli with super- and sub-set feature combinations

Some investigations with VisNet (Wallis and Rolls, 1997) have involved groups of stimuli that might be identified by some unique feature common to all transformations of a particular stimulus. This might allow VisNet to solve the problem of transform invariance by simply learning to respond to a unique feature present in each stimulus. For example, even in the

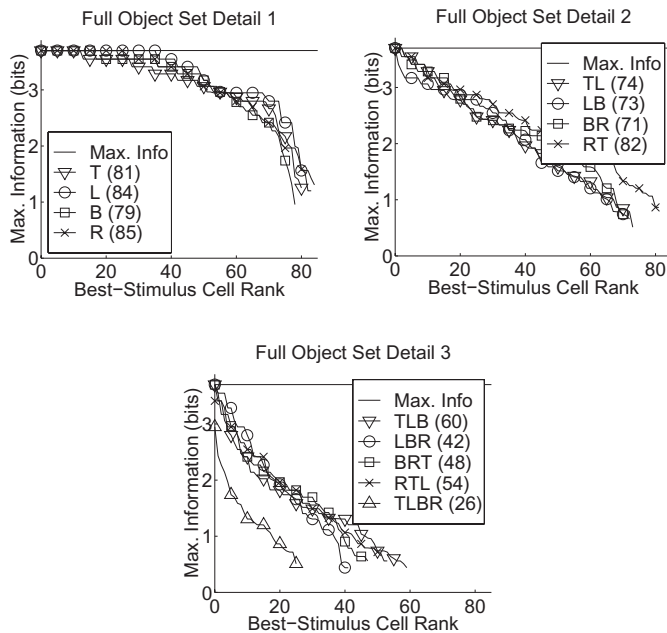

Fig. 2.53 Demonstration that VisNet can form separate representations of stimuli that are subsets or supersets of each other. Performance of VisNet on the full set of stimuli shown in Fig. 2.52. Separate graphs showing the information available about the stimulus for cells tuned to respond best to each of the stimuli are shown. The number of cells responding best to each of the stimuli is indicated in parentheses. The information values are shown for the different cells ranked according to how much information about that stimulus they encode. Separate graphs are shown for cells tuned to stimuli consisting of single features, pairs of features, and triples of features as well as the quadruple feature stimulus TLBR. (After Elliff, M.C.M., Rolls, E. T. and Stringer, S.M. (2002) Invariant recognition of feature combinations in the visual system. *Biological Cybernetics* 86: 59–71. Copyright © Springer Nature.)

case where VisNet was trained on invariant discrimination of T, L, and +, the representation of the T stimulus at the spatial filter level inputs to VisNet might contain unique patterns of filter outputs where the horizontal and vertical parts of the T join. The unique filter outputs thus formed might distinguish the T from for example the L.

Elliff, Rolls and Stringer (2002) tested whether VisNet is able to form transform invariant cells with stimuli that are specially composed from a common alphabet of features, with no stimulus containing any firing in the spatial filter inputs to VisNet not present in at least one of the other stimuli. The limited alphabet enables the set of stimuli to consist of feature sets which are subsets or supersets of those in the other stimuli.

For these experiments the common pool of stimulus features chosen was a set of two horizontal and two vertical 8×1 bars, each aligned with the sides of a 32×32 square. The stimuli can be constructed by arbitrary combination of these base level features. I note that effectively the stimulus set consists of four features, a top bar (T), a bottom bar (B), a left bar (L), and a right bar (R). Figure 2.52 shows the complete set used, containing every possible image feature combination.

To train the network a stimulus was presented in a randomized sequence of nine locations in a square grid across the 128×128 input retina. The central location of the square grid was in the centre of the ‘retina’, and the eight other locations were offset 8 pixels horizontally and/or vertically from this. Two different learning rules were used, ‘Hebbian’ (2.16), and ‘trace’ (2.17), and also an untrained condition with random weights. As in earlier work (Wallis and Rolls, 1997; Rolls and Milward, 2000) only the trace rule led to any cells with invariant responses, and the results shown here are for networks trained with the trace rule for layers 2–4.

The results with VisNet trained on the set of stimuli shown in Fig. 2.52 with the trace rule are as follows. Firstly, it was found that single neurons in the top layer learned to differentiate between the stimuli in that the responses of individual neurons were maximal for one of the stimuli and had no response to any of the other stimuli invariantly with respect to location. Secondly, to assess how well every stimulus was encoded for in this way, Fig. 2.53 shows the information available about each of the stimuli consisting of feature singles, feature pairs, feature triples, and the quadruple-feature stimulus ‘TLBR’. The single cell information available from the 26–85 cells with best tuning to each of the stimuli is shown. The cells in general conveyed translation invariant information about the stimulus to which they responded, with indeed cells which perfectly discriminated one of the stimuli from all others over every testing position (for all stimuli except ‘RTL’ and ‘TLBR’).

The results presented show clearly that the VisNet paradigm can accommodate networks that can perform invariant discrimination of objects which have a subset–superset relationship. The result has important consequences for feature binding and for discriminating stimuli for other stimuli which may be supersets of the first stimulus. For example, a VisNet cell which responds invariantly to feature combination TL can genuinely signal the presence of exactly that combination, and will not necessarily be activated by T alone, or by TLB. The basis for this separation by competitive networks of stimuli that are subsets and supersets of each other is described in Section B.4, by Rolls (2016b), and by Rolls and Treves (1998, Section 4.3.6).

2.8.5.5 Feature binding and re-use of feature combinations at different levels of a hierarchical network

A key property of a feature hierarchy object recognition system is that it may be possible at intermediate layers of the network to form feature combination neurons that can be useful for a number of different objects in each of which a particular feature combination may be present. If this is a property of encoding in the ventral visual system, this would help the capacity in terms of the number of objects that can be encoded to be high, because feature combination neurons in the intermediate layers could be used for many different objects, with orthogonal representations of whole objects only made explicit in neuronal firing at a late or the last stage of processing. Rolls and Mills (2018) tested the hypothesis that this could be implemented by the relatively simple and biologically plausible architecture of VisNet by training VisNet to identify separately every single feature and feature combinations of an object by its final layer (4); and then examining whether in VisNet’s intermediate layers (2 and 3) single neurons typically responded to features or low-order feature combinations that were components of several whole objects represented orthogonally in layer 4. The underlying overall hypothesis here is that at any layer of VisNet neurons need only learn low-order feature combinations; and that if this is repeated over several layers, then by the last layer neurons will become object selective (Rolls, 1992a, 2012d, 2016b). This overcomes any need at all for neurons to respond to high order feature combinations at any one layer, which would be biologically implausible as it would require so many neurons. At the same time, this feature-hierarchy approach would enable neurons in the final layer or layers to respond as if they were sensitive to a high order combination of features, that is, to be quite object selective (though using a sparse distributed representation), as has been found for neurons in the inferior temporal visual cortex (Rolls and Tovee, 1995b; Rolls et al., 1997d; Booth and Rolls, 1998; Franco et al., 2007; Rolls et al., 1997b; Rolls, 2012d, 2016b).

This was tested by training VisNet on the set of 13 objects shown in Fig. 2.54 (Rolls and Mills, 2018). Single neurons in layer 4 coded for each of the objects separately, as expected. In Layer 3 the neurons were a little less selective for separate objects, and might respond best to one object, but might also have good responses to one or more other objects. In layers 2

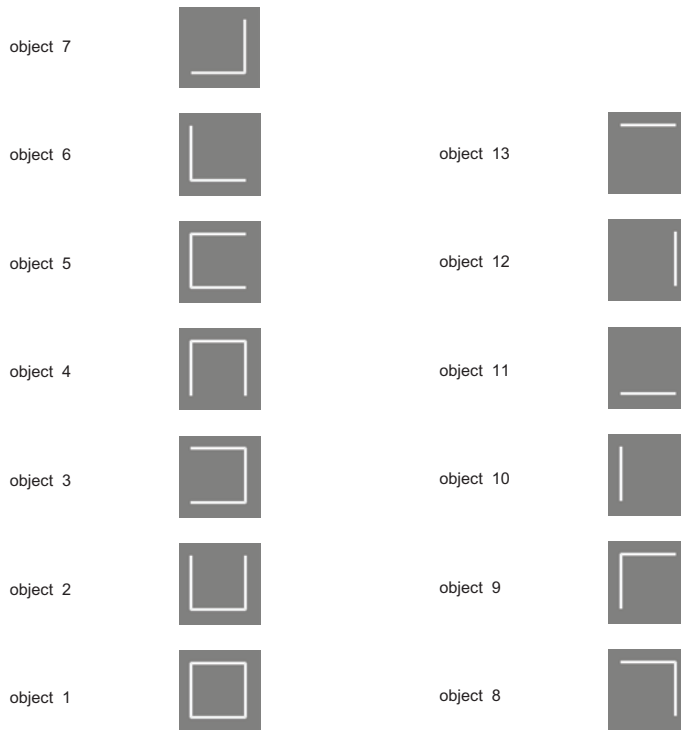

Fig. 2.54 Encoding of information in intermediate layers of VisNet. Stimuli used to investigate coding of feature combinations in intermediate layers of VisNet. Every feature or feature combination with adjacent features was a different object to be learned as a different object by VisNet. (After Rolls, E. T. and Mills, W.P.C. (2018) Non-accidental properties, metric invariance, and encoding by neurons in a model of ventral stream visual object recognition, *VisNet. Neurobiology of Learning and Memory* 152: 20–31. Copyright © Elsevier Inc.)

and 1 of Visnet, some neurons might respond best to one object, but might also have good responses to one or several other objects. For example, some of these intermediate layer neurons responded to features (such as a top edge) or feature combinations that are a component of several different objects.

This thus demonstrates the important principle in VisNet as a hierarchical unsupervised network approach to computations in the ventral visual system, that representations in intermediate layers can be used for several different objects represented as different objects in the top layer of the hierarchy (layer 4 in VisNet). The distributed tuning of neurons in intermediate layers enables the capacity, the number of objects that can be represented, to be high (Rolls and Mills, 2018; Rolls, 2021d).

2.8.5.6 Feature binding in a hierarchical network with invariant representations of local feature combinations

In this section we consider the ability of output layer neurons to learn new stimuli if the lower layers are trained solely through exposure to simpler feature combinations from which the new stimuli are composed. A key question we address is how invariant representations of low order feature combinations in the early layers of the visual system are able to uniquely specify the correct spatial arrangement of features in the overall stimulus and contribute to preventing false recognition errors in the output layer.

The problem, and its proposed solution, can be treated as follows. Consider an object

1234 made from the features 1, 2, 3 and 4. The invariant low order feature combinations might represent 12, 23, and 34. Then if neurons at the next layer respond to combinations of the activity of these neurons, the only neurons in the next layer that would respond would be those tuned to 1234, not to for example 3412, which is distinguished from 1234 by the input of a pair neuron responding to 41 rather than to 23. The argument (Rolls, 1992a) is that low-order spatial feature combination neurons in the early stage contain sufficient spatial information so that a particular combination of those low-order feature combination neurons specifies a unique object, even if the relative positions of the low-order feature combination neurons are not known, because they are somewhat invariant.

The architecture of VisNet is intended to solve this problem partly by allowing high spatial precision combinations of input features to be formed in layer 1. The actual input features in VisNet are, as described above, the output of oriented spatial-frequency tuned filters, and the combinations of these formed in layer 1 might thus be thought of in a simple way as for example a T or an L or for that matter a Y. Then in layer 2, application of the trace rule might enable neurons to respond to a T with limited spatial invariance (limited to the size of the region of layer 1 from which layer 2 cells receive their input). Then an 'object' such as H might be formed at a higher layer because of a conjunction of two Ts in the same small region.

To show that VisNet can actually solve this problem, Elliffe, Rolls and Stringer (2002) performed the experiments described next. They trained the first two layers of VisNet with feature pair combinations, forming representations of feature pairs with some translation invariance in layer 2. Then they used feature triples as input stimuli, allowed no more learning in layers 1 and 2, and then investigated whether layers 3 and 4 could be trained to produce invariant representations of the triples where the triples could only be distinguished if the local spatial arrangement of the features within the triple had effectively to be encoded in order to distinguish the different triples. For this experiment, they needed stimuli that could be specified in terms of a set of different features (they chose vertical (1), diagonal (2), and horizontal (3) bars) each capable of being shown at a set of different relative spatial positions (designated A, B and C), as shown in Fig. 2.55. The stimuli are thus defined in terms of what features are present and their precise spatial arrangement with respect to each other. The length of the horizontal and vertical feature bars shown in Fig. 2.55 is 8 pixels. To train the network a stimulus (that is a pair or triple feature combination) is presented in a randomized sequence of nine locations in a square grid across the 128×128 input retina. The central location of the square grid is in the centre of the 'retina', and the eight other locations are offset 8 pixels horizontally and/or vertically from this. We refer to the two and three feature stimuli as 'pairs' and 'triples', respectively. Individual stimuli are denoted by three numbers which refer to the individual features present in positions A, B and C, respectively. For example, a stimulus with positions A and C containing a vertical and diagonal bar, respectively, would be referred to as stimulus 102, where the 0 denotes no feature present in position B. In total there are 18 pairs (120, 130, 210, 230, 310, 320, 012, 013, 021, 023, 031, 032, 102, 103, 201, 203, 301, 302) and 6 triples (123, 132, 213, 231, 312, 321). This nomenclature not only defines which features are present within objects, but also the spatial relationships of their component features. Then the computational problem can be illustrated by considering the triple 123. If invariant representations are formed of single features, then there would be no way that neurons higher in the hierarchy could distinguish the object 123 from 213 or any other arrangement of the three features. An approach to this problem (see e.g. Rolls (1992a)) is to form early on in the processing neurons that respond to overlapping combinations of features in the correct spatial arrangement, and then to develop invariant representations in the next layer from these neurons which already contain evidence on the local spatial arrangement of features. An example might be that with the object 123, the invariant feature pairs would

Fig. 2.55 VisNet layer 4 neurons can generalize to transforms never previously seen of stimuli. Feature combinations for experiments of Section 2.8.5.6: there are 3 features denoted by 1, 2 and 3 (including a blank space 0) that can be placed in any of 3 positions A, B, and C. Individual stimuli are denoted by three consecutive numbers which refer to the individual features present in positions A, B and C respectively. In the experiments in Section 2.8.5.6, layers 1 and 2 were trained on stimuli consisting of pairs of the features, and layers 3 and 4 were trained on stimuli consisting of triples. Then the network was tested to show whether layer 4 neurons would distinguish between triples, even though the first two layers had only been trained on pairs. In addition, the network was tested to show whether individual cells in layer 4 could distinguish between triples even in locations where the triples were not presented during training. Experiment 2	no training	no training
Experiment 3	no training	trained on triples
Experiment 4	trained on triples	trained on triples

represent 120, 023, and 103. Then if neurons at the next layer correspond to combinations of these neurons, the only next layer neurons that would respond would be those tuned to 123, not to for example 213. The argument is that the low-order spatial feature combination neurons in the early stage contain sufficient spatial information so that a particular combination of those low-order feature combination neurons specifies a unique object, even if the relative positions of the low-order feature combination neurons are not known because these neurons are somewhat translation invariant (cf. also Fukushima (1988)).

The stimuli used in the experiments of Elliffe, Rolls and Stringer (2002) were constructed from pre-processed component features as discussed in Section 2.8.5.4. That is, base stimuli containing a single feature were constructed and filtered, and then the pairs and triples were constructed by merging these pre-processed single feature images. In the first experiment layers 1 and 2 of VisNet were trained with the 18 feature pairs, each stimulus being presented in sequences of 9 locations across the input. This led to the formation of neurons that responded to the feature pairs with some translation invariance in layer 2. Then they trained layers 3 and 4 on the 6 feature triples in the same 9 locations, while allowing no more learning in layers 1 and 2, and examined whether the output layer of VisNet had developed transform invariant neurons to the 6 triples. The idea was to test whether layers 3 and 4 could be trained to produce invariant representations of the triples where the triples could only be distinguished if the local spatial arrangement of the features within the triple had effectively

Fig. 2.56 VisNet layer 4 neurons can generalize to transforms never previously seen of stimuli. Numerical results for experiments 1–4 as described in Table 2.5, with the trace learning rule (2.17). On the left are single cell information measures, and on the right are multiple cell information measures. (After Elliffe, M.C.M., Rolls, E. T. and Stringer, S.M. (2002) Invariant recognition of feature combinations in the visual system. *Biological Cybernetics* 86: 59–71. Copyright © Springer Nature.)

to be encoded in order to distinguish the different triples. The results from this experiment were compared and contrasted with results from three other experiments which involved different training regimes for layers 1,2 and layers 3,4. All four experiments are summarized in Table 2.5. Experiment 2 involved no training in layers 1,2 and 3,4, with the synaptic weights left unchanged from their initial random values. These results are included as a baseline performance with which to compare results from the other experiments 1, 3 and 4. The model parameters used in these experiments were as described by Rolls and Milward (2000) and Rolls and Stringer (2001a).

In Fig. 2.56 we present numerical results for the four experiments listed in Table 2.5. On the left are the single cell information measures for all top (4th) layer neurons ranked in order of their invariance to the triples, while on the right are multiple cell information measures. To help to interpret these results we can compute the maximum single cell information measure according to

$$\text{Maximum single cell information} = \log_2(\text{Number of triples}), \quad (2.42)$$

where the number of triples is 6. This gives a maximum single cell information measure of 2.6 bits for these test cases. First, comparing the results for experiment 1 with the baseline performance of experiment 2 (no training) demonstrates that even with the first two layers trained to form invariant responses to the pairs, and then only layers 3 and 4 trained on feature triples, layer 4 is indeed capable of developing translation invariant neurons that can discriminate effectively between the 6 different feature triples. Indeed, from the single cell information measures it can be seen that a number of cells have reached the maximum level of performance in experiment 1. In addition, the multiple cell information analysis presented in Fig. 2.56 shows that all the stimuli could be discriminated from each other by the firing of a number of cells. Analysis of the response profiles of individual cells showed that a fourth layer cell could respond to one of the triple feature stimuli and have no response to any other of the triple feature stimuli invariantly with respect to location.

A comparison of the results from experiment 1 with those from experiment 3 (see Table 2.5 and Fig. 2.56) reveals that training the first two layers to develop neurons that respond invariantly to the pairs (performed in experiment 1) actually leads to improved invariance of 4th layer neurons to the triples, as compared with when the first two layers are left untrained (experiment 3).

Two conclusions follow from these results (Elliffe, Rolls and Stringer, 2002). First, a hierarchical network that seeks to produce invariant representations in the way used by VisNet

can solve the feature binding problem. In particular, when feature pairs in layer 2 with some translation invariance are used as the input to later layers, these later layers can nevertheless build invariant representations of objects where all the individual features in the stimulus must occur in the correct spatial position relative to each other. This is possible because the feature combination neurons formed in the first layer (which could be trained just with a Hebb rule) do respond to combinations of input features in the correct spatial configuration, partly because of the limited size of their receptive fields (see e.g. Fig. 2.31).

The second conclusion is that even though early layers can in this case only respond to small feature subsets, these provide, with no further training of layers 1 and 2, an adequate basis for learning to discriminate in layers 3 and 4 stimuli consisting of combinations of larger numbers of features. Indeed, comparing results from experiment 1 with experiment 4 (in which all layers were trained on triples, see Table 2.5) demonstrates that training the lower layer neurons to develop invariant responses to the pairs offers almost as good performance as training all layers on the triples (see Fig. 2.56).

2.8.5.7 Stimulus generalization to new locations

Another important aspect of the architecture of VisNet is that it need not be trained with every stimulus in every possible location. Indeed, part of the hypothesis (Rolls, 1992a) is that training early layers (e.g. 1–3) with a wide range of visual stimuli will set up feature analyzers in these early layers which are appropriate later on with no further training of early layers for new objects. For example, presentation of a new object might result in large numbers of low order feature combination neurons in early layers of VisNet being active, but the particular set of feature combination neurons active would be different for the new object. The later layers of the network (in VisNet, layer 4) would then learn this new set of active layer 3 neurons as encoding the new object. However, if the new object was then shown in a new location, the same set of layer 3 neurons would be active because they respond with spatial invariance to feature combinations, and given that the layer 3 to 4 connections had already been set up by the new object, the correct layer 4 neurons would be activated by the new object in its new untrained location, and without any further training.

To test this hypothesis, Elliffe, Rolls and Stringer (2002) repeated the general procedure of experiment 1 of Section 2.8.5.6, training layers 1 and 2 with feature pairs, but then instead trained layers 3 and 4 on the triples in only 7 of the original 9 locations. The crucial test was to determine whether VisNet could form top layer neurons that responded invariantly to the 6 triples when presented over all nine locations, not just the seven locations at which the triples had been presented during training. The results are presented in Fig. 2.57, with single cell information measures on the left and multiple cell information measures on the right. VisNet is still able to develop some fourth layer neurons with perfect invariance, that is which have invariant responses over all nine location, as shown by the single cell information analysis. The response profiles of individual fourth layer cells showed that they can continue to discriminate between the triples even in the two locations where the triples were not presented during training. In addition, the multiple cell analysis shown in Fig. 2.57 demonstrates that a small population of cells was able to discriminate between all of the stimuli irrespective of location, even though for two of the test locations the triples had not been trained at those particular locations during the training of layers 3 and 4.

2.8.5.8 Discussion of feature binding in hierarchical layered networks

Elliffe, Rolls and Stringer (2002) thus first showed (see Section 2.8.5.4) that hierarchical feature detecting neural networks can learn to respond differently to stimuli that consist of unique combinations of non-unique input features, and that this extends to stimuli that are direct subsets or supersets of the features present in other stimuli.

Fig. 2.57 VisNet layer 4 neurons can generalize to transforms never previously seen of stimuli. Generalization to new locations: numerical results for a repeat of experiment 1 of Section 2.8.5.6 with the triples presented at only 7 of the original 9 locations during training, and with the trace learning rule (2.17). On the left are single cell information measures, and on the right are multiple cell information measures. (After Elliffe, M.C.M., Rolls, E. T. and Stringer, S.M. (2002) Invariant recognition of feature combinations in the visual system. *Biological Cybernetics* 86: 59–71. Copyright © Springer Nature.)

Second, Elliffe, Rolls and Stringer (2002) investigated (see Section 2.8.5.6) the hypothesis that hierarchical layered networks can produce identification of unique stimuli even when the feature combination neurons used to define the stimuli are themselves partly translation invariant. The stimulus identification should work correctly because feature combination neurons in which the spatial features are bound together with high spatial precision are formed in the first layer. Then at later layers when neurons with some translation invariance are formed, the neurons nevertheless contain information about the relative spatial position of the original features. There is only then one object which will be consistent with the set of active neurons at earlier layers, which though somewhat translation invariant as combination neurons, reflect in the activity of each neuron information about the original spatial position of the features. I note that the trace rule training used in early layers (1 and 2) in Experiments 1 and 4 would set up partly invariant feature combination neurons, and yet the late layers (3 and 4) were able to produce during training neurons in layer 4 that responded to stimuli that consisted of unique spatial arrangements of lower order feature combinations. Moreover, and very interestingly, Elliffe, Rolls and Stringer (2002) were able to demonstrate that VisNet layer 4 neurons would respond correctly to visual stimuli at untrained locations, provided that the feature subsets had been trained in early layers of the network at all locations, and that the whole stimulus had been trained at some locations in the later layers of the network.

The results described by Elliffe, Rolls and Stringer (2002) thus provide one solution to the feature binding problem. The solution that has been shown to work in the model is that in a multilayer competitive network, feature combination neurons that encode the spatial arrangement of the bound features are formed at intermediate layers of the network. Then neurons at later layers of the network which respond to combinations of active intermediate layer neurons do contain sufficient evidence about the local spatial arrangement of the features to identify stimuli because the local spatial arrangement is encoded by the intermediate layer neurons. The information required to solve the visual feature binding problem thus becomes encoded by self-organization into what become hard-wired properties of the network. In this sense, feature binding is not solved at run time by the necessity to instantaneously set up arbitrary syntactic links between sets of co-active neurons. The computational solution proposed to the superset/subset aspect of the binding problem will apply in principle to other multilayer competitive networks, although the issues considered here have not been explicitly addressed in architectures such as the Neocognitron (Fukushima and Miyake, 1982).

Consistent with these hypotheses about how VisNet operates to achieve, by layer 4,

position-invariant responses to stimuli defined by combinations of features in the correct spatial arrangement, investigations of the effective stimuli for neurons in intermediate layers of VisNet showed as follows. In layer 1, cells responded to the presence of individual features, or to low order combinations of features (e.g. a pair of features) in the correct spatial arrangement at a small number of nearby locations. In layers 2 and 3, neurons responded to single features or to higher order combinations of features (e.g. stimuli composed of feature triples) in more locations. These findings provide direct evidence that VisNet does operate as described above to solve the feature binding problem.

A further issue with hierarchical multilayer architectures such as VisNet is that false binding errors might occur in the following way (Mozer, 1991; Mel and Fiser, 2000). Consider the output of one layer in such a network in which there is information only about which pairs are present. How then could a neuron in the next layer discriminate between the whole stimulus (such as the triple 123 in the above experiment) and what could be considered a more distributed stimulus or multiple different stimuli composed of the separated subparts of that stimulus (e.g. the pairs 120, 023, 103 occurring in 3 of the 9 training locations in the above experiment)? The problem here is to distinguish a single object from multiple other objects containing the same component combinations (e.g. pairs). We proposed that part of the solution to this general problem in real visual systems is implemented through lateral inhibition between neurons in individual layers, and that this mechanism, implemented in VisNet, acts to reduce the possibility of false recognition errors in the following two ways.

First, consider the situation in which neurons in layer N have learned to represent low order feature combinations with location invariance, and where a neuron n in layer $N + 1$ has learned to respond to a particular set Ω of these feature combinations. The problem is that neuron n receives the same input from layer N as long as the same set Ω of feature combinations is present, and cannot distinguish between different spatial arrangements of these feature combinations. The question is how can neuron n respond only to a particular favoured spatial arrangement Ψ of the feature combinations contained within the set Ω . We suggest that as the favoured spatial arrangement Ψ is altered by rearranging the spatial relationships of the component feature combinations, the new feature combinations that are formed in new locations will stimulate additional neurons nearby in layer $N + 1$, and these will tend to inhibit the firing of neuron n . Thus, lateral inhibition within a layer will have the effect of making neurons more selective, ensuring neuron n responds only to a single spatial arrangement Ψ from the set of feature combinations Ω , and hence reducing the possibility of false recognition.

The second way in which lateral inhibition may help to reduce binding errors is through limiting the sparseness of neuronal firing rates within layers. In our discussion above the spurious stimuli we suggested that might lead to false recognition of triples were obtained from splitting up the component feature combinations (pairs) so that they occurred in separate training locations. However, this would lead to an increase in the number of features present in the complete stimulus; triples contain 3 features while their spurious counterparts would contain 6 features (resulting from 3 separate pairs). For this simple example, the increase in the number of features is not dramatic, but if we consider, say, stimuli composed of 4 features where the component feature combinations represented by lower layers might be triples, then to form spurious stimuli we need to use 12 features (resulting from 4 triples occurring in separate locations). But if the lower layers also represented all possible pairs then the number of features required in the spurious stimuli would increase further. In fact, as the size of the stimulus increases in terms of the number of features, and as the size of the component feature combinations represented by the lower layers increases, there is a combinatorial explosion in terms of the number of features required as we attempt to construct spurious stimuli to trigger false recognition. And the construction of such spurious stimuli will then be prevented

through setting a limit on the sparseness of firing rates within layers, which will in turn set a limit on the number of features that can be represented. Lateral inhibition is likely to contribute in both these ways to the performance of VisNet when the stimuli consist of subsets and supersets of each other, as described in Section 2.8.5.4.

Another way in which the problem of multiple objects is addressed is by limiting the size of the receptive fields of inferior temporal cortex neurons so that neurons in IT respond primarily to the object being fixated, but with nevertheless some asymmetry in the receptive fields (see Section 2.8.10). Multiple objects are then ‘seen’ by virtue of being added to a visuo-spatial scratchpad, as addressed in Section 2.10.

A related issue that arises in this class of network is whether forming neurons that respond to feature combinations in the way described here leads to a combinatorial explosion in the number of neurons required. The solution to this issue that is proposed is to form only low-order combinations of features at any one stage of the network (Rolls (1992a); cf. Feldman (1985)). Using low-order combinations limits the number of neurons required, yet enables the type of computation that relies on feature combination neurons that is analyzed here to still be performed. The actual number of neurons required depends also on the redundancies present in the statistics of real-world images. Even given these factors, it is likely that a large number of neurons would be required if the ventral visual system performs the computation of invariant representations in the manner captured by the hypotheses implemented in VisNet. Consistent with this, a considerable part of the non-human primate brain is devoted to visual information processing. The fact that large numbers of neurons and a multilayer organization are present in the primate ventral visual system is actually thus consistent with the type of model of visual information processing described here.

2.8.6 Operation in a cluttered environment

In this section I consider how hierarchical layered networks of the type exemplified by VisNet operate in cluttered environments. Although there has been much work involving object recognition in cluttered environments with artificial vision systems, many such systems typically rely on some form of explicit segmentation followed by search and template matching procedure (see Ullman (1996) for a general review). In natural environments, objects may not only appear against cluttered (natural) backgrounds, but also the object may be partially occluded. Biological nervous systems operate in quite a different manner to those artificial vision systems that rely on search and template matching, and the way in which biological systems cope with cluttered environments and partial occlusion is likely to be quite different also.

One of the factors that will influence the performance of the type of architecture considered here, hierarchically organized series of competitive networks, which form one class of approaches to biologically relevant networks for invariant object recognition (Fukushima, 1980; Rolls, 1992a; Wallis and Rolls, 1997; Poggio and Edelman, 1990; Rolls and Treves, 1998; Rolls, 2016b, 2012d, 2021d), is how lateral inhibition and competition are managed within a layer. Even if an object is not obscured, the effect of a cluttered background will be to fire additional neurons, which will in turn to some extent compete with and inhibit those neurons that are specifically tuned to respond to the desired object. Moreover, where the clutter is adjacent to part of the object, the feature analysing neurons activated against a blank background might be different from those activated against a cluttered background, if there is no explicit segmentation process. We consider these issues next, following investigations of Stringer and Rolls (2000).

Fig. 2.58 Cluttered backgrounds used in VisNet simulations: backgrounds 1 and 2 are on the left and right respectively. (After Stringer, S.M. and Rolls, E. T. (2000) Position invariant recognition in the visual system with cluttered environments. *Neural Networks* 13: 305–315. Copyright © Elsevier Ltd.)

2.8.6.1 VisNet simulations with stimuli in cluttered backgrounds

In this section I show that recognition of objects learned previously against a blank background is hardly affected by the presence of a natural cluttered background. I go on to consider what happens when VisNet is set the task of learning new stimuli presented against cluttered backgrounds.

The images used for training and testing VisNet in the simulations described next performed by Stringer and Rolls (2000) were specially constructed. There were 7 face stimuli approximately 64 pixels in height constructed without backgrounds from those shown in Fig. 2.41. In addition there were 3 possible backgrounds: a blank background (greyscale 127, where the range is 0–255), and two cluttered backgrounds as shown in Fig. 2.58 which are 128×128 pixels in size. Each image presented to VisNet's 128×128 input retina was composed of a single face stimulus positioned at one of 9 locations on either a blank or cluttered background. The cluttered background was intended to be like the background against which an object might be viewed in a natural scene. If a background is used in an experiment described here, the same background is always used, and it is always in the same position, with stimuli moved to different positions on it. The 9 stimulus locations are arranged in a square grid across the background, where the grid spacings are 32 pixels horizontally or vertically. Before images were presented to VisNet's input layer they were pre-processed by the standard set of input filters which accord with the general tuning profiles of simple cells in V1 (Hawken and Parker, 1987); full details are given in Rolls and Milward (2000). To train the network a sequence of images is presented to VisNet's retina that corresponds to a single stimulus occurring in a randomized sequence of the 9 locations across a background. At each presentation the activation of individual neurons is calculated, then their firing rates are calculated, and then the synaptic weights are updated. After a stimulus has been presented in all the training locations, a new stimulus is chosen at random and the process repeated. The presentation of all the stimuli across all locations constitutes 1 epoch of training. In this manner the network is trained one layer at a time starting with layer 1 and finishing with layer 4. In the investigations described in this subsection, the numbers of training epochs for layers 1–4 were 50, 100, 100 and 75 respectively.

In this experiment (see Stringer and Rolls (2000), experiment 2), VisNet was trained with the 7 face stimuli presented on a blank background, but tested with the faces presented on each of the 2 cluttered backgrounds. Figure 2.59 shows results for experiment 2, with single and multiple cell information measures on the left and right respectively. It can be seen that

Fig. 2.59 VisNet can recognise stimuli against a cluttered background. Numerical results for experiment 2, with the 7 faces presented on a blank background during training and a cluttered background during testing. On the left are single cell information measures, and on the right are multiple cell information measures. (After Stringer,S.M. and Rolls, E. T. (2000) Position invariant recognition in the visual system with cluttered environments. *Neural Networks* 13: 305–315. Copyright © Elsevier Ltd.)

Fig. 2.60 VisNet can recognise stimuli against a cluttered background. Response profiles of a top layer neuron to the 7 faces from experiment 2 of Stringer and Rolls (2000), with the faces presented against cluttered background 1 during testing. (After Stringer,S.M. and Rolls, E. T. (2000) Position invariant recognition in the visual system with cluttered environments. *Neural Networks* 13: 305–315. Copyright © Elsevier Ltd.)

a number of cells have reached the maximum possible single cell information measure of 2.8 bits (\log_2 of the number of stimuli) for this test case, and that the multiple cell information measures also reach the 2.8 bits indicating perfect performance. Compared to performance when shown against a blank background, there was very little deterioration in performance when testing with the faces presented on either of the two cluttered backgrounds. This is an interesting result to compare with many artificial vision systems that would need to carry out computationally intensive serial searching and template matching procedures in order to achieve such results. In contrast, the VisNet neural network architecture is able to perform such recognition relatively quickly through a simple feedforward computation. Further results from this experiment are presented in Fig. 2.60 where we show the response profiles of a 4th layer neuron to the 7 faces presented on cluttered background 1 during testing. It can be seen that this neuron achieves excellent invariant responses to the 7 faces even with the faces presented on a cluttered background. The response profiles are independent of location but differentiate between the faces in that the responses are maximal for only one of the faces and minimal for all other faces.

This is an interesting and important result, for it shows that after learning, special mechanisms for segmentation and for attention are not needed in order for neurons already tuned by previous learning to the stimuli to be activated correctly in the output layer. Although the

experiments described here tested for position invariance, we predict and would expect that the same results would be demonstrable for size and view invariant representations of objects.

In experiments 3 and 4 of Stringer and Rolls (2000), VisNet was trained with the 7 face stimuli presented on either one of the 2 cluttered backgrounds, but tested with the faces presented on a blank background. Results for this experiment showed poor performance. The results of experiments 3 and 4 suggest that in order for a cell to *learn* invariant responses to different transforms of a stimulus when it is presented during training in a cluttered background, some form of segmentation is required in order to separate the figure (i.e. the stimulus or object) from the background. This segmentation might be performed using evidence in the visual scene about different depths, motions, colors, etc. of the object from its background. In the visual system, this might mean combining evidence represented in different cortical areas, and might be performed by cross-connections between cortical areas to enable such evidence to help separate the representations of objects from their backgrounds in the form-representing cortical areas.

Another mechanism that helps the operation of architectures such as VisNet and the primate visual system to learn about new objects in cluttered scenes is that the receptive fields of inferior temporal cortex neurons become much smaller when objects are seen against natural backgrounds (Sections 2.8.9.1 and 2.8.9). This will help greatly to learn about new objects that are being fixated, by reducing responsiveness to other features elsewhere in the scene.

Another mechanism that might help the learning of new objects in a natural scene is attention. An attentional mechanism might highlight the current stimulus being attended to and suppress the effects of background noise, providing a training representation of the object more like that which would be produced when it is presented against a blank background. The mechanisms that could implement such attentional processes are described in Chapter 13. If such attentional mechanisms do contribute to the development of view invariance, then it follows that cells in the temporal cortex may only develop transform invariant responses to objects to which attention is directed.

Part of the reason for the poor performance in experiments 3 and 4 was probably that the stimuli were always presented against the same fixed background (for technical reasons), and thus the neurons learned about the background rather than the stimuli. Part of the difficulty that hierarchical multilayer competitive networks have with learning in cluttered environments may more generally be that without explicit segmentation of the stimulus from its background, at least some of the features that should be formed to encode the stimuli are not formed properly, because the neurons learn to respond to combinations of inputs which come partly from the stimulus, and partly from the background. To investigate this, Stringer and Rolls (2000) performed experiment 5 in which layers 1–3 were pretrained with stimuli to ensure that good feature combination neurons for stimuli were available, and then allowed learning in only layer 4 when stimuli were presented in the cluttered backgrounds. Layer 4 was then trained in the usual way with the 7 faces presented against a cluttered background. The results for this experiment are shown in Fig. 2.61, with single and multiple cell information measures on the left and right respectively. It was found that prior random exposure to the face stimuli led to much improved performance. Indeed, it can be seen that a number of cells have reached the maximum possible single cell information measure of 2.8 bits for this test case, although the multiple cell information measures do not quite reach the 2.8 bits that would indicate perfect performance for the complete face set.

These results demonstrate that the problem of developing position invariant neurons to stimuli occurring against cluttered backgrounds may be ameliorated by the prior existence of stimulus-tuned feature-detecting neurons in the early layers of the visual system, and that these feature-detecting neurons may be set up through previous exposure to the relevant class of objects. When tested in cluttered environments, the background clutter may of course

Fig. 2.61 VisNet can recognise stimuli against a cluttered background. Numerical results for experiment 5 of Stringer and Rolls (2000). In this experiment VisNet is first exposed to a completely random sequence of faces in different positions against a blank background during which layers 1–3 are allowed to learn. This builds general feature detecting neurons in the lower layers that are tuned to the face stimuli, but cannot develop view invariance since there is no temporal structure to the order in which different views of different faces occur. Then layer 4 is trained in the usual way with the 7 faces presented against a cluttered background, where the images are now presented such that different views of the same face occur close together in time. On the left are single cell information measures, and on the right are multiple cell information measures. (After Stringer, S.M. and Rolls, E. T. (2000) Position invariant recognition in the visual system with cluttered environments. *Neural Networks* 13: 305–315. Copyright © Elsevier Ltd.)

activate some other neurons in the output layer, but at least the neurons that have learned to respond to the trained stimuli are activated. The result of this activity is sufficient for the activity in the output layer to be useful, in the sense that it can be read off correctly by a pattern associator connected to the output layer. Indeed, Stringer and Rolls (2000) tested this by connecting a pattern associator to layer 4 of VisNet. The pattern associator had seven neurons, one for each face, and 1,024 inputs, one from each neuron in layer 4 of VisNet. The pattern associator learned when trained with a simple associative Hebb rule (equation 2.16 on page 126) to activate the correct output neuron whenever one of the faces was shown in any position in the uncluttered environment. This ability was shown to be dependent on invariant neurons for each stimulus in the output layer of VisNet, for the pattern associator could not be taught the task if VisNet had not been previously trained with a trace learning rule to produce invariant representations. Then it was shown that exactly the correct neuron was activated when any of the faces was shown in any position with the cluttered background. This read-off by a pattern associator is exactly what we hypothesize takes place in the brain, in that the inferior temporal visual cortex (where neurons with invariant responses are found) projects to structures such as the orbitofrontal cortex and amygdala, where associations between the invariant visual representations and stimuli such as taste and touch are learned (Rolls and Treves, 1998; Rolls, 1999a, 2014a, 2019f,e) (see Chapter 11). Thus testing whether the output of an architecture such as VisNet can be used effectively by a pattern associator is a very biologically relevant way to evaluate the performance of this class of architecture.

2.8.6.2 Learning invariant representations of an object with multiple objects in the scene and with cluttered backgrounds

The results of the experiments just described suggest that in order for a neuron to *learn* invariant responses to different transforms of a stimulus when it is presented during training in a cluttered background, some form of segmentation is required in order to separate the figure (i.e. the stimulus or object) from the background. This segmentation might be performed using evidence in the visual scene about different depths, motions, colors, etc. of the object from its background. In the visual system, this might mean combining evidence represented in different cortical areas, and might be performed by cross-connections between cortical areas

to enable such evidence to help separate the representations of objects from their backgrounds in the form-representing cortical areas.

A second way in which training a feature hierarchy network in a cluttered natural scene may be facilitated follows from the finding that the receptive fields of inferior temporal cortex neurons shrink from in the order of 70 degrees in diameter when only one object is present in a blank scene to much smaller values of as little as 5–10 degrees close to the fovea in complex natural scenes (Rolls, Aggelopoulos and Zheng, 2003a). The proposed mechanism for this is that if there is an object at the fovea, this object, because of the high cortical magnification factor at the fovea, dominates the activity of neurons in the inferior temporal cortex by competitive interactions (Trappenberg, Rolls and Stringer, 2002; Deco and Rolls, 2004) (see Section 2.8.9). This allows primarily the object at the fovea to be represented in the inferior temporal cortex, and, it is proposed, for learning to be about this object, and not about the other objects in a whole scene.

Third, top-down spatial attention (Deco and Rolls, 2004, 2005b; Rolls and Deco, 2006; Rolls, 2008f, 2016b) (see Section 2.12) could bias the competition towards a region of visual space where the object to be learned is located.

Fourth, if object 1 is presented during training with different objects present on different trials, then the competitive networks that are part of VisNet will learn to represent each object separately, because the features that are part of each object will be much more strongly associated together, than are those features with the other features present in the different objects seen on some trials during training (Stringer and Rolls, 2008; Stringer, Rolls and Tromans, 2007b). It is a natural property of competitive networks that input features that co-occur very frequently together are allocated output neurons to represent the pattern as a result of the learning. Input features that do not co-occur frequently, may not have output neurons allocated to them. This principle may help feature hierarchy systems to learn representations of individual objects, even when other objects with some of the same features are present in the visual scene, but with different other objects on different trials. With this fundamental and interesting property of competitive networks, it has now become possible for VisNet to self-organize invariant representations of individual objects, even though each object is always presented during training with at least one other object present in the scene (Stringer and Rolls, 2008; Stringer, Rolls and Tromans, 2007b).

2.8.6.3 VisNet simulations with partially occluded stimuli

In this section I examine the recognition of partially occluded stimuli. Many artificial vision systems that perform object recognition typically search for specific markers in stimuli, and hence their performance may become fragile if key parts of a stimulus are occluded. However, in contrast it is demonstrated that the model of invariance learning in the brain discussed here can continue to offer robust performance with this kind of problem, and that the model is able to correctly identify stimuli with considerable flexibility about what part of a stimulus is visible.

In these simulations (Stringer and Rolls, 2000), training and testing was performed with a blank background to avoid confounding the two separate problems of occlusion and background clutter. In object recognition tasks, artificial vision systems may typically rely on being able to locate a small number of key markers on a stimulus in order to be able to identify it. This approach can become fragile when a number of these markers become obscured. In contrast, biological vision systems may generalize or complete from a partial input as a result of the use of distributed representations in neural networks, and this could lead to greater robustness in situations of partial occlusion.

In this experiment (6 of Stringer and Rolls (2000)), the network was first trained with the 7 face stimuli without occlusion, but during testing there were two options: either (i) the top

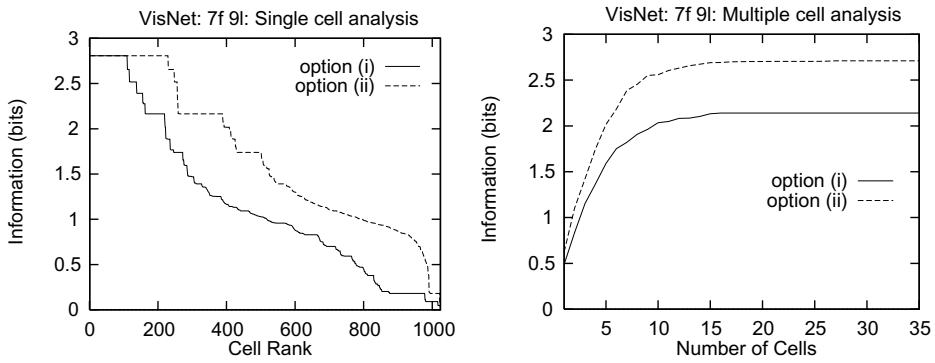

Fig. 2.62 VisNet can recognise correctly even when part of the object or face is occluded. Numerical results for experiment 6 of Stringer and Rolls, 2000, with the 7 faces presented on a blank background during both training and testing. Training was performed with the whole face. However, during testing there are two options: either (i) the top half of all the faces are occluded, or (ii) the bottom half of all the faces are occluded. On the left are single cell information measures, and on the right are multiple cell information measures. (After Stringer, S.M. and Rolls, E. T. (2000) Position invariant recognition in the visual system with cluttered environments. *Neural Networks* 13: 305–315. Copyright © Elsevier Ltd.)

halves of all the faces were occluded, or (ii) the bottom halves of all the faces were occluded. Since VisNet was tested with either the top or bottom half of the stimuli no stimulus features were common to the two test options. This ensures that if performance is good with both options, the performance cannot be based on the use of a single feature to identify a stimulus. Results for this experiment are shown in Fig. 2.62, with single and multiple cell information measures on the left and right respectively. When compared with the performance without occlusion (Stringer and Rolls, 2000), Fig. 2.62 shows that there is only a modest drop in performance in the single cell information measures when the stimuli are partially occluded.

For both options (i) and (ii), even with partially occluded stimuli, a number of cells continue to respond maximally to one preferred stimulus in all locations, while responding minimally to all other stimuli. However, comparing results from options (i) and (ii) shows that the network performance is better when the bottom half of the faces is occluded. This is consistent with psychological results showing that face recognition is performed more easily when the top halves of faces are visible rather than the bottom halves (see Bruce (1988)). The top half of a face will generally contain salient features, e.g. eyes and hair, that are particularly helpful for recognition of the individual, and it is interesting that these simulations appear to further demonstrate this point. Furthermore, the multiple cell information measures confirm that performance is better with the upper half of the face visible (option (ii)) than the lower half (option (i)). When the top halves of the faces are occluded the multiple cell information measure asymptotes to a suboptimal value reflecting the difficulty of discriminating between these more difficult images. Further results from experiment 6 are presented in Fig. 2.63 where we show the response profiles of a 4th layer neuron to the 7 faces, with the bottom half of all the faces occluded during testing. It can be seen that this neuron continues to respond invariantly to the 7 faces, responding maximally to one of the faces but minimally for all other faces.

Thus this model of the ventral visual system offers robust performance with this kind of problem, and the model is able to correctly identify stimuli with considerable flexibility about what part of a stimulus is visible, because it is effectively using distributed representations and associative processing (Stringer and Rolls, 2000).

Fig. 2.63 VisNet can recognise correctly even when part of the object or face is occluded. Response profiles of a top layer neuron to the 7 faces from experiment 6 of Stringer and Rolls (2000), with the bottom half of all the faces occluded during testing. 2.8.7 Learning 3D transforms

In this section investigations of Stringer and Rolls (2002) are described that show that trace learning can in the VisNet architecture solve the problem of in-depth rotation invariant object recognition by developing representations of the transforms which features undergo when they are on the surfaces of 3D objects. Moreover, it is shown that having learned how features on 3D objects transform as the object is rotated in depth, the network can correctly recognize novel 3D variations within a generic view of an object which is composed of previously learned feature combinations.

Rolls' hypothesis of how object recognition could be implemented in the brain postulates that trace rule learning helps invariant representations to form in two ways (Rolls, 1992a, 1994a, 1995a, 2000a, 2016b, 2012d, 2021d). The first process enables associations to be learned between different generic 3D views of an object where there are different qualitative shape descriptors. One example of this would be the front and back views of an object, which might have very different shape descriptors. Another example is provided by considering how the shape descriptors typical of 3D shapes, such as Y vertices, arrow vertices, cusps, and ellipse shapes, alter when most 3D objects are rotated in 3 dimensions. At some point in the 3D rotation, there is a catastrophic rearrangement of the shape descriptors as a new generic view can be seen (Koenderink, 1990). An example of a catastrophic change to a new generic view is when a cup being viewed from slightly below is rotated so that one can see inside the cup from slightly above. The bottom surface disappears, the top surface of the cup changes from a cusp to an ellipse, and the inside of the cup with a whole set of new features comes into view. The second process is that within a generic view, as the object is rotated in depth, there will be no catastrophic changes in the qualitative 3D shape descriptors, but instead the quantitative values of the shape descriptors alter. For example, while the cup is being rotated within a generic view seen from somewhat below, the curvature of the cusp forming the top boundary will alter, but the qualitative shape descriptor will remain a cusp. Trace learning could help with both processes. That is, trace learning could help to associate together qualitatively different sets of shape descriptors that occur close together in time, and describe for example the generically different views of a cup. Trace learning could also help with the second process, and learn to associate together the different quantitative values of shape descriptors that typically occur when objects are rotated within a generic view.

There is evidence that some neurons in the inferior temporal cortex may show the two types of 3D invariance. First, Booth and Rolls (1998) showed that some inferior temporal cortex neurons can respond to different generic views of familiar 3D objects. Second, some neurons do generalize across quantitative changes in the values of 3D shape descriptors while

faces (Hasselmo, Rolls, Baylis and Nalwa, 1989b) and objects (Tanaka, 1996; Logothetis, Pauls and Poggio, 1995) are rotated within generic views. Indeed, Logothetis, Pauls and Poggio (1995) showed that a few inferior temporal cortex neurons can generalize to novel (untrained) values of the quantitative shape descriptors typical of within-generic view object rotation.

In addition to the qualitative shape descriptor changes that occur catastrophically between different generic views of an object, and the quantitative changes of 3D shape descriptors that occur within a generic view, there is a third type of transform that must be learned for correct invariant recognition of 3D objects as they rotate in depth. This third type of transform is that which occurs to the surface features on a 3D object as it transforms in depth. The main aim here is to consider mechanisms that could enable neurons to learn this third type of transform, that is how to generalize correctly over the changes in the surface markings on 3D objects that are typically encountered as 3D objects rotate within a generic view. Examples of the types of perspectival transforms investigated are shown in Fig. 2.64. Surface markings on the sphere that consist of combinations of three features in different spatial arrangements undergo characteristic transforms as the sphere is rotated from 0 degrees towards -60 degrees and +60 degrees. We investigated whether the class of architecture exemplified by VisNet, and the trace learning rule, can learn about the transforms that surface features of 3D objects typically undergo during 3D rotation in such a way that the network generalizes across the change of the quantitative values of the surface features produced by the rotation, and yet still discriminates between the different objects (in this case spheres). In the cases being considered, each object is identified by surface markings that consist of a different spatial arrangement of the same three features (a horizontal, vertical, and diagonal line, which become arcs on the surface of the object).

It has been suggested that the finding that neurons may offer some degree of 3D rotation invariance after training with a single view (or limited set of views) represents a challenge for existing trace learning models, because these models assume that an initial exposure is required during learning to every transformation of the object to be recognized (Riesenhuber and Poggio, 1998). Stringer and Rolls (2002) showed as described here that this is not the case, and that such models can generalize to novel within-generic views of an object provided that the characteristic changes that the features show as objects are rotated have been learned previously for the sets of features when they are present in different objects.

Elliffe, Rolls and Stringer (2002) demonstrated for a 2D system how the existence of translation invariant representations of low order feature combinations in the early layers of the visual system could allow correct stimulus identification in the output layer even when the stimulus was presented in a novel location where the stimulus had not previously occurred during learning. The proposal was that the low-order spatial feature combination neurons in the early stages contain sufficient spatial information so that a particular combination of those low-order feature combination neurons specifies a unique object, even if the relative positions of the low-order feature combination neurons are not known because these neurons are somewhat translation invariant (see Section 2.8.5.6). Stringer and Rolls (2002) extended this analysis to feature combinations on 3D objects, and indeed in their simulations described in this section therefore used surface markings for the 3D objects that consisted of triples of features.

The images used for training and testing VisNet were specially constructed for the purpose of demonstrating how the trace learning paradigm might be further developed to give rise to neurons that are able to respond invariantly to novel within-generic view perspectives of an object, obtained by rotations in-depth up to 30 degrees from any perspectives encountered during learning. The stimuli take the form of the surface feature combinations of 3-dimensional rotating spheres, with each image presented to VisNet's retina being a 2-

Fig. 2.64 VisNet can learn 3D perspectival transforms of features. Representations of the 6 visual stimuli with 3 surface features (triples) presented to VisNet during the simulations described in Section 2.8.7. Each stimulus is a sphere that is uniquely identified by a unique combination of three surface features (a vertical, diagonal and horizontal arc), which occur in 3 relative positions A, B, and C. Each row shows one of the stimuli rotated through the 5 different rotational views in which the stimulus is presented to VisNet. From left to right the rotational views shown are: (i) -60 degrees, (ii) -30 degrees, (iii) 0 degrees (central position), (iv) $+30$ degrees, and (v) $+60$ degrees. (After Stringer, S.M. and Rolls, E. T. (2002) Invariant object recognition in the visual system with novel views of 3D objects. *Neural Computation* 14: 2585–2596. Copyright © Elsevier Ltd.)

dimensional projection of the surface features of one of the spheres. Each stimulus is uniquely identified by two or three surface features, where the surface features are (1) vertical, (2) diagonal, and (3) horizontal arcs, and where each feature may be centred at three different spatial positions, designated A, B, and C, as shown in Fig. 2.64. The stimuli are thus defined in terms of what features are present and their precise spatial arrangement with respect to each other. We refer to the two and three feature stimuli as ‘pairs’ and ‘triples’, respectively. Individual stimuli are denoted by three numbers which refer to the individual features present in positions A, B and C, respectively. For example, a stimulus with positions A and C containing a vertical and diagonal bar, respectively, would be referred to as stimulus 102, where the 0 denotes no feature present in position B. In total there are 18 pairs (120, 130, 210, 230, 310, 320, 012, 013, 021, 023, 031, 032, 102, 103, 201, 203, 301, 302) and 6 triples (123, 132, 213, 231, 312, 321).

To train the network each stimulus was presented to VisNet in a randomized sequence of five orientations with respect to VisNet’s input retina, where the different orientations are obtained from successive in-depth rotations of the stimulus through 30 degrees. That is, each stimulus was presented to VisNet’s retina from the following rotational views: (i) -60° , (ii) -30° , (iii) 0° (central position with surface features facing directly towards VisNet’s

retina), (iv) 30°, (v) 60°. Figure 2.64 shows representations of the 6 visual stimuli with 3 surface features (triples) presented to VisNet during the simulations. (For the actual simulations described here, the surface features and their deformations were what VisNet was trained and tested with, and the remaining blank surface of each sphere was set to the same greyscale as the background.) Each row shows one of the stimuli rotated through the 5 different rotational views in which the stimulus is presented to VisNet. At each presentation the activation of individual neurons is calculated, then the neuronal firing rates are calculated, and then the synaptic weights are updated. Each time a stimulus has been presented in all the training orientations, a new stimulus is chosen at random and the process repeated. The presentation of all the stimuli through all 5 orientations constitutes 1 epoch of training. In this manner the network was trained one layer at a time starting with layer 1 and finishing with layer 4. In the investigations described here, the numbers of training epochs for layers 1–4 were 50, 100, 100 and 75, respectively.

In experiment 1, VisNet was trained in two stages. In the first stage, the 18 feature pairs were used as input stimuli, with each stimulus being presented to VisNet's retina in sequences of five orientations as described above. However, during this stage, learning was only allowed to take place in layers 1 and 2. This led to the formation of neurons which responded to the feature pairs with some rotation invariance in layer 2. In the second stage, we used the 6 feature triples as stimuli, with learning only allowed in layers 3 and 4. However, during this second training stage, the triples were only presented to VisNet's input retina in the first 4 orientations (i)–(iv). After the two stages of training were completed, Stringer and Rolls (2002) examined whether the output layer of VisNet had formed top layer neurons that responded invariantly to the 6 triples when presented in all 5 orientations, not just the 4 in which the triples had been presented during training. To provide baseline results for comparison, the results from experiment 1 were compared with results from experiment 2 which involved no training in layers 1,2 and 3,4, with the synaptic weights left unchanged from their initial random values.

In Fig. 2.65 numerical results are given for the experiments described. On the left are the single cell information measures for all top (4th) layer neurons ranked in order of their invariance to the triples, while on the right are multiple cell information measures. To help to interpret these results we can compute the maximum single cell information measure according to

$$\text{Maximum single cell information} = \log_2(\text{Number of triples}), \quad (2.43)$$

where the number of triples is 6. This gives a maximum single cell information measure of 2.6 bits for these test cases. The information results from the experiment demonstrate that even with the triples presented to the network in only four of the five orientations during training, layer 4 is indeed capable of developing rotation invariant neurons that can discriminate effectively between the 6 different feature triples in all 5 orientations, that is with correct recognition from all five perspectives. In addition, the multiple cell information for the experiment reaches the maximal level of 2.6 bits, indicating that the network as a whole is capable of perfect discrimination between the 6 triples in any of the 5 orientations. These results may be compared with the very poor baseline performance from the control experiment, where no learning was allowed before testing. Further results from experiment 1 are presented in Fig. 2.66 where we show the response profiles of a top layer neuron to the 6 triples. It can be seen that this neuron has achieved excellent invariant responses to the 6 triples: the response profiles are independent of orientation, but differentiate between triples in that the responses are maximal for triple 132 and minimal for all other triples. In particular, the cell responses are maximal for triple 132 presented in all 5 of the orientations.

Fig. 2.65 VisNet can learn 3D perspectival transforms of features. Numerical results for experiments 1 and 2: on the left are single cell information measures, and on the right are multiple cell information measures. (After Stringer,S.M. and Rolls, E. T. Fig. 2.66 VisNet can learn 3D perspectival transforms of features. Numerical results for experiment 1: response profiles of a top layer neuron to the 6 triples in all 5 orientations. (After Stringer,S.M. and Rolls, E. T. (2002) Invariant object recognition in the visual system with novel views of 3D objects. *Neural Computation* 14: 2585–2596. Copyright © Elsevier Ltd.)

Stringer and Rolls (2002) also performed a control experiment to show that the network really had learned invariant representations specific to the kinds of 3D deformations undergone by the surface features as the objects rotated in-depth. In the control experiment the network was trained on ‘spheres’ with non-deformed surface features; and then as predicted the network failed to operate correctly when it was tested with objects with the features present in the transformed way that they appear on the surface of a real 3D object.

Stringer and Rolls (2002) were thus able to show how trace learning can form neurons that can respond invariantly to novel rotational within-generic view perspectives of an object, obtained by within-generic view 3D rotations up to 30 degrees from any view encountered during learning. They were able to show in addition that this could occur for a novel view of an object which was not an interpolation from previously shown views. This was possible given that the low order feature combination sets from which an object was composed had been learned about in early layers of VisNet previously. The within-generic view transform invariant object recognition described was achieved through the development of true 3-dimensional representations of objects based on 3-dimensional features and feature combinations, which, unlike 2-dimensional feature combinations, are invariant under moderate in-depth rotations of the object. Thus, in a sense, these rotation invariant representations encode a form of 3-dimensional knowledge with which to interpret the visual input from the real world, that is able provide a basis for robust rotation invariant object recognition with

novel perspectives. The particular finding in the work described here was that VisNet can learn how the surface features on 3D objects transform as the object is rotated in depth, and can use knowledge of the characteristics of the transforms to perform 3D object recognition. The knowledge embodied in the network is knowledge of the 3D properties of objects, and in this sense assists the recognition of 3D objects seen from different views.

The process investigated by Stringer and Rolls (2002) will only allow invariant object recognition over moderate 3D object rotations, since rotating an object through a large angle may lead to a catastrophic change in the appearance of the object that requires the new qualitative 3D shape descriptors to be associated with those of the former view. In that case, invariant object recognition must rely on the first process referred to at the start of this Section (2.8.7) in order to associate together the different generic views of an object to produce view invariant object identification. For that process, association of a few cardinal or generic views is likely to be sufficient (Koenderink, 1990). The process described in this section of learning how surface features transform is likely to make a major contribution to the within-generic view transform invariance of object identification and recognition.

Further investigation of how VisNet can learn to recognise objects despite catastrophic changes in view during 3D object rotation is described in Section 2.9.2 (Robinson and Rolls, 2015).

Poggio and colleagues (Leibo, Liao, Anselmi, Freiwald and Poggio, 2017) have further evidence that the type of learning rule used in VisNet, i.e. Hebbian associative learning combined with a mechanism to maintain the synaptic weight vector at a constant length, exemplified by the Oja rule (Oja, 1982; Wallis and Rolls, 1997) (Section B.4.9.2), is useful to account for the properties of some neurons recorded in the inferior temporal visual cortex. Although in our recordings many neurons responded differently to a right and left profile of a face, they refer to some neurons that respond to both the left and right profile of a face, similar to the type of neuron illustrated in the lower part of Fig. 2.11 (Hasselmo, Rolls, Baylis and Nalwa, 1989b). They show that this type of learning rule is particularly well suited to learning this type of responsiveness (Leibo et al., 2017), providing further support for the VisNet approach to invariant visual object and face learning in the brain which uses a learning rule of this type.

2.8.8 Capacity of the architecture, and incorporation of a trace rule into a recurrent architecture with object attractors

One issue that has not been considered extensively so far is the capacity of hierarchical feed-forward networks of the type exemplified by VisNet that are used for invariant object recognition. One approach to this issue is to note that VisNet operates in the general mode of a competitive network, and that the number of different stimuli that can be categorized by a competitive network is in the order of the number of neurons in the output layer, as described in Section B.4. Given that the successive layers of the real visual system (V1, V2, V4, posterior inferior temporal cortex, anterior inferior temporal cortex) are of the same order of magnitude⁷, VisNet is designed to work with the same number of neurons in each successive layer. The hypothesis is that because of redundancies in the visual world, each layer of the system by its convergence and competitive categorization can capture sufficient of the statistics of the visual input at each stage to enable correct specification of the properties of the world that specify objects. For example, V1 does not compute all possible combinations of a few lateral geniculate inputs, but instead represents linear series of geniculate inputs to form edge-like and bar-like feature analyzers, which are the dominant arrangement of pixels found

⁷Of course the details are worth understanding further. V1 is for example somewhat larger than earlier layers, but on the other hand serves the dorsal as well as the ventral stream of visual cortical processing.

at the small scale in natural visual scenes. Thus the properties of the visual world at this stage can be captured by a small proportion of the total number of combinations that would be needed if the visual world were random. Similarly, at a later stage of processing, just a subset of all possible combinations of line or edge analyzers would be needed, partly because some combinations are much more frequent in the visual world, and partly because the coding because of convergence means that what is represented is for a larger area of visual space (that is, the receptive fields of the neurons are larger), which also leads to economy and limits what otherwise would be a combinatorial need for feature analyzers at later layers. The hypothesis thus is that the effects of redundancies in the input space of stimuli that result from the statistical properties of natural images (Field, 1987), together with the convergent architecture with competitive learning at each stage, produces a system that can perform invariant object recognition for large numbers of objects. Large in this case could be within one or two orders of magnitude of the number of neurons in any one layer of the network (or cortical area in the brain). The extent to which this can be realized can be explored with simulations of the type implemented in VisNet, in which the network can be trained with natural images which therefore reflect fully the natural statistics of the stimuli presented to the real brain.

Another approach to the issue of the capacity of networks that use trace-learning to associate together different instances (e.g. views) of the same object is to reformulate the issue in the context of autoassociation (attractor) networks, where analytic approaches to the storage capacity of the network are well developed (see Section B.3, Amit (1989), and Rolls (2016b)). This approach to the storage capacity of attractor networks that associate together different instantiations of an object to form invariant representations has been developed by Parga and Rolls (1998) and Elliffe, Rolls, Parga and Renart (2000), and is described next.

In this approach, the storage capacity of a *recurrent* network which performs for example view invariant recognition of objects by associating together different views of the same object which tend to occur close together in time, was studied (Parga and Rolls, 1998; Elliffe, Rolls, Parga and Renart, 2000). The architecture with which the invariance is computed is a little different to that described earlier. In the model of Rolls ((1992a), (1994a), (1995a), Wallis and Rolls (1997), Rolls and Milward (2000), and Rolls and Stringer (2006b)), the postsynaptic memory trace enabled different afferents from the preceding stage to modify onto the same postsynaptic neuron (see Fig. 2.67). In that model there were no recurrent connections between the neurons, although such connections were one way in which it was postulated the memory trace might be implemented, by simply keeping the representation of one view or aspect active until the next view appeared. Then an association would occur between representations that were active close together in time (within e.g. 100–300 ms).

In the model developed by Parga and Rolls (1998) and Elliffe, Rolls, Parga and Renart (2000), there is a set of inputs with fixed synaptic weights to a network. The network itself is a recurrent network, with a trace rule incorporated in the recurrent collaterals (see Fig. 2.68). When different views of the same object are presented close together in time, the recurrent collaterals learn using the trace rule that the different views are of the same object. After learning, presentation of any of the views will cause the network to settle into an attractor that represents all the views of the object, that is which is a view invariant representation of an object.

We envisage a set of neuronal operations which set up a synaptic weight matrix in the recurrent collaterals by associating together because of their closeness in time the different views of the same object.

Parga and Rolls (1998) and Elliffe, Rolls, Parga and Renart (2000) were able to show that the number of objects P_o that can be stored is approximately

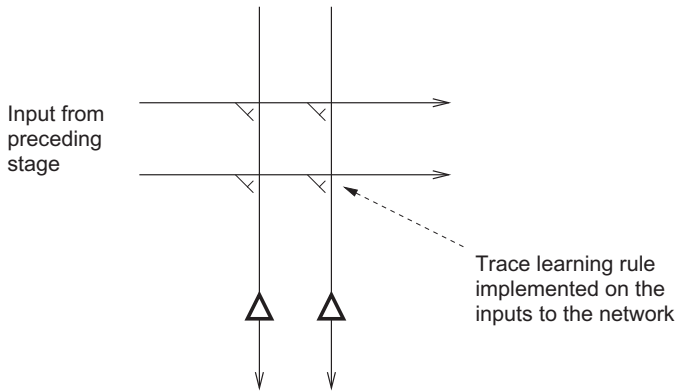

Fig. 2.67 The learning scheme implemented in VisNet. A trace learning rule is implemented in the feedforward inputs to a competitive network. (After Parga,N. and Rolls, E. T. (1998) Transform invariant recognition by association in a recurrent network. *Neural Computation* 10: 1507–1525. © Massachusetts Institute of Technology.)

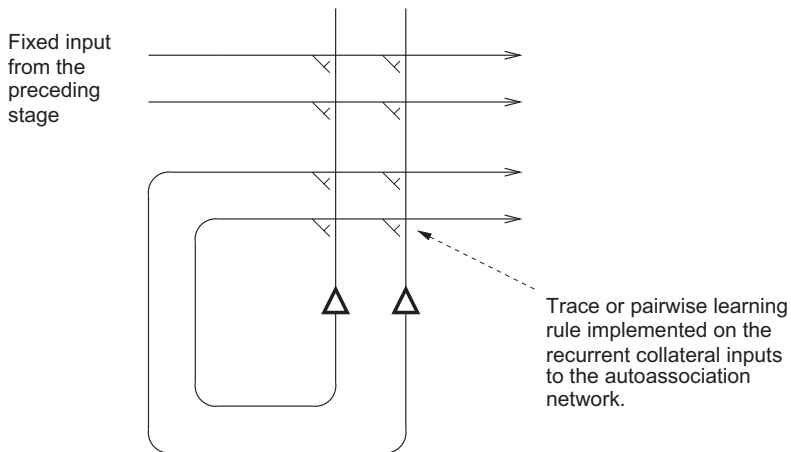

Fig. 2.68 The learning scheme considered by Parga and Rolls (1998) and Elliffe, Rolls, Parga and Renart (2000). There are inputs to the network from the preceding stage via unmodifiable synapses, and a trace or pairwise associative learning rule is implemented in the recurrent collateral synapses of an autoassociative memory to associate together the different exemplars (e.g. views) of the same object. (After Parga,N. and Rolls, E. T. (1998) Transform invariant recognition by association in a recurrent network. *Neural Computation* 10: 1507–1525. © Massachusetts Institute of Technology.)

$$P_o = \frac{k C}{s} \tag{2.44}$$

where C is the number of synapses on each neuron devoted to the recurrent collaterals from other neurons in the network, s is the number of views of each object, and k is a factor that is in the region of 0.07–0.09 (Parga and Rolls, 1998). There is a heavy cost to be paid for large numbers of views s , and the approach of using the recurrent collaterals as an attractor network to perform transform invariant object recognition has not been pursued further. However, the recurrent collaterals could be useful to help to store categories of objects learned by using VisNet-like mechanisms. The object recurrent attractor would help to ‘clean up’ a somewhat ambiguous image into one or another object category, and indeed evidence for this has been found (Akrami et al., 2009).

It is useful to contrast the different nature of the invariant object recognition problem studied here, and the paired associate learning task studied by Miyashita and colleagues (Miyashita and Chang, 1988; Fujimichi, Naya, Koyano, Takeda, Takeuchi and Miyashita, 2010; Miyashita, 2019). In the invariant object recognition case no particular learning pro-

Fig. 2.69 The visual search task. The monkey had to search for and touch an object (in this case a banana) when shown in a complex natural scene, or when shown on a plain background. In each case a second object is present (a bottle) which the monkey must not touch. The stimuli are shown to scale. The screen subtended 70 deg \times 55 deg. (After Rolls, E. T., Aggelopoulos, N.C., and Zheng, F. (2003) The receptive fields of inferior temporal cortex neurons in natural scenes. *Journal of Neuroscience* 23: 339–348. © by The Society for Neuroscience.)

toloc is required to produce an activity of the inferior temporal cortex cells responsible for invariant object recognition that is maintained for 300 ms. The learning can occur rapidly, and the learning occurs between stimuli (e.g. different views) which occur with no intervening delay. In the paired associate task, which had the aim of providing a model of semantic memory, the monkeys must learn to associate together two stimuli that are separated in time (by a number of seconds), and this type of learning can take weeks to train. During the delay period the sustained activity is rather low in the experiments, and thus the representation of the first stimulus that remains is weak, and can only poorly be associated with the second stimulus.

2.8.9 Vision in natural scenes – effects of background versus attention

Object-based attention refers to attention to an object. For example, in a visual search task the object might be specified as what should be searched for, and its location must be found. In spatial attention, a particular location in a scene is pre-cued, and the object at that location may need to be identified. Here we consider some of the neurophysiology of object selection and attention in the context of a feature hierarchy approach to invariant object recognition. The computational mechanisms of attention, including top-down biased competition, are described in Chapter 13.

2.8.9.1 Neurophysiology of object selection in the inferior temporal visual cortex

Much of the neurophysiology, psychophysics, and modelling of attention has been with a small number, typically two, of objects in an otherwise blank scene. In this Section, I consider how attention operates in complex natural scenes, and in particular describe how the inferior temporal visual cortex operates to enable the selection of an object in a complex natural scene (see also Rolls and Deco (2006)). The inferior temporal visual cortex contains distributed and invariant representations of objects and faces (Rolls, 2000a; Booth and Rolls, 1998; Rolls, Treves and Tovee, 1997b; Rolls and Tovee, 1995b; Tovee, Rolls and Azzopardi, 1994; Hasselmo, Rolls and Baylis, 1989a; Rolls and Baylis, 1986; Rolls, 2007e,f,c, 2011d, 2012d, 2016b).

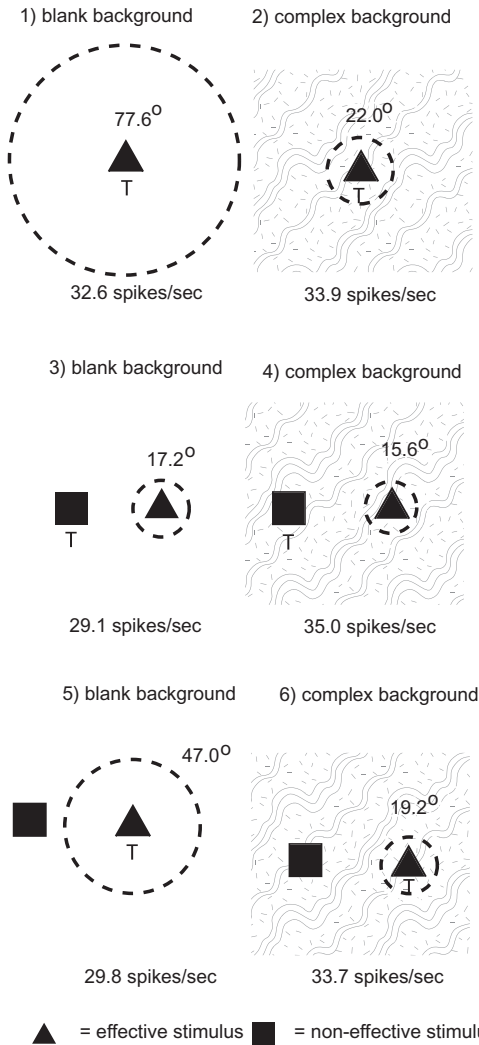

Fig. 2.70 Receptive field sizes of inferior temporal cortex neurons shrink in complex natural scenes. Summary of the receptive field sizes of inferior temporal cortex neurons to a 5 degree effective stimulus presented in either a blank background (blank screen) or in a natural scene (complex background). The stimulus that was a target for action in the different experimental conditions is marked by **T**. When the target stimulus was touched, a reward was obtained. The mean receptive field diameter of the population of neurons analyzed, and the mean firing rate in spikes/s, is shown. The stimuli subtended 5 deg × 3.5 deg at the retina, and occurred on each trial in a random position in the 70 deg × 55 deg screen. The dashed circle is proportional to the receptive field size. Top row: responses with one visual stimulus in a blank (left) or complex (right) background. Middle row: responses with two stimuli, when the effective stimulus was not the target of the visual search. Bottom row: responses with two stimuli, when the effective stimulus was the target of the visual search. (After Rolls, E. T., Aggelopoulos, N.C., and Zheng, F. (2003) The receptive fields of inferior temporal cortex neurons in natural scenes. *Journal of Neuroscience* 23: 339–348. © by The Society for Neuroscience.)

To investigate how attention operates in complex natural scenes, and how information is passed from the inferior temporal cortex (IT) to other brain regions to enable stimuli to be selected from natural scenes for action, Rolls, Aggelopoulos and Zheng (2003a) analyzed the responses of inferior temporal cortex neurons to stimuli presented in complex natural backgrounds. The monkey had to search for two objects on a screen, and a touch of one object was rewarded with juice, and of another object was punished with saline (see Fig. 2.7 for a schematic illustration and Fig. 2.69 for a version of the display with examples of the stimuli shown to scale). Neuronal responses to the effective stimuli for the neurons were

compared when the objects were presented in the natural scene or on a plain background. It was found that the overall response of the neuron to objects was hardly reduced when they were presented in natural scenes, and the selectivity of the neurons remained. However, the main finding was that the magnitudes of the responses of the neurons typically became much less in the real scene the further the monkey fixated in the scene away from the object (see Fig. 2.8). A small receptive field size has also been found in inferior temporal cortex neurons when monkeys have been trained to discriminate closely spaced small visual stimuli (DiCarlo and Maunsell, 2003).

It is proposed that this reduced translation invariance in natural scenes helps an unambiguous representation of an object which may be the target for action to be passed to the brain regions that receive from the primate inferior temporal visual cortex. It helps with the binding problem, by reducing in natural scenes the effective receptive field of at least some inferior temporal cortex neurons to approximately the size of an object in the scene.

It is also found that in natural scenes, the effect of object-based attention on the response properties of inferior temporal cortex neurons is relatively small, as illustrated in Fig. 2.70 (Rolls, Aggelopoulos and Zheng, 2003a).

2.8.9.2 Attention in natural scenes – a computational account

The results summarized in Fig. 2.70 for 5 degree stimuli show that the receptive fields were large (77.6 degrees) with a single stimulus in a blank background (top left), and were greatly reduced in size (to 22.0 degrees) when presented in a complex natural scene (top right). The results also show that there was little difference in receptive field size or firing rate in the complex background when the effective stimulus was selected for action (bottom right, 19.2 degrees), and when it was not (middle right, 15.6 degrees) (Rolls, Aggelopoulos and Zheng, 2003a). (For comparison, the effects of attention against a blank background were much larger, with the receptive field increasing from 17.2 degrees to 47.0 degrees as a result of object-based attention, as shown in Fig. 2.70, left middle and bottom.)

Trappenberg, Rolls and Stringer (2002) have suggested what underlying mechanisms could account for these findings, and simulated a model to test the ideas. The model utilizes an attractor network representing the inferior temporal visual cortex (implemented by the recurrent connections between inferior temporal cortex neurons), and a neural input layer with several retinotopically organized modules representing the visual scene in an earlier visual cortical area such as V4 (see Fig. 2.71). The attractor network aspect of the model produces the property that the receptive fields of IT neurons can be large in blank scenes by enabling a weak input in the periphery of the visual field to act as a retrieval cue for the object attractor. On the other hand, when the object is shown in a complex background, the object closest to the fovea tends to act as the retrieval cue for the attractor, because the fovea is given increased weight in activating the IT module because the magnitude of the input activity from objects at the fovea is greatest due to the higher magnification factor of the fovea incorporated into the model. This results in smaller receptive fields of IT neurons in complex scenes, because the object tends to need to be close to the fovea to trigger the attractor into the state representing that object. (In other words, if the object is far from the fovea, then it will not trigger neurons in IT which represent it, because neurons in IT are preferentially being activated by another object at the fovea.) This may be described as an attractor model in which the competition for which attractor state is retrieved is weighted towards objects at the fovea.

Attentional top-down object-based inputs can bias the competition implemented in this attractor model, but have relatively minor effects (in for example increasing receptive field size) when they are applied in a complex natural scene, as then as usual the stronger forward inputs dominate the states reached. In this network, the recurrent collateral connections may be thought of as implementing constraints between the different inputs present, to help arrive

Fig. 2.71 A model of receptive field size of inferior temporal visual cortex (IT) neurons in natural scenes and the effects of top-down attention. The architecture of the inferior temporal cortex (IT) model of Trappenberg, Rolls and Stringer (2002) operating as an attractor network with inputs from the fovea given preferential weighting by the greater cortical magnification factor of the fovea. The model also has a top-down object-selective bias input. The model was used to analyze how object vision and recognition operate in complex natural scenes. (After Trappenberg, T.P., Rolls, E. T. and Stringer, S.M. 2002. Effective size of receptive fields of inferior temporal cortex neurons in natural scenes. Pp. 293–300 in *Advances in Neural Information Processing Systems 14*, Volume 1, Eds. T.G. Dietterich, S. Becker, Z. Ghahramani. MIT Press: Cambridge, MA.)

at firing in the network which best meets the constraints. In this scenario, the preferential weighting of objects close to the fovea because of the increased magnification factor at the fovea is a useful principle in enabling the system to provide useful output. The attentional object biasing effect is much more marked in a blank scene, or a scene with only two objects present at similar distances from the fovea, which are conditions in which attentional effects have frequently been examined. The results of the investigation (Trappenberg, Rolls and Stringer, 2002) thus suggest that top-down attention may be a much more limited phenomenon in complex, natural, scenes than in reduced displays with one or two objects present. The results also suggest that the alternative principle, of providing strong weight to whatever is close to the fovea, is an important principle governing the operation of the inferior temporal visual cortex, and in general of the output of the visual system in natural environments. This principle of operation is very important in interfacing the visual system to action systems, because the effective stimulus in making inferior temporal cortex neurons fire is in natural scenes usually on or close to the fovea. This means that the spatial coordinates of where the object is in the scene do not have to be represented in the inferior temporal visual cortex, nor passed from it to the action selection system, as the latter can assume that the object making IT neurons fire is close to the fovea in natural scenes.

There may of course be in addition a mechanism for object selection that takes into account the locus of covert attention when actions are made to locations not being looked at. However, the simulations described in this section suggest that in any case covert attention is likely to be a much less significant influence on visual processing in natural scenes than in reduced scenes with one or two objects present.

Given these points, one might question why inferior temporal cortex neurons can have such large receptive fields, which show translation invariance. At least part of the answer to this may be that inferior temporal cortex neurons must have the capability to be large if they are to deal with large objects. A V1 neuron, with its small receptive field, simply could not receive input from all the features necessary to define an object. On the other hand, inferior temporal cortex neurons may be able to adjust their size to approximately the size of objects, using in part the interactive effects described in Chapter 13, and need the capability for translation invariance because the actual relative positions of the features of an object could be at different relative positions in the scene. For example, a car can be recognized whichever way it is viewed, so that the parts (such as the bonnet or hood) must be identifiable as parts wherever they happen to be in the image, though of course the parts themselves also have to be in the correct relative positions, as allowed for by the hierarchical feature analysis architecture described in this chapter.

Some details of the simulations follow. Each independent module within ‘V4’ in Fig. 2.71 represents a small part of the visual field and receives input from earlier visual areas represented by an input vector for each possible location which is unique for each object. Each module was 6 degrees in width, matching the size of the objects presented to the network. For the simulations Trappenberg, Rolls and Stringer (2002) chose binary random input vectors representing objects with $N^{V4}a^{V4}$ components set to ones and the remaining $N^{V4}(1 - a^{V4})$ components set to zeros. N^{V4} is the number of nodes in each module and a^{V4} is the sparseness of the representation which was set to be $a^{V4} = 0.2$ in the simulations.

The structure labelled ‘IT’ represents areas of visual association cortex such as the inferior temporal visual cortex and cortex in the anterior part of the superior temporal sulcus in which neurons provide distributed representations of faces and objects (Booth and Rolls, 1998; Rolls, 2000a). Nodes in this structure are governed by leaky integrator dynamics (similar to those used in the mean field approach described in Section B.8.1) with time constant τ

$$\tau \frac{dh_i^{IT}(t)}{dt} = -h_i^{IT}(t) + \sum_j (w_{ij}^{IT} - c^{IT})y_j^{IT}(t) + \sum_k w_{ik}^{IT-V4}y_k^{V4}(t) + k^{IT-BIAS}I_i^{OBJ}. \quad (2.45)$$

The firing rate y_i^{IT} of the i th node is determined by a sigmoidal function from the activation h_i^{IT} as follows

$$y_i^{IT}(t) = \frac{1}{1 + \exp[-2\beta(h_i^{IT}(t) - \alpha)]}, \quad (2.46)$$

where the parameters $\beta = 1$ and $\alpha = 1$ represent the gain and the bias, respectively.

The recognition functionality of this structure is modelled as an attractor neural network (ANN) with trained memories indexed by μ representing particular objects. The memories are formed through Hebbian learning on sparse patterns,

$$w_{ij}^{IT} = k^{IT} \sum_{\mu} (\xi_i^{\mu} - a^{IT})(\xi_j^{\mu} - a^{IT}), \quad (2.47)$$

where k^{IT} (set to 1 in the simulations) is a normalization constant that depends on the learning rate, $a^{IT} = 0.2$ is the sparseness of the training pattern in IT, and ξ_i^{μ} are the components of the

pattern used to train the network. The constant c^{IT} in Equation 2.45 represents the strength of the activity-dependent global inhibition simulating the effects of inhibitory interneurons. The external ‘top-down’ input vector I^{OBJ} produces object-selective inputs, which are used as the attentional drive when a visual search task is simulated. The strength of this object bias is modulated by the value of $k^{IT, BIAS}$ in equation (2.45).

The weights w_{ij}^{IT-V4} between the V4 nodes and IT nodes were trained by Hebbian learning of the form

$$w_{ij}^{IT-V4} = k^{IT-V4}(k) \sum_{\mu} (\xi_i^{\mu} - a^{V4})(\xi_j^{\mu} - a^{IT}). \quad (2.48)$$

to produce object representations in IT based on inputs in V4. The normalizing modulation factor $k^{IT-V4}(k)$ allows the gain of inputs to be modulated as a function of their distance from the fovea, and depends on the module k to which the presynaptic node belongs. The model supports translation invariant object recognition of a single object in the visual field if the normalization factor is the same for each module and the model is trained with the objects placed at every possible location in the visual field. The translation invariance of the weight vectors between each ‘V4’ module and the IT nodes is however explicitly modulated in the model by the module-dependent modulation factor $k^{IT-V4}(k)$ as indicated in Fig. 2.71 by the width of the lines connecting V4 with IT. The strength of the foveal V4 module is strongest, and the strength decreases for modules representing increasing eccentricity. The form of this modulation factor was derived from the parameterization of the cortical magnification factors given by Dow et al. (1981)⁸.

To study the ability of the model to recognize trained objects at various locations relative to the fovea the system was trained on a set of objects. The network was then tested with distorted versions of the objects, and the ‘correlation’ between the target object and the final state of the attractor network was taken as a measure of the performance. The correlation was estimated from the normalized dot product between the target object vector that was used during training the IT network, and the state of the IT network after a fixed amount of time sufficient for the network to settle into a stable state. The objects were always presented on backgrounds with some noise (introduced by flipping 2% of the bits in the scene which were not the test stimulus) in order to utilize the properties of the attractor network, and because the input to IT will inevitably be noisy under normal conditions of operation.

In the first simulation only one object was present in the visual scene in a plain (blank) background at different eccentricities from the fovea. As shown in Fig. 2.72a by the line labelled ‘blank background’, the receptive fields of the neurons were very large. The value of the object bias $k^{IT, BIAS}$ was set to 0 in these simulations. Good object retrieval (indicated by large correlations) was found even when the object was far from the fovea, indicating large IT receptive fields with a blank background. The reason that any drop is seen in performance as a function of eccentricity is because flipping 2% of the bits outside the object introduces some noise into the recall process. This demonstrates that the attractor dynamics can support translation invariant object recognition even though the translation invariant weight vectors between V4 and IT are explicitly modulated by the modulation factor k^{IT-V4} derived from the cortical magnification factor.

In a second simulation individual objects were placed at all possible locations in a natural and cluttered visual scene. The resulting correlations between the target pattern and the asymptotic IT state are shown in Fig. 2.72a with the line labelled ‘natural background’. Many objects in the visual scene are now competing for recognition by the attractor network, and

⁸This parameterization is based on V1 data. However, it was shown that similar forms of the magnification factor hold also in V4 (Gattass, Sousa and Covey, 1985). Similar results to the ones presented here can also be achieved with different forms of the modulation factor such as a shifted Gaussian.

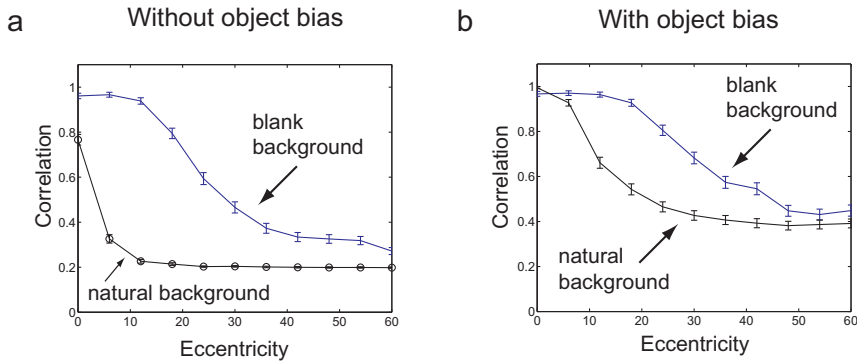

Fig. 2.72 A model of receptive field size of inferior temporal visual cortex neurons in natural scenes and the effects of top-down attention. Correlations as measured by the normalized dot product between the object vector used to train IT and the state of the IT network after settling into a stable state with a single object in the visual scene (blank background) or with other trained objects at all possible locations in the visual scene (natural background). There is no object bias included in the results shown in graph a, whereas an object bias is included in the results shown in b with $k_{IT-BIAS}^{IT} = 0.7$ in the experiments with a natural background and $k_{IT-BIAS}^{IT} = 0.1$ in the experiments with a blank background. (After Trappenberg, T.P., Rolls, E. T. and Stringer, S.M. 2002. Effective size of receptive fields of inferior temporal cortex neurons in natural scenes. Pp. 293–300 in *Advances in Neural Information Processing Systems 14*, Volume 1, Eds. T.G. Dietterich, S. Becker, Z. Ghahramani. MIT Press: Cambridge, MA.)

the objects around the foveal position are enhanced through the modulation factor derived from the cortical magnification factor. This results in a much smaller size of the receptive field of IT neurons when measured with objects in natural backgrounds.

In addition to this major effect of the background on the size of the receptive field, which parallels and may account for the physiological findings outlined above and in Section 2.8.9.1, there is also a dependence of the size of the receptive fields on the level of object bias provided to the IT network. Examples are shown in Fig. 2.72b where an object bias was used. The object bias biases the IT network towards the expected object with a strength determined by the value of $k_{IT-BIAS}^{IT}$, and has the effect of increasing the size of the receptive fields in both blank and natural backgrounds (see Fig. 2.72b compared to a). This models the effect found neurophysiologically (Rolls, Aggelopoulos and Zheng, 2003a)⁹.

Some of the conclusions are as follows (Trappenberg, Rolls and Stringer, 2002). When single objects are shown in a scene with a blank background, the attractor network helps neurons to respond to an object with large eccentricities of this object relative to the fovea of the agent. When the object is presented in a natural scene, other neurons in the inferior temporal cortex become activated by the other effective stimuli present in the visual field, and these forward inputs decrease the response of the network to the target stimulus by a competitive process. The results found fit well with the neurophysiological data, in that IT operates with almost complete translation invariance when there is only one object in the scene, and reduces the receptive field size of its neurons when the object is presented in a cluttered environment. The model described here provides an explanation of the responses of real IT neurons in natural scenes.

In natural scenes, the model is able to account for the neurophysiological data that the IT neuronal responses are larger when the object is close to the fovea, by virtue of fact that objects close to the fovea are weighted by the cortical magnification factor related modulation k_{IT-V4}^{IT} .

⁹ $k_{IT-BIAS}^{IT}$ was set to 0.7 in the experiments with a natural background and to 0.1 with a blank background, reflecting the fact that more attention may be needed to find objects in natural cluttered environments because of the noise present than in blank backgrounds. Equivalently, a given level of attention may have a smaller effect in a natural scene than in a blank background, as found neurophysiologically (Rolls, Aggelopoulos and Zheng, 2003a).

The model accounts for the larger receptive field sizes from the fovea of IT neurons in natural backgrounds if the target is the object being selected compared to when it is not selected (Rolls, Aggelopoulos and Zheng, 2003a). The model accounts for this by an effect of top-down bias which simply biases the neurons towards particular objects compensating for their decreasing inputs produced by the decreasing magnification factor modulation with increasing distance from the fovea. Such object-based attention signals could originate in the prefrontal cortex and could provide the object bias for the inferior temporal visual cortex (Renart, Parga and Rolls, 2000) (see Section 2.12).

Important properties of the architecture for obtaining the results just described are the high magnification factor at the fovea and the competition between the effects of different inputs, implemented in the above simulation by the competition inherent in an attractor network.

We have also been able to obtain similar results in a hierarchical feedforward network where each layer operates as a competitive network (Deco and Rolls, 2004). This network thus captures many of the properties of our hierarchical model of invariant object recognition (Rolls, 1992a; Wallis and Rolls, 1997; Rolls and Milward, 2000; Stringer and Rolls, 2000; Rolls and Stringer, 2001a; Elliffe, Rolls and Stringer, 2002; Stringer and Rolls, 2002; Rolls and Deco, 2002; Stringer, Perry, Rolls and Proske, 2006; Rolls and Stringer, 2006a,b; Rolls, 2012d, 2016b, 2021d), but incorporates in addition a foveal magnification factor and top-down projections with a dorsal visual stream so that attentional effects can be studied, as shown in Fig. 2.73.

Deco and Rolls (2004) trained the network shown in Fig. 2.73 with two objects, and used the trace learning rule (Wallis and Rolls, 1997; Rolls and Milward, 2000) in order to achieve translation invariance. In a first experiment we placed only one object on the retina at different distances from the fovea (i.e. different eccentricities relative to the fovea). This corresponds to the blank background condition. In a second experiment, we also placed the object at different eccentricities relative to the fovea, but on a cluttered natural background. Larger receptive fields were found with the blank as compared to the cluttered natural background.

Deco and Rolls (2004) also studied the influence of object-based attentional top-down bias on the effective size of the receptive field of an inferior temporal cortex neuron for the case of an object in a blank or a cluttered background. To do this, they repeated the two simulations but now considered a non-zero top-down bias coming from prefrontal area 46v and impinging on the inferior temporal cortex neuron specific for the object tested. When no attentional object bias was introduced, a shrinkage of the receptive field size was observed in the complex vs the blank background. When attentional object bias was introduced, the shrinkage of the receptive field due to the complex background was somewhat reduced. This is consistent with the neurophysiological results (Rolls, Aggelopoulos and Zheng, 2003a). In the framework of the model (Deco and Rolls, 2004), the reduction of the shrinkage of the receptive field is due to the biasing of the competition in the inferior temporal cortex layer in favour of the specific IT neuron tested, so that it shows more translation invariance (i.e. a slightly larger receptive field). The increase of the receptive field size of an IT neuron, although small, produced by the external top-down attentional bias offers a mechanism for facilitation of the search for specific objects in complex natural scenes (see further Section 2.12).

I note that it is possible that a ‘spotlight of attention’ (Desimone and Duncan, 1995) can be moved covertly away from the fovea as described in Section 2.12. However, at least during normal visual search tasks in natural scenes, the neurons are sensitive to the object at which the monkey is looking, that is primarily to the object that is on the fovea, as shown by Rolls, Aggelopoulos and Zheng (2003a) and Aggelopoulos and Rolls (2005), and described in Sections 2.8.9.1 and 2.8.10.

Fig. 2.73 Cortical architecture for hierarchical and attention-based visual perception. The system has five modules structured such that they resemble the two main visual paths of the primate visual cortex. Information from the retino-geniculo-striate pathway enters the visual cortex through area V1 in the occipital lobe and proceeds into two processing streams. The occipital-temporal stream leads ventrally through V2–V4 and IT (inferior temporal visual cortex), and is mainly concerned with object recognition. The occipito-parietal stream leads dorsally into PP (posterior parietal complex), and is responsible for maintaining a spatial map of an object's location. The solid lines with arrows between levels show the forward connections, and the dashed lines the top-down backprojections. Short-term memory systems in the prefrontal cortex (PF46) apply top-down attentional bias to the object or spatial processing streams. (After Deco, G. and Rolls, E. T. (2004) A neurodynamical cortical model of visual attention and invariant object recognition. *Vision Research* 44: 621–644. © Elsevier Ltd.)

2.8.10 The representation of multiple objects in a scene

When objects have distributed representations, there is a problem of how multiple objects (whether the same or different) can be represented in a scene, because the distributed representations overlap, and it may not be possible to determine whether one has an amalgam of several objects, or a new object (Mozer, 1991), or multiple instances of the same object, let alone the relative spatial positions of the objects in a scene. Yet humans can determine the relative spatial locations of objects in a scene even in short presentation times without eye movements (Biederman, 1972) (and this has been held to involve some spotlight of attention). Aggelopoulos and Rolls (2005) analyzed this issue by recording from single inferior temporal

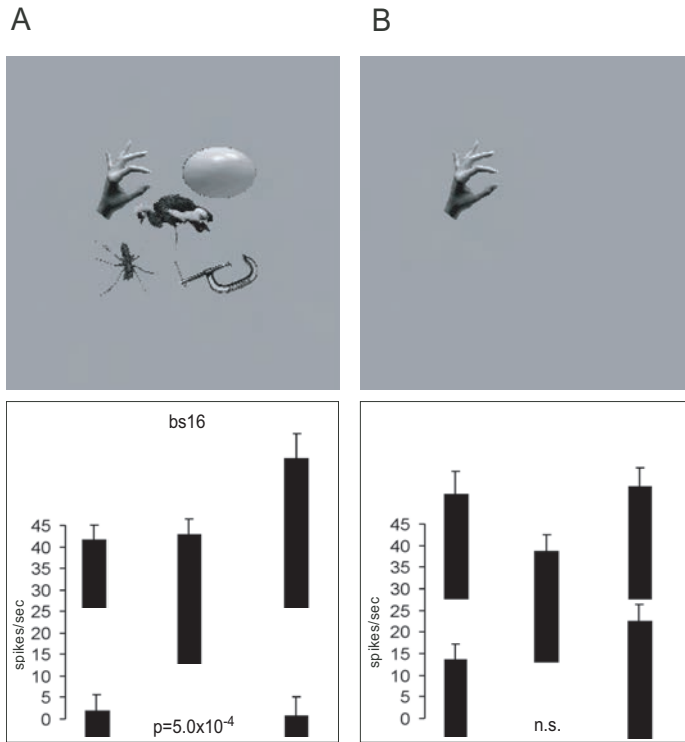

Fig. 2.74 Object-selective receptive fields of inferior temporal cortex neurons that allow the positions of multiple objects close to the fovea to be encoded. (A). The responses (firing rate with the spontaneous rate subtracted, means \pm sem) of an inferior temporal cortex neuron when tested with 5 stimuli simultaneously present in the close (10 deg) configuration with the parafoveal stimuli located 10 degrees from the fovea. (B). The responses of the same neuron when only the effective stimulus was presented in each position. The firing rate for each position is that when the effective stimulus (in this case the hand) was in that position. The p value is that from the ANOVA calculated over the four parafoveal positions. (After Aggelopoulos, N.C. and Rolls, E. T. (2005) Natural scene perception: inferior temporal cortex neurons encode the positions of different objects in the scene. *European Journal of Neuroscience* 22: 2903–2916. © Federation of European Neuroscience Societies and John Wiley and Sons Ltd.)

cortex neurons with five objects simultaneously present in the receptive field. They found that although all the neurons responded to their effective stimulus when it was at the fovea, some could also respond to their effective stimulus when it was in some but not other parafoveal positions 10 degrees from the fovea. An example of such a neuron is shown in Fig. 2.74. The asymmetry is much more evident in a scene with 5 images present (Fig. 2.74A) than when only one image is shown on an otherwise blank screen (Fig. 2.74B). Competition between different stimuli in the receptive field thus reveals the asymmetry in the receptive field of inferior temporal visual cortex neurons.

The asymmetry provides a way of encoding the position of multiple objects in a scene. Depending on which asymmetric neurons are firing, the population of neurons provides information to the next processing stage not only about which image is present at or close to the fovea, but where it is with respect to the fovea. This information is provided by neurons that have firing rates that reflect the relevant information, and stimulus-dependent synchrony is not necessary. Top-down attentional biasing input could thus, by biasing the appropriate neurons, facilitate bottom-up information about objects without any need to alter the time relations between the firing of different neurons. The exact position of the object with respect to the fovea, and effectively thus its spatial position relative to other objects in the scene, would then be made evident by the subset of asymmetric neurons firing.

This is thus the solution that these experiments indicate is used for the representation of

multiple objects in a scene, an issue that has previously been difficult to account for in neural systems with distributed representations (Mozer, 1991) and for which ‘attention’ has been a proposed solution. The learning of invariant representations of objects when multiple objects are present in a scene is considered in Section 2.8.6.2.

2.8.11 Learning invariant representations using spatial continuity: Continuous Spatial Transformation learning

The temporal continuity typical of objects has been used in an associative learning rule with a short-term memory trace to help build invariant object representations in the networks described previously in this chapter. Stringer, Perry, Rolls and Proske (2006) showed that spatial continuity can also provide a basis for helping a system to self-organize invariant representations. They introduced a new learning paradigm ‘continuous spatial transformation (CT) learning’ which operates by mapping spatially similar input patterns to the same postsynaptic neurons in a competitive learning system. As the inputs move through the space of possible continuous transforms (e.g. translation, rotation, etc.), the active synapses are modified onto the set of postsynaptic neurons. Because other transforms of the same stimulus overlap with previously learned exemplars, a common set of postsynaptic neurons is activated by the new transforms, and learning of the new active inputs onto the same postsynaptic neurons is facilitated.

The concept is illustrated in Fig. 2.75. During the presentation of a visual image at one position on the retina that activates neurons in layer 1, a small winning set of neurons in layer 2 will modify (through associative learning) their afferent connections from layer 1 to respond well to that image in that location. When the same image appears later at nearby locations, so that there is spatial continuity, the same neurons in layer 2 will be activated because some of the active afferents are the same as when the image was in the first position. The key point is that if these afferent connections have been strengthened sufficiently while the image is in the first location, then these connections will be able to continue to activate the same neurons in layer 2 when the image appears in overlapping nearby locations. Thus the same neurons in the output layer have learned to respond to inputs that have similar vector elements in common.

As can be seen in Fig. 2.75, the process can be continued for subsequent shifts, provided that a sufficient proportion of input cells stay active between individual shifts. This whole process is repeated throughout the network, both horizontally as the image moves on the retina, and hierarchically up through the network. Over a series of stages, transform invariant (e.g. location invariant) representations of images are successfully learned, allowing the network to perform invariant object recognition. A similar CT learning process may operate for other kinds of transformation, such as change in view or size.

Stringer, Perry, Rolls and Proske (2006) demonstrated that VisNet can be trained with continuous spatial transformation learning to form view invariant representations. They showed that CT learning requires the training transforms to be relatively close together spatially so that spatial continuity is present in the training set; and that the order of stimulus presentation is not crucial, with even interleaving with other objects possible during training, because it is spatial continuity rather than the temporal continuity that drives the self-organizing learning with the purely associative synaptic modification rule.

Perry, Rolls and Stringer (2006) extended these simulations with VisNet of view invariant learning using CT to more complex 3D objects, and using the same training images in human psychophysical investigations, showed that view invariant object learning can occur when spatial but not temporal continuity applies in a training condition in which the images of different objects were interleaved. However, they also found that the human view invariance

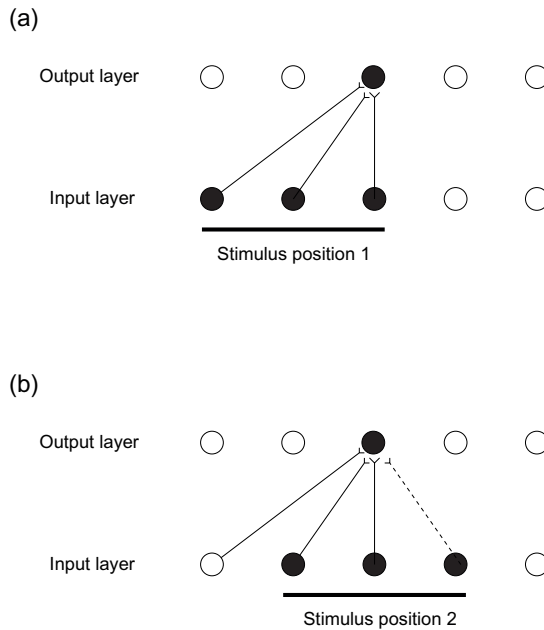

Fig. 2.75 Continuous spatial transformation learning of transform-invariant visual representations of objects. This illustrates how continuous spatial transformation (CT) learning would function in a network with a single layer of forward synaptic connections between an input layer of neurons and an output layer. Initially the forward synaptic weights are set to random values. The top part (a) shows the initial presentation of a stimulus to the network in position 1. Activation from the (shaded) active input cells is transmitted through the initially random forward connections to stimulate the cells in the output layer. The shaded cell in the output layer wins the competition in that layer. The weights from the active input cells to the active output neuron are then strengthened using an associative learning rule. The bottom part (b) shows what happens after the stimulus is shifted by a small amount to a new partially overlapping position 2. As some of the active input cells are the same as those that were active when the stimulus was presented in position 1, the same output cell is driven by these previously strengthened afferents to win the competition again. The rightmost shaded input cell activated by the stimulus in position 2, which was inactive when the stimulus was in position 1, now has its connection to the active output cell strengthened (denoted by the dashed line). Thus the same neuron in the output layer has learned to respond to the two input patterns that have similar vector elements in common. As can be seen, the process can be continued for subsequent shifts, provided that a sufficient proportion of input cells stay active between individual shifts. (After Stringer, S.M., Perry, G., Rolls, E. T. and Proske, H. (2006) Learning invariant object recognition in the visual system with continuous transformations. *Biological Cybernetics* 94: 128–142. © Springer Nature.)

learning was better if sequential presentation of the images of an object was used, indicating that temporal continuity is an important factor in human invariance learning.

Perry, Rolls and Stringer (2010) extended the use of continuous spatial transformation learning to translation invariance. They showed that translation invariant representations can be learned by continuous spatial transformation learning; that the transforms must be close for this to occur; that the temporal order of presentation of each transformed image during training is not crucial for learning to occur; that relatively large numbers of transforms can be learned; and that such continuous spatial transformation learning can be usefully combined with temporal trace training as explored further (Spoerer, Eguchi and Stringer, 2016).

2.8.12 Lighting invariance

Object recognition should occur correctly even despite variations of lighting. In an investigation of this, Rolls and Stringer (2006b) trained VisNet on a set of 3D objects generated with OpenGL in which the viewing angle and lighting source could be independently varied (see Fig. 2.76). After training with the trace rule on all the 180 views (separated by 1 deg, and rotated about the vertical axis in Fig. 2.76) of each of the four objects under the left lighting

Fig. 2.76 Lighting invariance. VisNet was trained on a set of 3D objects (cube, tetrahedron, octahedron and torus) generated with OpenGL in which for training the objects had left lighting, and for testing the objects had right lighting. Just one view of each object is shown in the Figure, but for training and testing 180 views of each object separated by 1 deg were used. (After Rolls, E. T. and Stringer, S.M. (2007) Invariant visual object recognition: a model, with lighting invariance. *Journal of Physiology - Paris* 100: 43–62. © Elsevier Ltd.)

Fig. 2.77 Lighting invariance. The performance of the network after training with 180 views of each object lit from the left, when tested with the lighting again from the left (Left-light), and when tested with the lighting from the right (Right-light). The single cell information measure shows that many single neurons in layer 4 had the maximum amount of information about the objects, 2 bits, which indicates that they responded to all 180 views of one of the objects, and none of the 180 views of the other objects. The multiple cell information shows that the cells were sufficiently different in the objects to which they responded invariantly that all of the objects were perfectly represented when tested with the training images, and very well represented (with nearly 2 bits of information) when tested in the untrained lighting condition. (After Rolls, E. T. and Stringer, S.M. (2007) Invariant visual object recognition: a model, with lighting invariance. *Journal of Physiology - Paris* 100: 43–62. © Elsevier Ltd.)

condition, we tested whether the network would recognize the objects correctly when they were shown again, but with the source of the lighting moved to the right so that the objects appeared different (see Fig. 2.76). Figure 2.77 shows that the single and multiple cell information measures for the set of objects tested with the light source in the same position as during training (Left-light), and that the measures were almost as good with testing with the light source moved to the right position (Right-light). Thus lighting invariant object recognition was demonstrated (Rolls and Stringer, 2006b).

Some insight into the good performance with a change of lighting is that some neurons in the inferior temporal visual cortex respond to the outlines of 3D objects (Vogels and Biederman, 2002), and these outlines will be relatively consistent across lighting variations. Although the features about the object represented in VisNet will include more than the representations of the outlines, the network may be able to generalize correctly provided that some of the features are similar to those present during training. Under very difficult lighting conditions, it is likely that the performance of the network could be improved by including variations in the lighting during training, so that the trace rule could help to build representations that are explicitly invariant with respect to lighting.

Fig. 2.78 Deformation-invariant object recognition. The flag stimuli used to train VisNet. Each flag is shown with different wind forces and rotations. Starting on the left the first pair, both the 0° and 180° views are shown for windspeed 0, and each successive pair is shown for wind force increased by 50 Blender units. (After Webb, T.J. and Rolls, E. T. (2014) Deformation-specific and deformation-invariant visual object recognition: pose vs identity recognition of people and deforming objects. *Frontiers in Computational Neuroscience* 8: 37.)

2.8.13 Deformation-invariant object recognition

When we see a human sitting down, standing up, or walking, we can recognise one of these poses independently of the individual, or we can recognise the individual person, independently of the pose. The same issues arise for deforming objects. For example, if we see a flag deformed by the wind, either blowing out or hanging languidly, we can usually recognise the flag, independently of its deformation; or we can recognise the deformation independently of the identity of the flag.

We hypothesized that these types of recognition can be implemented by the primate visual system using temporo-spatial continuity as objects transform as a learning principle. In particular, we hypothesized that pose or deformation can be learned under conditions in which large numbers of different people are successively seen in the same pose, or objects in the same deformation. We also hypothesized that person-specific representations that are independent of pose, and object-specific representations that are independent of deformation and view, could be built, when individual people or objects are observed successively transforming from one pose or deformation and view to another (Webb and Rolls, 2014).

These hypotheses were tested in VisNet. The images to be learned consisted of for example a set of flags with different deformations. The deformation invariant recognition of flags was investigated with a set of 4 flags (each with 5 deformations each with two views, as illustrated in Fig. 2.78). Another set of stimuli consisted of three different people shown with three different poses (sitting, standing, or walking), all presented with 12 different views. It was found that depending on the statistics of the visual input, two types of representation could be built by VisNet.

Pose-specific or deformation-specific representations could be built that were invariant with respect to individual and view, if the statistics of the inputs included in temporal proximity the same pose or deformation. This might occur for example if one saw a scene with several people sitting down, and the people were successively fixated.

Identity-specific representations could be built that were invariant with respect to pose or

deformation and view, if the statistics of the inputs included in temporal proximity the same person in different poses, or the same flag in different deformations. This might occur for example if one saw an individual person moving through different poses (sitting, standing up, and walking); or if one saw the same flag blowing into different shapes in the wind (Webb and Rolls, 2014).

We proposed that this is how pose-specific and pose-invariant, and deformation-specific and deformation-invariant, perceptual representations are built in the brain (Webb and Rolls, 2014).

This illustrates an important principle, that information is present in the statistics of the inputs, and can be taken advantage of by the brain to learn different types of representation. This was powerfully illustrated in this investigation in that the functional architecture and stimuli were identical, and it was just the temporal statistics of the inputs that resulted in different types of representation being built.

The utility of these statistics of the input are not taken advantage of in current deep learning models of object recognition (Section B.14).

2.8.14 Learning invariant representations of scenes and places

The primate hippocampal system has neurons that respond to a view of a spatial scene, or when that location in a scene is being looked at in the dark or when it is obscured (Georges-François et al., 1999; Robertson et al., 1998; Rolls et al., 1997a, 1998b; Rolls and Xiang, 2006; Rolls, 2023c). The representation is relatively invariant with respect to the position of the macaque in the environment, and of head direction, and eye position. The requirement for these spatial view neurons is that a position in the spatial scene is being looked at (see Chapter 9). (There is an analogous set of place neurons in the rat hippocampus that respond in this case when the rat is in a given place in space, relatively invariantly with respect to head direction (McNaughton et al., 1983; Muller et al., 1991; O'Keefe, 1984).) How might these spatial view neurons be set up in primates?

Before addressing this, it is useful to consider the difference between a spatial view or scene representation, and an object representation. An object can be moved to different places in space or in a spatial scene. An example is a motor car that can be moved to different places in space. The object is defined by a combination of features or parts in the correct relative spatial position, but its representation is independent of where it is in space. In contrast, a representation of space has landmarks or objects in defined relative spatial positions, which cannot be moved relative to one another in space. An example might be Trafalgar Square, in which Nelson's column is in the middle, and the National Gallery and St Martin's in the Fields church are at set relative locations in space, and cannot be moved relative to one another. This draws out the point that there may be some computational similarities between the construction of an object and of a scene or a representation of space, but there are also important differences in how they are used. The evidence that the hippocampus represents spatial views and not objects is described in Section 9.2.4.1. In the present context we are interested in how the brain may set up a spatial view representation in which the relative position of the objects in the scene defines the spatial view. That spatial view representation may be relatively invariant with respect to the exact position from which the scene is viewed (though extensions are needed if there are central objects in a space through which one moves). The spatial scene representations described here built in the ventral visual system may provide part of the input to the hippocampus that contributes to the presence there of allocentric spatial view cells (Section 9.2.4.1).

It is now possible to propose a unifying hypothesis of the relation between the ventral visual system, and primate hippocampal spatial view representations (Rolls, 2016b; Rolls,

Tromans and Stringer, 2008f), which is introduced in Section 9.3.12. Let us consider a computational architecture in which a fifth layer is added to the VisNet architecture, as illustrated in Fig. 9.35. In the anterior inferior temporal visual cortex, which corresponds to the fourth layer of VisNet, neurons respond to objects, but several objects close to the fovea (within approximately 10°) can be represented because many object-tuned neurons have asymmetric receptive fields with respect to the fovea (Aggelopoulos and Rolls, 2005) (see Section 2.8.10). If the fifth layer of VisNet performs the same operation as previous layers, it will form neurons that respond to combinations of objects in the scene with the positions of the objects relative spatially to each other incorporated into the representation (as described in Section 2.8.5). The result will be spatial view neurons in the case of primates when the visual field of the primate has a narrow focus (due to the high resolution fovea), and place cells when as in the rat the visual field is very wide (Critchley and Rolls, 1996a; Rolls, 2016b) (Fig. 9.34). The trace learning rule in layer 5 should help the spatial view or place fields that develop to be large and single, because of the temporal continuity that is inherent when the agent moves from one part of the view or place space to another (Rolls, 2021d), in the same way as has been shown for the entorhinal grid cell to hippocampal place cell mapping (Rolls, Stringer and Elliot, 2006c; Rolls, 2016b) (Section 9.3.3).

The hippocampal dentate granule cells form a network expected to be important in this competitive learning of spatial view or place representations based on visual inputs. As the animal navigates through the environment, different spatial view cells would be formed. Because of the overlapping fields of adjacent spatial view neurons, and hence their coactivity as the animal navigates, recurrent collateral associative connections at the next stage of the system, CA3, could form a continuous attractor representation of the environment (Rolls, 2016b). We thus have a hypothesis for how the spatial representations are formed as a natural extension of the hierarchically organised competitive networks in the ventral visual system. The expression of such spatial representations in CA3 may be particularly useful for associating those spatial representations with other inputs, such as objects or rewards (Rolls, 2016b, 2023c) (Chapter 9).

We have performed simulations to test this hypothesis with VisNet simulations with conceptually a fifth layer added (Rolls, Tromans and Stringer, 2008f). Training now with whole scenes that consist of a set of objects in a given fixed spatial relation to each other results in neurons in the added layer that respond to one of the trained whole scenes, but do not respond if the objects in the scene are rearranged to make a new scene from the same objects. The formation of these scene-specific representations in the added layer is related to the fact that in the inferior temporal cortex (Aggelopoulos and Rolls, 2005), and in the VisNet model (Rolls et al., 2008f), the receptive fields of inferior temporal cortex neurons shrink and become asymmetric when multiple objects are present simultaneously in a natural scene. This also provides a solution to the issue of the representation of multiple objects, and their relative spatial positions, in complex natural scenes (Rolls, 2016b, 2012d).

A key concept here is that spatial scenes are built by associating together ventral visual stream features in scenes in a continuous attractor network (Stringer, Rolls and Trappenberg, 2005; Rolls, Tromans and Stringer, 2008f). It is proposed that these spatial scene representations are built in regions such as the retrosplenial scene area and parahippocampal scene area in the Ventromedial Visual Cortical stream (Rolls et al., 2023e; Rolls, 2023c), as described for humans in Section 9.2.8.1 and illustrated in Fig. 9.18. The parahippocampal scene area is proposed to implement its spatial representations using spatial view cells, and in this way to provide the spatial input to the hippocampus for episodic memory (Rolls et al., 2023e; Rolls, 2023c). This is a key proposal for how the ‘where’ spatial representations for episodic memory are built in primates including humans (Rolls et al., 2023e; Rolls, 2023c), and is in contrast to what is envisaged in the rat where spatial ‘where’ representations of place not

spatial view are assumed to involve the parietal cortex as well as the hippocampus (Hartley, Lever, Burgess and O’Keefe, 2014; Bicanski and Burgess, 2018).

Consistently, in a more artificial network trained by gradient ascent with a goal function that included forming relatively time invariant representations and decorrelating the responses of neurons within each layer of the 5-layer network, place-like cells were formed at the end of the network when the system was trained with a real or simulated robot moving through spatial environments (Wyss, König and Verschure, 2006), and slowness as an asset in learning spatial representations has also been investigated by others (Wiskott and Sejnowski, 2002; Wiskott, 2003; Franzius, Sprekeler and Wiskott, 2007; Schonfeld and Wiskott, 2015; Weghenkel and Wiskott, 2018). It will be interesting to test whether spatial view cells develop in a VisNet fifth layer if trained with foveate views of the environment, or place cells if trained with wide angle views of the environment (cf. Critchley and Rolls (1996a), and the utility of testing this with a VisNet-like architecture is that it embodies a biologically plausible implementation based on neuronally plausible competitive learning and a short-term memory trace learning rule.

2.8.15 Finding and recognising objects in natural scenes: complementary computations in the dorsal and ventral visual systems

Here I consider how the brain solves the major computational task of recognising objects in complex natural scenes, still a major challenge for computer vision approaches.

One mechanism that the brain uses to simplify the task of recognising objects in complex natural scenes is that the receptive fields of inferior temporal cortex neurons change from approximately 70° in diameter when tested under classical neurophysiology conditions with a single stimulus on a blank screen to as little as a radius of 8° (for a 5° stimulus) when tested in a complex natural scene (Rolls, Aggelopoulos and Zheng, 2003a; Aggelopoulos and Rolls, 2005) (with consistent findings described by Sheinberg and Logothetis (2001)) (see Section 2.8.9 and Fig. 2.70). This greatly simplifies the task for the object recognition system, for instead of dealing with the whole scene as in traditional computer vision approaches, the brain processes just a small fixated region of a complex natural scene at any one time, and then the eyes are moved to another part of the screen. During visual search for an object in a complex natural scene, the primate visual system, with its high resolution fovea, therefore keeps moving the eyes until they fall within approximately 8° of the target, and then inferior temporal cortex neurons respond to the target object, and an action can be initiated towards the target, for example to obtain a reward (Rolls et al., 2003a). The inferior temporal cortex neurons then respond to the object being fixated with view, size, and rotation invariance (Rolls, 2012d, 2021d), and also need some translation invariance, for the eyes may not be fixating the centre of the object when the inferior temporal cortex neurons respond (Rolls et al., 2003a).

The questions then arise of how the eyes are guided in a complex natural scene to fixate close to what may be an object; and how close the fixation is to the centre of typical objects for this determines how much translation invariance needs to be built into the ventral visual system. It turns out that the dorsal visual system (Ungerleider and Mishkin, 1982; Ungerleider and Haxby, 1994) (Chapter 3) implements bottom-up saliency mechanisms by guiding saccades to salient stimuli, using properties of the stimulus such as high contrast, color, and visual motion (Miller and Buschman, 2013). (Bottom-up refers to inputs reaching the visual system from the retina.) One particular region, the lateral intraparietal cortex (LIP), which is an area in the dorsal visual system, seems to contain saliency maps sensitive to strong sensory inputs (Arcizet, Mirpour and Bisley, 2011). Highly salient, briefly flashed, stimuli

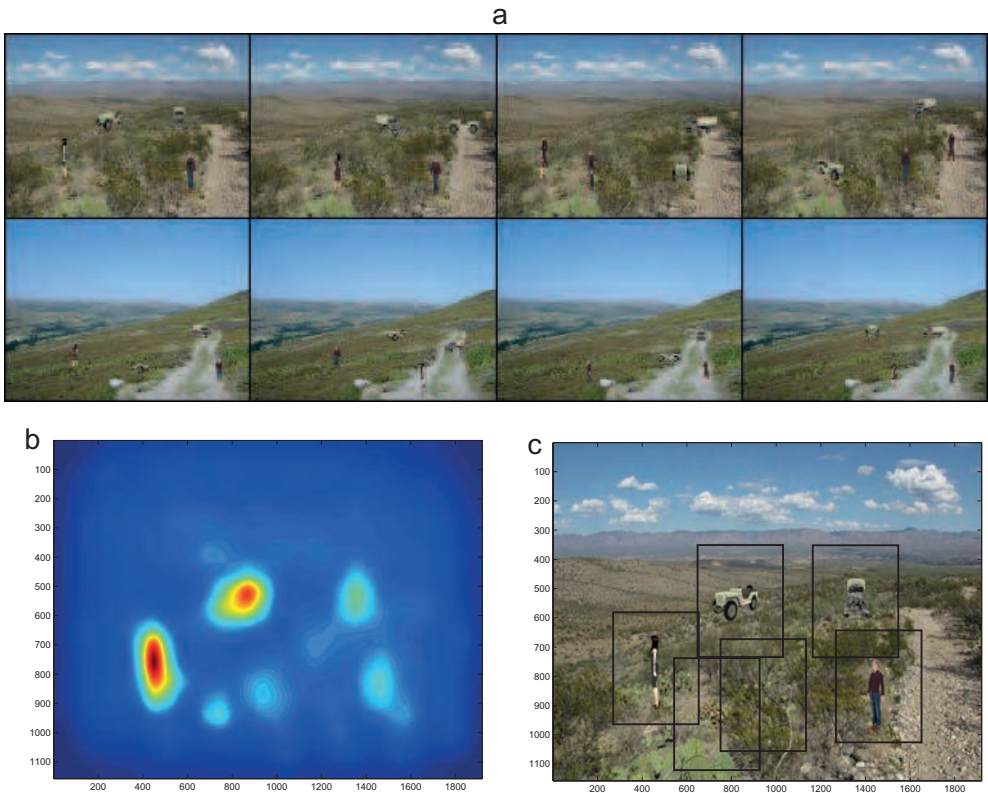

Fig. 2.79 Finding and recognising objects in natural scenes. a. Eight of the 12 test scenes. Each scene has 4 objects, each in one of its four views.

b. The bottom up saliency map generated by the GBVS code for one of the scenes. The highest levels in the saliency map are red, and the lowest blue.

c. Rectangles (384x384 pixels) placed around each peak in the scene for which the bottom-up saliency map is illustrated in (b). (Reproduced from Rolls, E.T. and Webb, T.J. (2014) Finding and recognizing objects in natural scenes: complementary computations in the dorsal and ventral visual systems. *Frontiers in Computational Neuroscience* 8: 85.)

capture both behavior and the response of LIP neurons (Goldberg et al., 2006; Bisley and Goldberg, 2003, 2006). Inputs reach LIP via dorsal visual stream areas including area MT, and via V4 in the ventral stream (Miller and Buschman, 2013; Soltani and Koch, 2010). Although top-down attention using biased competition can facilitate the operation of attentional mechanisms, and is a subject of great interest (Desimone and Duncan, 1995; Rolls and Deco, 2002; Deco and Rolls, 2004; Miller and Buschman, 2013), top-down object-based attention makes only a small contribution to visual search in a natural scene for an object, increasing the receptive field size from a radius of approximately 7.8° to approximately 9.6° (Rolls, Aggelopoulos and Zheng, 2003a), and is not considered further here.

In research described by Rolls and Webb (2014) we investigated computationally how a bottom-up saliency mechanism in the dorsal visual stream reaching for example area LIP could operate in conjunction with invariant object recognition performed by the ventral visual stream reaching the inferior temporal visual cortex to provide for invariant object recognition in natural scenes. The hypothesis is that the dorsal visual stream, in conjunction with structures such as the superior colliculus (Knudsen, 2011), uses saliency to guide saccadic eye movements to salient stimuli in large parts of the visual field, and that once a stimulus has been fixated, the ventral visual stream performs invariant object recognition on the region being fixated. The dorsal visual stream in this process knows little about invariant object

recognition, so cannot identify objects in natural scenes. Similarly, the ventral visual stream cannot perform the whole process, for it cannot efficiently find possible objects in a large natural scene, because its receptive fields are only approximately 9° in radius in complex natural scenes. It is how the dorsal and ventral streams work together to implement invariant object recognition in natural scenes that we investigated. By investigating this computationally, we were able to test whether the dorsal visual stream can find objects with sufficient accuracy to enable the ventral visual stream to perform the invariant object recognition. The issue here is that the ventral visual stream has in practice some translation invariance in natural scenes, but this is limited to approximately 9° (Rolls et al., 2003a; Aggelopoulos and Rolls, 2005). The computational reason why the ventral visual stream does not compute translation invariant representations over the whole visual field as well as view, size and rotation invariance, is that the computation is too complex. Indeed, it is a problem that has not been fully solved in computer vision systems when they try to perform invariant object recognition over a large natural scene. The brain takes a different approach, of simplifying the problem by fixating on one part of the scene at a time, and solving the somewhat easier problem of invariant representations within a region of approximately 9° .

For this scenario to operate, the ventral visual stream needs then to implement view-invariant recognition, but to combine it with some translation invariance, as the fixation position produced by bottom up saliency will not be at the centre of an object, and indeed may be considerably displaced from the centre of an object. In the model of invariant visual object recognition that we have developed, VisNet, which models the hierarchy of visual areas in the ventral visual stream by using competitive learning to develop feature conjunctions supplemented by a temporal trace or by spatial continuity or both, all previous investigations have explored either view or translation invariance learning, but not both (Rolls, 2012d). Combining translation and view invariance learning is a considerable challenge, for the number of transforms becomes the product of the numbers of each transform type, and it is not known how VisNet (or any other biologically plausible approach to invariant object recognition) will perform with the large number, and with the two types of transform combined. Indeed, an important part of the research was to investigate how well architectures of the VisNet type generalize between both trained locations and trained views. This is important for setting the numbers of different views and translations of each object that must be trained. Rolls and Webb (2014) described an investigation that takes these points into account, and measured the performance of a model of the dorsal visual system with VisNet to test how the system would perform to implement view-invariant object recognition in natural scenes.

The operation of the dorsal visual system in providing a saliency map that would guide the locations to which visual fixations would occur was simulated with a bottom up saliency algorithm that is one of the standard ones that has been developed, which adopts the Itti and Koch (2000) approach to visual saliency, and implements it by graph-based visual saliency (GBVS) algorithms (Harel, Koch and Perona, 2006a,b). The basis for the saliency map consists of features such as high contrast edges, and the system knows nothing about objects, people, vehicles etc. This system performs well, that is similarly to humans, in many bottom-up saliency tasks. With the scene illustrated in Fig. 2.79a, the saliency map that was produced is illustrated in Fig. 2.79b. The peaks in this saliency map were used as the site of successive ‘fixations’, at each of which a rectangles (of 384×384 pixels) was placed, and was used as the input image to VisNet as illustrated in Fig. 2.79c. VisNet had been trained on four views spaced 45° apart of each of the 4 objects as illustrated in Fig. 2.80.

VisNet was trained on a 25-location grid with size 64×64 with spacing of 16 pixels, and with 4 different views of each object, as it was not expected that the peak of a saliency map would be the centre of an object. Part of the aim was to investigate how much translation invariance needs to be present in the ventral visual system, in the context of where the dorsal

Fig. 2.80 Finding and recognising objects in natural scenes. Training images for the identification of objects in a natural scene: 4 views of each of 4 objects were used. Each image was 256x256 pixels. (Reproduced from Rolls, E.T. and Webb, T.J. (2014) Finding and recognizing objects in natural scenes: complementary computations in the dorsal and ventral visual systems. *Frontiers in Computational Neuroscience* 8: 85.)

visual system found salient regions in a scene. We found that performance was reasonably good, 90% correct where chance was 25% correct, for which object had been shown. That is, even when the fixation was not on the centre of the object, performance was good. Moreover, the performance was good independently of the view of the person or object, showing that in VisNet both view and position invariance can be trained into the system (Rolls and Webb, 2014). Further, the system also generalized reasonably to views between the training views which were 45° apart. Further, this good performance was obtained when inevitably what was extracted as what was close to the fovea included parts of the background scene within the rectangles shown in Fig. 2.79c.

This investigation elucidated how the brain may solve this major computational problem of recognition of multiple objects seen in different views in complex natural scenes, by moving the eyes to fixate close to objects in a natural scene using bottom-up saliency implemented in the dorsal visual system, and then performing object recognition successively for each of the fixated regions using the ventral visual system modelled to have both translation and view invariance in VisNet. The research described by Rolls and Webb (2014) emphasises that because the eyes do not locate the centre of objects based on saliency, then translation invariance as well as view, size etc invariance needs to be implemented in the ventral visual system. The research showed how a model of invariant object recognition in the ventral visual system, VisNet, can perform the required combination of translation and view invariant recognition, and moreover can generalize between views of objects that are 45° apart during training, and can also generalize to intermediate locations when trained in a coarse training grid with the spacing between trained locations equivalent to 1–3°. Part of the utility of this research is that it helps to identify how much translation invariance needs to be incorporated into the ventral visual system to enable object recognition with successive fixations guided by saliency to different positions in a complex natural scene (Rolls and Webb, 2014).

2.8.16 Non-accidental properties, and transform invariant object recognition

Non-accidental properties (NAPs) of images of objects are those that are relatively invariant over rotations in depth, and can be distinguished from metric properties (MPs), such as the

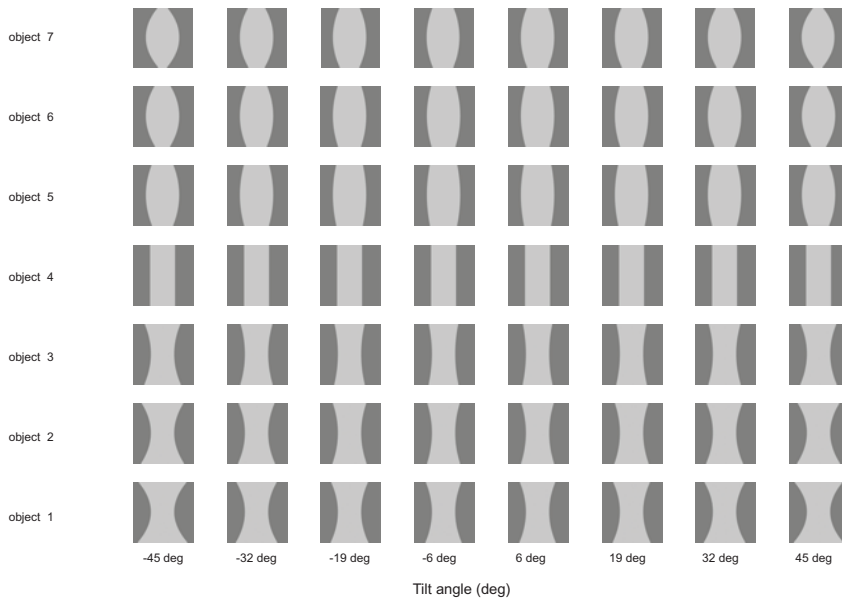

Fig. 2.81 Encoding of non-accidental properties. Stimuli used to investigate non-accidental properties (NAP) vs metric properties (MP). Each object is shown as white on a grey background. Objects 1–3 have the non-accidental property of concave edges. Object 4 has the non-accidental property of parallel edges. Objects 5–7 have the non-accidental property of convex edges. The vertical view of each object was at 0 deg, with the images at -6 and 6 deg of tilt illustrated. Different amounts of tilt of the top towards or away from the viewer are shown at the tilt angles indicated. Each object was thin, and was cut off at the top and bottom to ensure that any view of the top or bottom of the object did not appear, so that the type of curvature of the edges (concave, straight, or convex) was the main cue available. (After Rolls, E. T. and Mills, W.P.C. (2018) Non-accidental properties, metric invariance, and encoding by neurons in a model of ventral stream visual object recognition, *VisNet. Neurobiology of Learning and Memory* 152: 20–31. © Elsevier Ltd.)

aspect ratio of a part or the degree of curvature of a contour, which do vary continuously with rotation in depth (Biederman, 1987), as described next.

It has been proposed that non-accidental properties of objects as they transform into different views are useful for view-invariant object recognition processes, and that metric properties are much less useful (Biederman, 1987; Biederman and Gerhardstein, 1993; Kayaert, Biederman and Vogels, 2005a; Amir, Biederman and Hayworth, 2011; Kayaert, Biederman, Op de Beeck and Vogels, 2005b). Non-accidental properties (NAPs) are relatively invariant over rotations in depth (Biederman, 1987). A NAP is an image property, such as the linearity of a contour or the cotermination of a pair of contours, that is unaffected by rotation in depth, as long the surfaces manifesting that property are still present in the image (Lowe, 1985). NAPs can be distinguished from metric properties (MPs), such as the aspect ratio of a part or the degree of curvature of a contour, which do vary continuously with rotation in depth. There is psychophysical and functional neuroimaging evidence that supports this distinction (Kayaert et al., 2005a; Amir et al., 2011; Kayaert et al., 2005b). In addition, there is evidence that neurons in the lateral occipital cortex and inferior temporal visual cortex of the macaque are tuned more to non-accidental than to metric properties (Kim and Biederman, 2012; Vogels, Biederman, Bar and Lorincz, 2001).

These concepts are illustrated in Fig. 2.81. If we take object 1 as an example (Fig. 2.81), then we can see that it is approximately cylindrical but with concave sides. Its appearance when vertical is at 0 deg (close to the view illustrated of -6 and 6 deg). As the object is tilted towards or away from the viewer, the degree of curvature appears larger. The degree of curvature is thus a metric property (MP) of the object which is not very useful in transform-

invariant object recognition. On the other hand, the fact that object 1 has concave sides is apparent across all these transforms, and therefore is a non-accidental property (NAP) used in identifying an object. This is made evident by a comparison with object 7, which has convex edges, which are always convex through these transforms, while the degree of curvature is a metric property and again varies as a function of the tilt transform. Further, object 4, a cylinder, always has straight sides whatever its tilt, so having straight sides is in this case also a NAP.

We tested VisNet with these sets of stimuli to investigate whether it would learn to represent the three cylinder types based on the non-accidental properties, and would treat the metric properties as transforms, and we found that VisNet did indeed operate in this way (Rolls and Mills, 2018).

Consideration of what is illustrated in Fig. 2.81 leads in fact to a new theory about how Non-Accidental Properties are learned, and how they are relatively invariant with respect to metric changes (Rolls and Mills, 2018; Rolls, 2021d). If we look at object 1, we see that a range of curvatures are shown as the object transforms. These different curvatures are all learned as properties of this class of object by the temporal trace learning rule, because those different views were presented close together in time so that the trace learning rule could learn that these were transforms of the same object. But if we then look at object 2, we see that some of the degrees of curvature in some of its views are similar to what has already been learned for object 1. So without further training of any association between object 1 and object 2, there will be some generalization across these two objects with different degrees of curvature, because some of the degrees of curvature are similar for some of the views of these two objects. *It is in this way, Rolls and Mills (2018) proposed, that non-accidental properties are learned by the brain, and generalize across a range of objects with the same non-accidental property (e.g. concave sides), even though the degree of curvature, the metric property, may be quite different.*

2.9 Further approaches to invariant object recognition

2.9.1 Other types of slow learning

In a more artificial network trained by gradient ascent with a goal function that included forming relatively time invariant representations and decorrelating the responses of neurons within each layer of the 5-layer network, place-like cells were formed at the end of the network when the system was trained with a real or simulated robot moving through spatial environments (Wyss, König and Verschure, 2006), and slowness as an asset in learning spatial representations has also been investigated by others (Wiskott and Sejnowski, 2002; Wiskott, 2003; Franzius, Sprekeler and Wiskott, 2007; Schonfeld and Wiskott, 2015; Weghenkel and Wiskott, 2018). It will be interesting to test whether spatial view cells develop in a VisNet fifth layer if trained with foveate views of the environment, or place cells if trained with wide angle views of the environment (cf. Critchley and Rolls (1996a), and the utility of testing this with a VisNet-like architecture is that it embodies a biologically plausible implementation based on neuronally plausible competitive learning and a short-term memory trace learning rule.

2.9.2 HMAX

A related approach to invariant object recognition is HMAX (Riesenhuber and Poggio, 1999b,a, 2000; Serre, Oliva and Poggio, 2007b; Serre, Wolf, Bileschi, Riesenhuber and Poggio, 2007c),

Fig. 2.82 Sketch of Riesenhuber and Poggio's (1999a,b) HMAX model of invariant object recognition. The model includes layers of 'S' cells which perform template matching (solid lines), and 'C' cells (solid lines) which pool information by a non-linear MAX function to achieve invariance (see text). (After Riesenhuber, H. and Poggio, T. (1999) Hierarchical models of object recognition in cortex. *Nature Neuroscience* 2: 1019–1025. © Springer Nature.)

which builds on the hypothesis that not just shift invariance (as implemented in the Neocognitron of Fukushima (1980)), but also other invariances such as scale, rotation and even view, could be built into a feature hierarchy system such as VisNet (Rolls, 1992a; Wallis, Rolls and Földiák, 1993; Wallis and Rolls, 1997; Rolls and Milward, 2000; Rolls and Stringer, 2006a; Rolls, 2016b, 2012d). HMAX is a feature hierarchy approach that uses alternate 'simple or S cell' and 'complex or C cell' layers in a way analogous to Fukushima (1980) (see Fig. 2.82). The inspiration for this architecture (Riesenhuber and Poggio, 1999b) may have come from the simple and complex cells found in V1 by Hubel and Wiesel (1968).

The function of each S cell layer is to represent more complicated features from the inputs, and works by template matching. In particular, when images are presented to HMAX, a set of firings is produced in a patch of S cells, and this patch is propagated laterally so that the same processing is performed throughout the layer. The use of patches of activity produced by an input image to select synaptic weights for the patch while not typical learning, does mean that the synaptic weights in the network are set up to reflect some effects produced by input images. Learning within the model is performed by sampling patches of the C layer output that are produced by a randomly selected image from the training set, and setting the S neurons that receive from the patch to have the weights that would enable the S neuron to be selective for that patch. Then in forward passes, a C layer set of firings is convolved with the S filters that follow the C layer to produce the next S level activity. The convolution is a non-local operator that acts over the whole C layer and effectively assumes that a given type of S neuron has identical connectivity throughout the spatial extent of the layer.

The function of each ‘C’ cell layer is to provide some translation invariance over the features discovered in the preceding simple cell layer (as in Fukushima (1980)), and operates by performing a MAX function on the inputs. The non-linear MAX function makes a complex cell respond only to whatever is the highest activity input being received, and is part of the process by which invariance is achieved according to this proposal. This C layer process involves ‘implicitly scanning over afferents of the same type differing in the parameter of the transformation to which responses should be invariant (for instance, feature size for scale invariance), and then selecting the best-matching afferent’ (Riesenhuber and Poggio, 1999b). Brain mechanisms by which this computation could be set up are not part of the scheme.

The final complex cell layer (of in some instantiations several S-C pairs of layers) is then typically used as an input to a non-biologically plausible support vector machine or least squares computation to perform classification of the representations of the final layer into object classes. This is a supervised type of training, in which a target is provided from the outside world for each neuron in the last C layer. The inputs to both HMAX and VisNet are Gabor-filtered images intended to approximate V1. One difference is that VisNet is normally trained on images generated by objects as they transform in the world, so that view, translation, size, rotation etc invariant representations of objects can be learned by the network. In contrast, HMAX is typically trained with large databases of pictures of different exemplars of for example hats and beer mugs as in the Caltech databases, which do not provide the basis for invariant representations of objects to be learned, but are aimed at object classification.

Robinson and Rolls (2015) compared the performance of HMAX and VisNet in order to help identify which principles of operation of these two models of the ventral visual system best accounted for the responses of inferior temporal cortex neurons. The aim was to identify which of their different principles of operation might best capture the principles of cortical computation. The outputs of both systems were measured in the same way, with a biologically plausible pattern association network receiving input from the final layer of HMAX or VisNet, and with one neuron for each class to be identified. That is, a non-biologically plausible support vector machine or least squares regression were not used to measure the performance. A standard HMAX model (Mutch and Lowe, 2008; Serre, Wolf, Bileschi, Riesenhuber and Poggio, 2007c; Serre, Oliva and Poggio, 2007b) was used in the implementation by Mutch and Lowe (2008) which has two S-C layers. I note that an HMAX family model has in the order of 10 million computational units (Serre, Oliva and Poggio, 2007b), which is at least 100 times the number contained within the current implementation of VisNet (which uses 128x128 neurons in each of 4 layers, i.e. 65,536 neurons).

First, Robinson and Rolls (2015) tested the performance of both nets on an HMAX type of problem, learning to identify classes of object (e.g. hats vs bears) from a set of exemplars, chosen in this case from the CalTech database. The performance of the nets in terms of percentage correct was similar, but a major difference was that it was found that the final layer C neurons of HMAX have a very non-sparse representation (unlike that in the brain or in VisNet) that provides little information in the single neuron responses about the object class. This highlighted an important principle of cortical computation, that the neuronal representation must be in a form in which it can be read, by for example a pattern association network, which is what the cortex and VisNet achieve by producing a sparse distributed representation.

Second, when trained with different views of each object, HMAX performed very poorly because it has no mechanism to learn view invariance, i.e. that somewhat different images produced by a single object seen in different views are in fact of the same object. In contrast, VisNet learned this well, because its short-term memory trace learning rule enabled the different views of the same object appearing in short time periods to be associated together. This highlighted another important principle of cortical computation, that advantage is taken of

Fig. 2.83 View invariant representations of cups. The two objects, each with four views. HMAX of Riesenhuber and Poggio (1999) fails to categorize these objects correctly, because, unlike VisNet, it has no mechanism to associate together different views of the same object. (After Robinson, L. and Rolls, E. T. (2015) Invariant visual object recognition: biologically plausible approaches. *Biological Cybernetics* 109: 505–535.)

the statistics of inputs from the world to help learning, with in this case temporal and spatial continuity being relevant.

Third, it was shown that VisNet neurons, like many neurons in the inferior temporal visual cortex (Rolls, Tovee, Purcell, Stewart and Azzopardi, 1994b; Perrett, Rolls and Caan, 1982), do not respond to scrambled images of faces, and thus encode shape information. HMAX neurons responded with similarly high rates to the unscrambled and scrambled faces, indicating that low level features including texture may be relevant to HMAX performance. The VisNet and inferior temporal cortex neurons at the same time encoded the identity of the unscrambled faces. Some other neurons in the inferior temporal visual cortex respond to parts of faces such as eyes or mouth (Perrett, Rolls and Caan, 1982; Issa and DiCarlo, 2012), and this is consistent with the hypothesis that the inferior temporal visual cortex builds configuration-specific whole face or object representations from their parts, helped by feature combination neurons learned at earlier stages of the ventral visual system hierarchy (Rolls, 1992a, 2012d, 2021d). HMAX has no learning to enable it to respond to non-linear combinations of features in the correct relative spatial positions (Robinson and Rolls, 2015). This highlights another important principle of cortical architecture, that neurons learn to respond to non-linear combinations of their inputs using processes such as competitive learning (Section B.4), and that this is essential for correct operation of most sensory systems.

Fourth, it was shown that VisNet can learn to recognise objects even when the view provided by the object changes catastrophically as it transforms, whereas HMAX has no learning mechanism in its S-C hierarchy that provides for view-invariant learning. The objects used in the experiment are shown in Fig. 2.83. There were two objects, two cups, each with four views, constructed with Blender. VisNet was trained with all views of one object shown in random permuted sequence, then all views of the other object shown in random permuted sequence, to enable VisNet to use its temporal trace learning rule to learn about the different images that occurring together in time were likely to be different views of the same object. VisNet performed 100% correct in this task by forming neurons in its layer 4 that responded either to all views of one cup (labelled ‘Bill’) and to no views of the other cup (labelled ‘Jane’), or vice versa. HMAX neurons did not discriminate between the objects, but instead responded more to the images of each object that contained text. This dominance by text is consistent with the fact that HMAX is operating to a considerable extent as a set of image filters, the activity in which included much produced by the text. HMAX has no mechanism within its S-C layers that enables it to learn which input images belong to one object vs another, whereas VisNet can solve this computational problem, by using temporal and spatial continuity present in the way that objects are viewed in a natural environment.

These investigations (Robinson and Rolls, 2015) draw out a fundamental difference between VisNet and HMAX. The output layer neurons of VisNet can represent transform-invariant properties of objects, and can form single neurons that respond to the different views of objects even when the images of the different views may be quite different, as is the case for many real-world objects when they transform in the world. Thus basing object recognition on image statistics, and categorisation based on these, is insufficient for transform-invariant object recognition. VisNet can learn to respond to the different transforms of objects using the trace learning rule to capture the properties of objects as they transform in the world. In contrast, HMAX up to the C2 layer sets some of its neurons to respond to exemplars in the set of images, but has no way of knowing which exemplars may be of the same object, and no way therefore to learn about the properties of objects as they transform in the real world, showing catastrophic changes in the image as they transform (Koenderink, 1990), exemplified in the example in experiment 4 by the new views as the objects transform from not showing to showing writing in the base of the cup (Fig. 2.83). Moreover, because the C2 neurons reflect mainly the way in which all the Gabor filters respond to image exemplars, the firing of C2 neurons is typically very similar and non-sparse to different images, though if the images have very different statistics in terms of for example text or not, it is these properties that dominate the firing of the C2 neurons.

For all these reasons, HMAX is ruled out as a model of invariant visual object recognition for further consideration here (Rolls, 2021d).

Further evidence consistent with the approach developed in the investigations of VisNet described in this chapter comes from psychophysical studies. Wallis and Bühlhoff (1999) and Perry, Rolls and Stringer (2006) describe psychophysical evidence for learning of view invariant representations by experience, in that the learning can be shown in special circumstances to be affected by the temporal sequence in which different views of objects are seen.

Some other approaches to biologically plausible invariant object recognition are being developed with hierarchies that may allow unsupervised learning (Pinto, Doukhan, DiCarlo and Cox, 2009; DiCarlo, Zoccolan and Rust, 2012; Yamins, Hong, Cadieu, Solomon, Seibert and DiCarlo, 2014). For example, a hierarchical network has been trained with unsupervised learning, and with many transforms of each object to help the system to learn invariant representations in an analogous way to that in which VisNet is trained, but the details of the network architecture are selected by finding parameter values for the specification of the network structure that produce good results on a benchmark classification task (Pinto et al., 2009). However, formally these are convolutional networks, so that the neuronal filters for one local region are replicated over the whole of visual space, which is computationally efficient but biologically implausible. Further, a general linear model is used to decode the firing in the output level of the model to assess performance, so it is not clear whether the firing rate representations of objects in the output layer of the model are very similar to that of the inferior temporal visual cortex. In contrast, with VisNet (Rolls and Milward, 2000; Rolls, 2012d) the information measurement procedures that we use (Rolls et al., 1997d,b) are the same as those used to measure the representation that is present in the inferior temporal visual cortex (Rolls and Treves, 2011; Tovee et al., 1993; Rolls and Tovee, 1995b; Tovee and Rolls, 1995; Abbott et al., 1996; Rolls et al., 1997b; Baddeley et al., 1997; Rolls et al., 1997d; Treves et al., 1999; Panzeri et al., 1999b; Rolls et al., 2004; Franco et al., 2004; Aggelopoulos et al., 2005; Franco et al., 2007; Rolls et al., 2006b; Rolls, 2012d).

In addition, an important property of inferior temporal cortex neurons is that they convey information about the individual object or face, not just about a class such as face vs non-face, or animal vs non-animal (Rolls and Tovee, 1995b; Rolls, Treves and Tovee, 1997b; Abbott, Rolls and Tovee, 1996; Rolls, Treves, Tovee and Panzeri, 1997d; Baddeley, Abbott, Booth,

Sengpiel, Freeman, Wakeman and Rolls, 1997; Rolls, 2016b; Rolls and Treves, 2011; Rolls, 2011d, 2012d). This key property is essential for recognising a particular person or object, and is frequently not addressed in models of invariant object recognition, which still typically focus on classification into e.g. animal vs non-animal, or classes such as hats and bears from databases such as the CalTech (Serre, Wolf, Bileschi, Riesenhuber and Poggio, 2007c; Serre, Oliva and Poggio, 2007b; Mutch and Lowe, 2008; Serre, Kreiman, Kouh, Cadieu, Knoblich and Poggio, 2007a; Yamins, Hong, Cadieu, Solomon, Seibert and DiCarlo, 2014). It is clear that VisNet has this key property of representing individual objects, faces, etc., as is illustrated in the investigations of Robinson and Rolls (2015), and previously (Rolls and Milward, 2000; Stringer and Rolls, 2000, 2002; Rolls and Webb, 2014; Webb and Rolls, 2014; Stringer, Perry, Rolls and Proske, 2006; Perry, Rolls and Stringer, 2006, 2010; Rolls, 2012d, 2021d). VisNet achieves this by virtue of its competitive learning, in combination with its trace learning rule to learn that different images are of the same object. The investigations of Robinson and Rolls (2015) provide evidence that HMAX categorises together images with similar low level feature properties (such as the presence of text), and does not perform shape recognition relevant to the identification of an individual in which the spatial arrangements of the parts is important.

An important point here is that testing whether networks categorise images into different classes of object is insufficient as a measure of whether a network is operating biologically plausibly (Yamins, Hong, Cadieu, Solomon, Seibert and DiCarlo, 2014), for there are many more criteria that must be satisfied, including many highlighted here, including correct identification of individuals with all the perceptual invariances, operation using combinations of features in the correct spatial configuration, and producing a biologically plausible sparse distributed representation, all without an external teacher for the output neurons (Rolls, 2021d) (cf. Pinto, Cox and DiCarlo (2008), Pinto, Doukhan, DiCarlo and Cox (2009), DiCarlo et al. (2012), Cadieu, Hong, Yamins, Pinto, Ardila, Solomon, Majaj and DiCarlo (2014), and Yamins, Hong, Cadieu, Solomon, Seibert and DiCarlo (2014)). More recently, unsupervised training of deep convolutional neural networks has advanced (Zhuang, Yan, Nayebi, Schrimpf, Frank, DiCarlo and Yamins, 2021), but these still implement convolution and deep learning using non-local learning rules including backpropagation of error to optimize representations, so are still biologically implausible.

These investigations (Robinson and Rolls, 2015) thus highlighted several principles of cortical computation. One is that advantage is taken of the statistics of inputs from the world to help learning, with for example temporal and spatial continuity being relevant. Another is that neurons need to learn to respond to non-linear combinations of their inputs, in the case of vision including their spatial arrangement which is provided by the convergent topology from area to area of the visual cortex. Another principle is that the system must be able to form sparse distributed representations with neurons that encode perceptual and invariance properties, so that the next stage of cortical processing can read the information using dot product decoding as in a pattern associator, autoassociator, or competitive network. None of these properties are provided by HMAX, and all are provided by VisNet, highlighting the importance of these principles of cortical computation (Rolls, 2021d).

2.9.3 Minimal recognizable configurations

Ullman and colleagues have suggested that minimal recognizable configurations (MIRCs) may be building blocks of object and face recognition (Nam et al., 2021; Gruber et al., 2021; Holzinger et al., 2019). This approach is based on empirical investigations which show that some small patches of images can be used to represent how human perception builds up from components. Reducing these components by image cropping or reducing their resolu-

tion leads to different responses. The theory of how the whole system would be computed, and how it would learn invariances, does not appear to be well developed, but the approach is consistent with the feature hierarchy approach used in VisNet.

2.9.4 Hierarchical convolutional deep neural networks

A different approach has been to compare neuronal activity in visual cortical areas with the neurons that are learned in artificial models of object recognition such as hierarchical convolutional deep neural networks (HCNN) (Yamins and DiCarlo, 2016; Rajalingham, Issa, Bashivan, Kar, Schmidt and DiCarlo, 2018). Convolutional networks are described in Section B.14 (see also Section 2.6.5). They involve non-biologically plausible operations such as error backpropagation learning, and copying what has been set up in one part of a layer to all other parts of the same layer (see Section 19.4), which is also a non-local operation. They also require a teacher for each output neuron, which again is biologically implausible (see Section 2.6.5). The parameters of the hierarchical convolutional deep neural network are selected or trained until the neurons in the artificial neural network become similar to the responses of neurons found in the brain. The next step of the argument then seems to need some care. The argument that appears to be tempting (Yamins and DiCarlo, 2016; Rajalingham, Issa, Bashivan, Kar, Schmidt and DiCarlo, 2018) is that because the neurons in the HCNN are similar to those in for example the inferior temporal visual cortex, the HCNN provides a model of how the computations are performed in the ventral visual system. But of course the model has been trained so that its neurons do appear similar to those of real neurons in the brain. So the similarity of the artificial and real neurons is not surprising. What would be surprising is if it were proposed that the HCNN is a model of how the ventral visual stream computes (Yamins and DiCarlo, 2016; Rajalingham, Issa, Bashivan, Kar, Schmidt and DiCarlo, 2018), given that a HCNN with its non-local operation does not appear to be biologically plausible (Section 19.4). VisNet, in contrast, utilises only local information such as the presynaptic and postsynaptic firing rates and a slowly decaying traces of previous activity (that could be implemented by a local attractor network using the recurrent collateral connections), so is a biologically plausible approach to invariant visual object recognition.

As noted above, unsupervised training of deep convolutional neural networks has advanced (Zhuang, Yan, Nayebi, Schrimpf, Frank, DiCarlo and Yamins, 2021), but these networks still implement convolution and deep learning using non-local learning rules including backpropagation of error to optimize representations, so are still biologically implausible.

Importantly, as noted earlier, comparing neurons recorded in the brain with the units found in deep learning algorithms tuned to produce neurons that resemble those in the brain (Cadieu, Hong, Yamins, Pinto, Ardila, Solomon, Majaj and DiCarlo, 2014; Yamins, Hong, Cadieu, Solomon, Seibert and DiCarlo, 2014; Yamins and DiCarlo, 2016; Rajalingham, Issa, Bashivan, Kar, Schmidt and DiCarlo, 2018; Jia, Hong and DiCarlo, 2021; Zhuang, Yan, Nayebi, Schrimpf, Frank, DiCarlo and Yamins, 2021) seems like a poorly founded exercise, for two reasons.

First, the solutions found by deep convolution networks and other machine learning algorithms for image to category mapping may be very different to those found in a system such as the brain that uses only local learning rules and is restricted to only 4–5 layers in the hierarchy.

Second, it is difficult to know what can be learned about how primate including human vision works computationally from deep learning and related machine learning algorithms, given that the understanding of exactly how these machine learning algorithms reach their mapping is almost un-understood, apart from the recipe that makes them work (Plebe and Grasso, 2019).

A different approach is to use unsupervised learning with a spike-timing dependent local synaptic learning rule, with a winner-take-all algorithm, and to transmit spikes, and this is reported to enable features to be extracted that are useful for classification (Ferre, Mamalet and Thorpe, 2018). This has been extended to deep convolutional neural networks for object recognition (Kheradpisheh, Ganjtabesh, Thorpe and Masquelier, 2018).

2.9.5 Sigma-Pi synapses

Another approach to the implementation of invariant representations in the brain is the use of neurons with Sigma-Pi synapses. Sigma-Pi synapses, described in Section A.2.3, effectively allow one input to a synapse to be multiplied or gated by a second input to the synapse. The multiplying input might gate the appropriate set of the other inputs to a synapse to produce the shift or scale change required. For example, the x^c input in Equation A.14 could be a signal that varies with the shift required to compute translation invariance, effectively mapping the appropriate set of x_j inputs through to the output neurons depending on the shift required (Mel, Ruderman and Archie, 1998; Mel and Fiser, 2000; Olshausen, Anderson and Van Essen, 1993, 1995). Local operations on a dendrite could be involved in such a process (Mel, Ruderman and Archie, 1998). The explicit neural implementation of the gating mechanism seems implausible, given the need to multiply and thus remap large parts of the retinal input depending on shift and scale modifying connections to a particular set of output neurons. Moreover, the explicit control signal to set the multiplication required in V1 has not been identified. Moreover, if this was the solution used by the brain, the whole problem of shift and scale invariance could in principle be solved in one layer of the system, rather than with the multiple hierarchically organized set of layers actually used in the brain, as shown schematically in Fig. 2.2. The multiple layers actually used in the brain are much more consistent with the type of scheme incorporated in VisNet. Moreover, if a multiplying system of the type hypothesized by Mel, Ruderman and Archie (1998), Olshausen, Anderson and Van Essen (1993) and Olshausen, Anderson and Van Essen (1995) was implemented in a multilayer hierarchy with the shift and scale change emerging gradually, then the multiplying control signal would need to be supplied to every stage of the hierarchy. A further problem with such approaches is how the system is trained in the first place (Mel et al., 2017).

2.9.6 A principal dimensions approach to coding in the inferior temporal visual cortex

Doris Tsao and colleagues have adopted a principal dimensions approach to what is encoded by neurons in the inferior temporal visual cortex to represent faces and objects (Hesse and Tsao, 2020; Chang and Tsao, 2017; Chang, Egger, Vetter and Tsao, 2021). They started with the face patch system, in which there are a number of face patches distributed from posterior to anterior in the inferior temporal visual cortex with the most anterior in the perirhinal cortex (Tsao, 2014). The more anterior patches have greater invariance, e.g. more view invariance. A descriptive set of 50 measures of face parameters such as the distances between different parts of the face and appearance / texture was used to measure many faces, and then principal components analysis was performed to obtain 25 shape and 25 appearance principal components. When testing many face cells, they found that the neurons were tuned to a subset of the principal component features. In particular, it was found that some neurons had linear responses to one of these principal components, with either a linearly graded ramping increase of firing related to the principal component, or a linearly graded decrease of firing related to the component (Hesse and Tsao, 2020; Chang and Tsao, 2017). Different neurons responded to one of the different principal components. Because this was a linear systems analysis, any

face could be represented by linearly combining all of the relevant principal components each encoded by different neurons. In that way, it was shown that an image of any person's face, and the identity of the person could be encoded by a sample of 205 neurons in the ML-MF and AM inferior temporal visual cortex face patches (Hesse and Tsao, 2020; Chang and Tsao, 2017; Chang et al., 2021).

The approach was extended to other patches of neurons in the inferior temporal visual cortex (Hesse and Tsao, 2020). By using a large number of test stimuli, and again a dimension reduction approach that included AlexNet and principal components analysis, it was found that neurons in patches X1, X2 and X3 encoded for stubby vs spiky objects, with an example of an object low on this 'stubby' dimension a chair with four protruding legs. This was termed an X dimension. Another dimension coded for body parts, such as hands, legs, etc. (Hesse and Tsao, 2020).

By measuring the responses of several hundred inferior temporal visual cortex neurons in different patch types, it was found that many objects / faces / body parts could be reasonably well represented by such neurons, by reconstructing the image from the linear components encoded by the different neurons, in which each neuron encodes one of these principal dimensions (Hesse and Tsao, 2020; Chang et al., 2021). The approach has been described as 'analysis by synthesis' in that the different components are used together ('synthesised') to describe an object, and in that an image of the object being seen can be generated from the neuronal responses. This approach can account for the responses of inferior temporal cortex neurons better than deep learning models, which fail for example because they do not take into account other relevant variables such as illumination (Chang et al., 2021), and perhaps because they overfit the data provided.

A strength of the approach is that this type of principal dimensions representation with linear combinations used to read out the information can work for objects / faces / body parts where continuously variable properties along these dimensions can be used to describe objects.

A possible limitation of this approach is that other information may be needed to specify objects, such as the relative spatial location of the parts, or the number of protruding parts, and how they protrude from objects, to distinguish for example a chair with four legs, from a chair with three legs, from a table with five legs and one protrusion on top such as an umbrella pole. And of course many other dimensions, such as color, and visual texture, that are encoded by inferior temporal cortex neurons, need to be included in the components that are utilised for the encoding. So it is not clear so far that this approach can deal with all that is required for object representation, identification, and description.

Another potential limitation is about how the code is read out not by a scientist who can estimate the weighting of a large number of linearly varying principal components, but by the receiving neurons in brain regions such as the orbitofrontal cortex and hippocampus for which a sparse distributed code is useful so that they can perform associations in the way implemented in pattern association and autoassociation networks (Sections B.2 and B.3). Neurons that respond to possibly non-linear combinations of the linear components advocated in this approach (Hesse and Tsao, 2020) may be useful, and indeed combinations of features that are orthogonal to other combinations can be useful building blocks in feature hierarchies (Section 2.6.6). We found in our information theoretic analyses that the responses of inferior temporal cortex neurons are well suited for the readout by such associative neuronal networks, in that the information about the identity of which face was presented increased linearly with the number of neurons in the population, at least up to reasonable numbers of neurons (Rolls, Treves and Tovee, 1997b; Abbott, Rolls and Tovee, 1996). This shows that the number of face identities that can be decoded from the firing of inferior temporal cortex neurons increases

exponentially with the number of neurons in the population, even with biologically plausible dot-product decoding (Rolls, Treves and Tovee, 1997b; Abbott, Rolls and Tovee, 1996).

Another area needing further exploration is how such a system might be built in the brain. It is possible that competitive networks of the type used in VisNet (Rolls, 2021d), which can help to encode independent components if not principal components, may be part of a solution, it is proposed. Competitive networks do perform a type of dimension reduction (Section B.4). Moreover, competitive networks of the type used in VisNet (Rolls, 2021d) learn to respond to combinations of features such as the relative spatial position of several features that are likely to be key in enabling more details of objects to be represented than in a system using only a restricted set of principal components.

In the inferior temporal cortex patch system, it is also proposed that after an initial forward pass from early visual cortical regions up to the anterior inferior temporal cortex, top-down backprojections to the earlier patches may help to stabilize the system in consistent activity at all levels of the hierarchy or system (Hesse and Tsao, 2020). Exactly this has been proposed as a key function for cortico-cortical top-down backprojections, which can help to bias what is represented at earlier processing stages in a hierarchy to be consistent with a possible high level interpretation (Chapter 11 of Rolls (2016b); see also Sections 4.3.5, 13.6.2, B.3.5 and B.9). This can help with ambiguous figures, such as Necker cubes, and with binocular rivalry, and with degraded scenes such as the Dalmation dog or face example illustrated in Fig. 2.15. In the system proposed for this (Rolls, 2016b), associatively modifiable back-projection top-down synapses may be sufficient to implement this functionality, and are also consistent with using the same synapses for memory recall. In the system considered by Tsao and colleagues (Hesse and Tsao, 2020) it is suggested that there may be repeated forward and backward passes, but in a system of this general type described by Rolls (2016b), the top-down effects can operate continuously in time, and ‘flips’ or alternations between states should only be necessary when there is an alteration of the interpretation. Such an alteration of the high-level interpretation might be caused for example by adaptation of neuronal firing at a high level in the hierarchy, which would then make an alternative account for the bottom-up input emerge from the neuronal noise (in the decision-making mechanism described in this book), to cause a ‘flip’ at first at the high, and then the lower levels, in the hierarchy. This could apply for example in ambiguous figure-ground illusions, or in binocular rivalry.

2.10 Visuo-spatial scratchpad memory, and change blindness

Given the fact that the responses of inferior temporal cortex neurons are quite locked to the stimulus being viewed, it is unlikely that IT provides the representation of the visual world that we think we see, with objects at their correct places in a visual scene. In fact, we do not really see the whole visual scene, as most of it is a memory reflecting what was seen when the eyes were last looking at a particular part of the scene. The evidence for this statement comes from change blindness experiments, which show that humans rather remarkably do not notice if, while they are moving their eyes and cannot respond to changes in the visual scene, a part of the scene changes (O’Regan, Rensink and Clark, 1999; Rensink, 2000, 2014, 2018). A famous example is that in which a baby was removed from the mother’s arms during the subject’s eye movement, and the subject failed to notice that the scene was any different. Similarly, unless we are fixating the location that is different in two alternated versions of a visual scene, we are remarkably insensitive to differences in the scene, such as a glass being present on a dining table in one but not another picture of a dining room. Given then that much of the apparent richness of our visual world is actually based on what was seen at previously fixated

Local attractor networks for a visuo-spatial scratchpad

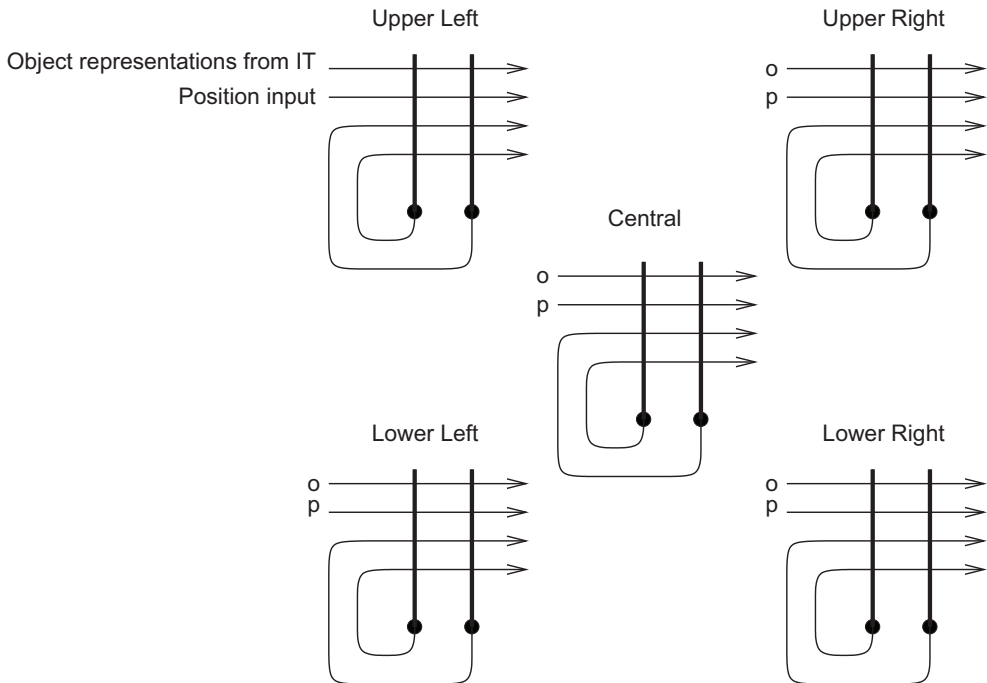

Fig. 2.84 A schematic model of a visuo-spatial scratchpad memory: multiple separate attractor networks could form associations between objects and their place in a scene, and maintain the activity of all the attractors active simultaneously. IT, inferior temporal visual cortex.

positions in the scene (with this being what the inferior temporal visual cortex represents), we may ask where this ‘visuo-spatial’ scratchpad (short-term, iconic, memory) (Rensink, 2014) is located in the brain. One possibility is in the right parieto-occipital area, for patients with lesions in the parieto-occipital region have (dorsal) simultanagnosia, in which they can recognize objects, but cannot see more than one object at a time (Farah, 2004). Alternatively, the network could be in the left inferior temporo-occipital regions, for patients with (ventral) simultanagnosia cannot recognize but can see multiple objects in a scene (Farah, 2004).

The computational basis for this could be a number of separate, that is local, attractors each representing part of the space, and capable of being loaded by inputs from the inferior temporal visual cortex. According to this computational model, the particular attractor network in the visuo-spatial scratchpad memory would be addressed by information based on the position of the eyes, of covert attention, and probably the position of the head. While being so addressed, inputs to the scratch-pad from the inferior temporal cortex neurons would then provide information about the object at the fovea, together with some information about the location of objects in different parafoveal regions (see Section 2.8.10), and this would then enable object information to be associated by synaptic modification with the active neurons in the attractor network representing that location (see Fig. 2.84). Because there are separate spatially local attractors for each location, each of the attractors with its associated object information could be kept active simultaneously, to maintain for short periods information about the relative spatial position of multiple objects in a scene. The attractor for each spatial location would need to represent some information about the object present at that location (as otherwise a binding problem would arise between the multiple objects and the multiple

locations), and this may be a reason why the object information in the visuo-spatial scratchpad is not detailed. The suggestion of different attractors for different regions of the scene is consistent with the architecture of the cerebral neocortex, in which the high density of connections including those of inhibitory interneurons is mainly local, within a range of 1–2 mm (see Section 1.14). (If the inhibitory connections were more widespread, so that the inhibition became more global within the visuo-spatial scratchpad memory, the system would be more like a continuous attractor network with multiple activity packets (Stringer, Rolls and Trappenberg, 2004) (see Section B.5.4).)

It may only be when the inferior temporal visual cortex is representing objects at or close to the fovea in a complex scene that a great deal of information is present about an object, given the competitive processes described in this chapter combined with the large cortical magnification factor of the fovea. The perceptual system may be built in this way for the fundamental reasons described in this chapter (which enable a hierarchical competitive system to learn invariant representations that require feature binding), which account for why it cannot process a whole scene simultaneously. The visual system can, given the way in which it is built, thereby give an output in a form that is very useful for memory systems, but mainly about one or a few objects close to the fovea.

2.11 Different processes involved in different types of object identification

To conclude this chapter, it is proposed that there are (at least) three different types of process that could be involved in object identification. The first is the simple situation where different objects can be distinguished by different non-overlapping sets of features (see Section 2.6.1). An example might be a banana and an orange, where the list of features of the banana might include yellow, elongated, and smooth surface; and of the orange its orange color, round shape, and dimpled surface. Such objects could be distinguished just on the basis of a list of the properties, which could be processed appropriately by a competitive network, pattern associator, etc. No special mechanism is needed for view invariance, because the list of properties is very similar from most viewing angles. Object recognition of this type may be common in animals, especially those with visual systems less developed than those of primates. However, this approach does not describe the shape and form of objects, and is insufficient to account for primate vision. Nevertheless, the features present in objects are valuable cues to object identity, and are naturally incorporated into the feature hierarchy approach.

A second type of process might involve the ability to generalize across a small range of views of an object, that is within a generic view, where cues of the first type cannot be used to solve the problem. An example might be generalization across a range of views of a cup when looking into the cup, from just above the near lip until the bottom inside of the cup comes into view. This type of process includes the learning of the transforms of the surface markings on 3D objects which occur when the object is rotated, as described in Section 2.8.7. Such generalization would work because the neurons are tuned as filters to accept a range of variation of the input within parameters such as relative size and orientation of the components of the features. Generalization of this type would not be expected to work when there is a catastrophic change in the features visible, as for example occurs when the cup is rotated so that one can suddenly no longer see inside it, and the outside bottom of the cup comes into view. VisNet, with its temporal trace learning rule, is able to learn that quite different views may be views of the same object, as illustrated in Section 2.9.2.

The third type of process is one that can deal with the sudden catastrophic change in the features visible when an object is rotated to a completely different view, as in the cup example just given (cf. Koenderink (1990)). Another example, quite extreme to illustrate the point, might be when a card with different images on its two sides is rotated so that one face and then the other is in view. This makes the point that this third type of process may involve arbitrary pairwise association learning, to learn which features and views are different aspects of the same object. Another example occurs when only some parts of an object are visible. For example, a red-handled screwdriver may be recognized either from its round red handle, or from its elongated silver-colored blade. Again, VisNet, with its temporal trace learning rule, is able to learn that quite different views may be views of the same object, as illustrated in Section 2.9.2 (Rolls, 2021d).

The full view-invariant recognition of objects that occurs even when the objects share the same features, such as color, texture, etc. is an especially computationally demanding task which the primate visual system is able to perform with its highly developed temporal lobe cortical visual areas. The neurophysiological evidence and the neuronal networks described in this chapter provide clear hypotheses about how the primate visual system may perform this object recognition task in which shape is important, and which is the major computation performed by the ventral visual stream described in this chapter (Rolls, 2021d).

2.12 Top-down attentional modulation is implemented by biased competition

Top-down modulation of visual and other processing by attention is probably implemented by biased competition. In top-down selective attention, a short-term memory holds online what is to be attended to, for example in vision the location or the object that is the target of attention. This short-term memory is used to bias neurons at earlier stages of processing to help them to respond to competing locations or competing objects on the visual field.

In more detail, the **biased competition hypothesis** of attention proposes that multiple stimuli in the visual field activate populations of neurons that engage in competitive interactions. Attending to a stimulus at a particular location or with a particular feature biases this competition in favour of neurons that respond to the feature or location of the attended stimulus. This attentional effect is produced by generating signals in cortical areas outside the visual cortex that are then fed back (or down) to extrastriate areas, where they bias the competition such that when multiple stimuli appear in the visual field, the neurons representing the attended stimulus ‘win’, thereby suppressing neurons representing distracting stimuli (Duncan and Humphreys, 1989; Desimone and Duncan, 1995; Duncan, 1996).

A modern neuronal network diagram of how the biased competition theory of attention operates is provided in Fig. 2.85 (Rolls, 2016b). There is usually a single attractor network that can enter different attractor states to provide the source of the top-down bias (as shown). If it is a single network, there can be competition within the short-term memory attractor states, implemented through the local GABA inhibitory neurons. The top-down continuing firing of one of the attractor states then biases in a top-down process some of the neurons in a ‘lower’ cortical area to respond more to one than the other of the bottom-up inputs, with competition implemented through the GABA inhibitory neurons (symbolized by a filled circle) that make feedback inhibitory connections onto the pyramidal cells (symbolized by a triangle) in the ‘lower’ cortical area.

We have seen in Fig. 2.85 how given forward (bottom-up) inputs to a network, competition between the principal (excitatory) neurons can be implemented by inhibitory neurons

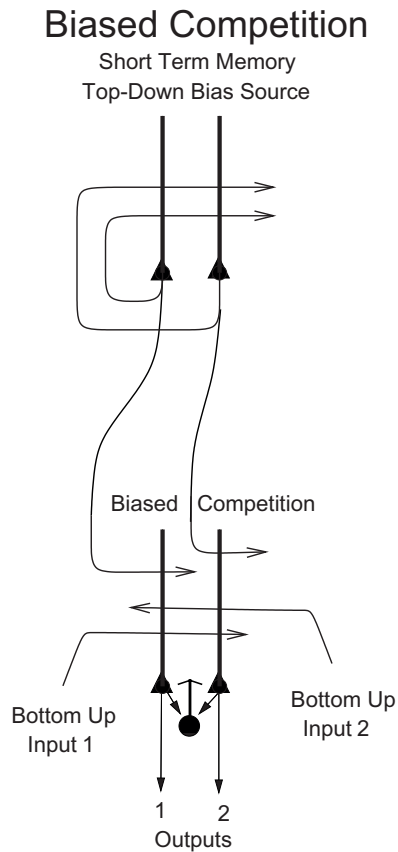

Fig. 2.85 Biased competition mechanism for top-down attention. There is usually a single attractor network that can enter different attractor states to provide the source of the top-down bias (as shown). If it is a single network, there can be competition within the short-term memory attractor states, implemented through the local GABA inhibitory neurons. The top-down continuing firing of one of the attractor states then biases in a top-down process some of the neurons in a cortical area to respond more to one than the other of the bottom-up inputs, with competition implemented through the GABA inhibitory neurons (symbolized by a filled circle) which make feedback inhibitory connections onto the pyramidal cells (symbolized by a triangle) in the cortical area. The thick vertical lines above the pyramidal cells are the dendrites. The axons are shown with thin lines and the excitatory connections by arrow heads. (After Rolls, E. T. (2013) A biased activation theory of the cognitive and attentional modulation of emotion. *Frontiers in Human Neuroscience* 7: 74.)

which receive from the principal neurons in the network and send back inhibitory connections to the principal neurons in the network. This competition can be biased by a top-down input to favour some of the populations of neurons, and this describes the biased competition hypothesis.

The implementation of biased competition in a computational model can be at the mean-field level, in which the average firing rate of each population of neurons is specified. Equations to implement the dynamics of such a model are given in Section B.8.4. The advantages of this level of formulation are relative simplicity, and speed of computation. The architecture of Fig. B.38 is that of a competitive network (described in Section B.4) but with top-down backprojections as illustrated in Fig. B.19. However, the network could equally well include associatively modifiable synapses in recurrent collateral connections between the excitatory (principal) neurons in the network, making the network into an autoassociation or attractor network capable of short-term memory, as described in Section B.3. The competition between the neurons in the attractor network is again implemented by the inhibitory feedback neurons.

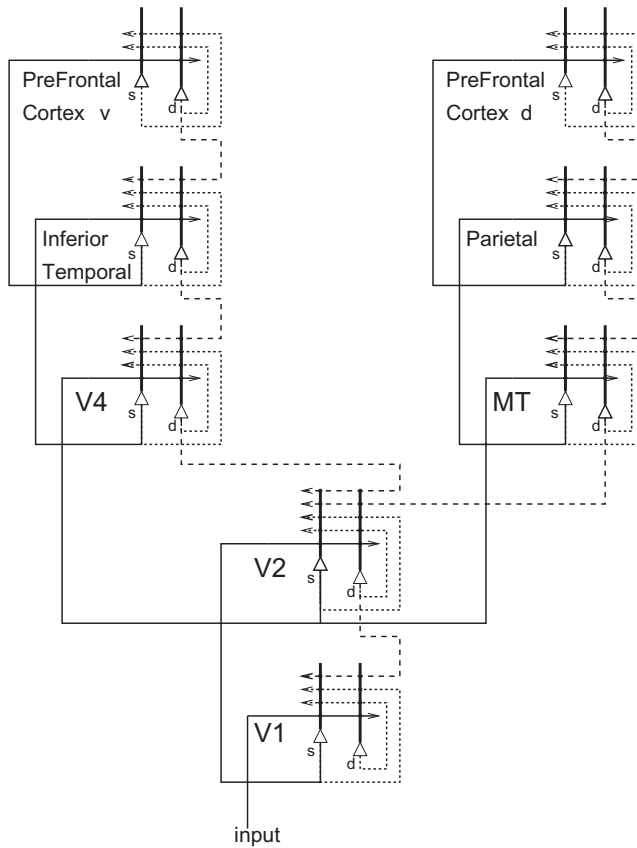

Fig. 2.86 The overall architecture of the model of object and spatial processing and attention, including the prefrontal cortical areas that provide the short-term memory required to hold the object or spatial target of attention active. Forward connections are indicated by solid lines; backprojections, which could implement top-down processing, by dashed lines; and recurrent connections within an area by dotted lines. The triangles represent pyramidal cell bodies, with the thick vertical line above them the dendritic trees. The cortical layers in which the cells are concentrated are indicated by s (superficial, layers 2 and 3) and d (deep, layers 5 and 6). The prefrontal cortical areas most strongly reciprocally connected to the inferior temporal cortex 'what' processing stream are labelled v to indicate that they are in the more ventral part of the lateral prefrontal cortex, area 46, close to the inferior convexity in macaques. The prefrontal cortical areas most strongly reciprocally connected to the parietal visual cortical 'where' processing stream are labelled d to indicate that they are in the more dorsal part of the lateral prefrontal cortex, area 46, in and close to the banks of the principal sulcus in macaques (see text). (After Deco, G. and Rolls, E. T. (2004) A neurodynamical cortical model of visual attention and invariant object recognition. *Vision Research* 44: 621–644.)

The implementation can also be at the level of the spiking neuron by using an integrate-and-fire simulation (see Section B.6). The integrate-and-fire level allows single neuron findings to be modelled, allows more details of the neuronal implementation to be incorporated, and also allows statistical effects related to the probability that spikes from different neurons will occur at different times to be investigated. Integrate-and-fire simulations are more difficult to set up, and are slow to run. Equations for such simulations are given in Section B.6, and as applied to a biased competition model of attention by Deco and Rolls (2004).

The computational investigations can be extended to systems with many interacting modules, as described in Section B.8.5.

Using these approaches, Deco and Rolls (2004) described a cortical model of visual attention for object recognition and visual search with the architecture illustrated in Fig. 2.86. The model has been extended to the level of spiking neurons which allows biophysical properties of the ion channels affected by synapses, and of the membrane dynamics, to be incorporated,

and shows how the non-linear interactions between bottom-up effects (produced for example by altering stimulus contrast) and top-down attentional effects can account for neurophysiological results in areas MT and V4 (Deco and Rolls, 2004). Many further applications of these biased competition computational approaches to understanding attention have been described in Chapter 6 of Rolls (2016b), and we have produced a mathematical analysis of the operation of biased competition for a simple network (Turova and Rolls, 2019).

2.13 Highlights on how the computations are performed in the ventral visual system

1. We have seen in this chapter that the feature hierarchy approach has a number of advantages in performing object recognition over other approaches (see Section 2.6), and that some of the key computational issues that arise in these architectures have solutions (see Sections 2.7 and 2.8). The neurophysiological and computational approach taken here focuses on a feature hierarchy model in which invariant representations can be built by self-organizing learning based on the statistics of the visual input.
2. The model can use temporal continuity in an associative synaptic learning rule with a short-term memory trace, and/or it can use spatial continuity in Continuous Spatial Transformation learning.
3. The model of visual processing in the ventral cortical stream can build representations of objects that are invariant with respect to translation, view, size, spatial frequency, and lighting.
4. The model uses a feature combination neuron approach with the relative spatial positions of the objects specified in the feature combination neurons, and this provides a solution to the binding problem.
5. The model has been extended to provide an account of invariant representations in the dorsal visual system of the global motion produced by objects such as looming, rotation, and object-based movement (Section 3.3).
6. The model has been extended to incorporate top-down feedback connections to model the control of attention by biased competition in for example spatial and object search tasks (see further Section 2.12).
7. The model has also been extended to account for how the visual system can select single objects in complex visual scenes, how multiple objects can be represented in a scene, and how invariant representations of single objects can be learned even when multiple objects are present in the scene.
8. The model has also been extended to account for how the visual system can select multiple objects in complex visual scenes using a simulation of saliency computations in the dorsal visual system, and then with fixations on the salient parts of the scene perform view-invariant visual object recognition using the simulation of the ventral visual stream, VisNet.
9. It has also been suggested in a unifying proposal that adding a fifth layer to the model and training the system in spatial environments will enable hippocampus-like spatial view neurons or place cells to develop, depending on the size of the field of view (Section 9.3.12).
10. We have thus seen how many of the major computational issues that arise when formulating a theory of object recognition in the ventral visual system (such as feature binding, invariance learning, the recognition of objects when they are in cluttered natural scenes, the representation of multiple objects in a scene, and learning invariant representations of

single objects when there are multiple objects in the scene), could be solved in the cortex, with tests of the hypotheses performed by simulations that are consistent with complementary neurophysiological results.

11. The approach described in this chapter is unifying in a number of ways. First, a set of simple organizational principles involving a hierarchy of cortical areas with convergence from stage to stage, and competitive learning using a modified associative learning rule with a short-term memory trace of preceding neuronal activity, provide a basis for understanding much processing in the ventral visual stream, from V1 to the inferior temporal visual cortex. Second, the same principles help to understand some of the processing in the dorsal visual stream by which invariant representations of the global motion of objects may be formed. Third, the same principles continued from the ventral visual stream onwards to the hippocampus help to show how spatial view and place representations may be built from the visual input. Fourth, in all these cases, the learning is possible because the system is able to extract invariant representations because it can utilize the spatio-temporal continuities and statistics in the world that help to define objects, moving objects, and spatial scenes. Fifth, a great simplification and economy in terms of brain design is that the computational principles need not be different in each of the cortical areas in these hierarchical systems, for some of the important properties of the computations in these systems to be performed.
12. The principles of brain computation that are illustrated include the following:

One is that advantage is taken of the statistics of inputs from the world to help learning, with for example temporal and spatial continuity being relevant.

Another is that neurons need to learn to respond to non-linear combinations of their inputs, in the case of vision including their spatial arrangement which is provided by the convergent topology from area to area of the visual cortex, using principles such as competitive learning.

Another principle is that the system must be able to form sparse distributed representations with neurons that encode perceptual and invariance properties, so that the next stage of cortical processing can read the information using dot product decoding as in a pattern associator, autoassociator, or competitive network.

Another principle is the use of hierarchical cortical computation with convergence from stage to stage, which breaks the computation down into neuronally manageable computations.

Another principle is breaking the computation down into manageable parts, by for example not trying to analyze the whole of a scene simultaneously, but instead using successive fixations to objects in different parts of the scene, and maintaining in short-term memory a limited representation of the whole scene.

13. Comparing neurons recorded in the brain with the units found in deep learning algorithms tuned to produce neurons that resemble those in the brain (Cadieu, Hong, Yamins, Pinto, Ardila, Solomon, Majaj and DiCarlo, 2014; Yamins, Hong, Cadieu, Solomon, Seibert and DiCarlo, 2014; Yamins and DiCarlo, 2016; Rajalingham, Issa, Bashivan, Kar, Schmidt and DiCarlo, 2018; Jia, Hong and DiCarlo, 2021; Zhuang, Yan, Nayebi, Schrimpf, Frank, DiCarlo and Yamins, 2021) seems like a poorly founded exercise, for two reasons. First,

the solutions found by deep convolution networks and other machine learning algorithms for image to category mapping may be very different to those found in a system such as the brain that uses only local learning rules and is restricted to only 4–5 layers in the hierarchy. Second, it is difficult to know what can be learned about how primate including human vision works computationally from deep learning and related machine learning algorithms, given that the understanding of exactly how these machine learning algorithms reach their mapping is almost un-understood, apart from the recipe that makes them work (Plebe and Grasso, 2019).

14. The primate including human ventral visual system is very different to that of rats and mice, partly because of the fovea which simplifies the major computational problem of good invariant visual object including shape recognition by limiting the process to what is at the high resolution fovea, which is usually one or a very few objects, and not the whole scene at any one time. Moreover, the primate including human ventral visual system has a hierarchy of processing into the large temporal lobe, with specialized populations of neurons for different categories, including faces. Moreover, the primate visual system requires a whole set of specializations for moving the eyes to foveate an object, and also to track a moving object such as a hand that is about to pick up an object. These factors result in the rodent visual system being a poor model of the primate including human visual system.
15. In conclusion, we have seen in this chapter how a major form of perception, the invariant visual recognition of objects, involves not only the storage and retrieval of information, but also major computations to produce invariant representations. Once these invariant representations have been formed, they are used for many processes including not only recognition memory (see Section 9.2.7), but also associative learning of the rewarding and punishing properties of objects for emotion and motivation (see Chapter 11), the memory for the spatial locations of objects and rewards (see Chapter 9), the building of spatial representations based on visual input (Section 9.3.12), and as an input to short-term memory (Section 13.6.1), attention (Chapter 13), and decision systems (Section 11.5.1).
16. A tutorial version of VisNet written in Matlab is described in Section D.6, and is made available as part of the publication of this book at <https://www.oxcns.org>.

3 The dorsal visual system

3.1 Introduction, and overview of the dorsal cortical visual stream

The ‘dorsal’ or ‘where’ or ‘action’ visual processing stream shown in Figs. 3.1, 1.8, 2.3 and 3.12 is that from V1 to MT, MST and then to the parietal cortex (Ungerleider, 1995; Ungerleider and Haxby, 1994; Rolls and Deco, 2002; Perry and Fallah, 2014; Rolls et al., 2023e). This ‘dorsal’ pathway for primate (including human) vision is involved in representing where stimuli are relative to the individual (i.e. in egocentric space), and the motion of these stimuli, and in performing actions on objects at these locations in space (Gallivan and Goodale, 2018; Rolls et al., 2023e,d). Neurons here respond, for example, to stimuli in visual space around

Fig. 3.1 Lateral view of the macaque brain showing the connections in the ‘dorsal or where visual pathway’ from V1 to V2, MST, LIP, VIP, and parietal cortex area 7a, with some connections then reaching the dorsolateral prefrontal cortex. ip - intraparietal sulcus; LIP - lateral intraparietal area; VIP - ventral intraparietal area; FEF - frontal eye field. Other abbreviations: as, arcuate sulcus; cal, calcarine sulcus; cs, central sulcus; lf, lateral (or Sylvian) fissure; lun, lunate sulcus; ps, principal sulcus; io, inferior occipital sulcus; ip, intraparietal sulcus (which has been opened to reveal some of the areas it contains); sts, superior temporal sulcus (which has been opened to reveal some of the areas it contains). AIT, anterior inferior temporal cortex; FST, visual motion processing area; LIP, lateral intraparietal area; MST, visual motion processing area; MT, visual motion processing area (also called V5); OFC, orbitofrontal cortex; PIT, posterior inferior temporal cortex; STP, superior temporal plane; TA, architectonic area including auditory association cortex; TE, architectonic area including high order visual association cortex, and some of its subareas TEa and TEem; TG, architectonic area in the temporal pole; V1–V4, visual areas 1–4; VIP, ventral intraparietal area; TEO, architectonic area including posterior visual association cortex. The numbers refer to architectonic areas, and have the following approximate functional equivalence: 1, 2, 3, somatosensory cortex (posterior to the central sulcus); 4, motor cortex; 5, superior parietal lobule; 7a, inferior parietal lobule, visual part; 7b, inferior parietal lobule, somatosensory part; 6, lateral premotor cortex; 8, frontal eye field; 12, inferior convexity prefrontal cortex; 46, dorsolateral prefrontal cortex.

Fig. 3.2 The aperture problem. A large grating moving in three different directions can produce the same physical stimulus when viewed with a small circular aperture, so that the direction of motion within the aperture appears in all three cases to be the same, in this case at right angles to the grating orientation. (After Rolls, E. T. and Deco, G. (2002) *Computational Neuroscience of Vision*. Oxford University Press: Oxford.)

the individual, including the distance from the observer, and also respond to optic flow or to moving stimuli. Outputs of this system control eye movements to visual stimuli (both slow pursuit and saccadic eye movements). These outputs proceed partly via the frontal eye fields, which then project to the striatum, and then via the substantia nigra reach the superior colliculus (Goldberg and Walker, 2013; Sendhilnathan, Basu, Goldberg, Schall and Murthy, 2021). Other outputs of these dorsal visual system regions are to the dorsolateral prefrontal cortex, area 46, which is important as a short-term memory for where fixation should occur next, as shown by the effects of lesions to the prefrontal cortex on saccades to remembered targets, and by neuronal activity in this region (Goldman-Rakic, 1996; Passingham, 2021). The dorsolateral prefrontal cortex short-term memory systems in area 46 with spatial information received from the parietal cortex plays an important role in attention, by holding on-line the target being attended to, as described in Chapter 13.

Some neurons in the dorsal visual system respond to object-based motion (not to retinal optic flow), and mechanisms for this computation are described in Section 3.3.

A key feature of the dorsal visual system is that the representations start in retinal coordinates, but a coordinate transform takes place to head-based coordinates, which is useful for the interface to sound direction, which is in head-based coordinates.

After this in the hierarchy, a transform to world-based, or allocentric, coordinates, occurs in parietal cortex areas, and this is useful for idiothetic (self-motion) update of spatial view cells in the hippocampal system via the projections from the dorsal visual stream to the parahippocampal gyrus (Rolls, 2020b; Rolls et al., 2023e,d; Rolls, 2023c).

These spatial coordinate transforms up through the parietal cortex are implemented by gain modulation, probably assisted by a trace learning rule as new representations with invariance in a different coordinate system are being computed, as described in Sections 3.4 and 3.5. Other coordinate transforms are also implemented, for example into arm reaching coordinates, useful for actions to locations in space involving dorsal stream connectivity to the parietal cortex (Rolls et al., 2023d), described further in Chapter 10.

3.2 Global motion in the dorsal visual system

The motion or ‘where’ or ‘magnocellular’ pathway (see Fig. 2.4) starts in the M-type ganglion cells of the retina which project through the magnocellular (M) layers of the lateral geniculate nucleus to layer 4C α in V1, from there to layer 4B, then to the thick stripes of V2, then both directly and through V3 on to MT (V5), and finally from there to area MST (V5a) in the parietal cortex. The retinal M-type ganglion cells are not motion sensitive, but they respond more rapidly to change in stimulation than P-type cells, they are strongly sensitive to contrast and contrast variation, have large receptive fields, and have low spatial resolution. These make

M-type retinal ganglion cells specially suitable for pre-processing for motion. In the primary visual cortex (V1), some neurons are selective to a particular direction of motion.

In areas MT and MST, motion processing is further elaborated. Neurons in these areas show high selectivity to direction of motion and speed. In particular, Movshon and his colleagues (Movshon, Adelson, Gizzi and Newsome, 1985) found that there are two different types of motion-sensitive neurons in area MT: component direction-selective neurons, and (global) pattern direction-selective neurons. Component direction-selective neurons are similar to motion-sensitive neurons in V1, in the sense that they respond only to motion perpendicular to their axis of orientation. Thus, their responses provide information about only one-dimensional local components of motion of a global pattern or object, which of course can be ambiguous with respect to the real state of global motion of the whole pattern. This ambiguity can be understood by considering the so-called aperture problem. Figure 3.2 shows this phenomenon.

A large grating moving in three different directions can produce the same physical stimulus when viewed through a small circular aperture (or by the small receptive field of a neuron), so that the direction of motion within the aperture appears in all three cases to be the same. Movshon and his colleagues used a similar set up for distinguishing the detection of global motion versus component motion. They used plaid images, produced by overlapping two moving gratings (see Fig. 3.3), which make the aperture problem explicit. The global motion of the plaid pattern is different from the motion of the two component gratings. The responses of V1 neurons, and of component direction-selective neurons in MT, detect only the motion of each grating component and not the global motion of the plaid.

Movshon, Adelson, Gizzi and Newsome (1985) found that a small population of neurons in MT (about 20%), which they called pattern direction-selective neurons, responds to the perceived global motion of the plaid. These neurons integrate information about two- (or three-) dimensional global object motion by combining the output responses of component direction-selective neurons, for example of V1 neurons that extract just the motion of the components in different one-dimensional directions.

Further, Newsome, Britten and Movshon (1989) demonstrated experimentally that the responses of MT motion-sensitive neurons correlate with the perceptual judgements about motion performed by a monkey that has to report the direction of motion in a random dot display.

The implication of these findings is that the aperture problem is solved in MT primarily by summing motion direction-selective V1 afferents to produce larger receptive fields (Zaharia, Goris, Movshon and Simoncelli, 2019). The presence of a hierarchy in the dorsal visual system with convergence from stage to stage to generate larger receptive fields is a key part of the organisation that enables new representations to be formed, in a way similar to that implemented in the ventral visual stream.

These results are consistent with neuropsychological evidence on human motion perception. Zihl, Von Cramon and Mai (1983) described a patient with damage in an extrastriate brain region homologous to the MT and MST areas of monkeys who was unable to perceive motion. She reported that the world appeared to her as a series of frozen snapshots. Her primary visual cortex was intact, and this was the reason why she was able to detect simple one-dimensional motion in the plane, but unable to integrate this information to infer global motion.

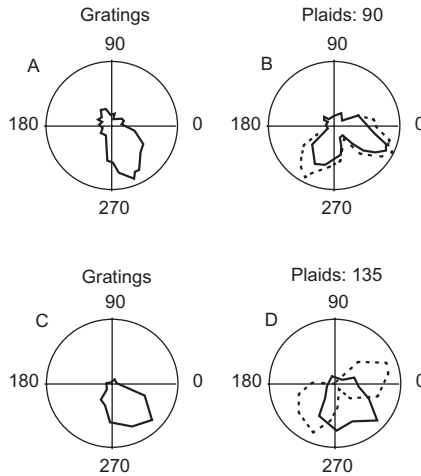

Fig. 3.3 Directional selectivity of component direction-selective neurons and (global) pattern direction-selective neurons in area MT to single versus plaid gratings. The combination of two gratings to produce a single plaid showing global motion is shown in the top part of the diagram. (A) Polar graph of a component direction-selective neuron responding to a single grating moving in different directions. (B) Polar graph of the same component direction-selective neuron responding to a plaid grating (solid line), together with how it should respond if it was responding to each single component (dashed line). (C) and (D) the same as (A) and (B) but for a pattern (or global) direction-selective neuron. (Reproduced from Movshon, J.A., Adelson, E.H., Gizzi, M.S. and Newsome, W.T. (1985) *The analysis of moving visual patterns*. In Chagas, C., Gattass, R. and Gross, C. (eds.) *Pattern Recognition Mechanisms*. Experimental Brain Research Series : 117–151. © Springer Nature.)

3.3 Invariant object-based motion in the dorsal visual system

A key issue in understanding the cortical mechanisms that underlie motion perception is how we perceive the motion of objects such as a rotating wheel invariantly with respect to position on the retina, and size. For example, we perceive the wheel shown in Fig. 3.4a rotating clockwise independently of its position on the retina. This occurs even though the local motion for the wheels in the different positions may be opposite. How could this invariance of the visual motion perception of objects arise in the visual system?

Invariant motion representations are known to be developed in the cortical dorsal visual system. Motion-sensitive neurons in V1 have small receptive fields (in the range 1–2 deg at the fovea), and can therefore not detect global motion, and this is part of the aperture problem. Neurons in MT, which receives inputs from V1 and V2 (see Fig. 2.3), have larger receptive fields (e.g. 5 degrees at the fovea), and are able to respond to planar global motion (Movshon et al., 1985; Newsome et al., 1989). One example is a field of small dots in which the majority (in practice as few as 55%) move in one direction. Another example is the overall direction of a moving plaid, the orthogonal grating components of which have motion at 45 degrees to the overall motion. Further on in the dorsal visual system, some neurons in macaque visual area MST (but not MT) respond to rotating flow fields or looming with considerable translation

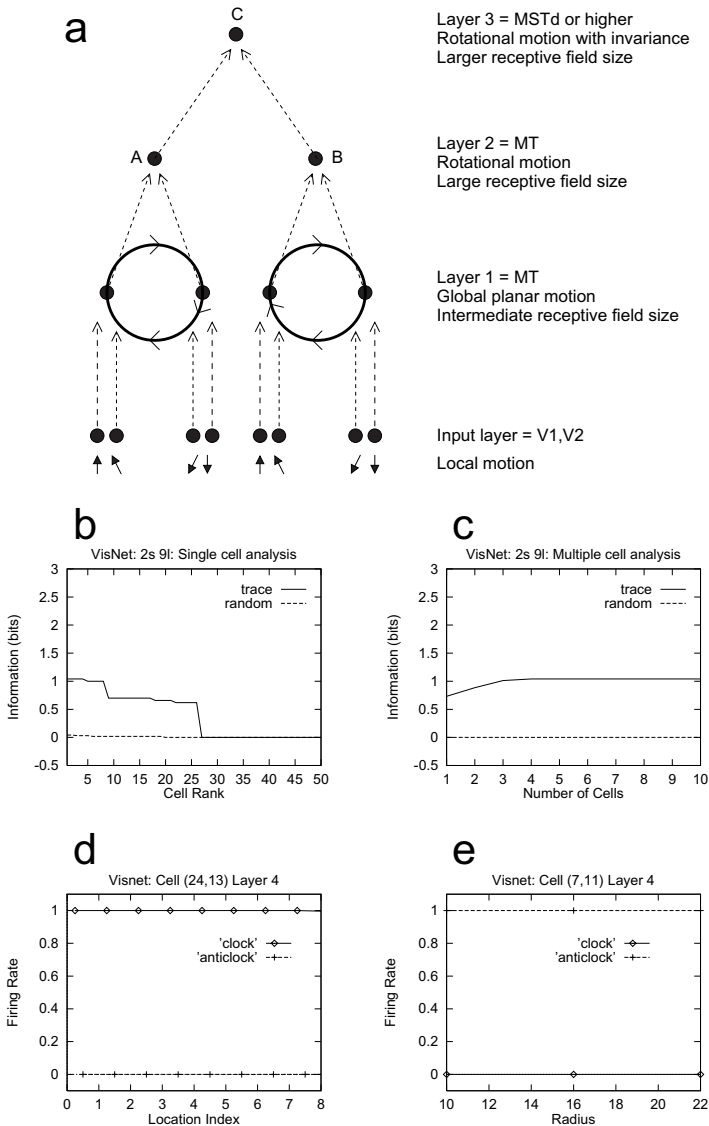

Fig. 3.4 Invariant global motion in the dorsal visual system. (a) Two rotating wheels at different locations rotating in opposite directions. The local flow field is ambiguous. Clockwise or counterclockwise rotation can only be diagnosed by a global flow computation, and it is shown how the network is expected to solve the problem to produce position invariant global motion-sensitive neurons. One rotating wheel is presented at any one time, but the need is to develop a representation of the fact that in the case shown the rotating flow field is always clockwise, independently of the location of the flow field. (b–d) Translation invariance, with training on 9 locations. (b) Single cell information measures showing that some layer 4 neurons have perfect performance of 1 bit (clockwise vs anticlockwise) after training with the trace rule, but not with random initial synaptic weights in the untrained control condition. (c) The multiple cell information measure shows that small groups of neurons have perfect performance. (d) Position invariance illustrated for a single cell from layer 4, which responded only to the clockwise rotation, and for every one of the 9 positions. (e) Size invariance illustrated for a single cell from layer 4, which after training with three different radii of rotating wheel, responded only to anticlockwise rotation, independently of the size of the rotating wheels. (After Rolls, E. T. and Stringer, S.M. (2007) Invariant global motion recognition in the dorsal visual system: a unifying theory. *Neural Computation* 19: 139–169. © MIT.)

invariance (Graziano et al., 1994; Geesaman and Andersen, 1996; Mineault et al., 2012), with MST especially involved in the representation of object motion in the visual field (Galletti and Fattori, 2018).

In the cortex in the anterior part of the superior temporal sulcus, which is a convergence zone for inputs from the ventral and dorsal visual systems, some neurons respond to object-based motion, for example to a head rotating clockwise but not anticlockwise, independently of whether the head is upright or inverted which reverses the optic flow across the retina (Hasselmo, Rolls, Baylis and Nalwa, 1989b) (see Section 2.4.6 and Fig. 2.12).

In a unifying hypothesis with the design of the ventral cortical visual system about *how* this might be computed, Rolls and Stringer (2006a) proposed that the dorsal visual system uses a hierarchical feedforward network architecture (V1, V2, MT, MSTd, parietal cortex) with training of the connections with a short-term memory trace associative synaptic modification rule to capture what is invariant at each stage. The principle is illustrated in Fig. 3.4a. Simulations showed that the proposal is computationally feasible, in that invariant representations of the motion flow fields produced by objects self-organize in the later layers of the architecture (see examples in Fig. 3.4b–e). The model produces invariant representations of the motion flow fields produced by global in-plane motion of an object, in-plane rotational motion, and looming vs receding of the object. The model also produces invariant representations of object-based rotation about a principal axis, of the type illustrated in Fig. 2.12 on page 71. Thus it is proposed that the dorsal and ventral visual systems may share some unifying computational principles (Rolls and Stringer, 2006a). Indeed, the simulations of Rolls and Stringer (2006a) used a standard version of VisNet, with the exception that instead of using oriented bar receptive fields as the input to the first layer, local motion flow fields provided the inputs.

The interesting and quite original principle proposed is that some of the same mechanisms including trace rule learning and hierarchical organisation that are used in the ventral visual system to compute invariant representations of stationary objects may also be used in the dorsal visual system to compute representations of the global motion of a moving object (Rolls and Stringer, 2006a; Rolls, 2021d).

This may well be an example of a *principle of cortical operation: the re-use of the same principles of cortical operation for different computations in different cortical areas.*

3.4 What is computed in the dorsal visual system: visual coordinate transforms

The dorsal visual system starts with representations that are in retinal coordinates. But to represent a position in space where we might wish to remember an object, it would be better if the representation was in world coordinates, so that we could remember that position in space even if we saw it later with a different eye position, or a different head direction, or indeed from a different place. There might be something valuable at that position in world space, and it would be highly non-adaptive if we could only remember that place in space with the original eye position, head direction, and from the same place. (Eye position refers to the angle of the eye in the head in the horizontal and vertical plane – looking left vs right, or up vs down. World coordinates for places are termed allocentric, meaning ‘other-centred’, to contrast them with egocentric coordinates, which are coordinates relative to the body or head. Another, perhaps better term for world based coordinates is ‘exocentric’, where exo is from the Greek word meaning ‘outside’, which captures the idea that the representation is not in ego or self-centred coordinates, but in outside-centred or world coordinates.) The top of the dorsal visual system, which we can identify as parietal area 7a in Fig. 3.1, has connections

Fig. 3.5 Gain modulation of retinal position by eye position to produce a head-centered representation. The eye position (ep) is the angle between straight ahead with respect to the head (indicated by the green line labelled head reference) and the direction of the eye (indicated by the black arrow labelled ep). A direction in head-centered space (labelled hc) is represented by all combinations of retinal position (rp) and eye position that reach a given head-centered direction indicated by the red arrow tip, with one combination of eye position and retinal position shown. This coordinate transform may be computed by gain modulation of retinal position by eye position. (After Rolls, E. T. (2020) Spatial coordinate transforms linking the allocentric hippocampal and egocentric parietal primate brain systems for memory, action in space, and navigation. *Hippocampus* 30: 332–353.)

via areas such as the retrosplenial cortex (RSC) and posterior cingulate cortex (PCC) into the hippocampal system (Fig. 9.1), where it has been shown that visual space is represented in primates in allocentric coordinates (Georges-François, Rolls and Robertson, 1999; Rolls and Xiang, 2006; Rolls, 2016b; Rolls and Wirth, 2018; Rolls, 2023c), as described in Chapter 9. There is evidence that the computations in the dorsal visual system involve a series of coordinate transforms from retinal towards allocentric visual coordinates, to provide inputs to the hippocampal system. En route, other coordinate transforms are also computed, into for example a space suitable for directing arm movements to locations in egocentric space, relative to the body. One situation in which coordinate transforms are required is in reaching for targets relative to visual landmarks, in which allocentric information must be transformed into egocentric information to implement the reaching (Chen and Crawford, 2020). Some of the evidence for what is being computed with respect to these coordinate transforms is described later.

3.4.1 The transform from retinal to head-based coordinates

Neurons in area LIP are active in visual, attentional and saccadic processing (Gnadt and Andersen, 1988; Colby et al., 1996; Munuera and Duhamel, 2020). The ventral part of LIP (LIPv) has strong connections with two oculomotor centres, the frontal eye field and the deep layers of the superior colliculus, and may be especially involved in the generation of saccades (Chen et al., 2016b). The dorsal part (LIPd) may be more involved in visual processing, responding for example to visual targets for saccades.

Neurons in area VIP represent the direction and speed of visual motion (Colby et al., 1993), and may be useful in for example tracking moving visual stimuli, and encoding optic flow which can be useful in assessing self-motion and thereby in navigation. These neurons do not respond in relation to saccades. In humans, VIP may have expanded into three sub-regions that code for the head or self in the environment, visual heading direction, and the peripersonal environment around the head (Foster et al., 2022).

A very interesting property of many neurons in both LIP and VIP is that they respond in relation to direction with respect to the head, i.e. use a head-based or head-centred coordinate system, rather than in retinal coordinates, as described next. One advantage of this is that

this simplifies associations with the positions of auditory stimuli, with auditory space represented with respect to the head (Chapter 7). We introduce *how* this is computed next, with the concepts developed and tested in Section 3.5.

The response of some neurons in parietal areas 7a, LIP and VIP (areas shown in Fig. 3.1) to a visual stimulus at a given position on the retina (the neuron's receptive field) can be modulated (decreased or increased) by a modulating factor, eye position (the angle of the eye in the head) (Andersen, 1989; Andersen et al., 1985; Andersen and Mountcastle, 1983; Duhamel et al., 1997). Each neuron thus responds best to particular combinations of retinal and eye position that correspond to a head-centred direction. The gain modulation by eye position produces a population of neurons that encodes the position of the stimulus relative to the head, by taking into account both retinal position and eye position (Salinas and Sejnowski, 2001; Salinas and Abbott, 2001). This gain modulation can be thought of as shifting the retinal receptive fields of the population of neurons so that they represent direction relative to the head, which is a spatial coordinate transform (see illustration in Fig. 3.5). The term gain field is used to refer to this process by which a representation (in this case retinal position) can be modulated by another (in this case eye position) to produce a coordinate transform (see further Section 3.5).

3.4.2 The transform from head-based to allocentric bearing coordinates

There is evidence that some neurons in parietal cortex regions respond in allocentric coordinates. Allocentric representations are where the reference frame is the world, for example a particular location in the world, or a bearing direction. A bearing direction is a direction to a stimulus or landmark from the place where one is located. The bearing is with reference to the world, that is, is in allocentric coordinates, and is usually provided as the angle relative to North, which provides an allocentric reference frame. (Bearing direction is well known to navigators, who use the bearings of several landmarks to identify the place in the world where they are located. The bearing direction of a landmark is different from head direction; and from the direction of motion or course travelled of the individual, vessel, etc.) Egocentric representations are where the reference frame is with respect to the head, body, etc, independently of where the organism is, or objects are, in allocentric space.

An allocentric representation has been described in primate parietal area 7a (Snyder et al., 1998) and a region to which it projects the posterior cingulate cortex (Dean and Platt, 2006).

The population of area 7a neurons was described as responding in a world-based coordinate frame, on the basis that they responded in a particular allocentric direction from the macaque when visually evoked or delayed saccades were made after combined head-and-body rotation in the dark (Snyder, Grieve, Brotchie and Andersen, 1998). The important point is that when the head was rotated, the area 7a neurons were gain modulated by the head direction. The parsimonious interpretation is that this 'world-based' or allocentric representation is thus in the coordinate frame of bearing direction to a stimulus or landmark. This could facilitate saccade-making in a given bearing direction, that is, independently of the head direction gain modulating factor. This evidence for area 7a is thus consistent with the hypothesis that some neurons in it code for (allocentric) bearing direction, in that the neuronal responses are gain modulated by head direction (Snyder, Grieve, Brotchie and Andersen, 1998) (see Fig. 3.6). The requisite signal for this gain modulation is head direction, which is represented by neurons in the primate presubiculum (Robertson, Rolls, Georges-François and Panzeri, 1999).

Similar results were found by Dean and Platt (2006) for the posterior cingulate cortex (which receives inputs from the parietal cortex including area 7a), who showed that for most

allocentric bearing coordinates to a landmark:
head centred coordinates gain modulated by head direction

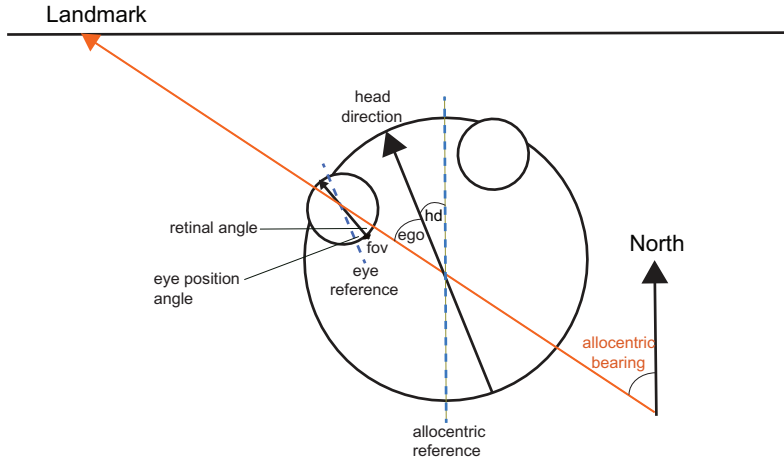

Fig. 3.6 Gain modulation by head direction (hd) to produce a representation in allocentric bearing coordinates (relative to North) to a location in space at which there is a landmark. The head direction is the angle between North (indicated by the long blue line) and the direction of the head (indicated by the long black arrow). A bearing coordinate to a landmark L is represented by all combinations of head direction, eye position (ep) and retinal position that correspond to a given bearing from the individual to a landmark in allocentric space indicated by the line with a red arrow. The large circle is the head, and the two small circles are the eyes. The allocentric bearing to the landmark L is given by the angle between North and the red line from the individual (observer) to the landmark. In this case the allocentric reference frame (indicated by the blue dashed line) is aligned with North, but it could be specified by dominant environmental cues in a particular environment. The large black arrow labelled 'head direction' specifies the direction relative to the allocentric reference framework in which the head is facing, with the head direction angle 'hd' as shown. The head direction (hd) is thus in allocentric coordinates. The egocentric bearing to a landmark ('ego') is the angle between the head direction and the line of sight to the landmark. (As the diagram makes clear, combining the egocentric bearing of the landmark and the head direction yields the allocentric bearing to a landmark.) The diagram also shows how the eye position (the angle between the eye reference frame which is aligned with the head direction as shown), and the retinal angle (the angle between the fovea ('fov') and the place on the retina of the image of the landmark) are relevant. (Modified from Rolls, E. T. (2020) Spatial coordinate transforms linking the allocentric hippocampal and egocentric parietal primate brain systems for memory, action in space, and navigation. *Hippocampus* 30: 332–353. © Wiley Periodicals Inc.)

neurons, tuning curves aligned more closely when plotted as a function of target position in the room than when plotted as a function of target position with respect to the monkey.

To make an arm reach movement, a transform into body-centred space is needed, as the arms are anchored to the body. Visual neurons that respond in body-centered coordinates have been recorded in area LIP (Snyder, Grieve, Brotchie and Andersen, 1998).

3.4.3 A transform from allocentric bearing coordinates to allocentric spatial view coordinates

A further interesting experiment to those described for area 7a (Snyder, Grieve, Brotchie and Andersen, 1998) and posterior cingulate cortex (Dean and Platt, 2006) would be to move the macaque sideways (or the world at which the monkey was looking), to distinguish bearing direction to a landmark in allocentric space from location of a landmark in allocentric space (see Fig. 3.7). That manipulation was in fact used by Feigenbaum and Rolls (1991), and showed that many hippocampal spatial view neurons code for location in allocentric space, with further experiments involving movement of the macaque to different places relative to the location being viewed providing evidence consistent with this (Rolls and O'Mara, 1995; Georges-François, Rolls and Robertson, 1999). It would be very interesting to try this experiment on neurons in the parietal cortex, and the areas connected to it including the posterior cingulate cortex and retrosplenial cortex. It is shown in Section 3.5 that such a

Fig. 3.7 Gain modulation by place of a bearing representation from the previous stage can produce a representation of a landmark L in a scene in allocentric spatial view coordinates. This signal could be used to idiothetically update spatial view cells. b1: bearing of the landmark from place 1; b2: bearing of the landmark from place 2; hd1: head direction 1; hd2: head direction 2; ep: eye position; rp: retinal position. A landmark L at a location being viewed in allocentric space, that is, a spatial view, is represented by transforms over all places, building on transforms over head direction learned in the previous stage, and transforms over eye position learned in the layer before that. Other conventions as in Figs. 3.5 and 3.6. (After Rolls, E. T. (2020). Spatial coordinate transforms linking the allocentric hippocampal and egocentric parietal primate brain systems for memory, action in space, and navigation. *Hippocampus* 30: 332–353. © Wiley Periodicals Inc.)

transform could be performed by the same type of mechanism that enables other coordinate transforms to take place in the dorsal visual system.

What use might such a transform to allocentric spatial view coordinates at the top of the primate dorsal visual system have? It has been proposed that the dorsal visual system, for whatever combination of retinal and eye positions, head direction, and place is present, generates representations in an allocentric coordinate framework that can be easily interfaced to hippocampal processing which is in the same allocentric spatial view / spatial location coordinate frame (Rolls, 2020b). For example, looking at one location in allocentric space as defined by the current status of the dorsal visual system could provide the allocentric spatial input to the hippocampal memory system via the retrosplenial cortex and/or posterior cingulate cortex (see Fig. 9.1) for location-object memory retrieval by hippocampal mechanisms including recall of the object when an appropriate allocentric spatial location cue is applied. Indeed, something like this is exactly what is proposed to account for the fact that hippocampal spatial view neurons update the allocentric location in space ‘out there’ to which they respond when eye movements, head direction changes, or even locomotion are performed in the dark (Robertson, Rolls and Georges-François, 1998). The idiothetic update could be performed in the dorsal visual system based on the vestibular, proprioceptive, and corollary discharge related signals that reach the dorsal stream visual areas and update spatial representations in it, with examples including the update of representations made for example by eye movements described here, and by vestibular signals (Chen, DeAngelis and Angelaki, 2018; Avila, Lakshminarasimhan, DeAngelis and Angelaki, 2019). Further, in virtual reality, some macaque hippocampal neurons can respond to a view location towards which eye movements are made even before the view has actually appeared on the screen (Wirth et al., 2017). This idiothetic update of an allocentric view location (Robertson et al., 1998; Wirth et al., 2017) is potentially adaptive, by speeding up the operation of the system, and enabling the system to operate in darkness or when a barrier obscures the spatial view location. This idiothetic update of hippocampal spatial view locations, can, it is proposed (Rolls, 2020b;

Rolls et al., 2023e,d; Rolls, 2023c), be produced by the input from the dorsal visual system (which has information about eye movements etc) but is converted into the correct allocentric view representation by mechanisms of the type illustrated in Fig. 3.7 and described in Section 3.5. Indeed, the empirical evidence for idiothetic update of hippocampal spatial view representations (Robertson et al., 1998; Wirth et al., 2017) is very much in support of the need for a system for coordinate transforms to the allocentric level in the dorsal visual system of the type proposed by Rolls (2020b).

3.5 How visual coordinate transforms are computed in the dorsal visual system

3.5.1 Gain modulation

A new theory of a whole set of hierarchically organised coordinate transforms that are performed in the primate dorsal visual system has been presented in Section 3.4 (Rolls, 2020b).

In this section (3.5), I consider **how** visual coordinate transforms are performed in the dorsal visual system, and describe how they have been tested with a new computational model (Rolls, 2020b).

Gain modulation to produce coordinate transforms is a well-established principle of operation of neuronal systems in the dorsal visual system, and has been applied in particular to the coordinate transform from retinal to head-based coordinates using modulation by eye position (Salinas and Sejnowski, 2001; Salinas and Abbott, 2001, 1996, 1995). The gain modulation by eye position occurs in a spatially systematic and nonlinear way such that the output of the population of neurons encodes the position of the stimulus relative to the head, by taking into account both retinal position and eye position (Salinas and Sejnowski, 2001; Salinas and Abbott, 2001). This gain modulation can be thought of as shifting the retinal receptive fields of the population of neurons so that they represent direction relative to the head, which is a spatial coordinate transform (see illustration in Fig. 3.5).

A problem with the gain modulation mechanism in practice is that it may not be perfect at each stage (Graf and Andersen, 2014), and when successive stages involving other coordinate transforms follow, the imperfections at each stage combine to make a system that operates very imperfectly, as is shown by the simulations described later. It has been proposed that a temporal trace synaptic learning mechanism can help by using the statistics of the natural world across time to help with the learning (Rolls, 2020b, 2021d), as described next.

3.5.2 Mechanisms of gain modulation using a trace learning rule

The new mechanism that has been proposed is to add to gain modulation a trace learning rule, similar to that utilized in the ventral visual system (Rolls, 2020b). The trace rule operates over for example the many combinations of retinal position and eye position that correspond to a given location in head-centred space. That corresponds to a primate (and that includes humans, of course), looking at a location in space relative to the head while the eyes move around the stimulus, so that a number of different retinal and eye positions occur that correspond to the stimulus being in the same position in head-centred space. The trace learning rule helps to ensure that the same neurons learn to encode a single position in head-centred space, in a sense learning invariances over a whole set of retinal and eye position combinations (Rolls, 2020b).

In more detail, a visual stimulus might be steady at a given position relative to the head for several seconds during which many eye movements would occur. The eye movements

Fig. 3.8 Coordinate transforms in the primate dorsal visual system. Three principal computational stages of coordinate transforms from retinal coordinates via head-centred coordinates and then via allocentric bearing-based coordinates to spatial view coordinates are shown, together with the brain regions in which the different types of neuron are found. The diagram shows the architecture of the VisNetCT model in which gain modulation combined with short-term memory trace associative learning was shown to implement these transforms (see text). Each neuron in a layer (or cortical area in the hierarchy) receives from neurons in a small region of the preceding layer. PCC - posterior cingulate cortex; RSC - retrosplenial cortex. (Modified from Rolls, E. T. (2020) Spatial coordinate transforms linking the allocentric hippocampal and egocentric parietal primate brain systems for memory, action in space, and navigation. *Hippocampus* 30: 332–353. © Wiley Periodicals Inc.)

would result in different combinations of eye position and retinal position occurring in those few seconds. If the active neurons maintained a short-term memory trace of recent neuronal or synaptic activity for a short period, of even a few hundred ms, the neurons could then learn about what was constant over short periods (such as the position of the visual stimulus relative to the head). The trace learning mechanism itself is very simple and biologically plausible, for it can be included in a competitive network, a standard network in cortical systems, just by utilizing for example the long time constant of NMDA receptors, or the continuing firing of cortical neurons for 100 ms or more that is characteristic of cortical networks with recurrent connections to form attractor networks (Földiák, 1991; Rolls, 1992a; Wallis and Rolls, 1997; Rolls, 2012d, 2016b; Wyss et al., 2006; Wiskott and Sejnowski, 2002; Franzius et al., 2007; Zhao et al., 2019; Eguchi et al., 2016). Exactly these cortical processes provide a theory and model for transform-invariant object representations in the ventral visual system as described in Chapter 2, and have recently been proposed to play an important role in several stages of the dorsal visual system, in relation to learning spatial coordinate transforms (Rolls, 2020b). The uses of these neural mechanisms for each stage of processing in the dorsal visual stream hierarchy are described next.

The following set of spatial coordinate transforms have been investigated in the 3-layer model of successive coordinate transforms, VisNetCT, illustrated in Fig. 3.8 (Rolls, 2020b). Each layer in the model corresponds to a different cortical processing area. The principles may, it is postulated, apply to other spatial coordinate transforms present in these and other cortical areas. The architecture and operation of the model is similar to that of VisNet as described in Chapter 2, except that gain modulation is performed for each presentation of a stimulus with a particular combination of input representation to be gain modulated (e.g. retinal position of the stimulus), and the modulator (e.g. eye position). The gain modulation

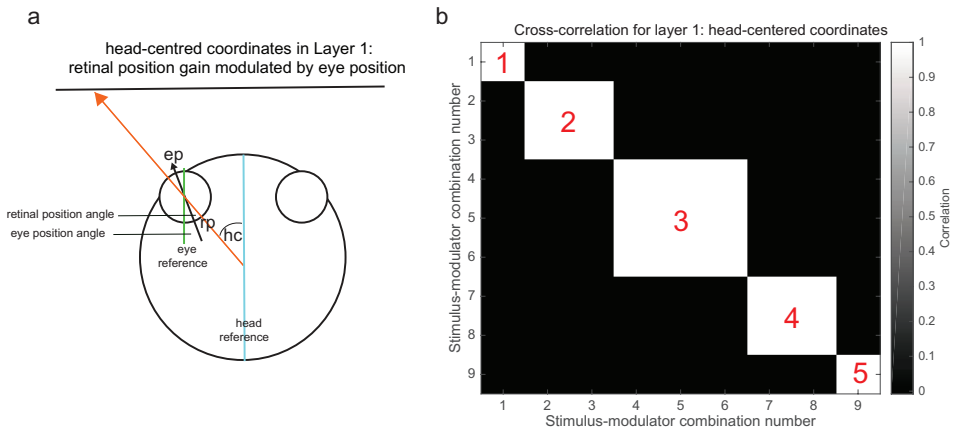

Fig. 3.9 Gain modulation by eye position to produce a head-centered representation in Layer 1. a. Schematic to show that gain modulation by eye position can produce a representation in head-centered coordinates in Layer 1. The abbreviations are as in Fig. 3.5. b. The correlation matrix represents the correlation of the firing between all the neurons in Layer 1 for every one of the five head centered positions (numbered in red) at which a stimulus was presented, after training Layer 1. During training, all combinations of eye position and retinal position that corresponded to one head-centered position were presented together enabling the trace rule to help with the learning, then another head-centered position was selected for training, as described by Rolls (2020). In the correlation matrix, the large white block in the middle thus indicates that the neurons across the whole of Layer 1 that responded to all three combinations of retinal and eye position for head-centered position 3 encoded only head-centered position 3, with no interference from or response to any other retinal and eye position combination that corresponded to other positions in head-centered space. (After Rolls, E. T. (2020) Spatial coordinate transforms linking the allocentric hippocampal and egocentric parietal primate brain systems for memory, action in space, and navigation. *Hippocampus* 30: 332–353. © Wiley Periodicals Inc.)

was performed in the general way described elsewhere (Salinas and Sejnowski, 2001; Salinas and Abbott, 2001), and was implemented by a convolution of firing in a layer with the gain modulation signal. In addition, the forward connections to a neuron in one layer came from a small region of the preceding layer defined by the radius that will contain approximately 67% of the connections from the preceding layer. This radius was set in VisNetCT to 2 for each layer of 32x32 neurons per layer, and each neuron received 100 synaptic connections from the neurons in the preceding layer. This resulted in the maintenance of some topology through the different layers of VisNetCT, which is different from VisNet, in which the aim is to produce neurons in the final layer with full translation (shift) invariance as well as other invariances.

3.5.3 Gain modulation by eye position to produce a head-centered representation in Layer 1 of VisNetCT

Retinal position is the input to Layer 1, where it is gain modulated by eye position to produce position with respect to the head. The coordinate framework thus becomes head-centered, as illustrated in Fig. 3.9a. Competitive learning with a temporal trace learning rule to select the Layer 1 neurons with good responses for each position with respect to the head occurs, learning over all combinations of retinal position and eye position that correspond to a given position in head-based coordinates. This enables neurons to respond to a given position in head-centered space over many combinations of retinal and eye position that correspond to that position in head-centered space, as found in macaque VIP and LIP.

The results of this training for Layer 1 are illustrated with the correlation matrix shown in Fig. 3.9b. This represents the correlation of the firing between all the neurons in Layer 1 for each of the five head-centered positions at which a stimulus was presented. This shows that the 5 different head-centered positions for a stimulus each produced different firing of Layer 1

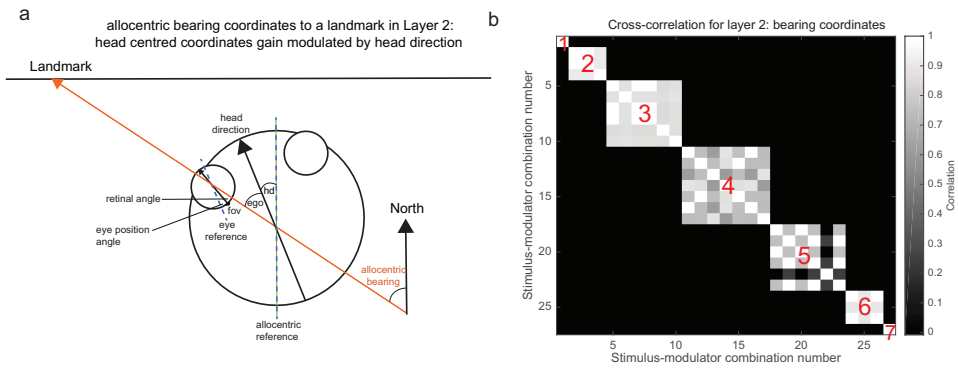

Fig. 3.10 Gain modulation by head direction to produce a representation in allocentric bearing coordinates (relative to North) to a location in space at which there is a landmark in Layer 2. a. Schematic to show that gain modulation by head direction (hd) can produce a representation in allocentric bearing coordinates to a stimulus or landmark (L) in Layer 2. The head direction is the angle between North (indicated by the long blue line) and the direction of the head (indicated by the long black arrow). A bearing coordinate to a landmark L is represented by all combinations of head direction, eye position (ep) and retinal angle that correspond to a given bearing from the individual to a landmark in allocentric space indicated by the line with a red arrow. Other conventions as in Fig. 3.6. b. The correlation matrix represents the correlation of the firing between all the neurons in Layer 2 for every one of the seven bearing directions (numbered in red) relative to the agent at which a stimulus was presented, after training Layers 1 and 2. There was one combination of retinal position, eye position, and head direction that corresponded to bearing direction of $X=-15$ and $+15$; three for each of $X=-10$ and $+10$; six for $X=-5$ and $+5$; and seven combinations for bearing direction 4 at $X=0$. During training, all combinations of head direction, eye position and retinal position that corresponded to one allocentric bearing to a landmark were presented to enable the trace rule to operate usefully; and each of the other allocentric bearings to a landmark were then trained similarly in turn. (After Rolls, E. T. (2020) Spatial coordinate transforms linking the allocentric hippocampal and egocentric parietal primate brain systems for memory, action in space, and navigation. *Hippocampus* 30: 332–353. © Wiley Periodicals Inc.)

neurons, even though each head-centred position was produced by a number of combinations of retinal stimulus and eye position, as explained in the legend to Fig. 3.9.

The simulation of Layer 1 thus shows that the competitive learning in Layer 1 using a short-term memory trace in combination with gain modulation by eye position can learn to allocate different neurons to respond to each head-centred position in space.

3.5.4 Gain modulation by head direction to produce an allocentric bearing to a landmark in Layer 2 of VisNetCT

For Layer 2, the five head-centred outputs of Layer 1 were gain-modulated by head direction to produce firing that was related to the bearing to a landmark L as illustrated in Fig. 3.10a, using the trace learning rule in the competitive network of Layer 2. There were three head-direction modulators, corresponding to the head directed towards $X=-5$, $X=0$, and $X=+5$. This produced seven possible bearing directions each to a different landmark L, from the single place where the viewer was located. The correlation matrix shown in Fig. 3.10b represents the correlation of the firing between all the neurons in Layer 2 for every one of the seven bearing directions to a landmark relative to the agent at which a stimulus was presented, after training Layers 1–2. This shows that the 7 different bearing directions for a stimulus each produced different firing of Layer 2 neurons, even though each bearing direction was produced by a number of combinations of retinal stimulus, eye position, and head direction.

This then provides a theory and model for how ‘allocentric bearing to a landmark cells’ can be produced (Rolls, 2020b). Such cells may correspond to those described in area 7a (Snyder, Grieve, Brotchie and Andersen, 1998) and posterior cingulate cortex (Dean and Platt, 2006).

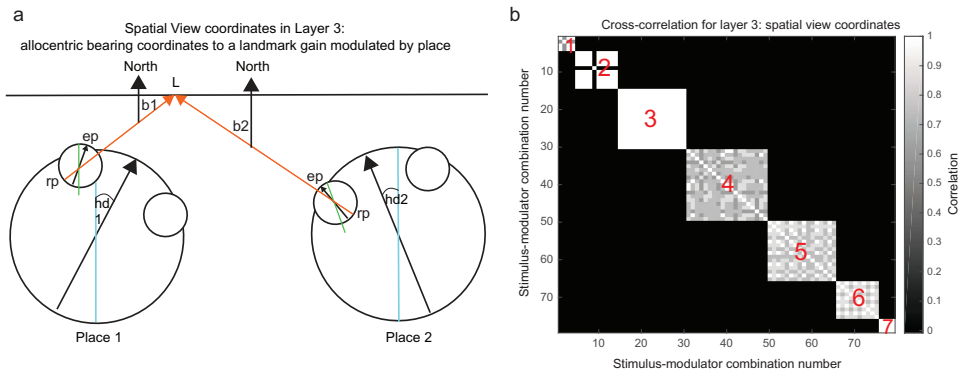

Fig. 3.11 Gain modulation by place to produce an allocentric spatial view representation in Layer 3. a. Schematic to show that gain modulation by place of a bearing representation from Layer 2 can produce a representation of a landmark L in a scene in spatial view coordinates in Layer 3. b1: bearing of the landmark from place 1; b2: bearing of the landmark from place 2; hd1: head direction 1; hd2: head direction 2; ep: eye position; rp: retinal position. A landmark L at a location being viewed in allocentric space, that is, a spatial view, is represented by transforms over all places in Layer 3, building on transforms over head direction learned in Layer 2, and transforms over eye position learned in Layer 1. Other conventions as in previous Figures. b. The correlation matrix represents the correlation of the firing between all the neurons in Layer 3 for 7 spatial views (numbered in red) presented, after training Layers 1–3. During training, all combinations of bearing to a landmark, head direction, eye position and retinal position that corresponded to one spatial view of a landmark from one place were presented to enable the trace rule to operate usefully; and each of the other places were then trained similarly in turn. The results show that the Layer 3 neurons responded selectively and only to all combinations of bearing and place that corresponded to each allocentric spatial view. (After Rolls, E. T. (2020) Spatial coordinate transforms linking the allocentric hippocampal and egocentric parietal primate brain systems for memory, action in space, and navigation. *Hippocampus* 30: 332–353. © Wiley Periodicals Inc.)

3.5.5 Gain modulation by place to produce an allocentric spatial view representation in Layer 3 of VisNetCT

For Layer 3, the seven bearing direction outputs of Layer 2 to different locations L were gain-modulated by place to produce an allocentric view-based representation using the trace learning rule in the competitive network of Layer 3. This might be produced by walking from one place to another while watching the same location in a scene. Fig. 3.11a shows a schematic for a single location L in the scene. Each location was encoded by spatial view cells that encoded the location in the scene, independently of the place where the viewer was located. There were three place modulators. This produced representations of 7 allocentric, world-based, views each of a different location in the scene. Each of the spatial view representations learned was of a different location L in the scene. Each spatial view representation was independent of the place where the viewer was located.

Fig. 3.11b shows that after training Layers 1–3, the firing of neurons in Layer 3 represented each of the spatial locations in the scene separately and independently. The correlation matrix represents the correlation of the firing between all the neurons in Layer 3 for every spatial location presented. Fig. 3.11 thus shows that the firing of Layer 3 represented each of the 7 spatial locations in the scene almost orthogonally to the other spatial locations, which is good performance.

In an important control condition, it was shown that training using gain modulation but no trace learning rule produced very much poorer performance (Rolls, 2020b). This shows the value of combining trace rule learning with gain modulation.

A neuron that responds allocentrically to a single location in the scene and relatively independently of the place where the viewer is located is termed an allocentric spatial view cell (Rolls, Robertson and Georges-François, 1997a; Georges-François, Rolls and Robertson, 1999; Rolls, 1999c; Rolls and Xiang, 2006; Rolls and Wirth, 2018; Rolls, 2023c), and neurons in these coordinates are what is produced in Layer 3 of VisNetCT (Rolls, 2020b, 2021d).

3.5.6 The utility of the coordinate transforms in the dorsal visual system

What is computed by this computational system is quite remarkable: a transform from retinal coordinates to allocentric representations of spatial locations ‘out there’ that are independent of retinal position, eye position, and the place where the viewer is located. This would be very useful for idiothetic (self-motion) update of spatial representations of locations ‘out there’ where there might be a goal object towards which one is navigating, in for example the dark, or when the view of the goal was obscured or not yet in sight. Hippocampal spatial view cells show exactly this type of update of the location being looked at during movements in the dark (Robertson, Rolls and Georges-François, 1998), and it is proposed that these computations in the dorsal visual system provide the necessary inputs to the hippocampus for navigation in the dark (Rolls, 2021f,d), using the pathways from parietal areas via brain regions such as the posterior cingulate cortex and retrosplenial cortex which project via the parahippocampal gyrus (areas TF and TH) into the hippocampal system, as shown in Figs. 9.1 and 3.12 (Rolls, 2021d; Rolls et al., 2023e,d; Rolls, 2023c). The same computation would account for the fact that some macaque hippocampal neurons can respond to a view location towards which eye movements are made even before the view has actually appeared on the projection screen in the virtual reality environment (Wirth et al., 2017).

Brain systems for navigation in primates including humans that make use of computations of the type described here are considered in Chapters 10 and 9 (Rolls, 2021f, 2023c).

The computations described here also account for the representation of allocentric bearing direction, which appears to be implemented by neurons in the primate parietal cortex area 7a (Snyder, Grieve, Brotchie and Andersen, 1998) and a region to which it projects the posterior cingulate cortex (Dean and Platt, 2006). (These allocentric bearing direction neurons are different from head direction cells, in that allocentric bearing cells to a location are independent of head direction.)

To make an arm reach movement, a transform into body-centred space is needed, as the arms are anchored to the body. Visual neurons that respond in body-centered coordinates have been recorded in area LIP (Snyder et al., 1998), and it is proposed that their responses are computed using similar mechanisms (Rolls, 2020b).

The rat has no fovea, and does not have the same mechanisms as those described here in primates for the control of foveation (Bisley and Goldberg, 2010), and probably can not represent transform-invariant locations in viewed scenes which are such important properties of the primate including human visual system. The rat therefore provides a poor model for the computations performed in this part of the primate brain, the dorsal visual system. There is however a model of coordinate transforms based on neurons found in rodents such as boundary-vector cells and object-vector cells (Bicanski and Burgess, 2018), and this is described in Section 9.3.14.3. A description of the model is: “Perceived and imagined egocentric sensory experience is represented in the ‘parietal window’ (PW), which consists of two neural populations - one coding for extended boundaries (‘PWb neurons’), and one for discrete objects (‘PWo neurons’)”. That model holds that “the transformation between egocentric (parietal) and allocentric (medial temporal lobe, MTL) reference frames is performed by a gain-field circuit in retrosplenial cortex” and uses head direction. In comparison, the present model introduces a new approach to coordinate transforms that includes a memory trace learning rule in competitive networks that is combined with gain modulation for multiple stages of the dorsal visual system; and specifically deals with the spatial transforms and representations known to be implemented in the primate dorsal visual system, and in areas such as the posterior cingulate cortex (not known to be present in rodents).

The issues of spatial representations in the parietal cortex, and a region to which it projects

the hippocampus, and their involvement in navigation, are considered further in Chapters 10 and 9.

3.6 The human Dorsal Visual Cortical Stream for visual motion leading to the intraparietal visual areas, and then to parietal area 7 regions for actions in space

The human Dorsal Visual Cortical Stream pathways described here lead via dorsal visual system cortical regions to regions in the intraparietal sulcus and parietal cortex area 7. This stream has visual motion outputs to the superior STS semantic system. This stream includes a dorsal ‘where’ / action system in which idiothetic update of spatial representations is performed.

The effective connectivity of the human Dorsal Visual Stream is shown in Fig. 3.12 (Rolls et al., 2023e). Effective connectivity from regions such as V2, V3, V3A and V3B, V6A and V7 reach the MT+ complex regions (FST, LO1, LO2, LO3, MST, MT, PH, V3CD and V4t) (Fig. 3.12). The MT+ complex regions then have effective connectivity to the intraparietal regions (AIP, LIPd, LIPv, MIP, VIP IP0, IP1 and IP2), which in turn have effective connectivity to the area 7 regions. Interestingly, in humans there are some inputs to this Dorsal Visual Stream from Ventrolateral Visual Stream regions such as FFC and TE2p, and these are shown with dashed lines in Fig. 3.12.

3.6.1 Dorsal stream visual division regions

V3A and V6 are motion-sensitive areas that project to the regions in the MT+ Complex division (Table 1.1) in what is described in macaques as a dorsolateral visual stream which eventually reaches the cortex in the superior temporal sulcus (Galletti and Fattori, 2018). V6 responds to coherent optic flow stimuli and may thus be useful in egomotion (Sulpizio et al., 2020). In macaques, V6 may also project to V6A which is involved in the fast control of prehension and in selecting appropriate postures during reach-to-grasp behaviors (Pitzalis et al., 2015, 2013; Monaco et al., 2011; Tosoni et al., 2015). V6A then projects to what is described as a dorsomedial visual stream directed towards the intraparietal areas such as MIP which are also involved in reach to grasp behavior (Galletti and Fattori, 2018). Neurons in V6A and VIP are invariant with respect to eye position, that is, they can respond in head-based coordinates (Galletti and Fattori, 2018). Coordinate transforms of this type can be implemented by gain modulation (Salinas and Sejnowski, 2001) (in which for example eye direction modulates retinotopic position) which is greatly helped by slow learning to capture the statistical continuities of an object in a fixed position relative to the head when the eyes move (Rolls, 2020b). The same principle can be extended to account for the next transform to allocentric direction in space, and then to a further transform to allocentric location in space independently of the place where the individual is located (Rolls, 2020b), as represented in the parahippocampal gyrus and hippocampus by spatial view cells (Rolls, 2023c). This dorsomedial part of the dorsal visual system provides for idiothetic (self-motion) update of allocentric spatial representations of the type provided by for example primate spatial view cells (Robertson et al., 1998), and is a key computation performed in the dorsal visual ‘where’ system enabling idiothetic update of the VentroMedial ‘Where’ Visual Cortical Stream for building scene representations in the VMV and PHA1-PHA3 parahippocampal areas (see Fig. 3.12) (Rolls et al., 2023e,d; Rolls, 2023c). These scene representations are likely to be involved in human navigation from viewed location to viewed location, which is frequently how navigational

object, disparity may be encoded, and vestibular inputs related to self-motion can influence some neurons (Wild and Treue, 2021).

In a unifying hypothesis with the design of the ventral cortical visual system about how these types of encoded motion might be computed, Rolls and Stringer (2006a) proposed that the dorsal visual system uses a hierarchical feedforward network architecture (V1, V2, MT, MST, parietal cortex) with training of the synaptic connections with a short-term memory trace associative synaptic modification rule to compute what is invariant at each stage by utilizing the temporal continuity inherent in the statistics of the visual inputs (Section 3.3). The same principle (Rolls and Stringer, 2006a) can account for the responses of neurons in the cortex in the superior temporal sulcus (which may receive from these dorsal visual stream regions) which it was discovered can respond to object-based rotation about a principal axis, for example to a head rotating clockwise, invariantly with respect to whether the head was upright or inverted (Hasselmo et al., 1989b).

3.6.3 Intraparietal sulcus posterior parietal cortex, regions (AIP, LIPd, LIPv, MIP, VIP; with IP0, IP1 and IP2)

Neurons in macaques in area VIP represent the direction and speed of visual motion (Colby et al., 1993), and may be useful in for example tracking moving visual stimuli, and encoding optic flow which can be useful in assessing self-motion and thereby in navigation. These neurons do not respond in relation to saccades. Neurons in macaques in LIP are active in visual, attentional and saccadic processing (Gnadt and Andersen, 1988; Colby et al., 1996; Munuera and Duhamel, 2020). The ventral part of LIP (LIPv) has strong connections with two oculomotor centres, the frontal eye field and the deep layers of the superior colliculus, and may be especially involved in the generation of saccades (Chen et al., 2016b). The dorsal part (LIPd) may be more involved in visual processing, responding for example to visual targets for saccades (Chen et al., 2016b). Neurons in MIP (which may be the parietal reach region, PRR (Connolly et al., 2003)) are related to arm movement preparation and execution (Passarelli et al., 2021; Prado et al., 2005; Filimon et al., 2009; Cavina-Pratesi et al., 2010; Gallivan et al., 2011). They are implicated in the sensory-to-motor transformations required for reaching toward visually defined targets (Gamberini et al., 2020). AIP is activated by grasping objects, for which shaping of the hand based on the visual properties of objects is needed (Culham et al., 2006, 2003).

As shown in Fig. 3.12, these regions have strong effective connectivity from early visual cortical areas including from several MT+ complex visual regions in which neurons respond to global optic flow (MST, FST, PH and V3CD), intraparietal sulcus area 1 (IPS1), V3B, V6A (which is a visuo-motor region involved in grasping seen objects (Gamberini et al., 2020)), V7, and superior parietal area 7 regions involved in visuo-motor actions. These intraparietal regions also receive in humans from ventral stream visual cortical areas including the fusiform face cortex (FFC), from inferior temporal cortex regions PIT, PHT, TE1p and TE2p (Fig. 3.12). These ventral stream regions are likely to bring shape / visual form information to the intraparietal cortex regions important in shaping the hand to grasp and manipulate objects and tools. Consistent with this, neurons in regions such as AIP in macaques can respond to 2D and 3D shape information which could be helpful in tool use (Kastner et al., 2017). These intraparietal and also area 7 regions may provide information to the inferior parietal cortex regions such as PFt, PF and PGi that have developed so greatly in humans and that are involved in human tool use (Rolls et al., 2023d). These intraparietal regions also have connectivity with the inferior frontal gyrus and with the dorsolateral prefrontal cortex (especially 46, 8C, a9-46, i6-8 and p9-46v), which are likely to be important when there is a delay between the visual input and when the action can be performed (Funahashi, Bruce

and Goldman-Rakic, 1989). These connectivities are stronger to these prefrontal areas, as is appropriate for the operation of short-term memory systems so that the memory does not dominate sensory inputs (Rolls, 2016b, 2021b). There is also connectivity directed towards the parahippocampal TH cortex (PHA3) which may be useful in providing information about visuo-motor actions to the hippocampal memory system. There is also connectivity with the frontal pole p10p, which is likely to be important when sequencing and planning is involved in actions (Shallice and Cipolotti, 2018; Shallice and Burgess, 1996; Gilbert and Burgess, 2008).

The connectivity from the intraparietal areas is strongly towards premotor cortical areas including especially 6a, and to the frontal eye field FEF and prefrontal eye field PEF (from especially AIP, LIPd, LIPv and VIP), which provide action-related outputs from these visuo-motor intraparietal regions. There is also connectivity especially for IP1 and IP2 from the orbitofrontal cortex (medial regions, 11 and OFC) which may provide reward feedback (Rolls, 2019e,f) of potential utility in learning whether actions made are correct, and with the frontal pole. There is also connectivity with inferior parietal regions including PGp and PGs, with PGp having effective connectivity to the parahippocampal scene area PHA1-3 to provide, it is proposed here, for idiothetic update of parahippocampal and hippocampal spatial view representations (Rolls et al., 2023d; Rolls, 2023c). Interestingly, this intraparietal part of the parietal cortex has relatively little effective connectivity with the posterior or anterior (or mid) cingulate cortex. The connectivity from MT+ regions such as MT and MST to intraparietal regions from auditory cortical regions such as A4 and A5, and from somatosensory regions such as 5L and 5m, provides a basis for the auditory and somatosensory responses evident in some macaque intraparietal neurons that also respond to visual stimuli (Kastner et al., 2017).

The functional connectivity is largely consistent with the effective connectivity (Rolls et al., 2023e), but indicates more interactions with early visual cortical areas; with somatosensory/premotor areas; with the hippocampal system; with TE1p and TE2p, with posterior cingulate including DVT; and with supragenual anterior cingulate 33pr and p24pr (Rolls et al., 2023c). The diffusion tractography (Rolls et al., 2023e) is also consistent, but suggests in addition connections with auditory cortex that may be useful in orienting gaze towards sounds.

The intraparietal cortical regions in humans thus are likely in terms of their connectivity (Rolls et al., 2023e) to perform visuomotor functions (without substantial somatosensory processing unlike area 7 regions), and the extensive research on these regions in macaques provides a guide to their functions in humans, including the control of eye movements to acquire and track visual stimuli given the outputs to the FEF and PEF. There are also outputs to regions 6a and 6r that might produce head and body movements to help stabilize images for the visual system. The output to the posterior inferior temporal visual cortex PHT is of interest, and might be involved in the stabilization of images for processing in later parts of the ventral visual system.

3.6.4 Area 7 regions

Area 7 regions in the posterior parietal cortex receive from the intraparietal areas, and are involved in actions in space, and their connectivity in humans is considered in Chapter 10 (Rolls et al., 2023d).

4 The taste and flavor system

4.1 Introduction and overview

4.1.1 Introduction

There are taste receptors in the mouth for at least five tastes, sweet (e.g. sucrose), salt (e.g. sodium chloride), bitter (e.g. quinine), sour (e.g. citric acid and hydrochloric acid), and umami (e.g. monosodium glutamate). The taste receptors project by three gustatory (taste) nerves (facial 7, glossopharyngeal 9, and vagus 10) to the nucleus of the solitary tract (NTS) in the brainstem. From there, the taste pathways project differently in primates and rodents, as shown in Fig. 4.1. As we are concerned in this book with the computations in the primate including human brain, we will focus on the macaque pathways shown in the left of Fig. 4.1, and how they converge with other pathways later on as shown in Fig. 11.1. The points made refer to the primate including human unless otherwise stated, as the connections and functioning of the rodent taste system are so different. Somatosensory information about the texture of food in the mouth, and its temperature, are represented in the primary taste cortex in the anterior insula; and beyond that, convergence with olfactory and visual information in the primate orbitofrontal cortex enables the full flavor of a food to be represented.

4.1.2 Overview of what is computed in the taste and flavor system

What is computed in the taste system is described in Sections 4.2.1 to 4.2.9 with an overview here.

1. The rostral part of the nucleus of the solitary tract contains taste neurons that are not very specifically tuned to individual tastes (Scott et al., 1986b; Rolls, 1989d), and which do not reduce their responses during feeding to satiety (Yaxley et al., 1985).
2. Neurons in the primary taste cortex in the anterodorsal insula and adjoining frontal operculum respond more selectively to tastes, but not to only one taste: it is a sparse distributed code. Neurons in these regions do not reduce their responses during feeding to satiety, so the reward value of taste is not represented in the primary taste cortex. Instead, their firing rates are usually related to the concentration of the tastant, and thus to the intensity of the taste.
3. Some neurons in the primary taste cortex respond to oral texture, including food thickness which is related to viscosity, and the texture of fat which is related to the coefficient of sliding friction. Some neurons combine taste and/or oral texture and/or oral temperature. Neurons in the primary taste cortex do not respond to odor or to visual stimuli (although if a taste is recalled in humans by for example an olfactory stimulus some activation may be found). These features of the insular primary taste cortex allow tastes independently of visual and olfactory associations to be identified, and learned about, and this can occur even if hunger is not present.
4. Neurons in the primary taste cortex project into the orbitofrontal cortex, which thus ranks in the taste hierarchy as secondary taste cortex. Some orbitofrontal cortex neurons are more specifically tuned to taste than in earlier taste processing stages in the hierarchy.

Fig. 4.1 Taste pathways in the macaque and rat. In the macaque, gustatory information reaches the nucleus of the solitary tract (NTS), which projects directly to the taste thalamus (ventral posteromedial nucleus, pars parvocellularis, VPMpc) which then projects to the taste cortex in the anterior insula (Insula). The insular taste cortex then projects to the orbitofrontal cortex and amygdala. The orbitofrontal cortex projects taste information to the anterior cingulate cortex. Both the orbitofrontal cortex and the amygdala project to the hypothalamus (and to the ventral striatum). In macaques, feeding to normal self-induced satiety does not decrease the responses of taste neurons in the NTS or taste insula (and by inference not VPMpc) (see text). In the rat, in contrast, the NTS projects to a pontine taste area, the parabrachial nucleus (PbN). The PbN then has projections directly to a number of subcortical structures, including the hypothalamus, amygdala, and ventral striatum, thus bypassing thalamo-cortical processing. The PbN in the rat also projects to the taste thalamus (VPMpc), which projects to the rat taste insula. The taste insula in the rat then projects to an agranular orbitofrontal cortex (AgOFC), which probably corresponds to the most posterior part of the primate OFC, which is agranular. (In primates, most of the orbitofrontal cortex is granular cortex, and the rat may have no equivalent to this.) In the rat, satiety signals such as gastric distension and satiety-related hormones decrease neuronal responses in the NTS (see text), and by inference therefore in the other brain areas with taste-related responses, as indicated in the Figure. (After Rolls, E. T. (2016) Reward systems in the brain and nutrition. *Annual Review of Nutrition* 36: 435–470. Reproduced with permission from the *Annual Review of Nutrition*, Volume 36 © 2016 by Annual Reviews, <http://www.annualreviews.org>.)

5. Some orbitofrontal cortex neurons respond not only to taste but also to olfactory and/or visual stimuli, with these multimodal responses learned by associative learning, and providing a representation of flavor in the brain. Some of these neurons also respond to oral texture and/or temperature. The resulting neurons can respond to specific combinations of their inputs which allow selectivity for particular foods. Convergence of the taste, olfactory, and visual pathways in the orbitofrontal cortex, as shown in Fig. 11.1, provides the anatomical basis for these multimodal responses.
6. Most orbitofrontal cortex neurons decrease their responses to a food that is eaten to satiety, providing evidence that the reward value of taste and more generally food is represented in the orbitofrontal cortex.
7. The effect of feeding to satiety on neurons in the orbitofrontal cortex is relatively specific to the food eaten to satiety, and this is termed sensory-specific satiety. This is one of the most important principles of operation of the flavor system, and indeed more generally of reward systems in the brain. Because of this selectivity of the reward systems in relation to satiety, made possible by the selective tuning of orbitofrontal cortex neurons, presenting a wide variety of foods can lead to overeating, and is likely to be an important contributor to obesity in humans.
8. Human functional neuroimaging investigations provide consistent evidence for humans. They also show that activations in the insular primary taste cortex are related to the subjective intensity but not pleasantness of taste; and that top-down attention to intensity can increase the activations in the primary taste cortex. Activations in the human orbitofrontal

cortex are related to the subjective pleasantness but not intensity of taste; and top-down attention to pleasantness can increase activations in the orbitofrontal cortex. Top-down cognitive modulation of pleasantness, for example describing at the word level a stimulus as rich and delicious, can also enhance activations in the human olfactory cortex to flavor and other reward stimuli.

9. The orbitofrontal cortex projects to the anterior cingulate cortex, in which taste and also multimodal flavor neurons are found (Rolls, 2008c). The pregenual anterior cingulate cortex represents pleasant flavors and other rewarding stimuli, and the supracallosal anterior cingulate cortex represents unpleasant flavors and other aversive stimuli. The anterior cingulate cortex may provide a route for the orbitofrontal cortex reward system to connect to the goal-directed action system that learns actions to obtain the rewards (Rolls, 2019e,c; Rolls et al., 2023c) (Section 12.2).

4.1.3 Overview of how computations are performed in the taste and flavor system

How the computations are performed in the taste system is described in Section 4.3 with an overview here.

1. The taste system is hierarchically organised, and competitive learning in the cortex (complemented by lateral inhibition in the thalamus) is the probable mechanism that sharpens the tuning through the hierarchy.
2. Multimodal associations of visual and olfactory stimuli with taste are learned in the orbitofrontal cortex, with the probable mechanism pattern association. This learning may also involve competitive learning, helping neurons to become selective for different multimodal combinations of their inputs.
3. Visual to taste associations can be reversed in one trial by orbitofrontal cortex neurons, providing evidence for a rule-based mechanism. This is very adaptive in evolutionary terms, and is not known to be possible in rodents, but is an important computation in primates. A model for this is described in Chapter 11.
4. Sensory-specific satiety is probably implemented in the orbitofrontal cortex by adaptation with a time course of several minutes of the active synapses onto orbitofrontal cortex neurons. A simple model is described.
5. Top-down modulation of orbitofrontal cortex activity by attention and cognition is probably implemented by top-down biased competition (Sections 2.12 and B.8.4) or top-down biased activation (Section 4.3.5).

4.2 Taste and related pathways: what is computed

4.2.1 Hierarchically organised anatomical pathways

The hierarchical organisation of taste processing in primates is shown in Figs. 4.1, 4.3 and 11.1 (Rolls, 2015d, 2016c,g). The taste nerves lead to the first central synapse of the gustatory system, in the rostral part of the nucleus of the solitary tract (Beckstead and Norgren, 1979; Beckstead et al., 1980). Second-order gustatory projections that arise from rostral NTS project directly to the taste thalamus VPMpc (ventral posteromedial nucleus, pars parvocellularis) in primates (Beckstead, Morse and Norgren, 1980; Pritchard, Hamilton and Norgren, 1989). The taste thalamus then projects to the primary taste cortex in the rostradorsal part of the insula and the adjoining frontal operculum (Pritchard et al., 1986). The primary taste

Fig. 4.2 Some of the connections of the primate orbitofrontal cortex and amygdala shown on this lateral view of the brain of the macaque monkey, showing the connections from the primary taste and olfactory cortices. Connections are also shown in the 'ventral visual system' from V1 to V2, V4, the inferior temporal visual cortex, etc., with some connections reaching the amygdala and orbitofrontal cortex. In addition, connections from the somatosensory cortical areas 1, 2, and 3 that reach the orbitofrontal cortex directly and via the insular cortex, and that reach the amygdala via the insular cortex, are shown. as, arcuate sulcus; cal, calcarine sulcus; cs, central sulcus; lf, lateral (or Sylvian) fissure; lun, lunate sulcus; ps, principal sulcus; io, inferior occipital sulcus; ip, intraparietal sulcus (which has been opened to reveal some of the areas it contains); AIT, anterior inferior temporal cortex; FST, visual motion processing area; LIP, lateral intraparietal area; MST, visual motion processing area; MT, visual motion processing area (also called V5); PIT, posterior inferior temporal cortex; STP, superior temporal plane; TA, architectonic area including auditory association cortex; TE, architectonic area including high order visual association cortex, and some of its subareas TEa and TEem; TG, architectonic area in the temporal pole; V1–V4, visual areas V1–V4; VIP, ventral intraparietal area; TEO, architectonic area including posterior visual association cortex. The numerals refer to architectonic areas, and have the following approximate functional equivalence: 1,2,3, somatosensory cortex (posterior to the central sulcus); 4, motor cortex; 5, superior parietal lobule; 7a, inferior parietal lobule, visual part; 7b, inferior parietal lobule, somatosensory part; 6, lateral premotor cortex; 8, frontal eye field; 12, part of orbitofrontal cortex; 46, dorsolateral prefrontal cortex. (After Rolls, E. T. (2016) Reward systems in the brain and nutrition. Annual Review of Nutrition 36: 435–470. Reproduced with permission from the Annual Review of Nutrition, Volume 36 © 2016 by Annual Reviews, <http://www.annualreviews.org>.)

cortex then projects to the orbitofrontal cortex (Baylis, Rolls and Baylis, 1995), which is secondary taste cortex. The orbitofrontal cortex then has connections with the anterior cingulate cortex (Ongur and Price, 2000; Rolls, 2019c; Du, Rolls, Cheng, Li, Gong, Qiu and Feng, 2020; Hsu, Rolls, Huang, Chong, Lo, Feng and Lin, 2020; Rolls, Deco, Huang and Feng, 2023c) where taste neurons are found (Rolls, 2008c).

This hierarchical architecture provides a foundation for some of the computations revealed in properties of the primate including human taste system that are described in the rest of this chapter. One is the increasing selectivity of neurons as information progresses up through the taste system, which is helped in the orbitofrontal cortex by combining taste with olfactory and visual information. A second is processing of taste, oral texture, and temperature information only in the primary taste cortex, before olfactory and visual information converges with taste information in the orbitofrontal cortex. A consequence is that it is possible for humans to identify a taste separately from the flavor that results after combination of taste and olfactory information. A third type of computation that is afforded by the primary taste cortex is that reward processing is not implemented until satiety and related computations are performed in the orbitofrontal cortex. This enables humans to identify and learn about tastes

independently of hunger, which is highly biologically adaptive, if primates encounter a food when they are not hungry.

In humans the primary taste cortex is in the anterior insula (Rolls, 2015d, 2016c, 2019g) in regions that in the HCP-MMP atlas include parts of AVI, FOP5 and FOP4 (Fig. 6.7 see Rolls et al. (2023f) which has coronal slices in the Supplementary Material to show these regions better). The insular and frontal opercular taste regions then have connectivity with the orbitofrontal cortex and anterior cingulate cortex, and also with some prefrontal cortex regions (Rolls et al., 2023f). The lateral orbitofrontal cortex has effective connectivity directed towards language regions in for example Broca's area, and this may provide a route for the representations in orbitofrontal cortex to contribute to the declarative aspects of reward value, subjective emotion, and hedonics (Rolls et al., 2023c,b). Interesting, the amygdala has much less connectivity to cortical areas including these language regions, and partly for this reason may play only a small role in experienced, declarative, human emotions and hedonics (Rolls et al., 2023b).

There are major differences in the neural pathways for taste in rodents (Rolls and Scott, 2003; Small and Scott, 2009; Scott and Small, 2009; Rolls, 2015d, 2016c,g) (Fig. 4.1). In rodents the majority of NTS taste neurons responding to stimulation of the taste receptors of the anterior tongue project to the ipsilateral medial aspect of the pontine parabrachial nucleus (PbN), the rodent 'pontine taste area' (Small and Scott, 2009; Cho et al., 2002). From the PbN the rodent gustatory pathway bifurcates into two pathways; 1) a ventral 'affective' projection to the hypothalamus, central gray, ventral striatum, bed nucleus of the stria terminalis and amygdala and 2) a dorsal 'sensory' pathway, which first synapses in the thalamus and then the agranular and dysgranular insular gustatory cortex (Norgren, 1990; Norgren and Leonard, 1971; Norgren, 1974, 1976; Kosar et al., 1986) (Fig. 4.1). These regions, in turn, project back to the PbN to "sculpt the gustatory code" and guide complex feeding behaviors (Norgren, 1990, 1976; Li and Cho, 2006; Li et al., 2002; Lundy and Norgren, 2004; Di Lorenzo, 1990; Scott and Small, 2009; Small and Scott, 2009). It may be noted that there is strong evidence to indicate that the PbN gustatory relay is absent in the human and the nonhuman primate (Small and Scott, 2009; Scott and Small, 2009). First, second-order gustatory projections that arise from rostral NTS appear not to synapse in the PbN and instead join the central tegmental tract and project directly to the taste thalamus in primates (Beckstead, Morse and Norgren, 1980; Pritchard, Hamilton and Norgren, 1989). Second, despite several attempts, no one has successfully isolated taste responses in the monkey PbN (Norgren (1990); and Small and Scott (2009) who cite Ralph Norgren, personal communication and Tom Pritchard, personal communication). Third, in monkeys the projection arising from the PbN does not terminate in the region of ventral basal thalamus that contains gustatory responsive neurons (Pritchard et al., 1989).

It is surprising from an evolutionary perspective that such a fundamental brain system as the taste system should have such different connections (and functioning as shown in Section 4.2.4) in primates and rodents. It is suggested that there are computational reasons for this: the primate visual system has evolved its multiple-layer hierarchy to solve the major computational problem of what object is represented with invariance, and this provides advantage in being able to learn about for example where foods are even when they are not rewarding because no hunger is present. This implies a separation of perceptual from reward value processing in primates. It is suggested that with this evolutionary advance made possible by visual cortical computation, it became advantageous to perform a similar separation of perceptual from reward value processing in other sensory modalities, leading to the advantage in primates of having a primary taste cortex that represents the sensory qualities of taste, so that it can be matched at the object level to perceptual representations in other modalities. Consistent with that, a later stage of processing, the orbitofrontal cortex, then evolved to specialise

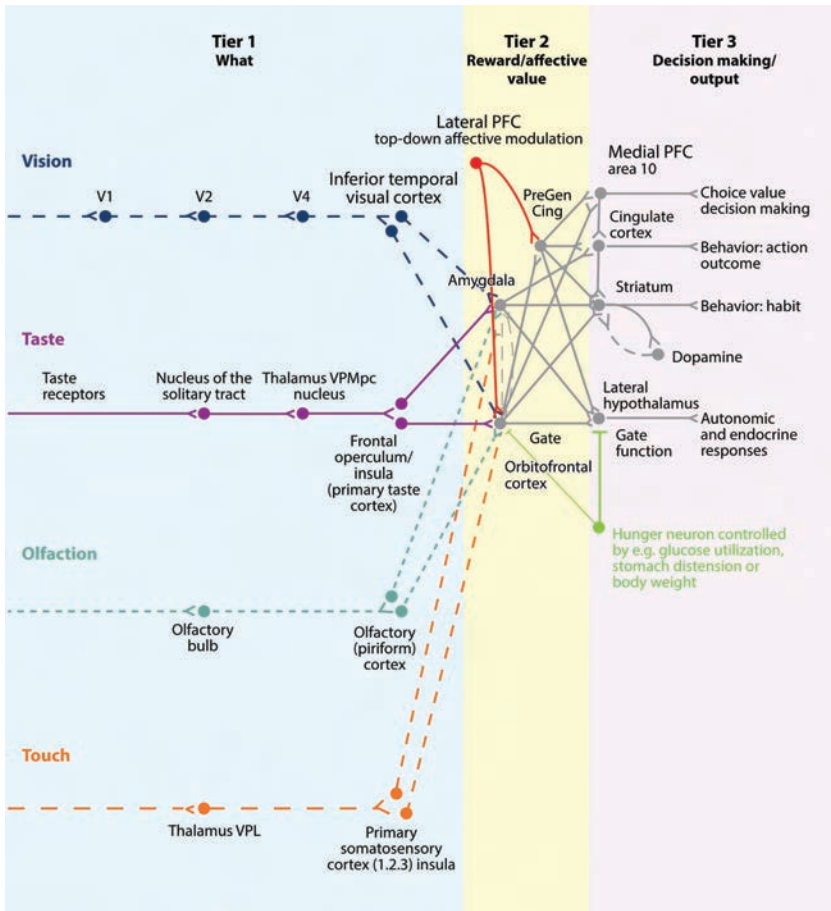

Fig. 4.3 Schematic diagram showing some of the connections of the taste, olfactory, somatosensory, and visual pathways in the primate brain. V1, primary visual (striate) cortex; V2 and V4, further cortical visual areas. PFC, prefrontal cortex. VPL, ventro-postero-lateral nucleus of the thalamus, which conveys somatosensory information to the primary somatosensory cortex (areas 1, 2 and 3). VPMpc, ventro-postero-medial nucleus pars parvocellularis of the thalamus, which conveys taste information to the primary taste cortex. Pregen Cing, pregenual cingulate cortex. For purposes of description, the stages can be described as Tier 1, representing what object is present independently of reward value; Tier 2 in which reward value is represented; and Tier 3 in which decisions between stimuli of different value are taken, and in which value is interfaced to behavioral output systems. (After Rolls, E. T. (2016) Reward systems in the brain and nutrition. Annual Review of Nutrition 36: 435–470. Reproduced with permission from the Annual Review of Nutrition, Volume 36 © 2016 by Annual Reviews, <http://www.annualreviews.org>.)

in reward value processing, for all sensory modalities. In contrast, the rodent taste system sends taste information to many subcortical areas without processing in the taste cortex, and given that even at early stages of taste processing in rodents reward value becomes part of what is encoded, this makes the rodent system not only much more difficult to analyze and understand computationally, but also a poor model of the computations in primates including humans (Rolls, 2015d, 2016c,g, 2019e).

4.2.2 Taste neuronal tuning become more selective through the taste hierarchy

The tuning of taste receptors and the taste nerves has been described as selective for the individual tastes sweet, salt, sour, bitter and umami in mice (Barretto, Gillis-Smith, Chandrashekar, Yarmolinsky, Schnitzer, Ryba and Zuker, 2015). However, there is further evi-

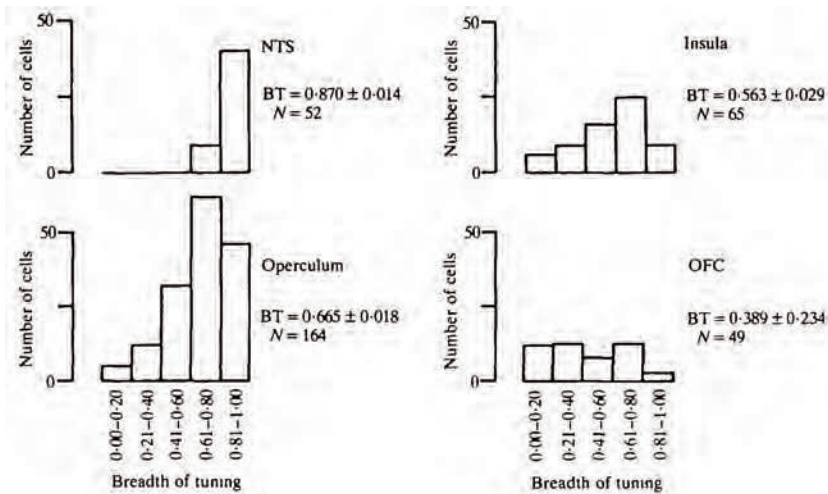

Fig. 4.4 The breadth of tuning index H (see text) for neurons recorded in the nucleus of the solitary tract (NTS), the primary taste cortical areas in the frontal operculum and insula, and the secondary taste cortical area in the caudolateral orbitofrontal cortex (OFC) of macaques is shown. The means (\pm sem) and the number of neurons in the sample for each area are shown. (After Rolls, E. T. (1989) Information processing in the taste system of primates. *Journal of Experimental Biology* 146: 141–164. © The Company of Biologists Limited.)

dence also in mice that many taste nerves respond to several tastes, especially at midrange concentrations, with a breadth of tuning that was often in the range 0.3 to 0.4, not close to 0 expected of neurons that respond to only one basic taste (Wu et al., 2015; Roper and Chaudhari, 2017)¹⁰. For comparison, in macaques the tuning in the taste nerves is quite distributed, with values between $H = 0.37$ and 0.81 (Hellekant et al., 1997). This most of the evidence is that in the periphery, the taste tuning is not of highly selective (‘labelled line’) encoding, but instead of a more distributed representation.

The first central synapse of the gustatory system is in the rostral part of the nucleus of the solitary tract (Beckstead and Norgren, 1979; Beckstead, Morse and Norgren, 1980; Scott, Yaxley, Sienkiewicz and Rolls, 1986b; Yaxley, Rolls, Sienkiewicz and Scott, 1985), and this projects via the thalamic taste relay to the primary taste cortex in the anterior insula and adjoining frontal operculum (Pritchard et al., 1986). The cortical hierarchy for taste can be thought of as the primary taste cortex in the anterior insula, the secondary taste cortex in the orbitofrontal cortex, and the tertiary taste cortex in the anterior cingulate cortex (Rolls, 2014a, 2015d).

When we consider the different stages of processing in macaques, we find evidence that the breadth of tuning becomes lower, i.e. the neurons become more selective, from the first central relay, the nucleus of the solitary tract, to the primary taste cortex (insula and adjoining frontal operculum), and then to the secondary taste cortex in the orbitofrontal cortex, as shown in Fig. 4.4 (Rolls, 1989d). The tuning of one insula neuron is shown in Fig. 4.5, and its breadth of tuning across the five basic tastes was $H = 0.4$ (with the sparseness $a = 0.36$).

The utility of this computation of a more selective encoding up through the taste hierarchy is that this helps with the computation of sensory-specific satiety, as described in Section 4.2.5; and it facilitates the learning of associations of visual and olfactory with taste stimuli,

¹⁰The breadth of tuning or entropy measure H used in some taste research is $H = -K \sum p_i \log_{10} p_i$ where the sum is over the $i = 1$ to n stimuli, p_i is the proportion of the total response over all stimuli to the i th stimulus, and K is set so that if all stimuli produce equal responses, $H = 1$. If the neuron responds to only one stimulus, $H = 0$. The values are numerically similar to the sparseness measure a defined in Equation C.45, except that when a neuron responds to only one stimulus, the lowest value of H is 0, and the lowest value of the sparseness is close to $1/n$.

Fig. 4.5 The responses of an insular taste cortex neuron (bo135) with differential responses to taste but no responses to temperature, viscosity, fat, or any of the other stimuli. The neuron did not respond to odor or to the sight of food (visual). The spontaneous (Spon) firing rate is shown by the horizontal line. The taste stimuli were 1 M glucose (G), 0.1 M NaCl (N), 0.1 M MSG (M), 0.01 M HCl (H), and 0.001 M quinine-HCl (Q); the temperature stimuli were T10, T23, T37, and T42 where the number indicates the temperature in degrees celsius; the viscosity stimuli were V1, V10, V100, V1000, and V10000 where the numeral indicates the viscosity in centiPoise at 23°C; fat texture stimuli were SiO10, SiO100, SiO1000 (silicone oil with the viscosity indicated), vegetable oil (VO), coconut oil (CO), and safflower oil (SaO). BJ, fruit juice; Cap, 10 μ M capsaicin; LaA, 0.1 mM lauric acid; LiA, 0.1 mM linoleic acid; Gr, the gritty stimulus. (After Verhagen, J. V., Kadohisa, M., and Rolls, E. T. (2004) The primate insular/opercular taste cortex: neuronal representations of the viscosity, fat texture, grittiness, temperature, and taste of foods. *Journal of Neurophysiology* 92: 1685–1699. © American Physiological Society.)

because the capacity of a pattern associator is higher with sparse representations, as described in Section B.2.

4.2.3 The primary, insular, taste cortex represents what taste is present and its intensity

In the primary gustatory cortex of primates in the frontal operculum and insula, neurons are more sharply tuned to gustatory stimuli than in the nucleus of the solitary tract, with some neurons responding, for example, primarily to sweet, and much less to salt, bitter, or sour stimuli (Scott, Yaxley, Sienkiewicz and Rolls, 1986a; Yaxley, Rolls and Sienkiewicz, 1990) (as illustrated in Figs. 4.5 and 4.4).

Hunger does not influence the magnitude of neuronal responses to gustatory stimuli in the primary taste cortex, so taste reward is not represented in the primary taste cortex (Rolls, Scott, Sienkiewicz and Yaxley, 1988; Yaxley, Rolls and Sienkiewicz, 1988).

The firing rates of the neurons in the primary taste cortex increase with stimulus concentration (Scott et al., 1986a; Yaxley et al., 1990). Consistent with these neuronal findings in macaques, activations in the human insular primary taste cortex are linearly related to the subjective intensity of the taste (which depends on the concentration of the tastant (Rolls, Rolls and Rowe, 1983a)) and not to the pleasantness rating (Fig. 4.13) (Grabenhorst and Rolls, 2008). Further, activations in the human insular primary taste cortex are related to the concentration of the tastant, for example monosodium glutamate (Grabenhorst, Rolls and Bilderbeck, 2008a). Activation of the human insular cortex by taste is illustrated in Fig. 4.6 and is further described in Section 4.2.8.

Some of the computational advantages of what is being computed and represented in the primary taste cortex are described in the second paragraph of Section 4.2.1.

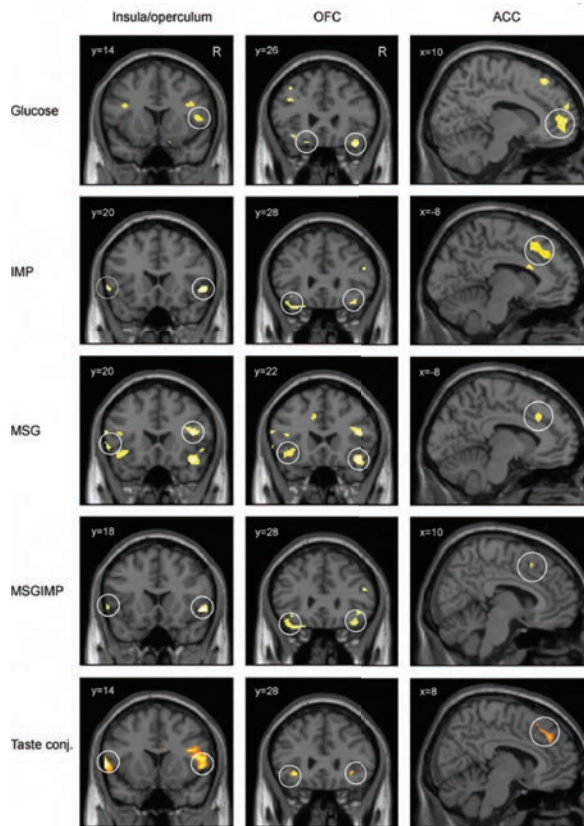

Fig. 4.6 Activation of the human primary taste cortex in the insula/frontal operculum; the orbitofrontal cortex (OFC); and the anterior cingulate cortex (ACC) by taste. The stimuli used included glucose, two umami taste stimuli (monosodium glutamate (MSG) and inosine monophosphate (IMP)), and a mixture of the two umami stimuli. Taste conj. refers to a conjunction analysis over all the taste stimuli. (Reproduced from I. E. T. De Araujo, M. L. Kringelbach, E. T. Rolls, and P. Hobden (2003) Representation of umami taste in the human brain. *Journal of Neurophysiology* 90: 313–319. © The American Physiological Society.)

4.2.4 The secondary, orbitofrontal, taste cortex, and its representation of the reward value and pleasantness of taste

A secondary cortical taste area has been discovered in the caudolateral orbitofrontal cortex of the primate in which gustatory neurons can be even more finely tuned to particular taste (and oral texture) stimuli (Rolls, Yaxley and Sienkiewicz, 1990; Rolls and Treves, 1990; Rolls, Sienkiewicz and Yaxley, 1989d; Verhagen, Rolls and Kadohisa, 2003; Rolls, Verhagen and Kadohisa, 2003e; Kadohisa, Rolls and Verhagen, 2004, 2005a; Rolls, Critchley, Verhagen and Kadohisa, 2010a) (as illustrated in Figs. 4.7, 4.8, and 4.4). In addition to representations of the ‘prototypical’ taste stimuli sweet, salt, bitter, and sour, different neurons in this region respond to other taste stimuli including umami or delicious savory taste as exemplified by monosodium glutamate which is present in tomatoes, mushroom, fish and meat, and human mothers’ milk (Baylis and Rolls, 1991; Rolls, 1996b; Rolls et al., 1998a), with corresponding activations in humans (De Araujo, Kringelbach, Rolls and Hobden, 2003b). Umami is a component of many foods which helps to make them taste pleasant, especially when the umami taste is paired with a consonant savoury odor (Rolls, Critchley, Browning and Hernadi, 1998a; McCabe and Rolls, 2007; Rolls, 2009b). In addition, water in the mouth activates some orbitofrontal cortex neurons (Rolls et al., 1990).

There is also evidence from functional neuroimaging that taste can activate the human

Fig. 4.7 Examples of the responses recorded from one orbitofrontal taste cortex neuron to the six taste stimuli, water, 20% blackcurrant juice (BJ), 1 M glucose, 1 M NaCl, 0.01 M HCl, and 0.001 M quinine HCl (QHCl). The stimuli were placed in the mouth at time 0. The neuron was quite selective, in that its best response was to glucose, even though the complex flavor of the blackcurrant juice included sweet taste. (Reproduced from E. T. Rolls, S. Yaxley and Z. J. Sienkiewicz (1990) Gustatory responses of single neurons in the caudolateral orbitofrontal cortex of the macaque monkey. *Journal of Neurophysiology* 64: 1055–1066. © The American Physiological Society.)

orbitofrontal cortex. For example, Francis, Rolls, Bowtell, McGlone, O’Doherty, Browning, Clare and Smith (1999) showed that the taste of glucose can activate the human orbitofrontal cortex, and O’Doherty, Rolls, Francis, Bowtell and McGlone (2001b) showed that the taste of glucose and salt activate nearby but separate parts of the human orbitofrontal cortex. De Araujo, Kringelbach, Rolls and Hobden (2003b) showed that umami taste (the taste of protein) as exemplified by monosodium glutamate is represented in the human orbitofrontal cortex as well as in the primary taste cortex as shown by functional magnetic resonance imaging (fMRI) (Fig. 4.6). The taste effect of monosodium glutamate (present in e.g. tomato, green vegetables, fish, and human breast milk) was enhanced in an anterior part of the orbitofrontal cortex in particular by combining it with the nucleotide inosine monophosphate (present in e.g. meat and some fish including tuna), and this provides evidence that the activations found in the orbitofrontal cortex are closely related to subjectively reported taste effects (Rolls, 2009b; Rolls and Grabenhorst, 2008). Small and colleagues have also described activation of the orbitofrontal cortex by taste (Small et al., 1999, 2007).

Another fundamental computation takes place in the primate secondary taste cortex in the orbitofrontal cortex, a transform from the representation about the identity of the taste and texture of stimuli in the primary taste cortex that is independent of reward value and pleasantness, to a representation of the reward value and pleasantness of the taste in the secondary taste cortex. In particular, in the primate orbitofrontal cortex, it is found that the responses of taste neurons to the particular food with which a monkey is fed to satiety decrease to zero (Rolls, Sienkiewicz and Yaxley, 1989d). An example is shown in Fig. 4.8. This neuron reduced its responses to the taste of glucose during the course of feeding as much glucose as the monkey wanted to drink. When the monkey was fully satiated, and did not want to drink any more glucose, the neuron no longer responded to the taste of glucose. Thus the responses of these neurons decrease to zero when the reward value of the food decreases to zero, and

Fig. 4.8 The effect of feeding to satiety with glucose solution on the responses (rate \pm s.e.m.) of a neuron in the secondary taste cortex to the taste of glucose (open circles) and of blackcurrant juice (BJ). The spontaneous firing rate is also indicated (SA). Below the neuronal response data, the behavioral measure of the acceptance or rejection of the solution on a scale from +2 (strong acceptance) to -2 (strong rejection) is shown. The solution used to feed to satiety was 20% glucose. The monkey was fed 50 ml of the solution at each stage of the experiment as indicated along the abscissa, until he was satiated as shown by whether he accepted or rejected the solution. Pre is the firing rate of the neuron before the satiety experiment started. (Reproduced with permission from Rolls, E. T., Sienkiewicz, Z. J. and Yaxley, S. (1989) Hunger modulates the responses to gustatory stimuli of single neurons in the caudolateral orbitofrontal cortex of the macaque monkey. *European Journal of Neuroscience* 1: 53–60. Copyright © Federation of European Neuroscience Societies and John Wiley and Sons.)

they represent reward value. Further evidence that this is a representation of economic value is described in Chapter 11.

4.2.5 Sensory-specific satiety is computed in the orbitofrontal cortex

The neuron illustrated in Fig. 4.8 still responded to another food, blackcurrant juice, after the monkey had been fed to satiety with glucose, and the monkey chose to eat the blackcurrant juice, and other foods. This is typical of orbitofrontal cortex neurons (Rolls et al., 1989d). Thus the modulation of the responses of these orbitofrontal cortex taste neurons occurs in a sensory-specific way, and they represent *reward value in a sensory-specific way*.

In humans, there is evidence that the reward value, and, what can be directly reported in humans, the subjective pleasantness, of food is represented in the orbitofrontal cortex. The evidence comes from an fMRI study in which humans rated the pleasantness of the flavor of chocolate milk and tomato juice, and then ate one of these foods to satiety. It was found that the subjective pleasantness of the flavor of the food eaten to satiety decreased, and that this decrease in pleasantness was reflected in decreased activation in the orbitofrontal cortex (Kringelbach, O'Doherty, Rolls and Andrews, 2003) (see Fig. 4.9). (This was measured in a functional magnetic resonance imaging (fMRI) investigation in which the activation as reflected by the blood oxygenation-level dependent (BOLD) signal was measured, which re-

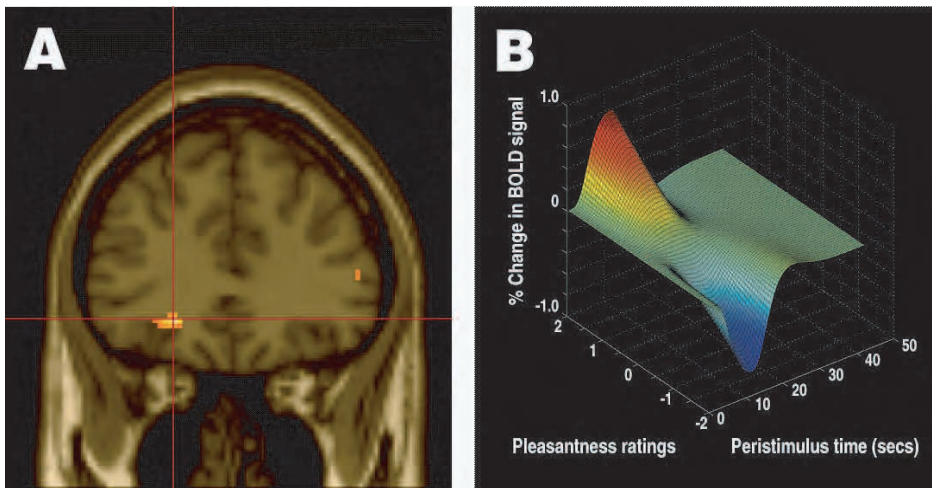

Fig. 4.9 Areas of the human orbitofrontal cortex with activations correlating with pleasantness ratings for food in the mouth. (A) Coronal section through the region of the orbitofrontal cortex from the random effects group analysis showing the peak in the left orbitofrontal cortex (Talairach co-ordinates X,Y,Z=[-22 34 -8], z-score=4.06), in which the BOLD signal in the voxels shown in yellow was significantly correlated with the subjects' subjective pleasantness ratings of the foods throughout an experiment in which the subjects were hungry and found the food pleasant, and were then fed to satiety with the food, after which the pleasantness of the food decreased to neutral or slightly unpleasant. The design was a sensory-specific satiety design, and the pleasantness of the food not eaten in the meal, and the BOLD activation in the orbitofrontal cortex, were not altered by eating the other food to satiety. The two foods were tomato juice and chocolate milk. (B) Plot of the magnitude of the fitted haemodynamic response from a representative single subject against the subjective pleasantness ratings (on a scale from -2 to +2) and peristimulus time in seconds. (Reproduced from M.L. Kringelbach, J.O'Doherty, E.T. Rolls and C. Andrews (2003) Activation of the human orbitofrontal cortex to a liquid food stimulus is correlated with its subjective pleasantness. *Cerebral Cortex* 13: 1064–1071. Copyright © Oxford University Press.)

flects increased blood flow due to increased neuronal activity (Stephan et al., 2007; Rolls et al., 2009).) Further evidence that the pleasantness of flavor is represented here is that the pleasantness of the food not eaten to satiety showed very little decrease, and correspondingly the activation of the orbitofrontal cortex to this food not eaten in the meal showed little decrease. The phenomenon itself is called sensory-specific satiety, is an important property of reward systems, and is described in more detail below and by Rolls (2014a).

The experiment of Kringelbach, O'Doherty, Rolls and Andrews (2003) was with a whole food, but further evidence that the pleasantness of taste, or at least a stimulus very closely related to a taste, is represented in the human orbitofrontal cortex is that the orbitofrontal cortex is activated by water in the mouth when thirsty but not when satiated (De Araujo, Kringelbach, Rolls and McGlone, 2003c). Thus, the neuroimaging findings with a whole food, and with water when thirsty, provide evidence that the activation to taste *per se* in the human orbitofrontal cortex is related to the subjective pleasantness or affective value of taste and flavor, that is, to *pleasure*. Further evidence on reward value for taste is that in fMRI investigations, activations in the human orbitofrontal cortex are linearly related to the subjective pleasantness of the taste (Grabenhorst and Rolls, 2008) (Fig. 4.12).

Sensory-specific satiety is one of the most important factors that affects reward value, and is therefore described briefly here, in the context that it is computed in the orbitofrontal cortex. Sensory-specific satiety is a decrease in the reward value of a stimulus that is at least partly specific to that reward, and is a result of delivering that reward (Rolls, 2014a). Sensory-specific satiety was discovered during neurophysiological experiments on brain mechanisms of reward and satiety by Edmund Rolls and colleagues in 1974. They observed that if a lateral hypothalamic neuron had ceased to respond to a food on which the monkey had been fed to

satiety (a discovery described in *The Brain and Reward* (Rolls, 1975)), then the neuron might still respond to a different food (see Rolls (2014a)). This occurred for neurons with responses associated with the taste (Rolls, 1981a,b; Rolls, Murzi, Yaxley, Thorpe and Simpson, 1986) or sight (Rolls, 1981a; Rolls and Rolls, 1982; Rolls, Murzi, Yaxley, Thorpe and Simpson, 1986) of food. Corresponding to this neuronal specificity of the effects of feeding to satiety, the monkey rejected the food on which he had been fed to satiety, but accepted other foods that he had not been fed. The neurophysiological finding was published for example in Rolls (1981a) and Rolls, Murzi, Yaxley, Thorpe and Simpson (1986). This is now described as a devaluation procedure, and provides evidence that these, and orbitofrontal cortex neurons that provide inputs to the lateral hypothalamus, encode **value**.

Subsequent research showed that sensory-specific satiety is present (and computed (Rolls, 2014a, 2016b)) in the orbitofrontal cortex (Rolls, Sienkiewicz and Yaxley, 1989d; Critchley and Rolls, 1996a; Kringsbach, O'Doherty, Rolls and Andrews, 2003) but not in earlier cortical areas such as the insula (Rolls, Scott, Sienkiewicz and Yaxley, 1988; Yaxley, Rolls and Sienkiewicz, 1988).

Following the neurophysiological discovery of sensory-specific satiety, I initiated a series of studies on sensory-specific satiety in humans, starting with an undergraduate practical class at Oxford, with Barbara Rolls participating, and also my daughter (Rolls and Rolls, 1997). We showed that sensory-specific satiety is one of the most important factors influencing in humans what and how much is ingested in a meal (Rolls and Rolls, 1982; Rolls et al., 1981b,c, 1982c,b; Rolls and Rolls, 1997; Rolls, 1999a, 2014a), showed that olfactory sensory-specific satiety can be produced in part by merely sniffing a food for as long as it would typically be eaten in a meal (Rolls and Rolls, 1997), and showed that there is a long-term form of sensory-specific satiety (Rolls and de Waal, 1985). Sensory-specific satiety is not a sensory adaptation, in that it does not occur in primary taste cortical areas, and the inferior temporal visual cortex (Rolls et al., 1977), and in that there is little decline in the intensity of the stimulus even though the pleasantness declines greatly (Rolls et al., 1983a). The hypothesis is that sensory-specific satiety is produced by adaptation of active afferent synapses onto neurons in the orbitofrontal cortex that represent reward value (Rolls, 2014a). I have argued that it is one of the factors that as a result of variety can overstimulate food intake and be associated with obesity, and is one of many factors that may all need to be taken into account in controlling food intake to prevent or minimize obesity (Rolls, 2016g, 2014a, 2018a, 2012f, 2023f; Rolls et al., 2023g). The evolutionary adaptive value of sensory-specific satiety is that it leads to animals not only eating a variety of food and maintaining good nutrition, but also in performing a whole set of different rewarded behaviors which promote successful reproduction and passing the successful set of genes into the next generation (Rolls, 2014a). Moreover, although sensory-specific satiety is a property of all reward systems, for the reason given, it is not a property of any punishment system, in that aversive stimuli such as a thorn on the foot must be the subject of action, for any single punishing event could threaten reproductive success making any sensory-specific reductions that might occur for punishers highly maladaptive (Rolls, 2014a).

Further evidence on the nature of the taste-related value representations, analyzed in a neuroeconomic framework, is described in Chapter 11.

Some of the computational advantages of what is being computed and represented in the primary taste cortex are described in the second paragraph of Section 4.2.1.

4.2.6 Oral texture is represented in the primary and secondary taste cortex: viscosity and fat texture

Single neurons in the insular primary taste cortex also represent the viscosity (measured with carboxymethylcellulose) and temperature of stimuli in the mouth, and fat texture, but not the sight and smell of food (Verhagen, Kadohisa and Rolls, 2004; Kadohisa, Rolls and Verhagen, 2005a). In humans, the insular primary taste cortex is activated not only by taste (Francis, Rolls, Bowtell, McGlone, O'Doherty, Browning, Clare and Smith, 1999; Small, Zald, Jones-Gotman, Zatorre, Petrides and Evans, 1999; De Araujo, Kringelbach, Rolls and Hobden, 2003b; De Araujo and Rolls, 2004; De Araujo, Kringelbach, Rolls and McGlone, 2003c; Grabenhorst, Rolls and Bilderbeck, 2008a), but also by oral texture including viscosity (with the activation linearly related to the log of the viscosity) and fat texture (De Araujo and Rolls, 2004), and temperature (Guest et al., 2007).

Some orbitofrontal cortex neurons respond to different combinations of taste and related oral texture stimuli. This shows that in the taste system too, in the hierarchy, neurons become tuned to low order combinations of sensory inputs, in order to separate the input space in a way that allows easy decoding by dot product decoding, allows specific tastes to be associated with particular stimuli in other modalities including olfaction and vision, and allows for sensory-specific satiety, as will soon be shown. (The computational mechanisms is probably competitive learning, as described in Section 1.9 and Chapter 2). Examples of the tuning of orbitofrontal cortex neurons to different combinations of taste and oral texture are illustrated in Fig. 4.10. For example, the neuron illustrated in Fig. 4.10 (lower) responded to the taste of sweet (glucose, blackcurrant juice BJ, sour (HCl), and bitter (quinine) but not to the taste of salt (NaCl) or umami (monosodium glutamate, MSG); to viscosity (as altered parametrically using the standard food thickening agent carboxymethylcellulose made up in viscosities of 1–10,000 cPoise (Rolls, Verhagen and Kadohisa, 2003e), where 10,000 cP is approximately the viscosity of toothpaste); did not respond to fat in the mouth (oils); and did respond to capsaicin (chilli pepper). In contrast, the neuron shown in the upper part of Fig. 4.10 had no response to taste; did respond to oral viscosity; did respond to oral fat (see Rolls, Critchley, Browning, Hernadi and Lenard (1999a) and Verhagen, Rolls and Kadohisa (2003)); and did not respond to capsaicin. This combinatorial encoding in the taste and oral texture system is important in the mechanism of the fundamental property of reward systems, sensory-specific satiety, as described in Section 4.2.5.

These findings have been extended to humans, with the finding with fMRI that activation of the orbitofrontal cortex and pregenual cingulate cortex is produced by the texture of fat in the mouth (De Araujo and Rolls, 2004). Moreover, activations in the orbitofrontal cortex and pregenual cingulate cortex are correlated with the pleasantness of fat texture in the mouth (Grabenhorst, Rolls, Parris and D'Souza, 2010b).

Texture in the mouth is an important indicator of whether fat is present in the food, which is important not only as a high value energy source, but also as a potential source of essential fatty acids. In the orbitofrontal cortex, Rolls, Critchley, Browning, Hernadi and Lenard (1999a) discovered a population of neurons that responds when fat is in the mouth. The fat-related responses of these neurons are produced at least in part by the texture of the food rather than by chemical receptors sensitive to certain chemicals, in that such neurons typically respond not only to foods such as cream and milk containing fat, but also to paraffin oil (which is a pure hydrocarbon) and to silicone oil (which contains $(\text{Si}(\text{CH}_3)_2\text{O})_n$) (Rolls et al., 1999a).

To investigate the bases of the responses of fat-sensitive neurons, we measured the correlations between their responses and physical measures of the properties of the set of stimuli, including viscosity and the coefficient of sliding friction (Rolls, Mills, Norton, Lazidis and

Fig. 4.10 Above. Firing rates (mean \pm s.e.m.) of orbitofrontal cortex viscosity-sensitive neuron bk244 which did not have taste responses. The firing rates are shown to the viscosity series (carboxymethylcellulose in the range 1–10,000 centiPoise), to the gritty stimulus (carboxymethylcellulose with Fillite microspheres), to the taste stimuli 1 M glucose (Gluc), 0.1 M NaCl, 0.1 M MSG, 0.01 M HCl and 0.001 M QuinineHCl, and to fruit juice (BJ). Spont = spontaneous firing rate. Below. Firing rates (mean \pm s.e.m.) of viscosity-sensitive neuron bo34 which had no response to the oils (mineral oil, vegetable oil, safflower oil and coconut oil, which have viscosities which are all close to 50 cP). The neuron did not respond to the gritty stimulus in a way that was unexpected given the viscosity of the stimulus, was taste tuned, and did respond to capsaicin. (Reproduced from E. T. Rolls, J. V. Verhagen, and M. Kadohisa (2003) Representations of the texture of food in the primate orbitofrontal cortex: neurons responding to viscosity, grittiness, and capsaicin. *Journal of Neurophysiology* 90: 3711–3724, © The American Physiological Society.)

Norton, 2018b). The coefficient of sliding friction is the force required to slide two surfaces divided by the force normal to the surfaces. This is also known as kinetic or dynamic friction. It measures effectively the lubricity or the slipperiness of a substance. We found that some fat-sensitive neurons increased their firing rates linearly as the coefficient of sliding friction of the stimuli became smaller. Another population of neurons had their firing rates non-linearly related to the coefficient of sliding friction, and increased their rates only when the coefficient of sliding friction became less than 0.04, and were thus highly selective to the fats and the non-fat oils (see example in Fig. 4.11) (Rolls et al., 2018b). These neurons were more likely to be found in the orbitofrontal cortex than the primary taste cortex, consistent with the hypothesis of non-linear encoding in hierarchical cortical systems (Rolls, 2016b). Another population of neurons had responses that were inhibited by fat: they had responses that increased linearly with the coefficient of sliding friction. The activity of these fat-sensitive

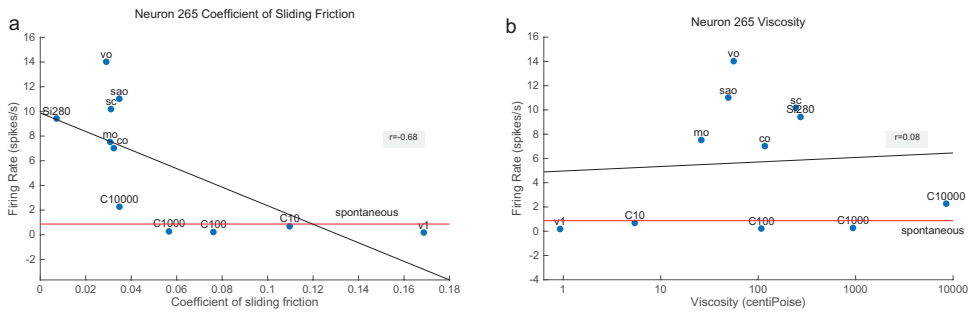

Fig. 4.11 An orbitofrontal cortex neuron with responses non-linearly correlated with decreases in the coefficient of sliding friction (a). The neuron responds almost not at all until the coefficient of sliding friction falls below 0.04. The neuron is thus very selective for fat texture, because of its non-linear response in relation to the coefficient of sliding friction. The linear regression line has a correlation of $r = -0.68$ ($p=0.02$). (b): There is a much weaker relation to viscosity ($r = 0.08$, $p=0.82$), with the oils producing a larger response than predicted linearly. Further, a regression line through the non-oil stimuli would have a lower slope. C10-C10000: carboxymethyl cellulose with the nominal viscosity of 10, 100, 1000 and 10,000 cP. v1: water (1 cP). co: coconut oil; mo: mineral oil; sao: safflower oil; vo: vegetable oil; sc: single cream. Si280: silicone oil with a nominal viscosity of 280 cP. Li: linoleic acid; La: lauric acid. The horizontal red line indicates the spontaneous firing rate. The Pearson correlation between the firing rate of each neuron and (a) the coefficient of sliding friction, and (b) the viscosity, was calculated to show to what extent the firing of a neuron reflected one or other of these measures. Linear regression lines are shown in the Figure for how the firing rates were related to the coefficient of sliding friction, or to the log of the viscosity. (Reproduced from Edmund T Rolls, Tom Mills, Abigail B Norton, Aris Lazidis, and Ian T Norton (2018) The Neuronal Encoding of Oral Fat by the Coefficient of Sliding Friction in the Cerebral Cortex and Amygdala. *Cerebral Cortex* 28: 4080-4089.)

neurons was not closely related to viscosity. The responses of these neurons are related to the reward value of fat in the mouth, in that the responses decrease to zero during feeding to satiety (Rolls, Critchley, Browning, Hernadi and Lenard, 1999a). The fat-sensitive neurons did not have responses to lauric or linoleic acid, so their responses were not related to fatty acid sensing. A separate population of neurons did have responses to linoleic or lauric fatty acids, but not to fat in the mouth. Their responses may be related to “off tastes” of food produced for example by butyric acid, which food manufacturers aim to minimize in foods (Rolls, 2020c). Another population of neurons had responses related to the log of viscosity (which correlates with subjective ratings of food thickness (Kadohisa et al., 2005a)), but not with the coefficient of sliding friction (Rolls et al., 2018b).

This new understanding of the representation of oral fat by the coefficient of sliding friction in the cerebral cortex opens the way for the systematic development of foods with the pleasant mouth-feel of fat, together with ideal nutritional content, and has great potential to contribute to healthy eating and a healthy body weight (Rolls et al., 2018b; Rolls, 2020c).

Thus we have seen that what is represented in the primary and secondary taste cortex in terms of texture plays an important role in detecting key nutrients such as fat in a food in the mouth.

4.2.7 Vision and olfaction converge using associative learning with taste to represent flavor in the secondary but not primary taste cortex

As illustrated in Fig. 4.5, the odor and the sight of food and other stimuli does not activate neurons in the insular primary taste cortex (Verhagen, Kadohisa and Rolls, 2004). A computational advantage of what is represented is thereby that taste can be represented independently of flavor (where flavor is produced by multimodal inputs that typically involve at least taste and odor), and this is likely to be important in the identification and selection of particular foods.

However, in the secondary taste cortex in the orbitofrontal cortex, many neurons respond

to combinations of taste and olfactory stimuli (Rolls and Baylis, 1994), and their tuning to individual food flavors can be selective. These neurons may learn which odor to respond to by olfactory-to-taste association learning. This was confirmed by reversing the taste with which an odor was associated in the reversal of an olfactory discrimination task. It was found that 73% of the sample of neurons analyzed altered the way in which they responded to odor when the taste reinforcer association of the odor was reversed (Rolls, Critchley, Mason and Wakeman, 1996b). Reversal was shown by 25% of the neurons, and 48% altered their activity in that they no longer discriminated after the reversal. These latter neurons thus respond to a particular odor only if it is associated with a taste reward, and not when it is associated with the taste of salt, a punisher. They do not respond to the other odor in the task when it is associated with reward. Thus they respond to a particular combination of an odor, and its being associated with taste reward and not a taste punisher. They may be described as *conditional olfactory-reward neurons*, and may be important in the mechanism by which stimulus-reinforcer (in this case olfactory-to-taste) reversal learning occurs (Deco and Rolls, 2005b), as described in Section 11.5.3.

The human orbitofrontal cortex also reflects the convergence of taste and olfactory inputs, as shown for example by the fact that activations in the human medial orbitofrontal cortex are correlated with both the cross-modal consonance of combined taste and olfactory stimuli (high for example for sweet taste and strawberry odor), as well as for the pleasantness of the combinations (De Araujo, Rolls, Kringelbach, McGlone and Phillips, 2003a). In addition, the combination of monosodium glutamate taste and a consonant savoury odor produced a supralinear effect in the medial orbitofrontal cortex to produce the rich delicious flavor of umami that makes many foods pleasant that are rich in protein (McCabe and Rolls, 2007; Rolls, 2009b).

We have been able to show that there is a major visual input to many neurons in the orbitofrontal cortex, and that what is represented by these neurons is in many cases the reinforcer (reward or punisher) association of visual stimuli. Many of these neurons reflect the relative preference or reward value of different visual stimuli, in that their responses decrease to zero to the sight of one food on which the monkey is being fed to satiety, but remain unchanged to the sight of other food stimuli. In this sense the visual reinforcement-related neurons predict the reward value that is available from the primary reinforcer, the taste. The visual input is from the ventral, temporal lobe, visual stream concerned with ‘what’ object is being seen, in that orbitofrontal visual neurons frequently respond differentially to objects or images (but depending on their reward association) (Thorpe, Rolls and Maddison, 1983; Rolls, Critchley, Mason and Wakeman, 1996b). The primary reinforcer that has been used is taste.

The fact that these neurons represent the reinforcer associations of visual stimuli and hence the expected value has been shown to be the case in formal investigations of the activity of orbitofrontal cortex visual neurons, which in many cases reverse their responses to visual stimuli when the taste with which the visual stimulus is associated is reversed by the experimenter (Thorpe, Rolls and Maddison, 1983; Rolls, Critchley, Mason and Wakeman, 1996b). An example of the responses of an orbitofrontal cortex neuron that reversed the visual stimulus to which it responded during reward reversal is shown in Fig. 11.5.

This reversal by orbitofrontal visual neurons can be very fast, in as little as one trial, and this is a key computation of the orbitofrontal cortex, for it is rule-based, as described in Chapter 11.

The research described in this section shows that a key computation performed in the orbitofrontal cortex is association of taste with visual and olfactory stimuli, and that this occurs with learning that can allow rapid reversal. These computations are very important for enabling primates with their well developed visual system to find foods based on their sight and odor, which is highly adaptive. It enables the sight of food to be treated as a goal for

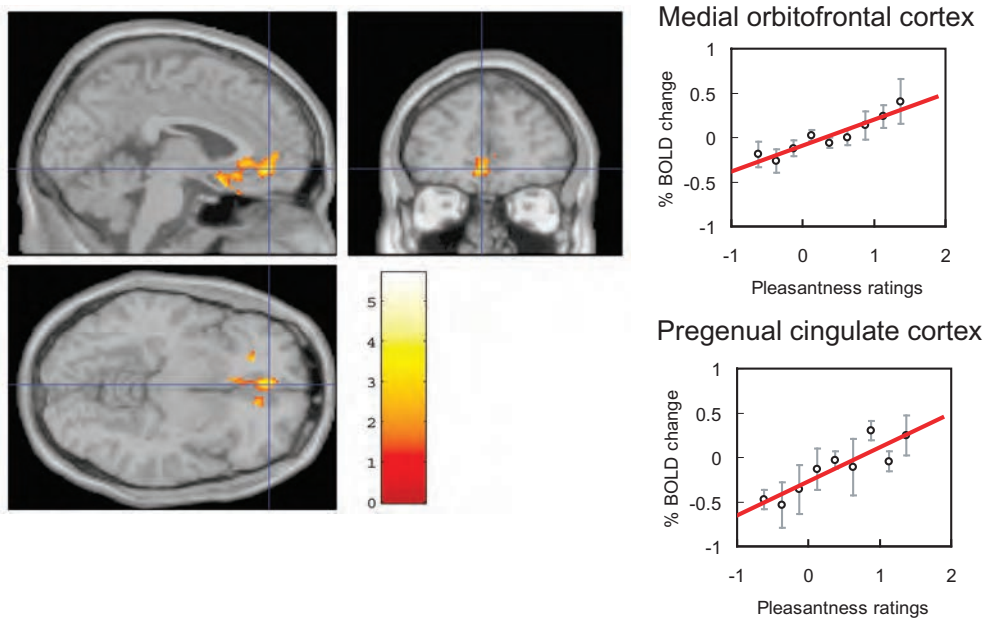

Fig. 4.12 Top-down attention and emotion. Effect of paying attention to the pleasantness of a taste. Left: A significant difference related to the taste period was found in the medial orbitofrontal cortex at $[-6\ 14\ -20]$ $z=3.81$ $p<0.003$ (towards the back of the area of activation shown) and in the pregenual cingulate cortex at $[-4\ 46\ -8]$ $z=2.90$ $p<0.04$ (at the cursor). Right upper: The correlation between the subjective pleasantness ratings and the activation (% BOLD change) in the orbitofrontal cortex ($r=0.94$, $df=8$, $p<<0.001$). Right lower: The correlation between the pleasantness ratings and the activation (% BOLD change) in the pregenual cingulate cortex $r=0.89$, $df=8$, $p=0.001$. The taste stimulus, monosodium glutamate, was identical on all trials. (Reproduced from Fabian Grabenhorst and Edmund T. Rolls (2008) Selective attention to affective value alters how the brain processes taste stimuli. *European Journal of Neuroscience* 27: 723–729.)

action, with the action to be performed learned by the cingulate cortex based on the value input from the orbitofrontal cortex, as described in Chapter 12. The same principles of visual to reinforcer learning apply to many stimuli other than taste, making the orbitofrontal cortex a key brain area for the computation of value, as described in Chapter 11.

4.2.8 Top-down attention and cognition can modulate taste and flavor representations in the taste cortical areas

Attentional instructions at a very high, linguistic, level (e.g. ‘pay attention to and rate intensity’ vs ‘pay attention to and rate pleasantness’) have a top-down modulatory influence on intensity representations in the primary taste cortex, and on value representations in the orbitofrontal cortex and anterior cingulate cortex. The attentional instructions can bias processing for a stimulus between streams involving sensory processing areas such as the insular taste cortex and pyriform primary olfactory cortex, and a stream through the orbitofrontal and cingulate cortices that processes value and affect.

In an investigation of the effects of selective attention to value and affect vs intensity on taste processing, when subjects were instructed to remember and rate the pleasantness of a savoury taste stimulus, 0.1 M monosodium glutamate, activations were greater in the medial orbitofrontal and pregenual cingulate cortex than when subjects were instructed to remember and rate the intensity of the taste (Grabenhorst and Rolls, 2008) (Fig. 4.12). When the subjects were instructed to remember and rate the intensity, activations were greater in the insular taste cortex and a mid-insular cortex region (Fig. 4.13).

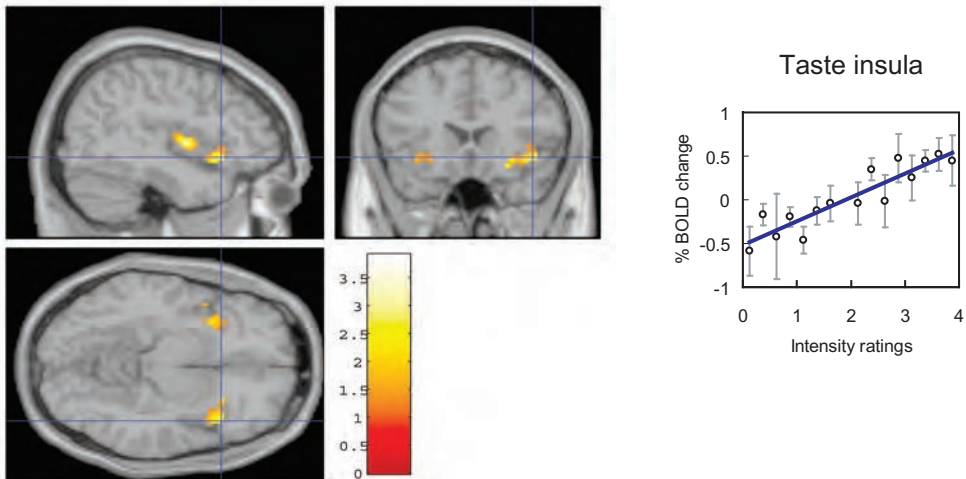

Fig. 4.13 Top-down attention and emotion. Left: Effect of paying attention to the intensity of a taste. Top: A significant difference related to the taste period was found in the taste insula at [42 18 -14] $z=2.42$ $p<0.05$ (indicated by the cursor) and in the mid insula at [40 -2 4] $z=3.03$ $p<0.025$. Right: The correlation between the intensity ratings and the activation (% BOLD change) in the taste insula ($r=0.91$, $df=14$, $p<<0.001$). The taste stimulus, monosodium glutamate, was identical on all trials. (Reproduced from Fabian Grabenhorst and Edmund T. Rolls (2008) Selective attention to affective value alters how the brain processes taste stimuli. *European Journal of Neuroscience* 27: 723–729.)

In an investigation of top-down cognitive modulation of affective processing in another modality, taste, it was found that activations related to the affective value of umami (delicious savoury) taste and flavor (as shown by correlations with pleasantness ratings) in the orbitofrontal cortex were modulated by word-level descriptors (Grabenhorst, Rolls and Bilderbeck, 2008a). The cognitive modulation was produced by presenting the taste with a visual word-level descriptor such as ‘rich and delicious flavor’ or ‘boiled vegetable water’ to influence the affective value of the taste, with the identical taste or flavor stimulus delivered for the different types of cognitive description. Affect-related activations to taste were modulated in a region that receives from the orbitofrontal cortex, the pregenual cingulate cortex, and to taste and flavor in another region that receives from the orbitofrontal cortex, the ventral striatum. Affect-related cognitive modulations were not found in the insular taste cortex, where the intensity but not the pleasantness of the taste was represented. Thus top-down language-level cognitive effects reach far down into the earliest cortical areas that represent the appetitive value of taste and flavor, and this type of modulation may be important in appetite control (Rolls, 2012f, 2016g).

Thus, depending on the context in which tastes are presented and whether affect is relevant, the brain responds to a taste differently. These findings show that when cognition or attention influences affective value, the brain systems engaged to represent a sensory stimulus are different from those engaged when attention is directed to the physical properties of a stimulus such as its intensity. The computational utility of this is that it provides a mechanism for focussing the activity of the brain on the task at hand to optimize, in the present case, what aspects of stimuli should be enhanced as part of the process of leading to optimized behavioral and subjective responses based on the environmental context. It is also of great interest that these word-level cognitive and attentional modulators have top-down effects on the orbitofrontal cortex, and even the primary taste cortex.

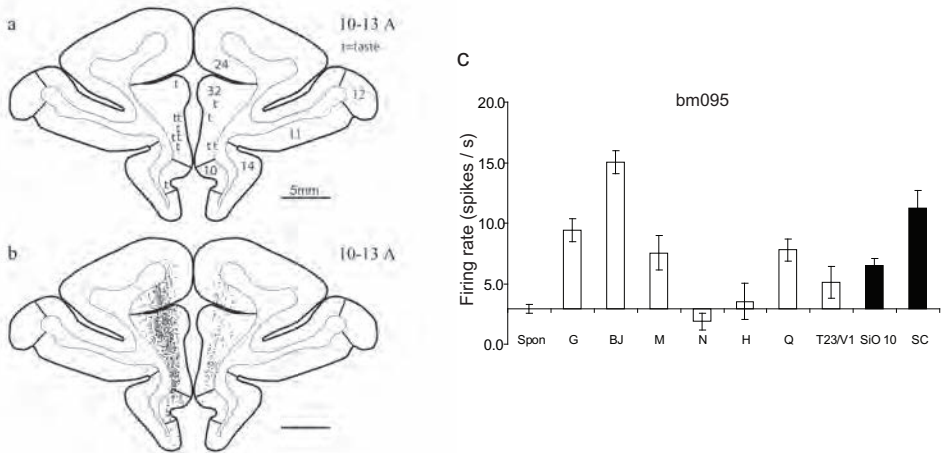

Fig. 4.14 Pregenual cortex taste neurons. The reconstructed positions of the anterior cingulate neurons with taste (t) responses, together with the cytoarchitectonic boundaries determined by Carmichael and Price (1994). Most (11/12) of the taste neurons were in the pregenual cingulate cortex (area 32), as shown. The neurons are shown on a coronal section at 12 mm anterior (A) to the sphenoid reference point. b. The locations of all the 749 neurons recorded in the anterior cingulate region in this study are indicated to show the regions sampled. c. Responses of a pregenual cingulate cortex neuron (bm095) with differential responses to tastes and oral fat texture stimuli. The mean (\pm sem) firing rate responses to each stimulus calculated in a 5 s period over several trials are shown. The spontaneous (Spon) firing rate of 3 spikes/s is shown by the horizontal line, with the responses indicated relative to this line. The taste stimuli were 1 M glucose (G), blackcurrant fruit juice (BJ), 0.1 M NaCl (N), 0.1 M MSG (M), 0.01 M HCl (H) and 0.001 M QuinineHCl (Q); water (T23/V1); single cream (SC); and silicone oil with a viscosity of 10 cP (SiO10). The neuron had significantly different responses to the different stimuli as shown by a one-way ANOVA ($F[9,46]=17.7$, $p < 10^{-10}$). (Data from E.T.Rolls, P.Gabbott, J.Verhagen, and M.Kadohisa. Reproduced from Rolls, E.T. (2008) Functions of the orbitofrontal and pregenual cingulate cortex in taste, olfaction, appetite and emotion. *Acta Physiologica Hungarica* 95: 131–164.)

4.2.9 The tertiary taste cortex in the anterior cingulate cortex provides the rewards for action-reward outcome learning

The orbitofrontal cortex projects to the anterior cingulate cortex (Carmichael and Price, 1995a; Morecraft and Tanji, 2009; Vogt, 2009), where taste neurons are also found in what is thereby a tertiary taste cortical area (Rolls, 2008c, 2009a). For example, Gabbott, Verhagen, Kadohisa and Rolls found neurons in the pregenual cingulate cortex that respond to taste (see example in Fig. 4.14), and it was demonstrated that the representation is of reward value, for devaluation by feeding to satiety selectively decreased neuronal responses to the food with which the animal was satiated (Rolls, 2008c, 2014a). Consistently, in humans (pleasant) sweet taste also activates the most anterior part of the anterior cingulate cortex, the pregenual cingulate cortex (De Araujo and Rolls, 2004; De Araujo, Kringelbach, Rolls and Hobden, 2003b). Less pleasant tastes activate an anterior cingulate cortex region just posterior and dorsal to this just above the corpus callosum, the supracallosal anterior cingulate cortex (De Araujo and Rolls, 2004; De Araujo, Kringelbach, Rolls and Hobden, 2003b; Rolls, 2019e; Grabenhorst and Rolls, 2011) (Chapter 12).

So far, this anterior cingulate cortex region appears to be a re-representation of what is already represented in the orbitofrontal cortex. But there is a large difference that occurs in this tertiary level of the taste cortical hierarchy. Whereas the orbitofrontal cortex represents the reward value of the sensory stimulus of taste (and other sensory stimuli) with little activity related to movements, motor events, and actions (Thorpe, Rolls and Maddison, 1983; Rolls, Critchley, Mason and Wakeman, 1996b; Critchley and Rolls, 1996a; Rolls and Baylis, 1994; Rolls, 2005a; Wallis and Miller, 2003; Padoa-Schioppa and Assad, 2006; Rolls, 2014a), in the anterior and midcingulate cortex there are representations also of movements, actions,

and errors about actions (Matsumoto et al., 2007; Luk and Wallis, 2009). Moreover, lesions to the cingulate cortex influence action selection when it is guided by the reward value of the goal, and this provides some of the evidence that the anterior cingulate cortex is involved in learning associations between actions and the reward (or punishment) outcome (Rushworth et al., 2004, 2011; Grabenhorst and Rolls, 2011; Rolls, 2014a, 2019e,c).

Thus the anterior cingulate stage of the taste cortical hierarchy can be conceptualized computationally as the level at which the representation of sensory reward value is interfaced to actions (Chapter 12). In primates, stimulus valuation performed in the orbitofrontal cortex is kept separate from motor and action systems. In terms of hierarchical organization, the impact is that the orbitofrontal cortex specialises in reward value representations and learns about the value of sensory stimuli using as we shall see information from all sensory modalities, so it performs one type of computation in which the expected reward value of a visual stimulus can be recomputed in one trial if the taste associated with the visual stimulus changes (Chapter 11). The next stage of the hierarchy, the anterior cingulate cortex, then follows the principle of further convergence as one progresses up the hierarchy, in this case convergence between the value of sensory stimuli and the actions needed to obtain them, which is a separate and typically slower learning process because it involves trial and error learning (Chapter 12), whereas the orbitofrontal cortex can perform its sensory-sensory processes by association in what can be as little as one trial (Rolls, 2019e) (Chapter 11).

4.2.10 Taste, oral texture and flavor provide the rewards for eating, and the gut provides satiety signals

Rewards can be defined as stimuli for which an individual (human or animal) will work instrumentally with an arbitrary action (Rolls, 2014a), and can be shown to be goal-directed in that the actions cease immediately the reward is devalued, for example by feeding to satiety. Reward-guided behavior can thus be distinguished from stimulus-response habits implemented in the basal ganglia (Chapter 16). A reward thus supports goal-directed actions, with brain regions involved in this the anterior cingulate cortex (Section 12.2), which receives information about reward outcome value from the orbitofrontal cortex. The expected value is also signalled by the orbitofrontal cortex, for example by the orbitofrontal cortex neurons that respond to the sight of food (Critchley and Rolls, 1996a; Rolls et al., 1996b).

Oral signals of taste, texture and temperature, and retronasally sensed olfactory effects, implement the reward value of food, with subjective pleasantness or hedonic value correlated with activations in the orbitofrontal cortex and anterior cingulate cortex to taste, olfactory and flavor stimuli, as described above and in Chapters 11 and 5. Part of the evidence comes from sham feeding (Rolls, 2014a). If food that has been eaten just drains out of the stomach or oesophagus and does not reach the intestines, then food remains rewarding, and animals and humans work for long periods for the taste and texture of the food, even though no food reaches the gut (Rolls, 2014a), and the same applies to water reward and drinking when thirsty (Maddison, Wood, Rolls, Rolls and Gibbs, 1980). This provides evidence that gut and postabsorptive signals are necessary for satiety, and indeed if the stomach is drained after eating to satiety, eating resumes again immediately, providing clear evidence that gut signals (gastric distension and intestinal stimulation with food) produce satiety (Gibbs, Maddison and Rolls, 1981).

Complementary evidence is that animals including humans work to obtain small quantities of these oral taste and flavor signals, even a few drops, providing clear evidence that taste and smell provide food reward. The converse type of evidence is that food placed directly into the gut or provided intravenously does not produce immediate unconditioned reward with small quantities: very large quantities of food have to be delivered for food provided

into the gut to lead to instrumental actions to obtain such gut infusions (Nicolaidis and Rowland, 1977; Sclafani et al., 2003). That is, a reduction in hunger produced by directly placing food into the gut and bypassing taste and smell is not very rewarding. Consistent with this, turning off hunger-related *Agrp* neurons in the arcuate nucleus of the hypothalamus is not a good reward for instrumental behavior, though it can produce some conditioned preferences for foods or places with which the hunger reduction is associated (Sternson, 2013). Corresponding evidence in humans is that patients in hospital obtain no food reward value or pleasure from being fed intragastrically.

This type of evidence shows clearly with a double dissociation that oral factors such as the taste, texture and flavor of food produce the reward for which humans and animals work, and that gut and post-absorptive signals produce satiety (Rolls, 2014a). Further evidence for this is that sensory-specific satiety is for the taste, texture and flavor of food, and not for its nutritional content, as shown by experiments in which for example different sensory stimuli with the same nutritional content provide reward value that is related to the sensory properties of the stimuli, and not to the nutritional content (Rolls, Rolls and Rowe, 1980a; Rolls, Rolls, Rowe and Sweeney, 1981b,a; Rolls, Rolls and Rowe, 1982a; Rolls, Rowe and Rolls, 1982b; Rolls, Rolls and Rowe, 1983a), all based on my discovery of sensory-specific satiety when recording from lateral hypothalamic neurons (Rolls, Perrett and Thorpe, 1980c; Rolls, Murzi, Yaxley, Thorpe and Simpson, 1986). One interesting demonstration of this is that just tasting a food for 15 minutes, or even just smelling a food for 15 minutes, can result in some decrease in its reward value, even though no food is swallowed to enter the stomach or gut (Rolls and Rolls, 1997).

This evidence shows that the reward value, and the subjectively reported pleasantness or hedonic value of food, depends on sensory factors such as taste, texture, flavor and smell, and not on signals directly from the gut, which in any case are too slow to implement the reward value and pleasantness of a tiny taste of food in the mouth, before it has even been swallowed. This evidence further shows that the main factor that produces satiety is food in the gut, which produces gastric distension and gut stimulation by food, with of course an additional sensory-specific contribution to satiety (Rolls, 2014a). Thus satiety signals in the gut, and postabsorptively, including the hormones that result from this, produce satiety, and those satiety signals then alter the reward value of food, implemented as shown here by reductions in the responses of neurons in the orbitofrontal cortex and lateral hypothalamus that show smaller responses to the taste, texture, smell, flavor, and sight of food when the food is eaten to satiety (Rolls, Perrett and Thorpe, 1980c; Rolls, Murzi, Yaxley, Thorpe and Simpson, 1986; Rolls, Sienkiewicz and Yaxley, 1989d; Critchley and Rolls, 1996a; Rolls, 2015d, 2016g).

However, food sensed in the gut after ingestion can produce conditioned (learned) appetite or preference for a food, and can also produce conditioned satiety (Booth, 1985). This was demonstrated by David Booth, who fed participants either high energy sandwiches with flavor 1, and low energy sandwiches with flavor 2. After several days with this pairing, when medium energy sandwiches were provided, subjects ate more of those with flavor 2, as it had previously been paired with low energy nutrition sensed after ingestion. This demonstrates how post-ingestive signals in humans can influence flavor preferences by conditioning. It is important to bear in mind these conditioned appetite and satiety effects when designing low-energy foods, for post-ingestive conditioning is likely to produce some compensation by increasing the amount eaten of such foods.

There is considerable interest in how signals sensed in the gut contribute to these post-ingestive effects of nutrients. When ingested food reaches the gastro-intestinal tract, it produces satiety by producing gastric distension and stimulation of intestinal hormone release (as shown by the absence of satiety in sham feeding when food drains from a gastric or duo-

denal cannula in primates (Gibbs, Maddison and Rolls, 1981), and the gastric distension only occurs if food enters the duodenum where it activates gut receptors so causing closing of the pyloric sphincter. This is probably an unconditioned satiety effect produced by gastric distension and intestinal hormonal release (Seeley, Kaplan and Grill, 1995). If the distension is reduced at the end of a meal, then feeding resumes very quickly, typically within one minute, in primates (Rolls, 2014a; Gibbs et al., 1981). Further evidence is that intraduodenal infusions of food produce satiety (Gibbs et al., 1981). In addition to unconditioned effects of food in the gut, there are also conditioned effects whereby the metabolic and other nutritive consequences of the ingestion of a flavor can influence the reward value of the flavor later, in for example conditioned appetite (Booth, 1985), sometimes referred to as *appetition* (Sclafani, 2013), with some of the mechanisms described next.

When food enters the gastro-intestinal (GI) tract it activates a wide range of gut receptors including gut taste receptors, which stimulate locally the release of peptides such as CCK, PYY, ghrelin and GLP-1 from endocrine cells (Depoortere, 2014; Kokrashvili et al., 2009b,a; Margolskee et al., 2007), which may be involved in the regulation of food intake (Price and Bloom, 2014; Hussain and Bloom, 2013; Parker et al., 2014), though with the evidence in humans not very clear (Crooks et al., 2021; Lim and Poppitt, 2019). The gut sensing mechanisms, and their role in conditioned appetite, are reviewed elsewhere (Ackroff and Sclafani, 2014; Sclafani, 2013; Kadohisa, 2015; Berthoud, Morrison, Ackroff and Sclafani, 2021). Many of these studies have been on conditioned preferences produced by food in the GI tract. It will be of interest in future research to analyze in addition how visceral signals can produce conditioned satiety for the flavor with which they are paired. It is of interest to develop our understanding of conditioned satiety and conditioned appetite and the role of gut signals in food reward, for this is relevant to food intake control and its disorders (Han, Tellez, Perkins, Perez, Qu, Ferreira, Ferreira, Quinn, Liu, Gao, Kaelberer, Bohorquez, Shammah-Lagnado, de Lartigue and de Araujo, 2018; De Araujo, Schatzker and Small, 2020; Berthoud, Morrison, Ackroff and Sclafani, 2021).

It has been claimed that food reward is produced by gut signals (Han, Tellez, Perkins, Perez, Qu, Ferreira, Ferreira, Quinn, Liu, Gao, Kaelberer, Bohorquez, Shammah-Lagnado, de Lartigue and de Araujo, 2018; De Araujo, Schatzker and Small, 2020). However, that does not fit with the wealth of evidence just described, showing that food reward is produced by the taste, texture, smell and sight of food. Instead, the evidence about the functions of gut signals in the control of food intake is that their main function is to influence satiety, with gut and hormonal signals often operating through conditioned appetite or satiety, rather than by acting directly as rewards (Berthoud, Morrison, Ackroff and Sclafani, 2021). These gut and hormonal signals are likely to act to slowly modulate the reward value of food produced by the taste, texture, flavor and sight of food acting on food reward neurons in the orbitofrontal cortex, with these satiety signals reaching the orbitofrontal cortex (Rolls, 2016g), in part via the visceral representation in the anteroventral insula region AAIC (Rolls et al., 2023c). In this situation, the reward value of food is signalled by the food reward neurons that respond to the taste, texture, smell, flavor and sight of food that relate to the subjective pleasantness / hedonic value of food, described in this book and elsewhere (Rolls, 2016g), and the reward value that they signal is controlled by gut and many other factors as described next.

The factors including gut signals that influence the reward value of food, the amount of food eaten, and thereby influence obesity (Morton et al., 2014; van der Klaauw and Farooqi, 2015; Berthoud et al., 2021) include the following (Rolls, 2016g) (see also Section 19.9.2).

1. Genetic factors. The ‘obesity epidemic’ that has occurred since 1990 cannot be attributed to genetic changes, for which the time scale is far too short, but instead to factors such as the increased palatability, variety, and availability of food which are some of the crucial

Obesity: sensory and cognitive factors that make food increasingly palatable may override existing satiety signals

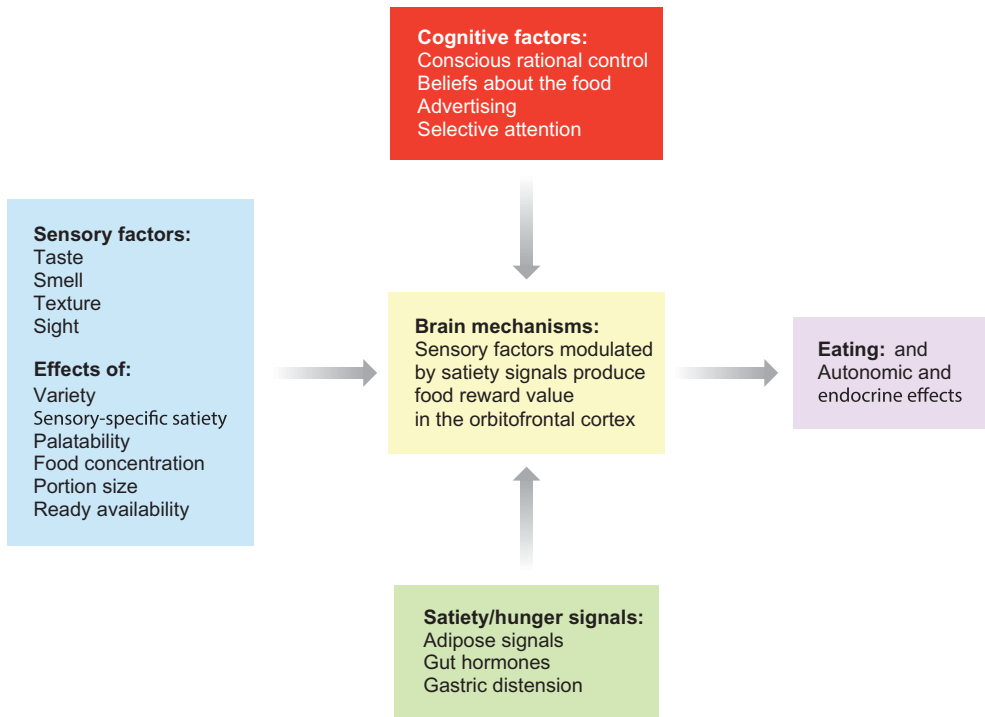

Fig. 4.15 Sensory factors such as the taste, texture, smell, flavor and sight of food are modulated in the orbitofrontal cortex by satiety signals to produce the hedonic, rewarding value of food, which leads to appetite and eating. Cognitive and attentional factors directly modulate the reward system in the orbitofrontal cortex.

drivers of food intake and the amount of food that is eaten in our changed modern environment (Heitmann et al., 2012; Rolls, 2014a, 2016g). Evidence for genetic contributions to body weight comes from family, twin, and adoption studies, which demonstrate that the heritability (fraction of the total phenotypic variance of a quantitative trait attributable to genes in a specified environment) of Body Mass Index is between 0.71 and 0.86 (Silventoinen et al., 2008).

- Endocrine factors, and their interaction with brain systems. A small proportion of cases of obesity can be related to gene-related dysfunctions of the peptide systems in the hypothalamus, with for example 2-5% of obese people having deficient (MC4) receptors for melanocyte stimulating hormone (van der Klaauw and Farooqi, 2015; Farooqi, 2022). Cases of obesity that can be related to changes in the leptin hormone satiety system are also rare (1-5%) (O’Rahilly, 2009; van der Klaauw and Farooqi, 2015; Farooqi, 2022).
- Brain processing of the sensory properties and pleasantness / reward value of food. Over the last 30 years, sensory stimulation produced by the taste, smell, texture and appearance of food, as well as its availability, have increased dramatically, yet the satiety signals produced by stomach distension, satiety hormones etc (Cummings and Overduin, 2007; Hussain and Bloom, 2013; Price and Bloom, 2014) have remained essentially unchanged, so that the effect on the brain’s control system for appetite (Fig. 4.15) is to lead to a net average increase in the reward value and palatability of food which over-rides the satiety signals, and contributes to the tendency to be overstimulated by food and to overeat.
- Sensory-specific satiety, and the effects of variety on food intake (Rolls, 2016g).

5. Fixed meal times, and the ready availability of food. The normal control of food intake is by alterations in inter-meal interval but is not readily available in humans because of fixed meal times, and food may be eaten at a meal-time even if hunger is not present (Rolls, 2014a). Even more than this, because of the high and easy availability of food (in the home and workplace) and stimulation by advertising, there is a tendency to start eating again when satiety signals after a previous meal have decreased only a little, and the consequence is that the system again becomes overloaded.
6. Food saliency, and portion size. Making food salient, for example by placing it on display, may increase food selection particularly in the obese (Schachter, 1971), and portion size is a factor, with more being eaten if a large portion of food is presented (Rolls, 2016g).
7. Energy density of food. Gastric emptying rate only partially compensates for the high energy density of food (Rolls, 2016g).
8. Eating rate is typically fast in the obese, and may provide insufficient time for the full effect of satiety signals as food reaches the intestine to operate.
9. Stress (Rolls, 2016g).
10. Food craving and binge eating may be associated with the release of dopamine, which may exacerbate the problem (Rolls, 2016g).
11. Energy output. Although exercise is important for health, it may not have very significant effects on body weight gain and adiposity in the obese or those who become obese (Wilks et al., 2011; Johns et al., 2014; Niemi et al., 2022).
12. Cognitive factors, and attention. As shown in this book, cognitive descriptions and attention can modulate reward value as represented in the orbitofrontal cortex, and this may influence human liking for a food and how much is eaten (Rolls, 2016g).

4.3 Taste and related pathways: how the computations are performed

4.3.1 Increased selectivity of taste and flavor neurons through the hierarchy by competitive learning and convergence

The taste system is hierarchically organised, and competitive learning in the cortex (complemented by lateral inhibition in the thalamus) is the probable mechanism that sharpens the tuning through the hierarchy. The mechanisms are described in Section B.18 and B.4.

One key feature of taste processing is that because orbitofrontal cortex taste neurons code for some primary reinforcers which must be different for sweet, salt, and bitter, there may need to be genetic specification through the taste pathways from the receptor right through to the orbitofrontal cortex. That is, an orbitofrontal cortex neuron needs to know whether it is connected indirectly to a sweet receptor or a bitter receptor, because in the orbitofrontal cortex the reward / punishment valence is encoded. This is an interesting issue, for although neurons in the insular primary taste cortex have responses that can be moderately tuned to e.g. sweet vs bitter vs salt, their tuning is not fully sparse, but is somewhat distributed.

4.3.2 Pattern association learning of associations of visual and olfactory stimuli with taste

Multimodal associations of visual and olfactory stimuli with taste are learned in the orbitofrontal cortex, with the probable mechanism pattern association as described in Sections B.2. This learning may also involve competitive learning, helping neurons to become selective for different multimodal combinations of their inputs (Section B.4).

4.3.3 Rule-based reversal of visual to taste associations in the orbitofrontal cortex

Visual to taste associations can be reversed in one trial by orbitofrontal cortex neurons, providing evidence for a rule-based mechanism. This is very adaptive in evolutionary terms, and is not known to be possible in rodents, but is an important computation in primates. A model for this is described in Chapter 11.

4.3.4 Sensory-specific satiety is implemented by adaptation of synapses onto orbitofrontal cortex neurons

The findings described in this Chapter lead to the following proposed neuronal mechanism for sensory-specific satiety (see also Rolls and Treves (1990) and Rolls (2014a)). The tuning of neurons becomes more specific for gustatory stimuli through the nucleus of the solitary tract, gustatory thalamus, and frontal opercular taste cortex. Satiety, habituation and adaptation are not features of the responses here. This is what is found in primates (see above). The tuning of neurons becomes even more specific in the orbitofrontal cortex, but here there is some effect of satiety by internal signals such as gastric distension and glucose utilization, and in addition habituation or adaptation with a time course of several minutes which lasts for 1–2 h is a feature of the synapses that are activated. Because of the relative specificity of the tuning of orbitofrontal taste neurons, this results in a decrease in the response to that food, but different foods continue to activate other neurons or even the same neuron. This is an important part of the theory, for it shows the adaptive utility for why different orbitofrontal cortex neurons respond to different combinations of sensory inputs, and in this sense as a population encode a *high-dimensional space of reward value* (Rolls, 2016b). For orbitofrontal cortex neurons that respond to two flavors before satiety, it is suggested that the habituation that results in a loss of the response to the taste eaten to satiety (see e.g. Fig. 4.8, and for sensory-specific satiety for the texture of fat Rolls et al. (1999a)) occurs because of habituation or adaptation of the afferent neurons or synapses onto these orbitofrontal cortex neurons. Because an orbitofrontal cortex neuron can still respond to a food not eaten to satiety, the mechanism can not be neuronal adaptation, and for that reason adaptation of the afferent synapses to a neuron is the mechanism proposed for how the computation is implemented. This would result in the orbitofrontal cortex neurons having the required response properties, and it is then only necessary for other parts of the brain to use the activity of the orbitofrontal cortex neurons to reflect the reward value of that particular taste. One output of these neurons may be to the anterior cingulate cortex; and another to the hypothalamic neurons with food-related responses, for their responses to the sight and/or taste of food show a decrease that is partly specific to a food that has just been eaten to satiety (see above and Rolls (2019e)). Another output may be to the ventral and adjoining striatum, which may provide an important link between reward systems and response habits (see Chapter 16).

It is suggested that the computational significance of this architecture is as follows (see also Rolls (1986b), Rolls (1989d), Rolls and Treves (1990), and Rolls (2016b)). If satiety were to operate at an early level of sensory analysis, then because of the broadness of tuning of neurons, responses to non-foods would become attenuated as well as responses to foods (and this could well be dangerous if poisonous non-foods became undetectable). This argument becomes even more compelling when it is realized that satiety typically shows some specificity for the particular food eaten, with others not eaten in the meal remaining relatively pleasant (see above). Unless tuning were relatively fine, this mechanism could not operate, for reduction in neuronal firing after one food had been eaten would inevitably reduce behavioral responsiveness to other foods. Indeed, it is of interest to note that such a sensory-specific sati-

ety mechanism can be built by arranging for tuning to particular foods to become relatively specific at one level of the nervous system (as a result of categorization processing in earlier stages), and then at this stage (but not at prior stages) to allow habituation to be a property of the synapses, as proposed above.

In summary, the computational hypothesis about how sensory-specific satiety is implemented is in the orbitofrontal cortex by adaptation with a time course of several minutes of the active synapses of specifically tuned neurons onto orbitofrontal cortex neurons. Once adapted, the synapses remain adapted for 1–2 hours (or as long as necessary) to account for the duration of sensory-specific satiety. Sensory-specific satiety applies to all rewards, and to no punishers (Rolls, 2014a).

4.3.5 Top-down cognitive and attentional modulation is implemented by biased activation

We have seen in Section 4.2.8 that whole cortical areas and even processing streams can be biased by top-down selective attention or cognitive modulation. For example, we have seen that paying attention to the pleasantness of a stimulus, or describing a flavor as rich and delicious, can by a top-down language-level bias increase activations in the orbitofrontal cortex. This can occur for example if some processing attributes of stimuli such as reward value are processed in one cortical stream (the orbitofrontal cortex and anterior cingulate cortex), and other attributes such as the intensity and identity of a stimulus in other cortical streams such as the insula (Grabenhorst and Rolls, 2008), and the same occurs for olfactory stimuli, as described in Chapter 5 (Rolls, Grabenhorst, Margot, da Silva and Velazco, 2008b). A biased activation theory of top-down selective attention and cognitive modulation has been described to account for this (Rolls, 2013a).

The way that we think of top-down biased competition as operating normally in for example visual selective attention (Desimone and Duncan, 1995) is that within an area, e.g. a cortical region, some neurons receive a weak top-down input that increases their response to the bottom-up stimuli, potentially supralinearly if the bottom-up stimuli are weak (Rolls and Deco, 2002; Deco and Rolls, 2005b; Rolls, 2016b). The enhanced firing of the biased neurons then, via the local inhibitory neurons, inhibits the other neurons in the local area from responding to the bottom-up stimuli. This is a local mechanism, in that the inhibition in the neocortex is primarily local, being implemented by cortical inhibitory neurons that typically have inputs and outputs over no more than a few mm (Chapter 1, Douglas et al. (2004)). This model of biased competition is described in Sections 2.12 and B.8.4, and is illustrated in Fig. 2.85.

This locally implemented biased competition situation may not apply in the present case, where we have facilitation of processing in a whole cortical area (e.g. orbitofrontal cortex, or pregenual cingulate cortex) or even cortical processing stream (e.g. the linked orbitofrontal and pregenual cingulate cortex) in which any taste neurons may reflect pleasantness and not intensity. So the attentional effect might more accurately be described in this case as biased activation, without local competition being part of the effect. This biased activation theory and model of attention, illustrated in Fig. 4.16 (Rolls, 2013a), is a rather different way to implement attention in the brain than biased competition, and each mechanism may apply in different cases, or both mechanisms in some cases.

The biased activation theory of top-down attentional and cognitive control is as follows (Rolls, 2013a), and is illustrated in Fig. 4.16. There are short-term memory systems implemented as cortical attractor networks with recurrent collateral connections to maintain neuronal activity that provide the source of the top-down activation. The short-term memory systems may be separate (as shown in Fig. 4.16), or could be a single network with diff-

Biased Activation

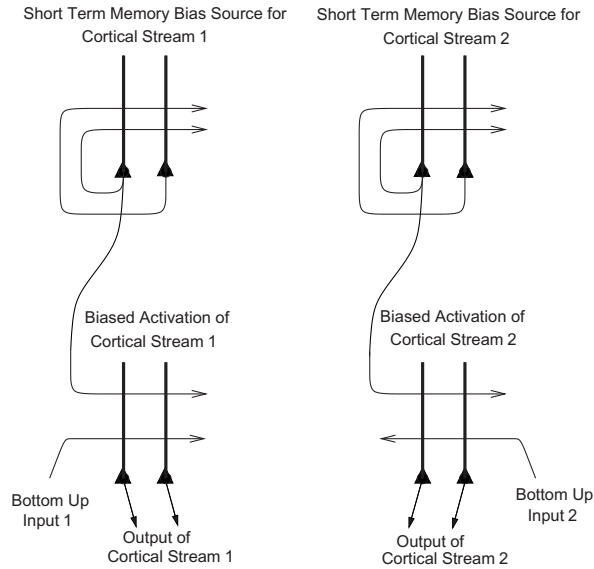

Fig. 4.16 Biased activation mechanism for top-down attention. The short-term memory systems that provide the source of the top-down activations may be separate (as shown), or could be a single network with different attractor states for the different selective attention conditions. The top-down short-term memory systems hold what is being paid attention to active by continuing firing in an attractor state, and bias separately either cortical processing system 1, or cortical processing system 2. This weak top-down bias interacts with the bottom up input to the cortical stream and produces an increase of activity that can be supralinear (Deco and Rolls 2005c). Thus the selective activation of separate cortical processing streams can occur. In the example, stream 1 might process the affective value of a stimulus, and stream 2 might process the intensity and physical properties of the stimulus. The outputs of these separate processing streams then must enter a competition system, which could be for example a cortical attractor decision-making network that makes choices between the two streams, with the choice biased by the activations in the separate streams (see text). The thick vertical lines above the pyramidal cells are the dendrites. The axons are shown with thin lines and the excitatory connections by arrow heads. (Reproduced from Rolls, E. T. (2013) A biased activation theory of the cognitive and attentional modulation of emotion. *Frontiers in Human Neuroscience* 7: 74.)

erent attractor states for the different selective attention conditions. The top-down short-term memory systems hold what is being paid attention to active by continuing firing in an attractor state, and bias separately either cortical processing system 1, or cortical processing system 2. This weak top-down bias interacts with the bottom-up input to the cortical stream and produces an increase of activity that can be supralinear (Deco and Rolls, 2005b). Thus the selective activation of separate cortical processing streams can occur. In the example, stream 1 might process the affective value of a stimulus, and stream 2 might process the intensity and physical properties of the stimulus.

The top-down bias needs to be weak relative to the bottom-up input, for the top-down bias must not dominate the system, otherwise bottom-up inputs, essential for perception and survival, would be over-ridden. Under such conditions, top-down attentional and cognitive effects will be largest when the bottom-up inputs are not too strong or are ambiguous, and that has been shown to be the case in realistic simulations with integrate-and-fire neurons (Deco and Rolls, 2005b; Rolls, 2016b). The weakness of the top-down biasing input is included as a part of brain design, for the top-down inputs are effectively backprojections from higher cortical areas, and these end on the apical dendrites of cortical pyramidal cells, and so have weaker effects than the bottom up inputs, which make connections lower down the dendrite towards the cell body (Rolls, 2016b). I suggest here that the correct connections could be set up in such a system by the following associative (Hebbian) synaptic learning process. The top-down backprojection synapses would increase in strength when there is activity in a pop-

ulation of short-term memory neurons that by their firing hold attention in one direction (e.g. the short-term memory system for cortical stream 1 shown in Fig. 4.16, and simultaneously there is activity in the neurons that receive the top-down inputs (e.g. in cortical stream 1 shown in Fig. 4.16).

The outputs of the separate processing streams showing biased activation (Fig. 4.16) may need to be compared at a later stage of processing, in order to lead to a single behavior (Rolls, 2013a). One way in which this comparison could take place is by both outputs entering a single network cortical attractor model of decision-making, in which positive feedback implemented by the excitatory recurrent collateral connections leads through non-linear dynamics to a single winner, which is ensured by competition between the different possible attractor states produced through inhibitory neurons (Wang, 2002; Deco and Rolls, 2006; Deco, Rolls, Albantakis and Romo, 2013). A second way in which the competition could be implemented is by that usually conceptualized as important in biased competition (Desimone and Duncan, 1995; Rolls and Deco, 2002; Deco and Rolls, 2005b), in which a feedforward competitive network using inhibition through local inhibitory neurons provides a way for a weak top-down signal to bias the output especially if the bottom-up inputs are weak, and this implementation is what is shown at the bottom of Fig. 2.85. A third way in which the biased activation reflected in the output of the streams shown in Fig. 4.16 could be taken into account is by a mechanism such as that in the basal ganglia, where in the striatum the different excitatory inputs activate GABA (gamma-amino-butyric acid) neurons, which then directly inhibit each other to make the selection (Chapter 16, and Rolls (2014a)).

The difference between biased competition and biased activation may be especially important in the context of functional neuroimaging, for biased activation, in which processing in whole cortical areas is facilitated by selective attention, can be revealed by functional neuroimaging, which operates at relatively low spatial resolution, in the order of mm. In contrast, biased competition may selectively facilitate some pyramidal neurons within a local cortical area which then through the local GABA inhibitory neurons compete with the other pyramidal neurons in the area receiving bottom-up input. In this situation, in which some but not other neurons within a cortical area are showing enhanced firing, functional neuroimaging may not be able to show which local population of pyramidal cells is winning the competition due to the top-down bias. The evidence presented by Grabenhorst and Rolls (2010) is that not only the processing streams, but also even the short-term memory systems in the prefrontal cortex that provide the top-down source of the biased activation, are physically separate (see Fig. 13.8).

A possibility arising from this model is that some competition may occur somewhere in the attentional system before the output stage, and one possible area is within the prefrontal cortex, where it is a possibility that the attractors that implement the short-term memory for attention to pleasantness (at MNI coordinate $Y \approx 50$) may inhibit the attractors that implement the short-term memory for attention to intensity (at $Y \approx 37$), which could occur if there is some physical overlap between their zones of activation, even if the peaks are well separated. Some evidence for this possibility was found (Grabenhorst and Rolls, 2010), in that the correlation between the % BOLD activations in these two prefrontal cortex regions was $r = -0.72$ ($p = 0.0034$) on the pleasantness trials; and $r = -0.8$ ($p < 0.001$) on the intensity trials. In a biased competition model (Fig. 2.85) we would normally think of the short-term memory attractors that provide the source of the bias as being within the same single attractor network, so that there would be competition between the two attractor states through the local inhibitory interneurons. In the biased activation model (Fig. 4.16), it is an open issue about whether the attractors that provide the source of the top-down bias are in the same single network, or are physically separate making interactions between the attractor states difficult through the short-range cortical inhibitory neurons. The findings just described indicate that

in the case of top-down control of affective vs intensity processing of taste stimuli, although the two attractors are somewhat apart in the prefrontal cortex, there is some functional inhibitory interaction between them. Further evidence for separate top-down attractor networks for biased activation was found in an investigation in which Granger causality was measured (Ge, Feng, Grabenhorst and Rolls, 2012) (see Section 13.4 and Fig. 13.8).

The principle of biased activation providing a mechanism for selective attention (Rolls, 2013a) probably extends beyond processing in the affective vs sensory coding cortical streams. It may provide the mechanism also for effects in for example the dorsal vs the ventral visual streams, in which attention to the motion of a moving object may enhance processing in the dorsal stream, and attention to the identity of the moving object may enhance processing in the ventral visual stream (Brown, 2009). Similar biased activation may contribute to the different localization in the prefrontal cortex of systems involved in ‘what’ vs ‘where’ working memory (Deco, Rolls and Horwitz, 2004; Rottschy, Langner, Dogan, Reetz, Laird, Schulz, Fox and Eickhoff, 2012). Biased activation as a mechanism for top-down selective attention may be widespread in the brain, and may be engaged when there is segregated processing of different attributes of stimuli (Grabenhorst and Rolls, 2010; Rolls, 2013a).

5 The olfactory system

5.1 Introduction

The olfactory pathways are shown in Figs. 4.3, 11.1 on page 476 and 11.4.

In the primate olfactory system, the olfactory bulb projects to the primary olfactory cortex (the pyriform cortex, directly and via the mediodorsal nucleus of the thalamus), which in turn projects to the orbitofrontal cortex, which is thereby defined as a secondary cortical olfactory area, and the orbitofrontal cortex in turn projects to the anterior cingulate cortex (Fig. 11.1) (Price et al., 1991; Morecraft et al., 1992; Barbas, 1993; Carmichael et al., 1994; Price, 2006). The olfactory system is thus organised hierarchically.

Olfactory projections from the olfactory bulb do though reach some other areas, including the olfactory tubercle which is part of the ventral striatum, and the lateral entorhinal cortex, which in turn projects to the hippocampus (Rolls, 2014a; Wilson et al., 2014a; Wilson and Sullivan, 2011). At the hippocampal stage of the hierarchy, the principle of convergence is evident, for in the hippocampus flavor information (which has an olfactory component) can be combined with spatial information to allow learning of where the flavor is in allocentric space (Rolls and Xiang, 2005; Kesner and Rolls, 2015) (see Chapter 9). The principle of convergence in cortical hierarchies is also evident in the fact that olfactory information is combined with taste information to produce flavor in the orbitofrontal cortex, but not at earlier cortical stages (Section 4.2.7).

We should at the outset note that the principles of olfactory as well as taste processing are very different in rodents at least in terms of sensory vs value encoding, in that reward value may influence olfactory processing in the periphery in rodents, so that rodents may not provide a good guide to the principles of olfactory (as well as taste and visual) cortical processing in primates including humans (Rolls, 2015d) (see Section 19.10).

5.1.1 Overview of what is computed in the olfactory system

What is computed in the olfactory system is described in Section 5.2 with an overview here.

1. There are approximately 1000 genes each coding for a different olfactory receptor in the olfactory epithelium in rodents (Buck and Axel, 1991). Each olfactory receptor type projects to a different glomerulus in the olfactory bulb, so that there are 1000 glomeruli in the olfactory bulb (or in fact 2000, as the representation is doubled up in different parts of the olfactory bulb). Although each glomerulus has different encoding of odors, with different glomeruli tuned for example to different carbon chain lengths of aliphatic aldehydes, the tuning of each glomerulus is rather broad, with each glomerulus having a non-sparse representation of odors, and considerable correlations between the response profiles of different glomeruli to a set of odors (Verhagen, Baker, Vasan, Pieribone and Rolls, 2023). In humans, approximately one third of the olfactory receptor genes are disabled. This may be because with other senses such as vision and hearing so much more developed in primates, there is less evolutionary pressure and advantage in maintaining all the 1000 genetically specified olfactory receptor types.

2. In rodents and many other mammals there is an accessory olfactory system that includes the vomeronasal organ and the accessory olfactory bulb, and this system is involved in response to pheromones which are important in sexual and other types of behavior (Wyatt, 2014; Li and Dulac, 2018; Rolls, 2014a). However, this system, and many of its associated genes, are not present or are vestigial at best in humans and Old World monkeys (Meredith, 2001), and whether pheromones operate in humans is questionable (Wyatt, 2020; Cherry and Baum, 2020).
3. Most odors also have trigeminal effects, that is, somatosensory effects that reach the central nervous system via the trigeminal nerve. Although in a much lower dimensional space than in the (up to) 1000 dimensional space encoded by the olfactory receptors, these trigeminal components do differ for different odors, and what is computed to represent an odor may include trigeminal components that are different for different odors. Examples of trigeminal stimuli include air pollutants (e.g. sulphur dioxide), ammonia, ethanol, acetic acid (vinegar), carbon dioxide (in soft drinks), menthol (in some inhalants), and capsaicin (present in chili peppers).
4. The olfactory bulb projects directly to a number of brain regions, including the pyriform cortex. In the pyriform cortex, the tuning may become more selective for odors, partly because neurons learn to respond to combinations of what is encoded in the glomeruli of the olfactory bulb. In humans, activations in the pyriform cortex are related to the subjective intensity of odors, and not to their pleasantness. The coding in the human pyriform cortex is therefore for what the odor is, and its intensity, rather than its reward value.
5. The pyriform, primary olfactory, cortex, projects forward to a part of the orbitofrontal cortex, which is secondary olfactory cortex. In the orbitofrontal cortex, some bimodal neurons are found that respond to olfactory and taste stimuli, so that flavor representations are computed. This association can be reversed, or partially reversed, in some orbitofrontal cortex olfactory neurons. The computation has involved moving the olfactory representation from a space using genetically specified encoding into a space where for some neurons the odor represented depends on the taste with which it is associated.
6. In the secondary olfactory cortex, the reward value of olfactory stimuli is represented, in that some olfactory neurons only respond when hunger is present; and activations in the humans orbitofrontal cortex are correlated with the subjective pleasantness of the odor or flavor. This is a further way in which olfactory representations move beyond a genetically specified code in the periphery, to in this case an olfactory reward value code.
7. The olfactory tubercle is part of the ventral striatum (see Chapter 16) and receives direct olfactory inputs from the olfactory nerve; but is not purely olfactory, for it receives visual inputs in primates.

5.1.2 Overview of how the computations are performed in the olfactory system

How computations are performed in the olfactory system is described in Section 5.3 with an overview here.

1. The olfactory system uses a computationally very simple way of representing different odors: it uses a large number of genes, 1000, approximately 1/30 of the genome, to encode odors. This allows encoding of differences between different odors. There are no invariances to compute, and so it is much simpler computationally than vision and audition.

2. Because the glomeruli are rather poorly tuned to specific odors, the next stage of the olfactory system, the pyriform cortex, primary olfactory cortex, produces more specifically tuned neurons.
3. The pyriform cortex may increase the selectivity of tuning partly by competitive learning, which would encourage pyramidal cells to learn to respond to specific combinations of the odors represented by the glomeruli in the olfactory bulb. This ‘feature combination learning’ could be achieved in part by competitive learning. But the pyriform cortex is well endowed with recurrent collateral connections, which are likely to operate as attractor networks. The attractor networks in the pyriform cortex may build representations of different categories of odors, and help to ensure that small variations in the odor profile represented by the glomeruli will activate the same subset of pyriform cortex neurons, which thus represent what the odor is, independently of small variations in the profile at the olfactory receptors.
4. Another function of the recurrent collateral connections in the pyriform cortex may be to smooth out the temporal changes in firing with each inhalation that are present in the olfactory bulb (Verhagen, Baker, Vasan, Pieribone and Rolls, 2023), but which are much less evident in the secondary olfactory cortex in the orbitofrontal cortex (Critchley and Rolls, 1996b; Rolls, Critchley, Mason and Wakeman, 1996b; Rolls, Critchley and Treves, 1996a). It is a property of attractor networks that they can act as short-term memories, and this may be the computation. Having a non-phasic odor representation in the olfactory system by the time that it is interfaced to taste and vision in the orbitofrontal cortex may be appropriate, for the information in the visual and taste modalities is represented by neurons with relatively steady firing rate responses over time, and the association with odor would be difficult in terms of synaptic modification if the olfactory representation was phasic with each inhalation, but not the visual, taste, and oral texture representations.
5. The pyriform cortex projects into the orbitofrontal cortex, which is thereby secondary olfactory cortex. But it also receives taste, oral texture, and visual inputs. In the orbitofrontal cortex, at least some neurons remap the olfactory representation from the genetic encoding present in the receptors and olfactory bulb into a space where associations are made to taste, as many orbitofrontal cortex olfactory neurons represent odors by the taste with which they are associated. This is probably learned by pattern association learning (see Section B.2.)
6. Many orbitofrontal cortex olfactory neurons represent odors in terms of their reward value, as shown by the effects of feeding to satiety. Part of this may be implemented by the association with taste, which also represents reward value in the orbitofrontal cortex. Further, olfactory sensory-specific is represented in the orbitofrontal cortex, and this may be computed by synaptic adaptation of the afferent connections to orbitofrontal cortex olfactory neurons, in that it is represented in the orbitofrontal cortex, and because just smelling an odor for several minutes can produce olfactory sensory-specific satiety (Rolls and Rolls, 1997).

5.2 What is computed in the olfactory system

5.2.1 1000 gene-encoded olfactory receptor types, and 1000 corresponding glomerulus types in the olfactory bulb

There are approximately 1000 gene-encoded types of olfactory receptor in the olfactory epithelium in the nose, each specialised to code for different olfactory receptor molecules (Buck

and Axel, 1991; Buck and Bargmann, 2013; Mombaerts, 2006; Mori and Sakano, 2011; Zapiec and Mombaerts, 2015; Horowitz et al., 2014). In humans, approximately 300 are disabled. The receptors that are disabled in humans may be somewhat different in different humans, leading to some differences in olfactory perception and hedonics. This reduced number of active olfactory receptor genes in humans may be because with other senses such as vision and hearing so much more developed in primates, there is less evolutionary pressure and advantage in maintaining all the 1000 genetically specified olfactory receptor types.

Each of the 1000 types of olfactory receptor connect to just one type of glomerulus in the olfactory bulb (Mombaerts, 2006; Mori and Sakano, 2011; Zapiec and Mombaerts, 2015). This type of connectivity must rely on a molecular signal that is specific for each genetically encoded receptor type.

In the rodent olfactory bulb, a coding principle is that in many cases each glomerulus (of which there are approximately 1000 types) is tuned to respond to its own characteristic hydrocarbon chain length of odorant (Mori et al., 1992; Imamura et al., 1992; Mori et al., 1999; Mori and Sakano, 2011). Evidence for this was that each mitral/tufted cell in the olfactory bulb has been described as quite sharply tuned, responding for example best to a 5-C length aliphatic odorant (e.g. acid or aldehyde), and being inhibited by nearby hydrocarbon chain-length aliphatic odorants.

The encoding in this early part of the olfactory system may thus be based on the stereochemical structure of the odorant, with receptors that have been produced in a genetically very expensive way, with one gene to build each receptor type. This is a very simple way for a sensory system to operate, with its sensory capability built largely by having one gene that has evolved to produce a single receptor type, with this repeated for 1000 genes, approximately 1/30th of the human genome.

The local inhibition in the olfactory bulb may be seen as a way to spread out (orthogonalize or decorrelate) the olfactory stimulus space by using the contrast enhancement provided by lateral inhibition.

Each olfactory receptor may be tuned to a stereochemical input to some extent, but in practice, even pure chemical stimuli typically activate many glomeruli. This is illustrated in an analysis (Verhagen, Baker, Vasan, Pieribone and Rolls, 2023) of calcium imaging data from the mouse olfactory bulb of the responses of up to 57 glomeruli to 6 olfactory stimuli: amyl acetate, carvone, heptanol, heptanone, hexanal and methyl valerate (Baker et al., 2019). The responses to different odors may be quite correlated over a population of glomeruli, and the coding is non-sparse, with a mean value for the sparseness a for 6 odors of 0.85 (Verhagen, Baker, Vasan, Pieribone and Rolls, 2023). There is a little information in the latencies with which these populations of glomeruli respond to different odors (mean 0.11 bits), but that is small compared to the amount of information conveyed by the firing rate (mean 1.35 bits) (Verhagen et al., 2023). Moreover, the latency information does not add to the rate information (Verhagen et al., 2023) (Fig. C.14), and so the principle that most of the information is conveyed by the firing rate is found in the olfactory system, as it is in most other sensory systems (see Appendix C, Rolls (2016b), and Rolls and Treves (2011)). With 6 stimuli, 2.58 bits of information would be needed to encode correctly the 6 odors, yet these populations of up to 57 glomeruli provided on average only 1.35 bits of information. Putting together the data from all 266 glomeruli in the investigation, the information did rise to the 2.58 bits needed for perfect discrimination between the 6 odors. I hypothesize that the very large number (1000) of gene-encoded olfactory receptors and glomeruli is needed to adequately encode olfactory stimuli, given that even tens of glomeruli provide only a moderate representation of 6 odors. I also suggest that this is the evolutionary background for why approximately 1/30th of the mammalian genome is used to encode olfactory receptors.

5.2.2 The primary olfactory, pyriform, cortex: olfactory feature combinations are what is represented

In the pyriform cortex, neurons may respond to combinations of the inputs received from different glomeruli, and thus to feature combinations of what is encoded by a number of different olfactory receptor genes. This enables neurons to be more selective for odors than in the olfactory bulb. The representations may be built for example by competitive learning (Rolls, 2016b), enabling neurons to learn to represent the co-occurrence of pairs or groups of odorants, so that particular smells in the environment, which typically are produced by combinations of chemical stimuli, are reflected in the responses of pyriform cortex neurons (Wilson and Sullivan, 2011; Barbaro and Shackelford, 2015; Courtiol and Wilson, 2017). Pyriform cortex neurons can for example respond to binary combinations of odors, and much less to the components. Thus what is computed in the olfactory system appears to follow what occurs in other sensory systems, namely that convergence occurs from stage to stage, and new feature combination neurons are formed at each stage of the hierarchy. In the case of the pyriform cortex, the convergence is from the single gene-specified representations in individual glomeruli in the olfactory bulb.

The pyriform cortex has a rich set of recurrent collateral connections between its pyramidal cells, and in line with this the hypothesis is that the pyriform cortex implements an autoassociative memory, which helps to form representations of olfactory mixtures as odor objects, which display a property of completion in which the whole odor may be represented even if some components are missing in the process known as completion (Haberly, 2001; Wilson and Sullivan, 2011) (see Section 5.3.2).

The anterior pyriform cortex is strongly influenced by the olfactory bulb inputs, and in turn influences the posterior pyriform cortex. In both humans (Gottfried et al., 2006; Gottfried, 2010) and rodents (Kadohisa and Wilson, 2006), the anterior pyriform cortex may encode information related to structural or perceptual identity of the odor, e.g. ‘banana’. More posterior regions, perhaps in accord with the dominance of association fiber input, appear to encode the perceptual category of an odor, e.g. ‘fruity’ (Wilson and Sullivan, 2011).

In humans, activity in the pyriform cortex appears to be related to ‘what’ stimulus is present (its identity), and its intensity, and not to its reward value, in that activations in the human pyriform cortex are linearly related to the intensity rating of odorants, and not to their pleasantness (Grabenhorst, Rolls, Margot, da Silva and Velazco, 2007); in that paying attention to the intensity vs the pleasantness of an odor increases activations in the pyriform cortex (Rolls, Grabenhorst, Margot, da Silva and Velazco, 2008b); and in that activations in the pyriform cortex were not decreased by odor devaluation by satiety (Gottfried, 2015).

In contrast, in rodents, reducing reward value by feeding to satiety or by administering leptin reduces the neural activity even in the olfactory bulb (Pager et al., 1972; Sun et al., 2019a). That is further difficult to reconcile with the fact that in humans during olfactory sensory-specific satiety, the pleasantness but much less the intensity of an odor is reduced (Rolls and Rolls, 1997). That finding makes it unlikely that peripheral modulation of olfactory neural responsiveness is a normal mechanism under physiological conditions of olfactory reward value processing in humans. As we will see, there is clear evidence in primates including humans that the reward value of olfactory stimuli is part of what is computed in the orbitofrontal cortex, in what is secondary olfactory cortex.

The effective connectivity of the pyriform cortex in humans can be summarized as follows, based on the research I have been performing on the connectivity of different cortical regions, some of which have connectivity with the pyriform cortex (Rolls et al., 2023c,b,f, 2022a). The human pyriform cortex has strong effective connectivity to the amygdala (0.031, with 0.0 in the reverse direction); strong and bidirectional effective connectivity with AAIC

Fig. 5.1 The responses of a bimodal neuron with taste and olfactory responses recorded in the caudolateral orbitofrontal cortex. G, 1 M glucose; N, 0.1 M NaCl; H, 0.01 M HCl; Q, 0.001 M Quinine HCl; M, 0.1 M monosodium glutamate; Bj, 20% blackcurrant juice; Tom, tomato juice; B, banana odor; Cl, clove oil odor; On, onion odor; Or, orange odor; S, salmon odor; C, control no-odor presentation. The mean responses \pm s.e.m. are shown. The neuron responded best to the savoury tastes of NaCl and monosodium glutamate and to the consonant odors of onion and salmon. (Reproduced from E. T. Rolls and L. L. Baylis (1994) Gustatory, olfactory and visual convergence within the primate orbitofrontal cortex. *Journal of Neuroscience* 14: 5437–5452. Copyright © Society for Neuroscience.)

(0.032), the Anterior Agranular Insula Complex which is just posterior to the lateral orbitofrontal cortex and probably the region in which we have shown that convergence between olfactory and taste stimuli occurs to produce flavor (De Araujo, Rolls, Kringelbach, McGlone and Phillips, 2003a); moderate effective connectivity with the medial orbitofrontal cortex (pOFC) and lateral orbitofrontal cortex (47m); some connectivity with posterior insular cortex regions (PoI1, PoI2); stronger effective connectivity towards hippocampal regions (Hipp, PeEc, and TF); and some effective connectivity from the supracallosal anterior cingulate cortex (a24pr and p24pr). The connectivity with the orbitofrontal cortex is consistent with its functions in food flavor, food reward (Chapter 11), and hedonically pleasant and unpleasant odors (Rolls, Kringelbach and De Araujo, 2003c). The connectivity with the hippocampus is useful for remembering odors as components of episodic memories.

5.2.3 Orbitofrontal cortex: olfactory neuronal response selectivity

Some neurons in the macaque orbitofrontal cortex can respond quite selectively to odor, for example with a large response to eugenol but not to the other 7 odors tested (Rolls et al., 1996a). However, for the majority of the neurons, the tuning to a set of odors was quite distributed, with a mean sparseness $a = 0.94$ (Rolls et al., 1996a). However, this value is from neurons measured typically in an olfactory discrimination task in which most odors were associated with reward, and as we will see, the association with taste reward influences how some primate orbitofrontal cortex neurons respond, thus potentially reducing their selectivity for particular odors.

Although the tuning in these experiments was not very sparse, nevertheless each single neuron did convey in its firing rates to the set of stimuli some information about which stimulus had been presented, with the mean mutual information across the set of stimuli 0.06 bits, and the highest information about any one stimulus (the stimulus-specific information, see Appendix 3) in the range 0.02 to 0.08 bits (Rolls, Critchley and Treves, 1996a). Importantly, the response profiles of the neurons to the set of 8 odors were relatively uncorrelated, so that the information increased approximately linearly with the number of neurons (Rolls, Critchley, Verhagen and Kadohisa, 2010a).

5.2.4 Orbitofrontal cortex: olfactory to taste convergence

In the orbitofrontal cortex, some single neurons respond to both gustatory and olfactory stimuli, often with correspondence between the two modalities (Rolls and Baylis, 1994) (see Fig. 5.1; cf. Fig. 11.1). It is probably here in the orbitofrontal cortex of primates that these two modalities converge to produce the representation of flavor (Rolls and Baylis, 1994), and, consistent with this, neurons in the macaque primary taste cortex do not have olfactory responses (Verhagen, Kadohisa and Rolls, 2004). Consistently, in a human fMRI investigation of olfactory and taste convergence in the brain, it was shown that there is a part of the human taste insula that is not activated by odor (De Araujo, Rolls, Kringelbach, McGlone and Phillips, 2003a), though if a taste is recalled by an odor the situation could be different because of the role of cortico-cortical backprojections in recall (Rolls, 2016b, 2015d). The evidence described below indicates that these bimodal representations are built by olfactory–gustatory association learning, an example of stimulus–reinforcer association learning.

The human orbitofrontal cortex also reflects the convergence of taste and olfactory inputs, as shown for example by the fact that activations in the human medial orbitofrontal cortex are correlated with both the cross-modal consonance of combined taste and olfactory stimuli (high for example for sweet taste and strawberry odor), as well as for the pleasantness of the combinations (De Araujo, Rolls, Kringelbach, McGlone and Phillips, 2003a). In addition, the combination of monosodium glutamate taste and a consonant savoury odor produced a supralinear effect in the medial orbitofrontal cortex to produce the rich delicious flavor of umami that makes many foods rich in protein pleasant (McCabe and Rolls, 2007; Rolls, 2009b).

5.2.5 Orbitofrontal cortex: olfactory to taste association learning and reversal

Rolls and colleagues have analyzed the rules by which orbitofrontal olfactory representations are formed and brought together with taste representations in primates as a model of olfactory processing in humans (Rolls, 2001; Rolls and Grabenhorst, 2008; Rolls, 2011a). For 65% of neurons in the orbitofrontal olfactory areas, Critchley and Rolls (1996b) showed that the representation of the olfactory stimulus was independent of its association with taste reward (analyzed in an olfactory discrimination task with taste reward, as some orbitofrontal cortex olfactory neurons are bimodal, with responses also to taste stimuli (Rolls and Baylis, 1994)). For the remaining 35% of the neurons, the odors to which a neuron responded were influenced by the taste (glucose or saline) with which the odor was associated (Critchley and Rolls, 1996b). Thus the odor representation for 35% of orbitofrontal neurons appeared to be built by olfactory-to-taste association learning, and thus by learning the neurons come to encode the **expected value** of olfactory stimuli.

This possibility that the odor representation of some primate orbitofrontal cortex olfactory neurons is built by olfactory-to-taste association learning to encode **expected value** was confirmed by reversing the taste with which an odor was associated in the reversal of an olfactory discrimination task. It was found that 73% of the sample of neurons analyzed altered the way in which they responded to odor when the taste reinforcer association of the odor was reversed (Rolls, Critchley, Mason and Wakeman, 1996b). Reversal was shown by 25% of the neurons (see, for example, Fig. 5.2), and 48% altered their activity in that they no longer discriminated after the reversal. These latter neurons thus respond to a particular odor only if it is associated with a taste reward, and not when it is associated with the taste of salt, a punisher. They do not respond to the other odor in the task when it is associated with reward. Thus they respond to a particular combination of an odor, and its being associated with taste

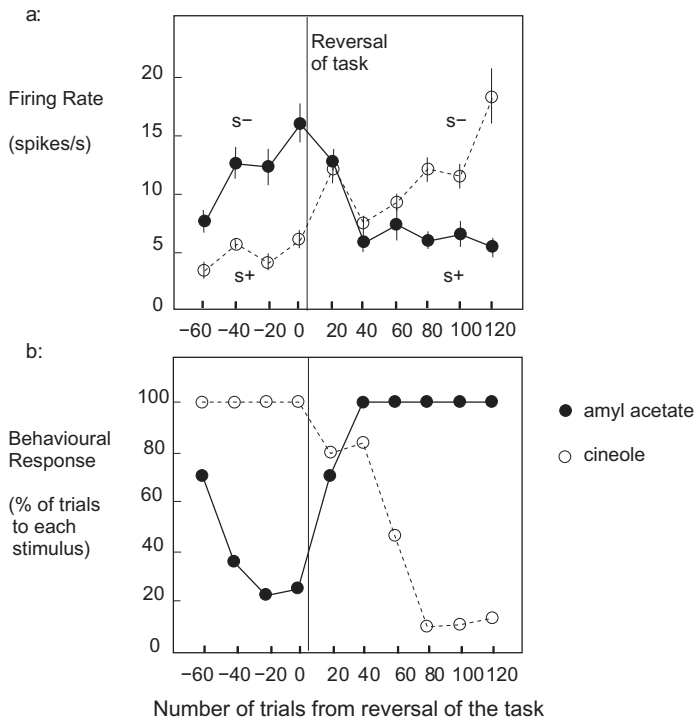

Fig. 5.2 Orbitofrontal cortex: olfactory to taste association reversal. (a) The activity of a single orbitofrontal olfactory neuron during the performance of a two-odor olfactory discrimination task and its reversal is shown. Each point represents the mean poststimulus activity of the neuron in a 500-ms period on approximately 10 trials of the different odorants. The standard errors of these responses are shown. The odorants were amyl acetate (closed circle) (initially S⁻) and cineole (o) (initially S⁺). After 80 trials of the task the reward associations of the stimuli were reversed. This neuron reversed its responses to the odorants following the task reversal. (b) The behavioral responses of the monkey during the performance of the olfactory discrimination task. The number of lick responses to each odorant is plotted as a percentage of the number of trials to that odorant in a block of 20 trials of the task. (Reproduced from E. T. Rolls, H. D. Critchley, R. Mason, E. A. Wakeman (1996) Orbitofrontal cortex neurons: role in olfactory and visual association learning. *Journal of Neurophysiology* 75: 1970–1981. Copyright © The American Physiological Society.)

reward and not a taste punisher. They may be described as **conditional olfactory-reward neurons**, and may be important in the mechanism by which stimulus–reinforcer (in this case olfactory-to-taste) reversal learning occurs (Deco and Rolls, 2005d), as described in Chapter 11.

The olfactory to taste reversal was quite slow, both neurophysiologically and behaviorally, often requiring 20–80 trials, consistent with the need for some stability of flavor (i.e. olfactory and taste combination) representations. The relatively high proportion of olfactory neurons with modification of responsiveness by taste association in the set of neurons in this experiment was probably related to the fact that the neurons were preselected to show differential responses to the odors associated with different tastes in the olfactory discrimination task. Thus the rule according to which the orbitofrontal olfactory representation was formed was for some neurons by association learning with taste.

Consistent findings were found in a human fMRI classical conditioning experiment in which odors were paired with a monetary cue, and representations in the orbitofrontal cortex and one of its subregions the ventromedial prefrontal cortex were influenced by this conditioning (Howard et al., 2015, 2016).

Fig. 5.3 The effect of feeding to satiety on the responses of an olfactory neuron in the orbitofrontal cortex. The monkey was fed to satiety with blackcurrant juice, and the neuronal response to the odor of blackcurrant juice, but not to other odors, decreased as the monkey was being fed to satiety. The neuronal responses reflected the monkey's preference for the blackcurrant juice, as shown in the lower graph. (Reproduced from H. D. Critchley and E. T. Rolls (1996) Hunger and satiety modify the responses of olfactory and visual neurons in the primate orbitofrontal cortex. *Journal of Neurophysiology* 75: 1673–1686. © The American Physiological Society.)

5.2.6 Orbitofrontal cortex: olfactory reward value is represented

The experiments just described (Rolls, Critchley, Mason and Wakeman, 1996b; Critchley and Rolls, 1996b) show that some olfactory neurons in the primate orbitofrontal cortex represent reward value, in that their responses depend on whether the odor is associated with a rewarding taste or an aversive taste. (Similar findings on associative learning in the mouse orbitofrontal cortex but not pyriform cortex have been reported (Wang, Boboila, Chin, Higashi-Howard, Shamash, Wu, Stein, Abbott and Axel, 2020e)). Further evidence for primates comes from devaluation experiments, in which the odor is devalued by feeding to satiety.

Critchley and Rolls (1996a) measured the responses of olfactory neurons that responded to food while they fed the monkey to satiety in a reward devaluation experiment. They found that the majority of orbitofrontal olfactory neurons reduced their responses to the odor of the food with which the monkey was fed to satiety (see Fig. 5.3). Thus for these neurons, the **expected reward value** of the odor is what is represented in the orbitofrontal cortex. This provides a basis for the olfactory sensory-specific satiety that is found in humans (Rolls and Rolls, 1997).

Consistent with this finding at the neuronal level in non-human primates, activation of a part of the human orbitofrontal cortex is related to the pleasantness and expected value of food odor, in that the activation measured with fMRI produced by one food odor, banana, decreased after banana was eaten for lunch to satiety, but remained strong to another food odor, vanilla, not eaten in the meal (O'Doherty, Rolls, Francis, Bowtell, McGlone, Kobal, Renner and Ahne, 2000). Consistent findings have been reported (Gottfried, O'Doherty and Dolan, 2003; Howard and Gottfried, 2014; Howard, Gottfried, Tobler and Kahnt, 2015).

Further evidence that pleasant odors are represented in the orbitofrontal cortex is that 3 pleasant odors (linalyl acetate [floral, sweet], geranyl acetate [floral], and alpha-ionone [woody, slightly food-related]) had overlapping activations in the medial orbitofrontal cortex in a region not activated by three unpleasant odors (hexanoic acid, octanol, and isovaleric acid) (Rolls, Kringelbach and De Araujo, 2003c) (see Fig. 5.5). Moreover, activation of the medial orbitofrontal cortex was correlated with the subjective pleasantness ratings of the odors, and activation of the lateral orbitofrontal cortex with the subjective unpleasant-

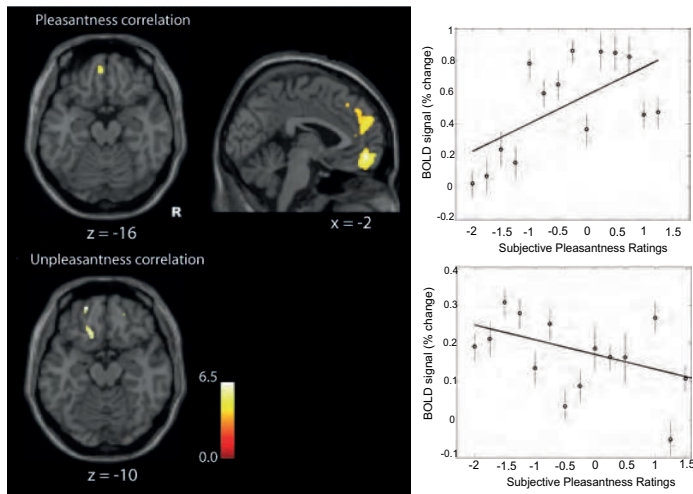

Fig. 5.4 The representation of pleasant and unpleasant odors in the human brain. Random effects group analysis correlation analysis of the BOLD signal with the subjective pleasantness ratings. On the top left is shown the region of the medio-rostral orbitofrontal (peak at $[-2\ 52\ -10]$ $z=4.28$) correlating positively with pleasantness ratings, as well as the region of the anterior cingulate cortex in the top middle. On the far top-right of the figure is shown the relation between the subjective pleasantness ratings and the BOLD signal from this cluster (in the medial orbitofrontal cortex at $Y=52$), together with the regression line. The means and s.e.m. across subjects are shown. At the bottom of the figure are shown the regions of left more lateral orbitofrontal cortex (peaks at $[-20\ 54\ -14]$ $z=4.26$ and $[-16\ 28\ -18]$ $z=4.08$) correlating negatively with pleasantness ratings. On the far bottom-right of the figure is shown the relation between the subjective pleasantness ratings and the BOLD signal from the first cluster (in the lateral orbitofrontal cortex at $Y=54$), together with the regression line. The means and s.e.m. across subjects are shown. The activations were thresholded at $p<0.0001$ for extent. (Reproduced from Edmund T. Rolls, Morten L. Kringelbach, and Ivan E. T. De Araujo (2003) Different representations of pleasant and unpleasant odors in the human brain. *European Journal of Neurosciences* 18: 695–703. Copyright © Federation of European Neuroscience Societies and John Wiley and Sons Ltd.)

ness ratings of the odors (see Fig. 5.4). Other studies have also shown activation of the human orbitofrontal cortex by odor (Zatorre, Jones-Gotman, Evans and Meyer, 1992; Zatorre, Jones-Gotman and Rouby, 2000; Royet, Zald, Versace, Costes, Lavenne, Koenig and Gervais, 2000; Anderson, Christoff, Stappen, Panitz, Ghahremani, Glover, Gabrieli and Sobel, 2003; Grabenhorst, Rolls, Margot, da Silva and Velazco, 2007; Rolls, Grabenhorst, Margot, da Silva and Velazco, 2008b).

5.2.7 Cognitive influences on olfactory representations in the orbitofrontal cortex

Cognitive input can bias reward value and emotional states. For example, word level descriptors can influence the subjective pleasantness of olfactory stimuli, and the representation of olfactory stimuli in the human orbitofrontal cortex (De Araujo, Rolls, Velazco, Margot and Cayeux, 2005). The modulation is rather like the top-down effects of attention on perception (Desimone and Duncan, 1995; Rolls and Deco, 2002; Deco and Rolls, 2003, 2005b), not only phenomenologically, as described for taste in Section 4.2.8, but also probably computationally using biased competition or biased activation as described in Section 4.3.5.

In the discovery of top-down effects of cognition on olfactory processing in the brain, a standard test odor, isovaleric acid (with a small amount of cheddar cheese odor added to make it more pleasant), was used as the test olfactory stimulus delivered with an olfactometer during functional neuroimaging with fMRI (De Araujo et al., 2005). This odor is somewhat ambiguous, and might be interpreted as the odor emitted by a cheese-like odor (rather like brie), or might be interpreted as a rather pungent and unpleasant body odor. A word was shown during the 8 s odor delivery. On some trials, the test odor was accompanied by the

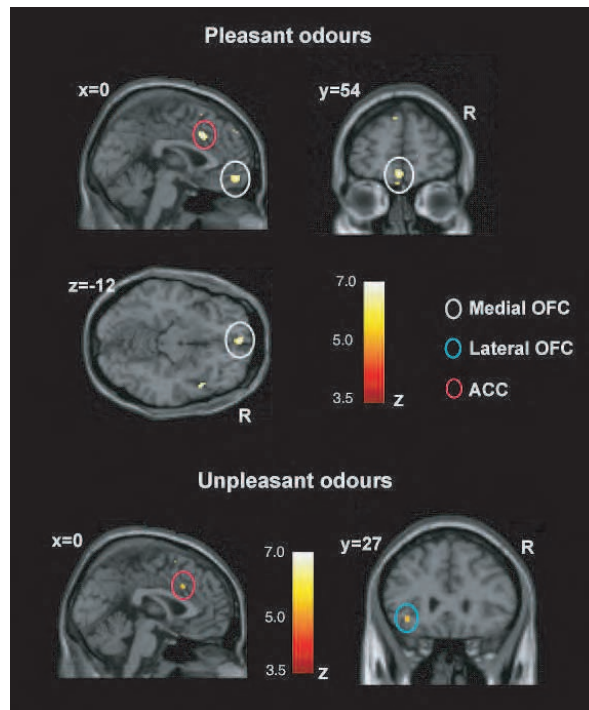

Fig. 5.5 The representation of pleasant and unpleasant odors in the human brain. Above : Group conjunction results for the 3 pleasant odors. Sagittal, horizontal and coronal views are shown at the levels indicated, all including the same activation in the medial orbitofrontal cortex, OFC [0 54 -12] $z=5.23$. Also shown is activation for the 3 pleasant odors in the anterior cingulate cortex, ACC [2 20 32] $z=5.44$. These activations were significant at $p<0.05$ fully corrected for multiple comparisons. Below : Group conjunction results for the 3 unpleasant odors. The sagittal view (left) shows an activated region of the anterior cingulate cortex [0 18 36] $z=4.42$, $p<0.05$, *svc*). The coronal view (right) shows an activated region of the lateral orbitofrontal cortex [-36 27 -8] $z=4.23$, $p<0.05$ *svc*). All the activations were thresholded at $p<0.00001$ to show the extent of the activations. (Reproduced from Edmund T. Rolls, Morten L. Kringelbach, and Ivan E. T. De Araujo (2003) Different representations of pleasant and unpleasant odors in the human brain. *European Journal of Neuroscience* 18: 695–703. Copyright © Federation of European Neuroscience Societies and John Wiley and Sons Ltd.)

visually presented word ‘Cheddar cheese’. On other trials, the test odor was accompanied by the visually presented word ‘Body odor’. A word label was used rather than a picture label to make the modulating input very abstract and cognitive. First, it was found that the word labels influenced the pleasantness ratings of the test odor.

We went on to show that the word label modulated the activation to the odor in brain regions activated by odors such as the orbitofrontal cortex (secondary olfactory cortex), cingulate cortex, and amygdala (De Araujo et al., 2005). For example, in the medial orbitofrontal cortex the word label ‘Cheddar cheese’ caused a larger activation to be produced to the test odor than when the word label ‘Body odor’ was being presented. In these medial orbitofrontal cortex regions and the amygdala, and even possibly in some parts of the primary olfactory cortical areas, the activations were correlated with the pleasantness ratings, as shown in Fig. 5.6. This is consistent with the finding that the pleasantness of odors is represented in the medial orbitofrontal cortex (Rolls, Kringelbach and De Araujo, 2003c).

These findings show that cognition can influence and indeed modulate reward-related (affective) processing as far down the human olfactory system as the secondary olfactory cortex in the orbitofrontal cortex, and in the amygdala (De Araujo, Rolls, Velazco, Margot and Cayeux, 2005).

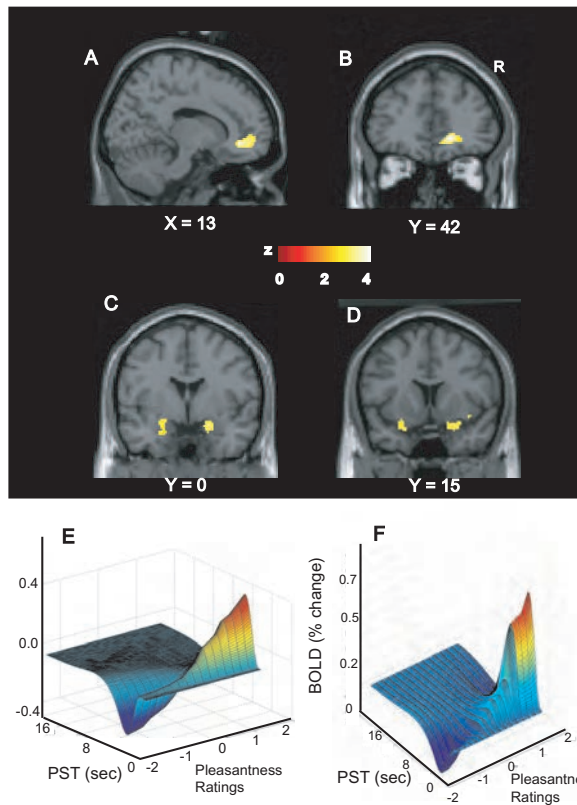

Fig. 5.6 Top-down effects of cognition on olfactory processing. Group (random) effects analysis showing the brain regions where the BOLD signal was correlated with pleasantness ratings given to the test odor. The pleasantness ratings were being modulated by the word labels. (A) Activations in the rostral anterior cingulate cortex, in the region adjoining the medial OFC, shown in a sagittal slice. (B) The same activation shown coronally. (C) Bilateral activations in the amygdala. (D) These activations extended anteriorly to the primary olfactory cortex. The image was thresholded at $p < 0.0001$ uncorrected in order to show the extent of the activation. (E) Parametric plots of the data averaged across all subjects showing that the percentage BOLD change (fitted) correlates with the pleasantness ratings in the region shown in A and B. The parametric plots were very similar for the primary olfactory region shown in D. PST - Post-stimulus time (s). (F) Parametric plots for the amygdala region shown in C. 5.3 How computations are performed in the olfactory system

5.3.1 Olfactory receptors, and the olfactory bulb

The encoding described in Section 5.2.1 in this early part of the olfactory system is based on the stereochemical structure of the odorant, with receptors that have been produced in a genetically very expensive way, with one gene to build each olfactory receptor type. This is a very simple way for a sensory system to operate, with its sensory capability built largely by having one gene that has evolved to produce a single receptor type, with this repeated for 1000 genes, approximately 1/30th of the human genome.

The convergence from a very large number of olfactory receptors of each type in the olfactory epithelium in the nose, with the different receptor types to some extent intermingled, into a single glomerulus in the bulb for each receptor type shows that the molecular specificity of olfactory encoding is kept largely separate (apart from some lateral inhibition) without feature combinations being formed up to the stage of the glomeruli in the olfactory bulb. The conver-

gence from many receptors onto a single glomerulus must be a way of increasing the signal to noise ratio, by averaging across many receptors of a given type. This, and the molecular specificity of the connectivity is important especially in the context that the olfactory receptor neurons show a constant turnover, being replaced every few days, presumably because in the nose they are in a vulnerable location.

The turnover of olfactory receptors is computationally possible because each glomerulus responds to a single olfactory receptor input, without feature combination neurons being learned at this stage. Once feature combinations have been learned by neurons by associative synaptic modification in for example a competitive network, neuronal turnover is no longer possible, for otherwise the learned combinations will be lost, and later stages of the neural system would not have a reliable input. This is a key reason why the formation of new neurons, neurogenesis, and neuronal regeneration, does not happen in the brain. Another is that in a system that operates by learning feature combinations, there is no molecular signal that can inform new neurons about which other neurons to make connections with. The possibility for neuronal turnover in the olfactory epithelium is just because the connections to the olfactory bulb are set by a gene-specified molecular mechanism. There is further discussion of these fundamental computational concepts on how the brain is built, and why neuronal turnover is not possible in the brain except in the dentate gyrus of the hippocampus where information is not stored in these particular synaptic connections, in Rolls (2016b).

The local inhibition in the olfactory bulb may be seen as a way to spread out (orthogonalize or decorrelate) the olfactory stimulus space by using the contrast enhancement provided by lateral inhibition. Feedback from the pyriform cortex may also help to increase the selectivity of neurons in the olfactory bulb (Chae, Banerjee, Dussauze and Albeanu, 2022).

5.3.2 Olfactory (pyriform) cortex

Olfactory (pyriform) cortex is a 3-layer type of cortex termed paleocortex, a type of allocortex (Pandya et al., 2015), with only one layer containing large pyramidal cells. Its structure is shown in Fig. 5.7. This represents my synthesis of what has been described based on these sources (Haberly, 2001; Luskin and Price, 1983) and on discussion with those who work on the pyriform cortex including Joel Price (Washington University School of Medicine), and has some different emphases to those in Figures 9 and 12A2 of Haberly (2001).

The anterior pyriform cortex especially has well-developed recurrent collateral connections, which it is hypothesized enable it to learn as an autoassociation network (Haberly, 2001) which forms combinations of inputs from the glomeruli of the olfactory bulb. Each glomerulus is connected to one of the 1000 types of olfactory receptor each specified by a separate gene, each tuned to a separate range of odors (Buck and Bargmann, 2013; Mombaerts, 2006). The pyriform cortex detects by its autoassociation which combinations of odors tend to occur together as a result of inputs being received from the natural world. This enables discrimination between, and later good recognition of, particular odor combinations.

In more detail, the anatomy suggests that the anterior pyriform cortex acts as an auto-association or attractor network that can form and remember representations that reflect combinations of simultaneous olfactory inputs. The anterior pyriform cortex has highly developed recurrent collaterals for the autoassociation. (Haberly (2001) distinguished a ventral part which he suggested provided for a first stage of autoassociation, and a dorsal part which provided he postulated a second stage.) The anterior pyriform cortex receives direct inputs from the olfactory bulb and the ‘anterior olfactory cortex’ (formerly known as the anterior olfactory nucleus). The anterior pyriform cortex necessarily represents the different parts that are being associated together by its recurrent collaterals, and computationally would enable completion of a whole combination from a part, and also short-term memory which might

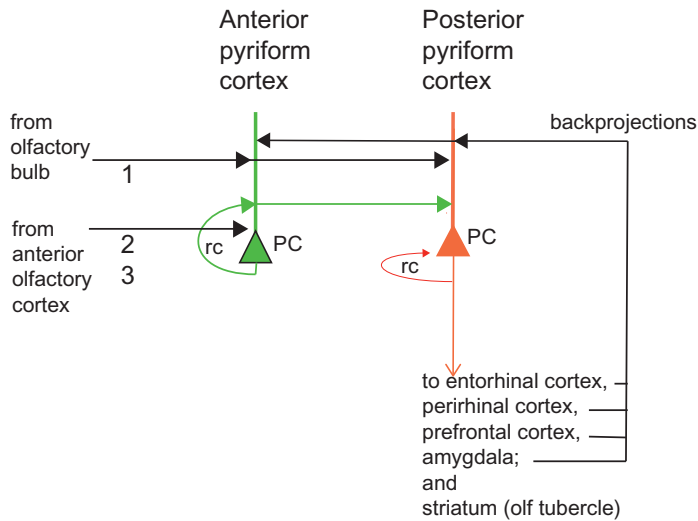

Fig. 5.7 Functional canonical microcircuit of the olfactory (pyriform) cortex. Recurrent collateral connections (rc) are shown as a loop back to a particular population of cells, of which just one neuron is shown. The pyriform cortex has an anterior part, the anterior pyriform cortex (APC), and a posterior part (PPC). Afferents from the olfactory bulb (OB) reach the apical dendrites in layer 1a of APC and PPC. Additional olfactory inputs from an anterior olfactory cortex (AOC) synapse onto the dendrites of the pyramidal cells in layer deep 1b of APC. APC has a highly developed recurrent collateral system, which reaches PPC. There are additional recurrent collaterals on the basal dendrites of the APC (not shown). The APC projects in a feedforward way to PPC, which has a less prominent recurrent collateral system, and which projects on to the recipient olfactory processing regions which include the entorhinal cortex, perirhinal cortex, olfactory tubercle / ventral striatum, prefrontal cortex, and amygdala. (From Rolls, E. T. (2016) *Cerebral Cortex: Principles of Operation*. Oxford University Press: Oxford.)

be useful in identifying an odor if the concentrations were continually varying, for example with each sniff or because of the wind. I hypothesize that in addition, competitive learning (Section B.4) may also take place in the anterior pyriform cortex, to help the neurons there respond to combinations of glomerular inputs. Consistent with this hypothesis, anterior pyriform cortex neurons do separate overlapping odor combinations better than olfactory bulb neurons (Barnes et al., 2008; Wilson and Sullivan, 2011).

A further useful computation that I propose is performed by the pyriform cortex is the temporal smoothing of the response of the olfactory bulb glomeruli, which is phasically locked to every inhalation, as described above. The proposed mechanism in the pyriform cortex is that an autoassociation network, implemented by the associatively modifiable recurrent collateral connections, provides a short-term memory (Section B.3), which in this case helps to smooth out the activity of pyriform neurons, so that when the outputs are sent to other regions such as the orbitofrontal cortex, they can be easily associated with the non-phasic taste and visual stimuli.

The posterior pyriform cortex receives inputs from the anterior pyriform cortex and also from the olfactory bulb, as shown in Fig. 5.7. Its recurrent collateral system may be less well developed than that of the anterior pyriform cortex (Haberly, 2001) (as indicated by the thinner line in Fig. 5.7), and makes synapses especially with the basal dendrites of the posterior pyriform cortex pyramidal cells (Luskin and Price, 1983). The posterior pyriform cortex then may act (with its feedforward inputs and less highly developed recurrent collateral system), to recode the parts represented in the anterior pyriform cortex into representations that reflect the combinations of the parts, using competitive learning. This corresponds to what I have proposed for the relation between the CA3 recurrent collateral system, and the CA1 competitive network, though the CA1 has essentially no recurrent collaterals (Rolls, 1990b,b; Treves and Rolls, 1994; Rolls, 1996d; Kesner and Rolls, 2015; Rolls, 2018b). The

code that is formed in the posterior pyriform cortex thus would be expected on this hypothesis to have different neurons that can respond to different combinations of odors, even when the combinations have overlapping components, and as predicted, this has been found in the Posterior Pyriform Cortex more than in the Anterior Pyriform Cortex, at least in naive animals (Kadohisa and Wilson, 2006). It is also useful to emphasize that the outputs from the pyriform cortex come primarily from the posterior pyriform cortex, which projects to the entorhinal cortex, perirhinal cortex, olfactory tubercle, prefrontal cortex, and amygdala; and not from the anterior pyriform cortex as shown by Haberly (2001).

The implication is that the principle of operation of the pyriform cortex is that it operates primarily as a two-stage system, with the anterior pyriform cortex autoassociation stage followed by a posterior pyriform cortex stage (which may perform competitive learning and some more autoassociation), and that the outputs come primarily from the second stage, the posterior pyriform cortex (see Fig. 5.7). However, the anatomy of the anterior and posterior pyriform cortex shows that any differences in connectivity may be quantitative rather than qualitative, in that some recurrent collaterals from the posterior pyriform cortex reach the anterior pyriform cortex, and the anterior pyriform cortex does have some outputs to other olfactory-related areas (Luskin and Price, 1983). The pyriform cortex does receive backprojections from its target structures, and these end in layer 1, consistent with what is found in neocortex.

The competitive learning proposed for the posterior pyriform cortex is likely to be important in allocating as a category particular combinations of odors that are encountered. This can be described as configural learning, and can result in some neurons responding much more to a combination of inputs than to either of the components (Section B.4). This configural responsiveness is a property of responses to some odor mixtures (Coureaud, Thomas-Danguin, Sandoz and Wilson, 2022). This type of category learning using competition can occur also in systems that in addition implement attractor dynamics related to the recurrent collaterals between the neurons (Rolls, 2021c).

Here is my hypothesis about how the pyriform cortex differs computationally from the neocortex. The pyriform cortex pyramidal cells correspond approximately to the superficial cortical layers of the cerebral neocortex, in which a key computational component is auto-association or attractor networks, but also competitive learning to form new combination-sensitive representations. Indeed, there is a hint that computationally the anterior pyriform cortex may specialise in autoassociation, and the posterior pyriform cortex, with its less prominent recurrent collateral system, as a competitive learning stage to emphasise encoding of combinations of odor components. The posterior pyriform cortex may thus be analogous to the CA1 neurons of the hippocampus, and to draw out this possibility, both are colored red in Figs. 5.7 and 9.22. Both the posterior pyriform cortex and the CA1 provide the prominent outputs of their cortical region, including projections to the striatum. However, continuing the comparison with the neocortex, the pyriform olfactory cortex evolved before there was any neocortex, or thalamus. So the olfactory cortex in early evolutionary history had no need of a layer 6, because there was no thalamus. Correspondingly, there was no preceding (neo)cortical area for a putative L5 of pyriform cortex to send backprojections to. So effectively, all that the olfactory cortex could do was to perform its autoassociation (and competitive) computation, and send its outputs on to whatever structure was present. There was no neocortex for a forward projection to reach. So the outputs of the pyriform cortex just went to whichever output region for behavior might be present, which was probably the striatum / basal ganglia, which was present at early evolutionary stages. Consistent with this, parts of the output targets of pyriform cortex include regions with a striatal structure, the olfactory tubercle, and parts of the amygdala. At later evolutionary stages, when neocortex was present, outputs from the pyriform cortex then reached neocortical areas such as the en-

torhinal cortex and prefrontal / orbitofrontal cortex. As in neocortex, the backprojections to the pyriform cortex terminate in layer 1, where they are likely to modulate rather than determine pyramidal cell firing under natural conditions. (This last point is very important. All the analyses that I have performed of cortical processing have been when the system is operating normally in the awake behaving animal, and much of this type of research remains to be performed for the pyriform cortex, instead of under anaesthesia or in slices in which effects may be demonstrated, but with the great need for their significance during normal computation to be evaluated.)

My hypothesis is that the olfactory cortex was then a 'primitive' form of cortex, and was part of the origin of 6-layer neocortex. To lead to neocortex, outputs had to be added in neocortex to drive pyramidal tract neurons with a non-sparse code (L5); and to provide a feedback signal from layer 6 to the thalamus, which of course was not present at early evolutionary stages when most of the cortex was pyriform cortex (Molnar, Kaas, de Carlos, Hevner, Lein and Nemeč, 2014). In evolution, the genes that specified the architecture of pyriform cortex might have provided a start to the design of neocortex. Molecular marker / gene comparisons of pyriform cortex with the superficial layers of neocortex might be of interest (Harris and Shepherd, 2015; Bernard et al., 2012; Molnar et al., 2014).

The representation of odors in the anterior pyriform cortex was found to be a little more sparse than in the posterior pyriform cortex in rats familiar with the odors (Kadohisa and Wilson, 2006). This may reflect a principle of cortical design, as follows. In the part of the cortex where the storage of large numbers of memories composed of parts is being performed, in attractor networks, there is an advantage to having a sparse representation, for this will increase the memory capacity. This advantage applies to the anterior pyriform cortex, to the hippocampal CA3 neurons, and to the superficial pyramidal cells (L2/L3) of the neocortex. In contrast, in the part of the cortex following an attractor network where a network operating in part as a competitive network is re-coding the parts of the memory into a single conjunctive representation (in which a neuron might respond to a combination of the parts), the representation may be less sparse, because the advantage here is to convey a large amount of information into a given number of neurons in the whole population, as this information will be used as a recall cue. This could apply to the hippocampal CA1 cells, to the deep layers of the neocortex (L5) which give rise to backprojections used for memory recall, and may apply to the posterior pyriform cortex, where the parts of the memory may no longer be as relevant, just the memory of specific combinations of odors. However, the components were more correlated with each other, and the components were more correlated with the binary mixtures, in the posterior pyriform cortex than in the anterior pyriform cortex (Kadohisa and Wilson, 2006). This does not suggest pattern separation from the anterior to the posterior pyriform cortex, and is consistent with the coding being less sparse in the posterior pyriform cortex. The authors comment that the posterior pyriform cortex encoding may reflect perceptual similarity, in that for example after experiencing a cherry + smoky mixture, the components may become more similar to each other, with for example the cherry being described as having a smoky component. So some recoding may be taking place from anterior to posterior pyriform cortex, but it is not just pattern separation, according to this evidence (Kadohisa and Wilson, 2006). What does appear to be the case is that the posterior pyriform cortex is a later stage in processing, in that it has highly developed axonal connections to entorhinal cortex, perirhinal cortex, prefrontal cortex, amygdala, and striatum (olfactory tubercle) (Haberly, 2001; Luskin and Price, 1983).

In addition, a L4 was not present in olfactory cortex, for there was no thalamus, and the inputs from the glomeruli in the olfactory bulb just appear as forward inputs projecting as they do in most neocortical areas to superficial layers of the cortex. However, an additional key difference (from the hippocampus too) is that there is no granule cell stage in the pyri-

form cortex to perform pattern separation before the inputs are applied to the pyriform cortex. Taking this concept one step further, the neocortex can be thought of as more advanced computationally (operationally) than the pyriform and hippocampal cortex, in that the neocortex has thalamic inputs, which as suggested above perform a useful and simple stage of pattern separation before inputs reach the primary sensory cortical areas, by virtue of the local lateral inhibition in the topologically mapped thalamic nuclei, which serves to operate as a high pass spatial filter. There is of course no (or very little) spatial topology in the 1000 dimensional odor space spanned by the olfactory receptor genes and glomeruli, and for this reason a thalamus for olfaction acting in the way just described with local lateral inhibition would not be operationally (computationally) very useful.

This provides an answer to why a thalamus evolved in conjunction with the neocortex. My hypothesis is that the thalamus, which performs primarily local lateral inhibition between its neurons, was useful as a cortical preprocessor, for exactly this computation performs hi-pass filtering of the inputs, making them more sparse, which helps the computations performed by the neocortex, including pattern separation and autoassociation (Appendix B).

5.3.3 Orbitofrontal cortex

In the orbitofrontal cortex, at least some neurons remap the olfactory representation from the genetic encoding present in the receptors and olfactory bulb into a space where associations are made to taste, as many orbitofrontal cortex olfactory neurons represent odors by the taste with which they are associated. This is probably learned by pattern association learning (see Section B.2).

The reversal learning implemented for olfactory to taste associations in the orbitofrontal cortex could be implemented by gradual relearning in the pattern association type of network described in Section B.2. The rapid rule-based reversal that can occur in the orbitofrontal cortex for at least visual stimuli (when for example their association with a taste is reversed) is a much more sophisticated system, for it requires a rule-based system, and the rule must be held online. A model for this is described in Chapter 11.

Many orbitofrontal cortex olfactory neurons represent odors in terms of their reward value, as shown by the effects of feeding to satiety. Part of this may be implemented by the association with taste, the reward value of which is represented in the orbitofrontal cortex.

Further, olfactory sensory-specific is represented in the orbitofrontal cortex, and this may be computed by synaptic adaptation of the afferent connections to orbitofrontal cortex olfactory neurons, in that it is represented in the orbitofrontal cortex, and because just smelling an odor for several minutes can produce some olfactory sensory-specific satiety (Rolls and Rolls, 1997).

A summary of what is computed in the olfactory system, and how it is computed, is provided at the start of this Chapter in Sections 5.1.1 and 5.1.2.

6 The somatosensory system

6.1 What is computed in the somatosensory system

The first few subsections (6.1.1–6.1.4) consider somatosensory processing in the parietal somatosensory cortex hierarchy (Delhaye, Long and Bensmaia, 2018), including the interface to visual representations.

Then somatosensory representations in the insular cortex are considered (Section 6.1.5).

The representation of the affective value of touch in the orbitofrontal cortex is described in Section 6.1.6.

Decision-making within the somatosensory system is considered in Section 6.1.7, with the network mechanisms for how the computations are performed to implement decision-making described in Sections 11.5.1 and B.6–B.8.

6.1.1 The receptors and periphery

The main touch receptor types in the skin are shown in Fig. 6.1 (Delhaye et al., 2018). The Meissner corpuscles are superficial, have small receptive fields, are used for fine discrimination, and adapt rapidly. The Pacinian corpuscles are deep, have large receptive fields, and adapt rapidly so respond to mechanical transients. The Merkel corpuscles are superficial and adapt only slowly, so are useful for measuring the force being applied, for example when grasping an object, as well as for fine discrimination. The Ruffini corpuscles are deeper, and adapt only slowly, so are useful for measuring strain forces in the skin and below it. These are relatively similar in glabrous skin (the palms of the hands and the soles of the feet) and non-glabrous skin.

In addition, there are receptors that respond to pain, and others to soft slow stroking movements across the skin (Olausson et al., 2010, 2016), and conduct via the slow C fibres.

Muscles have proprioceptors that signal muscle stretch, and joints have proprioceptors that signal the angle of the joint.

The somatosensory nerves project to the Ventral Posterior (VP) group of thalamic nuclei.

6.1.2 The anterior somatosensory cortex, areas 1, 2, 3a, and 3b, in the anterior parietal cortex

The main somatosensory cortical areas are shown in Fig. 6.2, and the main connections between them are shown in Fig. 6.3 (Delhaye et al., 2018). The ventral posterior (VP) nuclei of the thalamus project most strongly to area 3b, which can be considered as the primary somatosensory cortex, which projects on to areas 1, 2 and 3a. Parts of these anterior parietal cortex areas then project in a dorsal stream to posterior parietal cortex area 5, which in turn projects to area 7b, with this stream related to motor behavior, including reaching and grasping; and in a ventral stream to S2 (sometimes termed secondary somatosensory cortex) and the parietal ventral areas which are in the Sylvian fissure and adjoining insula, and are more involved in higher level feature extraction, attention, and decision-making for tactile stimuli. There is a clear analogy here to the dorsal and ventral visual streams described in Chapters 2 and 3. The system does have hierarchical organisation, even if it is not very strict as shown

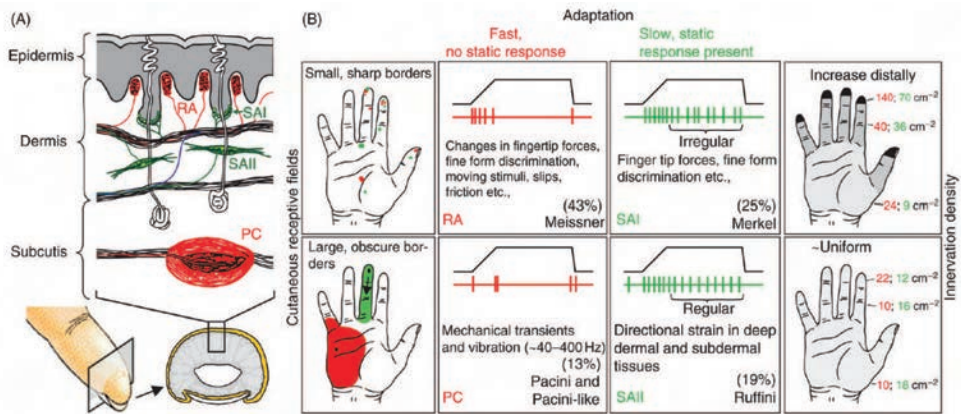

Fig. 6.1 Four classes of receptor in the skin (see text). (Reproduced from Delhaye, B.P., Long, K.H. and Bensmaia, S.J. (2018) Neural basis of touch and proprioception in primate cortex. *Comprehensive Physiology* 8: 1575–1602. Copyright © American Physiological Society.)

in Fig. 6.3, in that neurons higher in the somatosensory system have more complex and selective properties. There are specializations in each of these parietal areas, as described next (Delhaye et al., 2018).

Neurons in area 3b respond to cutaneous stimulation and have small receptive fields. The receptive fields tend to be elongated (with a mean aspect ratio of 1.7), and thus show orientation tuning analogous to that shown by simple cells in the primary visual cortex.

Neurons in area 1 respond to cutaneous stimulation and have larger receptive fields, which may for example span several digits. These neurons, and also neurons in area 2, have more complex feature selectivity than in 3a, such as a selectivity for curvature, or a shape-invariant selectivity for direction of motion, neither of which are reflected in the spatial structure of their RFs. The receptive fields of neurons in area 1, unlike those in area 3b, solve the aperture problem, in that the receptive fields are sufficiently large for global motion to be encoded, in a similar way to that which occurs in vision in area MT (Section 3.2). They are also sensitive to the speed of motion.

Neurons in area 3a respond to proprioceptive input signalling joint angle and muscle stretch. Some neurons respond to combinations of joint position, and so may respond for a particular reach direction. Some neurons in the head region are tuned to eye position. Some neurons respond to pain (Whitsel et al., 2019).

Neurons in area 2 respond to cutaneous or proprioceptive input or both, and have larger receptive fields than area 3b. Lesions of area 2 impair the coordination of finger movements and the ability to discriminate the shape and size of grasped objects. To determine the shape of a felt object, the tactile input but also the shape of the hand needs to be taken into account, and this process may start in area 2 where both tactile and proprioceptive information are present.

6.1.3 The ventral somatosensory stream: areas S2 and PV, in the lateral parietal cortex

Some neurons in S2 and the parietal ventral area (PV) are orientation tuned and show some position (translation) invariance. Some neurons are tuned to the direction of curved edges (Delhaye et al., 2018). Neurons here may be affected by attention. Some neurons respond to auditory stimuli, such as the sound of hands rubbing together, or to visual stimuli, as considered further below. Some neurons in S2 reflect decision-making about somatosensory stimuli,

Fig. 6.2 Organization of somatosensory cortical areas. (A) A lateral view of the brain showing the different somatosensory areas in macaque monkey cortex. Inset: Horizontal section of the postcentral gyrus at the level of the hand representation, showing the position of the different APC modules relative to the central and the intraparietal sulci. (B) Detailed view of the somatotopic representation of the body in the four fields of APC (areas 3a, 3b, 1, and 2) and in area 5L. (C) Coronal section showing the location of the lateral parietal cortex (LPC) in the lateral sulcus. Abbreviations: Anterior parietal cortex (APC); second somatosensory area (S2); parietal ventral area (PV); parietal reaching region (PRR); anterior (AIP), ventral (VIP) and lateral (LIP) intraparietal areas; post central sulcus (PCS); intraparietal sulcus (IPS). Somatotopic map: Upper lip (UL); lower lip (LL); chin (CN); snout/jaw (SN/J); digits of the hand (1{5}); (cutaneous) forearm ((CUT) FA); occiput (OCC); trunk (TR); toes (T1{5}); hindlimb (HL). (Reproduced from Delhaye, B.P., Long, K.H. and Bensmaia, S.J. (2018) Neural basis of touch and proprioception in primate cortex. *Comprehensive Physiology* 8: 1575–1602. Copyright © American Physiological Society.)

as described in Section 6.1.7. Lesions of the lateral parietal cortex lead to an impairment in shape discrimination, as do lesions in area 2, confirming that these two areas are part of a tactile shape processing pathway.

6.1.4 The dorsal somatosensory stream to area 5 and then 7b, in the posterior parietal cortex

Area 5 receives strongly from area 2, and has a lateral part (5L); and a part with arm reaching neurons, the parietal reaching region (PRR). Neurons in the posterior parietal cortex respond to cutaneous stimulation, and joint movements, and many respond to visual, and some to auditory and vestibular stimuli (Delhaye et al., 2018). These neurons are active during reaching and grasping movements, appear to encode not just limb position but also target locations and motor actions, and have connections with prefrontal, motor, and superior temporal gyrus

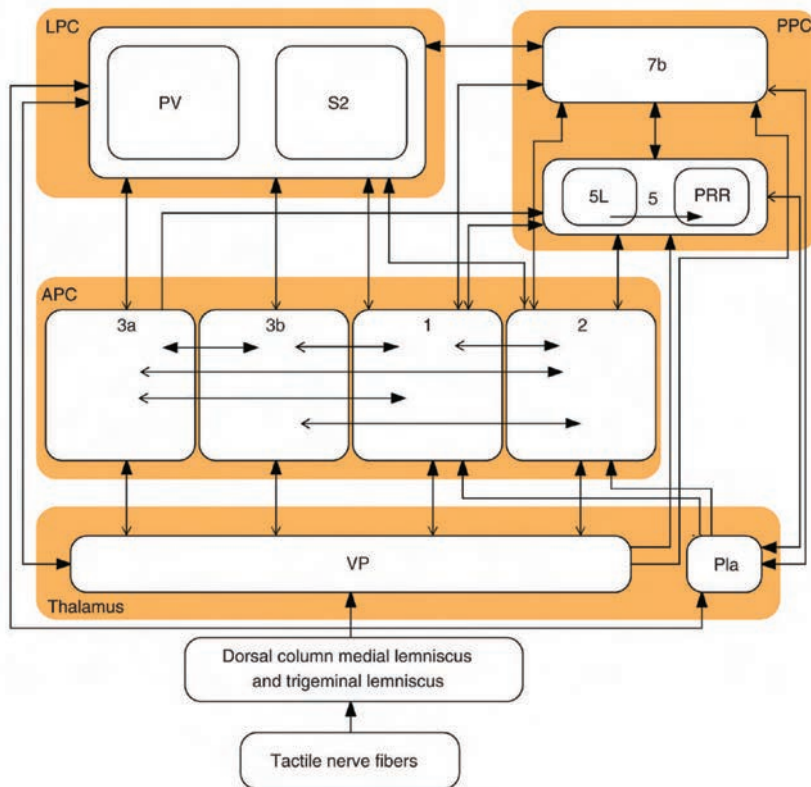

Fig. 6.3 Major connections between somatosensory areas in macaques. Schematic representation of the major connections between somatosensory areas in the central nervous system, split into four major regions: the thalamus, the anterior parietal cortex (APC), the lateral parietal cortex (LPC), and the posterior parietal cortex (PPC). Abbreviations: Ventral posterior nucleus (VP), anterior pulvinar nucleus (Pla), secondary somatosensory cortex (S2), parietal ventral area (PV), parietal reach region (PRR). Area 5 also receives input from the lateral posterior nucleus (LP) in the thalamus. (Reproduced from Delhaye, B.P., Long, K.H. and Bensmaïa, S.J. (2018) Neural basis of touch and proprioception in primate cortex. *Comprehensive Physiology* 8: 1575–1602. Copyright © American Physiological Society.)

areas. Lesions within the posterior parietal cortex impair the ability to reach and grasp objects or to recognize an object's shape through haptic exploration (stereognosis).

Area 7b receives from area 5, and has an anterior part primarily connected to somatosensory areas, and a posterior part that receives visual inputs from MST, temporal visual areas, and the lateral parietal areas. These neurons may respond better during active but also respond during passive movements, and some respond to visual stimuli.

There has been a strong debate about whether neurons in area 7 (7b or 7a) are sensory or motor. Because of their activity during reaching movements to a target in space, the pioneering neuroscientist Vernon Mountcastle and his colleagues described the neurons as 'command neurons', and argued that these neurons represent the value of the goal or target towards which the animal should reach (Mountcastle, Lynch, Georgopoulos, Sakata and Acuna, 1975). They described these neurons as responding 'during eye and hand movements directed towards desired objects, such as food when the animal is hungry'. They described these area 7 neurons as being 'conditional on the nature of the object and the motivational set of the animal' (Mountcastle et al., 1975). At the time, we were discovering neurons in the lateral hypothalamus that responded only to reward-associated objects, and not to aversive objects, and that responded only when hunger was present (Rolls, Burton and Mora, 1976; Burton, Rolls and Mora, 1976; Rolls, Sanghera and Roper-Hall, 1979b). I was sceptical that neurons in the parietal cortex

might be similar to these neurons involved in reward value, and so went to discuss with Vernon Mountcastle at Johns Hopkins University. He said that he thought they were specific for rewards, and would only respond if hunger was present. Having heard this, I thought it useful to run tests on area 7 neurons. We found that area 7 ‘visual fixation’ and ‘arm reaching’ neurons responded equally well to targets associated with reward and with punishment in visual discrimination and arm reaching tasks. The required condition was that the animal looked at the target, or reached, and not that the targets were associated with reward (Rolls, Perrett, Thorpe, Puerto, Roper-Hall and Maddison, 1979a). The parietal neurons did not appear to be processing reward value, but instead to be involved in looking at targets (irrespective of whether they were rewarding or punishing), and reaching to targets (whether it was to obtain a rewarding object or push away an aversive object) (Rolls et al., 1979a).

Following up on the hypothalamic neurons that respond to the reward value of visual stimuli, we investigated the orbitofrontal cortex, which projects to the hypothalamus, and discovered that reward value is represented in the orbitofrontal cortex (Thorpe, Rolls and Maddison, 1983; Rolls, Sienkiewicz and Yaxley, 1989d), and indeed is computed there (Rolls, 2019e) (see Chapter 11).

The issue of whether we should think of parietal neurons in some of these higher areas as ‘motor’ or ‘sensory’ is an important issue (Bisley and Goldberg, 2010). In fact, some of these parietal neurons make monosynaptic connections onto motor neurons for the hand, so the posterior parietal cortex although high up in somatosensory and dorsal visual stream sensory processing hierarchies is also involved in initiating movements, both directly, and by its connections to premotor cortical areas (Delhayé et al., 2018).

6.1.5 Somatosensory representations in the insula

The C-tactile afferents that respond to affectively positive soft slow stroking movements across the skin (Olausson et al., 2010, 2016) appear not to project to the anterior parietal cortex, but instead to the insula (Delhayé et al., 2018), which in turn has onward projections to the orbitofrontal cortex (Morecraft et al., 1992; Rolls, 2019e). Pain inputs (also mediated by C-fibres) reach the posterior insula directly from the thalamus (Craig, 2014).

The insula has been described as representing feelings from the body (Craig, 2011). Interestingly, the insula is a brain region that is activated by touch to the arm, but not by the sight of touch to someone else’s arm, implicating it in representations of especially one’s own body (McCabe, Rolls, Bilderbeck and McGlone, 2008).

The antero-dorsal part of the insula is the primary taste cortex, and has neurons that respond to the texture of food, including its viscosity and fat texture (Verhagen, Kadohisa and Rolls, 2004; Kadohisa, Rolls and Verhagen, 2005a; Rolls, 2016c, 2020c). The antero-ventral insula and nearby parts of the insula are probably visceral / autonomic cortex (Critchley and Harrison, 2013; Strigo and Craig, 2016; Kleckner et al., 2017; Hassanpour et al., 2018), which may account for its activation in some emotion-related processing (Rolls, 2014a, 2016c). The anterior ventral insula has strong interconnections with the orbitofrontal cortex (Baylis, Rolls and Baylis, 1995), which may enable visceral signals involved in for example satiety to reach the orbitofrontal cortex; and the orbitofrontal cortex to produce autonomic responses during emotional processing.

6.1.6 Somatosensory and temperature inputs to the orbitofrontal cortex, affective value, pleasant touch, and pain

In the periphery, C-tactile fibres on non-glabrous skin (most of the skin apart from the hands and feet) respond to soft slowly moving tactile stimuli, and are implicated in affectively pos-

itive touch, such as stroking and grooming (Olausson et al., 2016). For glabrous skin, there are no such C-tactile fibres. An interesting distinction may be that touch to non-glabrous skin may be by another individual, whereas for glabrous skin, the touch is more likely to be self-initiated, such as when an object is picked up (Delhay et al., 2018), leading to different processing in the brain.

Experiments have been performed to investigate where in the human touch-processing system (see Figs. 11.4 and 11.1) tactile stimuli are decoded and represented in terms of their rewarding value or the pleasure they produce. In order to investigate this, Rolls, O'Doherty, Kringelbach, Francis, Bowtell and McGlone (2003d) performed functional magnetic resonance imaging (fMRI) of humans who were receiving pleasant, neutral, and painful tactile stimuli. They found that a weak but very pleasant touch of the hand with velvet produced much stronger activation of the orbitofrontal cortex than a more intense but affectively neutral touch of the hand with wood. In contrast, the pleasant stimuli produced much less activation of the primary somatosensory cortex S1 than the neutral stimuli (see Fig. 6.4). It was concluded that part of the orbitofrontal cortex is concerned with representing the positively affective aspects of somatosensory stimuli. Nearby, but separate, parts of the human orbitofrontal cortex were shown in the same series of experiments to be activated by taste and olfactory stimuli. Thus the pleasantness of tactile stimuli, which can be powerful primary reinforcers (Taira and Rolls, 1996), is correlated with the activity of a part of the orbitofrontal cortex. This part of the orbitofrontal cortex probably receives its somatosensory inputs via the somatosensory cortex both via direct projections and via the insula (Mesulam and Mufson, 1982a,b; Rolls, 2019e, 2006b). In contrast, the pleasantness of a tactile stimulus does not appear to be represented explicitly in the somatosensory cortex. The indication thus is that only certain parts of the somatosensory input, which reflect its pleasantness, are passed on (perhaps after appropriate processing) to the orbitofrontal cortex by the somatosensory cortical areas. It was also notable that the pleasant touch activated the most anterior (pregenual) part of the anterior cingulate cortex (Rolls, O'Doherty, Kringelbach, Francis, Bowtell and McGlone, 2003d) (see Fig. 6.4).

Warm and cold stimuli have affective components such as feeling pleasant or unpleasant, and these components may have survival value, for approach to warmth and avoidance of cold may be reinforcers or goals for action built into us during evolution to direct our behavior to stimuli that are appropriate for survival. Understanding the brain processing that underlies these prototypical reinforcers provides a direct approach to understanding the brain mechanisms of emotion. In an fMRI investigation in humans, it was found that the mid-orbitofrontal and pregenual cingulate cortex and the ventral striatum have activations that are correlated with the subjective pleasantness ratings made to warm (41C) and cold (12C) stimuli, and combinations of warm and cold stimuli, applied to the hand (Rolls, Grabenhorst and Parris, 2008a) (see Fig. 6.5a-c). Activations in the lateral and some more anterior parts of the orbitofrontal cortex were correlated with the unpleasantness of the stimuli. In contrast, activations in the somatosensory cortex and ventral posterior insula were correlated with the intensity but not the pleasantness of the thermal stimuli (see Fig. 6.5d-f).

A principle thus is that processing related to the affective value and associated subjective emotional experience of thermal stimuli that are important for survival is performed in different brain areas to those where activations are related to sensory properties of the stimuli such as their intensity. This conclusion appears to be the case for processing in a number of sensory modalities, including taste and olfaction (see above), and the finding with such prototypical stimuli as warm and cold (Rolls, Grabenhorst and Parris, 2008a) provides strong support for this principle (Rolls, 2014a, 2019f, 2018a).

In another investigation, touch to the forearm (which has unmyelinated C fibre touch (CT) afferents sensitive to light touch) (Olausson et al., 2002) revealed activation in the mid-

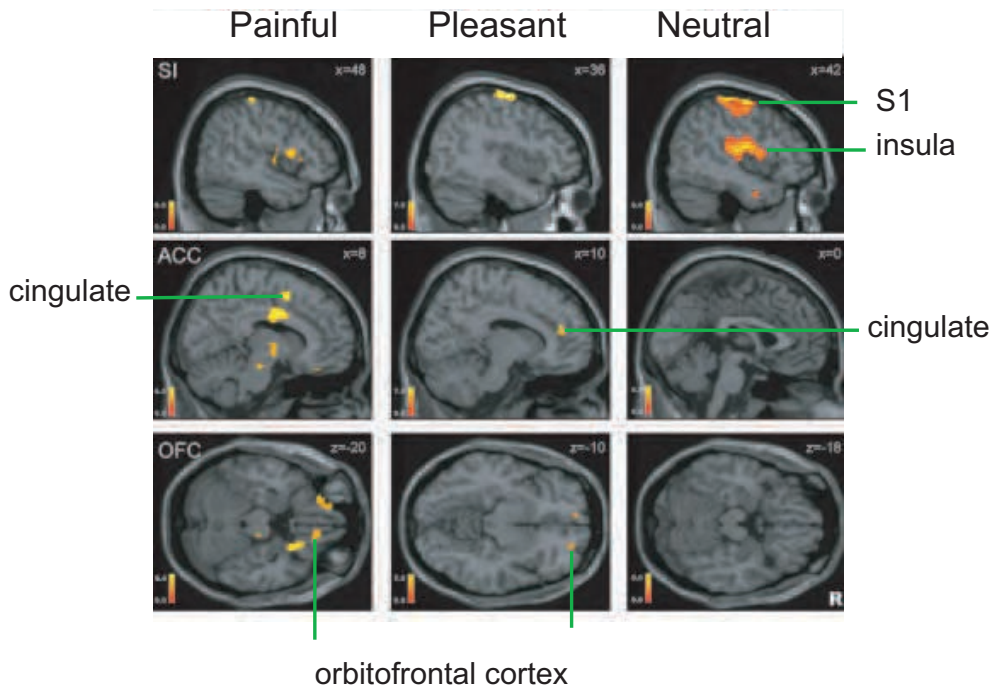

Fig. 6.4 Brain activation to painful, pleasant, and neutral touch of the human brain. The top row shows strongest activation of the somatosensory cortex S1/insula by the neutral touch, on sagittal sections (parallel to the midline). The middle row shows activation of the most anterior part of the anterior cingulate cortex by the pleasant touch, and of a more posterior part by the painful touch, on sagittal sections. The bottom row shows activation of the orbitofrontal cortex by the pleasant and by the painful touch, on axial sections (in the horizontal plane). The activations were thresholded at $p < 0.0001$ to show the extent of the activations. (After Rolls, E. T., O'Doherty, J., Kringelbach, M.L., Francis, S., Bowtell, R. and McGlone, F. (2003) Representations of pleasant and painful touch in the human orbitofrontal and cingulate cortices. *Cerebral Cortex* 13: 308–317. Copyright © Oxford University Press.)

orbitofrontal cortex, providing an indication that the orbitofrontal cortex may be involved in processing the effects of CT afferents, and thus potentially in any positively hedonic effects mediated through CT fibres (McCabe, Rolls, Bilderbeck and McGlone, 2008; Rolls, 2016a).

To investigate how the affective aspects of touch may be modulated by cognitive factors, in an fMRI investigation participants were shown word labels ('rich moisturizing cream' or 'basic cream') while cream was being applied to the forearm, or was seen being applied to a forearm (McCabe, Rolls, Bilderbeck and McGlone, 2008). The subjective pleasantness and richness were modulated by the word labels, and so were the fMRI activations to touch in parietal cortex area 7, the insular somatosensory cortex, and the ventral striatum. The cognitive labels influenced the activations to the sight of touch and also the correlations with pleasantness in the pregenual cingulate / orbitofrontal cortex and ventral striatum.

Comparison of the sight of an arm being rubbed with cream to a visual control with no contact revealed effects in the inferior frontal gyrus (a mirror neuron area, in which neurons respond to motor actions and to the sight of the action being performed (Rizzolatti and Craighero, 2004)), area 7, and even S1, implicating these regions in the imagined or intentional aspects of touch (McCabe et al., 2008). Although neurons in S1 are not activated by most visual or auditory stimuli, effects can be found if these stimuli are relevant to somatosensory processing, such as the sound of a stimulus rubbing the skin (Delhaye et al., 2018). In the experiment of McCabe et al. (2008), when the visual stimulus showed the hand being clearly touched, more brain activation was produced than when a similar visual stimulus was shown not quite touching the hand.

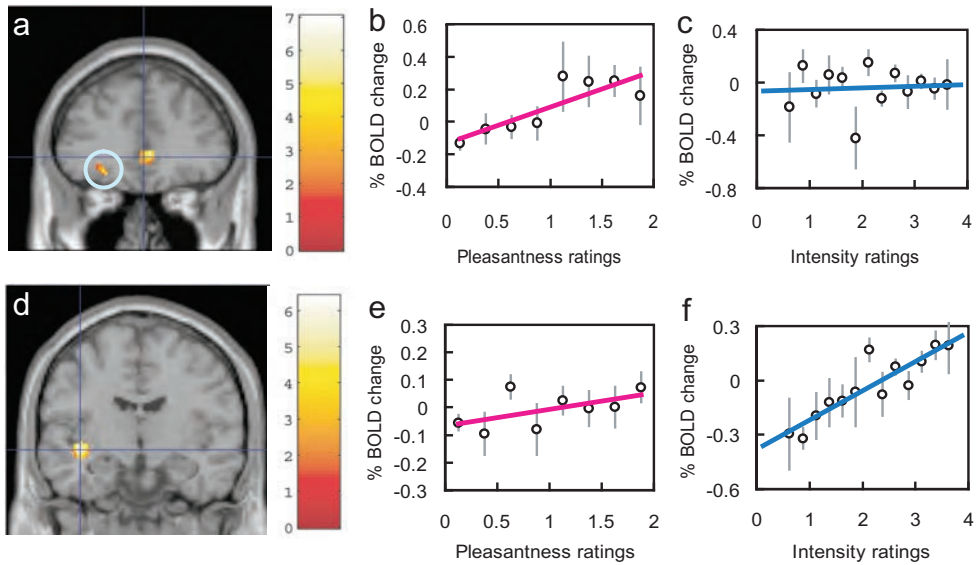

Fig. 6.5 Representation of the pleasantness but not intensity of thermal stimuli in the orbitofrontal cortex (top), and of the intensity but not the pleasantness in the mid ventral (somatosensory) insular cortex (bottom). a. SPM analysis showing a correlation in the mid orbitofrontal cortex (blue circle) at $[-26\ 38\ -10]$ between the BOLD signal and the pleasantness ratings of four thermal stimuli. Correlations are also shown in the pregenual cingulate cortex. For this mid orbitofrontal cortex region, (b) shows the positive correlation between the subjective pleasantness ratings and the BOLD signal ($r=0.84$, $df=7$, $p<0.01$), and (c) shows that there is no correlation between the subjective intensity ratings and the BOLD signal ($r=0.07$, $df=12$, $p=0.8$). d. SPM analysis showing a correlation with intensity in the posterior ventral insula with peak at $[-40\ -10\ -8]$ between the BOLD signal and the intensity ratings for the four thermal stimuli. For this ventral insula cortex region, (e) shows no correlation between the subjective pleasantness ratings and the BOLD signal ($r=0.56$, $df=7$, $p=0.15$), and (f) shows a positive correlation between the subjective intensity ratings and the BOLD signal ($r=0.89$, $df=12$, $p<0.001$). (Reprinted from Edmund T. Rolls, Fabian Grabenhorst and Benjamin A. Parris (2008) Warm pleasant feelings in the brain. *NeuroImage* 41: 1504–1513. Copyright © Elsevier Inc.)

It is proposed that the computational principle that operates here is that if an area such as S1 is being activated by touch, and simultaneously there is a top-down backprojected input to S1 from higher cortical areas that is simultaneously being received, such as the sight of the touch, then that backprojected input will be associatively synaptically modified onto S1 (or other active) neurons. Then later, that top-down input alone will be capable of activating these tactile neurons, in for example S1. The same principle could apply to other brain areas receiving visual inputs but also having touch or movement-related firing, in which associative Hebbian synaptic modification could account for touch or movement-related neurons also being activated by the sight of the touch or movement (Keysers and Perrett, 2004). This mechanism might be thought of as a somatosensory mirror neuron system. Similar principles could apply to the findings that neurons with movement-related activity in for example premotor cortex area F5 respond to the sight of grasping an object, as well as to actually grasping an object, in what we might now term the ‘motor’ mirror neuron system (Rizzolatti and Craighero, 2004; Rizzolatti and Sinigaglia, 2016; Rizzolatti and Rozzi, 2018).

It was notable that this sight of touch did not activate somatosensory regions in the insula, and it was therefore proposed that this area is especially important in representing that one is being actually touched (McCabe, Rolls, Bilderbeck and McGlone, 2008; Rolls, 2016a).

The issue of where the reinforcing and the subjectively unpleasant properties of activation of the pain pathways is represented is complex. There are clearly specialized peripheral nerves (including C fibres, with some activated via VR1 or capsaicin receptors) that convey

painful stimulation to the central nervous system (Delhaye et al., 2018). We have seen that area 3a has some neurons that respond to pain (Whitsel et al., 2019) (and loss of pain sensation has been described after a lesion to this region (Marshall, 1951)), and that nociceptive afferents from the thalamus reach the posterior insula (Craig, 2014), which is implicated in pain (Baumgartner et al., 2010; Wiech et al., 2014), and which projects to the orbitofrontal cortex (Morecraft et al., 1992; Rolls, 2019e).

There is evidence that structures as recently developed as the orbitofrontal cortex of primates are important in the subjective aspects of pain, for patients with lesions or disconnection of the orbitofrontal cortex may say that they can identify the input as painful, but that it does not produce the same affective feeling as previously (Freeman and Watts, 1950; Melzack and Wall, 1996). In the fMRI study of Rolls, O'Doherty, Kringsbach, Francis, Bowtell and McGlone (2003d) painful inputs (produced by a stylus) were also applied to the hand, and we found that the orbitofrontal cortex was more strongly activated by the painful touch than by the neutral touch, whereas the somatosensory cortex was relatively more activated by the physically heavier neutral touch (see Fig. 6.4). This provides evidence that negative as well as positive aspects of affective touch are especially represented in the orbitofrontal cortex. In this study, as in many studies (Vogt and Sikes, 2000; Vogt, 2009; Rolls, 2019c), a part of the anterior cingulate cortex in or near to the cingulate motor area which receives from the orbitofrontal cortex was also activated by pain (see example in Fig. 6.4 and Chapter 12).

The activation of parts of the orbitofrontal cortex by painful stimuli (Rolls, O'Doherty, Kringsbach, Francis, Bowtell and McGlone, 2003d; Rolls, Grabenhorst and Parris, 2008a) is likely to have great clinical relevance, for orbitofrontal cortex damage results in individuals knowing that a painful stimulus is being applied, but not feeling the strong negative affective component, of subjective pain (Rolls, 2014a, 2019e). The clinical relevance of these discoveries about the orbitofrontal cortex in relation to pain pathways and pain treatment as well as in subjective aspects of emotion (Rolls, 2019e) is likely to be of great importance, but appears to be under-appreciated at present, with the focus instead on other brain regions such as the posterior insula (Segerdahl, Mezue, Okell, Farrar and Tracey, 2015; Tracey, 2017).

6.1.7 Decision-making in the somatosensory system

The neuronal substrate of the ability to discriminate two sequential vibrotactile stimuli has been investigated by Romo and colleagues (Romo and Salinas, 2001; Hernandez, Zainos and Romo, 2002; Romo, Hernandez, Zainos, Lemus and Brody, 2002; Romo, Hernandez, Zainos and Salinas, 2003; Romo and Salinas, 2003; Romo, Hernandez and Zainos, 2004; de Lafuente and Romo, 2005). They used a task where trained macaques (*Macaca mulatta*) must decide and report which of two mechanical vibrations applied sequentially to their fingertips has the higher frequency of vibration by pressing one of two pushbuttons. This decision-making paradigm requires therefore the following processes: (1) the perception of the first stimulus, a 500 ms long vibration at frequency f_1 ; (2) the storing of a trace of the f_1 stimulus in short-term memory during a delay of typically 3 s; (3) the perception of the second stimulus, a 500 ms long vibration at frequency f_2 ; and (4) the comparison of the second stimulus f_2 to the trace of f_1 , and choosing a motor act based on this comparison (f_2 - f_1). The vibrotactile stimuli f_1 and f_2 utilized were in the range of frequencies called *flutter*, i.e. within approximately 5–50 Hz.

In the primary somatosensory cortex the average firing rates of neurons convey information about the vibrotactile frequency f_1 or f_2 during the stimulation period. The neuronal responses stop reflecting information about the stimuli immediately after the end of the stimulus. The firing rates increase monotonically with stimulus frequency (Romo and Salinas, 2003). Neurons in the secondary somatosensory area S2 respond to f_1 and show significant

Fig. 6.6 Activity of a single neuron of the ‘partially differential’ type recorded in the ventral premotor cortex (VPC) during the vibrotactile decision-making task, after Romo et al. (2004), as illustrated in Fig 2JLK of that paper. The f_1 period was from 500–1000 ms, there was then a delay period, and the f_2 period when f_2 was applied and the decision was made was from 4000–4500 ms. f_2 was in both cases 18 Hz. When f_1 was 26 Hz (red plot), the firing rate during f_1 , and at the end of the delay period, and during the comparison period when f_2 was being applied was higher than when f_1 was 10 Hz (black plot). Thus the firing of this type of neuron during f_2 helps in the decision that $f_1 > f_2$ when f_1 is 26 Hz, and that $f_1 < f_2$ when f_1 is 10 Hz. Approximately 30 trials were used to generate these peristimulus time histograms for each pair for this single neuron. (Reproduced from Deco, G., Rolls, E. T. and Romo, R. (2010) Synaptic dynamics and decision-making. *Proceedings of the National Academy of Sciences of the United States of America* 107: 7545–7549.)

delay activity for a few hundred milliseconds after the end of the f_1 stimulus (Romo et al., 2002). Some neurons in this region respond if $f_1 > f_2$; and some to the opposite, and so reflect the decision about which is the higher vibrotactile frequency. Similar neurons are also found in areas to which S2 projects such as the ventral premotor cortex (VPC) (Romo et al., 2004).

In the ventral premotor cortex, some ‘partial differential’ neurons reflect the memory of f_1 . The activity of one of these neurons recorded in the ventral prefrontal cortex (Romo et al., 2004) is illustrated in Fig. 6.6. Partial differential neurons respond to f_1 during the presentation of f_1 , do not respond in the first part of the delay period, then gradually ramp up towards the end of the delay period to a firing frequency that reflects f_1 , and then during the decision period when f_2 is presented are influenced by f_2 (Romo et al., 2004). The responses of partial differential neurons may be related to the decision-making (Romo et al., 2004), for as shown in Fig. 6.6, if $f_1 > f_2$ the firing during f_2 is higher than when $f_1 < f_2$, for a given f_2 .

Part of the mechanism that explains this vibrotactile decision-making reflected in the responses of S2 and VPC ‘partial differential’ neurons is the ‘remembering’ during the delay period of the firing that occurred to f_1 , as the firing rate ramps up again in the delay period, as shown in Fig. 6.6. One mechanism that can account for this is synaptic facilitation produced during f_1 . This will continue for several seconds into the delay period, and if a non-specific input is applied to the network as the delay period comes to an end, that will lead to reinstatement of the firing just of the neurons with facilitated synapses, thus accounting for the recall (Deco, Rolls and Romo, 2010; Martinez-Garcia, Rolls, Deco and Romo, 2011). This is explained in more detail in Section 11.5.1. Another mechanism is that if some neurons continue to have low firing rates in the delay period which reflect the value of f_1 (which is in fact illustrated in Fig. 6.6), then even without synaptic facilitation, the firing rates can be restored

by a nonspecific input because just a very few neurons are still active during the delay period (Martinez-Garcia, Rolls, Deco and Romo, 2011).

The other part of the mechanism is how the decision between f_1 and f_2 is taken. The proposal is that the decision is taken by comparing the firing rates of the partial differential neurons (which reflect both f_1 and f_2), with other neurons that fire only to f_2 . As shown in Fig. 6.6, if f_1 is $> f_2$, the firing of the partial differential neurons will be higher than of neurons that respond only to f_2 , and the decision that f_1 has a higher frequency than f_2 will be taken. On the other hand, if f_1 is $< f_2$, the firing of the partial differential neurons will be lower than of neurons that respond only to f_2 , and the decision that f_2 has a higher frequency than f_1 will be taken. The attractor decision-making network therefore just has as its two inputs the partial differential neurons, and the f_2 neurons. The operation of the whole integrate and fire attractor network that performs the decision-making is described by Deco and Rolls (2006), and in Sections 11.5.1, and B.6–B.8.

In another decision-making investigation using somatosensory stimuli, decisions about pleasantness were taken between a range of pleasant warm temperature stimuli to cold unpleasant stimuli applied with a thermode to the hand. The pleasantness vs the unpleasantness of the stimuli was represented in the orbitofrontal cortex (Rolls, Grabenhorst and Parris, 2008a), but the decision was represented anterior to this, in a part of (ventro) medial prefrontal cortex area 10 (Rolls, Grabenhorst and Deco, 2010b) (see Section 11.5.1). An important conclusion is that decisions can be made in a number of different brain areas depending on exactly what information the decision is about (Rolls and Deco, 2010), with in this case affective touch utilising parts of the human ventromedial prefrontal cortex.

6.1.8 Somatosensory cortical regions and connectivity in humans

It has become possible to understand much better the organisation of the human somatosensory cortical pathways by use of the Human Connectome Project - Multimodal Parcellation (HCP-MMP, Section 1.12), and measuring effective connectivity, complemented by functional connectivity and diffusion tractography (Section 1.13) with data from the Human Connectome Project, as described next (Rolls et al., 2023f). This has implications for understanding what is computed in different somatosensory cortical regions, including their connectivity via the insula to regions in the inferior parietal cortex that develop greatly in humans (Rolls et al., 2023f,d).

Physiological investigations in primates referred to above show that areas 3b and 1 represent cutaneous somatosensory information with area 1 having larger receptive fields, that area 3a represents proprioceptive information, and that neurons in area 2 can respond to cutaneous or proprioceptive information or both (Delhaye et al., 2018). As in humans, the legs are represented at the superior end of the somatosensory cortices 3a-2, and the face at the inferior end close to the operculum (Delhaye et al., 2018). In macaques, ventral to 3a-2 in the operculum are areas S2 and ‘parietal ventral’ (Fig. 6.2) which are described as a ventral somatosensory stream (Delhaye et al., 2018; Mishkin, 1979). In macaques the pathways to 5 and 7b are described as a dorsal somatosensory stream to the posterior parietal cortex (Delhaye et al., 2018; Gardner, 2008; Mishkin, 1979). It has been suggested that several somatosensory processing streams may be present in humans (de Haan and Dijkerman, 2020).

6.1.8.1 A ventral somatosensory stream via the insula to the inferior parietal cortex

First, the evidence shows that in humans there is a ventral somatosensory stream that connects via Frontal Opercular (FOP) regions to the insula, which in turn has connectivity to the inferior parietal cortex PF regions, as illustrated in Fig. 6.7 (Rolls et al., 2023f). The connec-

tivity from the primary somatosensory cortex 3b to the middle insula is shown with green arrows in Fig. 6.7. The onward connectivity of the middle insula (MI) to for example inferior parietal region PF, the PeriSylvian Language region PSL, and the supracallosal anterior cingulate cortex p32pr, a32pr and a24pr is shown with red arrows. The connectivity of the posterior insular region PoI2 is very similar to that of MI. The pathway in more detail is as follows, where > reflects an effective connectivity but does not exclude effects across levels: (3b + 3a <> 1 + 2) <> OP4 <> 43 <> FOP1 <> FOP3 <> (MI + PoI2 + PoI1) <> PF + PFop.

One of the fascinating features of the connectivity shown in Fig. 6.7 is that it draws out the point that some of the opercular and the frontal opercular (FOP) regions can be considered as a continuation ventrally of somatosensory cortex regions 3a, 3b, 1 and 2; with then a further ventral extension of the cortical sheet into the insula. Another important feature is that this ventral stream is probably a ‘what’ stream, for it does not have major connectivity with visuo-spatial action regions in area 7, but it does have connectivity with PFop and PF, in which representations appear to be about the properties of objects and one’s own body (Rolls et al., 2023d). Indeed part of the function of these PF areas may be related to somatosensory / body image and the sense of body ownership and of self that this provides, consistent with evidence that anosognosia and other disorders of awareness of the body can be produced by PF damage in humans (Ronchi et al., 2018). Another interesting feature is that PF may on its connectivity evidence (Rolls et al., 2023d) not only be the top of a somatosensory hierarchy, but it adds visual and reward inputs to form semantic representations of felt objects, enabling recognition of for example a tool not only by its touch, but also by its sight. Also consistent with the insula to PFop and PF stream being a ‘what’ stream is that it also has access to language systems, via the PeriSylvian Language Area (Rolls et al., 2022b), thus enabling verbal declarations to be made about what is felt, with declarative systems being ‘what’ systems in the brain, whereas action systems are typically procedural and not declarative (Squire and Zola, 1996; Squire, 1992; Milner and Goodale, 1995; Goodale and Milner, 1992). Another feature of the connectivity is the very directional input from the reward-related (Rolls, 2019e,f; Grabenhorst and Rolls, 2011) medial orbitofrontal cortex region 11l to the middle insula (Fig. 6.7), leading to the hypothesis that the somatosensory insula may encode some aspects of the reward or aversive value of somatosensory stimuli. Consistent with this, activation of the somatosensory insula was found by painful touch to the hand (Rolls, O’Doherty, Kringelbach, Francis, Bowtell and McGlone, 2003d), with a dorsal posterior insular region implicated in pain (Segerdahl et al., 2015).

An interesting property of insular function is that the insula was activated by touch to the arm, but not to the sight of touch to the arm, whereas the somatosensory cortical areas 1–3 responded to the sight of touch to the arm, as well as to touch to the arm (McCabe, Rolls, Bilderbeck and McGlone, 2008). It was therefore suggested that the insula provides evidence that it is one’s own body that is being touched, which might give it special status in body representations (McCabe et al., 2008; Craig, 2011, 2009). Consistent with this, most of the insula (MI, PoI1, PoI2 and also the FOP regions) does not receive connectivity from early cortical visual regions, whereas 3b, 3a, 1, 2, 5L, 5m and 5mv do (Rolls et al., 2023f). Another difference is that the somatomotor and paracentral areas have connectivity with parietal area 7 regions, whereas the insula does not; and the insula has more connectivity with inferior parietal PF regions than do the somatomotor and paracentral regions. Another difference is that as mentioned above the insula has connectivity directed towards language-related areas (the PeriSylvian Language area PSL, STV, TPOJ1, and TPOJ2 (Rolls et al., 2023f, 2022b)), whereas the somatomotor and paracentral regions do not. These findings support the hypothesis that the insula is part of a ventral (or inferior) ‘what’ stream of somatosensory processing that continues into inferior parietal cortex PF regions (Fig. 6.7); whereas as described next a

Ventral somatosensory pathway: lateral view

Ventral somatosensory pathway: medial view

Fig. 6.7 Ventral somatosensory / insula stream effective connectivity. The connectivity from the primary somatosensory cortex 3b to the middle insular area is shown with green arrows. The onward connectivity of the middle insular (MI) to for example inferior parietal region PF, the PeriSylvian Language region PSL, and the supracallosal anterior cingulate cortex p32pr, a32pr and a24pr is shown with red arrows. The connectivity of the posterior insular region PoI2 is very similar to that of MI. The width of the arrows reflects the effective connectivity with the size of the arrowheads reflecting the connectivity in each direction. The pathway in more detail is as follows, where > reflects an effective connectivity but does not exclude effects across levels: (3b + 3a <> 1 + 2) <> OP4 <> 43 <> FOP1 <> FOP3 <> (MI + PoI2 + PoI1) <> PF + PFop. The abbreviations are listed in Section 1.12. (From Rolls,E.T., Deco,G., Huang,C-C. and Feng,J. (2023) Prefrontal and somatosensory-motor cortex effective connectivity in humans. Cerebral Cortex doi: 10.1093/cercor/bhac391. Copyright © Oxford University Press.)

dorsal (or superior) ‘action’ stream of processing connects from somatomotor (areas 3b, 3a, 1, 2) and paracentral (area 5) cortical regions to posterior parietal cortex area 7 and thereby intraparietal regions (Fig. 6.8).

The supracallosal part of the anterior cingulate cortex is implicated in action-outcome learning, with information about the actions that have been performed available from the somatosensory/motor regions described here, and about the reward outcome received after an action being provided via the pregenual anterior cingulate cortex (Rolls et al., 2023c). This connectivity implicates the insula in this circuitry, and the effective connectivity from the reward-related medial orbitofrontal cortex 111 to the insula could provide reward outcome information to enable the insular cortex to also be involved in action-outcome learning (Rolls et al., 2023f). Consistent with this hypothesis, the insular cortex does have some connectivity to premotor cortex 6 regions, and to the mid-cingulate motor region (Rolls et al., 2023f).

6.1.8.2 A dorsal somatosensory stream

A diagram of a dorsal somatosensory stream connecting via somatosensory area 5 regions to posterior parietal area 7 regions is provided in Fig. 6.8. It should be noted that the area 5 regions in humans appear to be displaced dorsally with respect to their location in macaques such that the area 5 regions roll over to the medial wall of the hemispheres (Fig. 6.8).

In Fig. 6.8 the connectivity from the primary somatosensory cortex area 5b partly via areas 1 and 2 to area 5 somatosensory regions $5m > 5L > 5mv$ is shown with green arrows. The onward connectivity of $5mv$ to for example posterior parietal 7AL, 7Am and 7PC which have connectivity with intraparietal regions such as LIP is shown with red arrows. The pathway in more detail is as follows, where $>$ reflects an effective connectivity but does not exclude effects across levels:

$(3b + 3a << 1 + 2) << 5m << 5L << 5mv << 7AL, 7Am \text{ and } 7PC.$

$5mv$ also has connectivity to $6mp$, TPOJ2 and the supracallosal anterior cingulate cortex $p32pr$, $a32pr$ and $a24pr$. Given that area 7 is involved in actions in space (Snyder et al., 1998; Rolls, 2020b, 2021f; Dean and Platt, 2006; Vedder et al., 2017; Andersen, 1995b; Avila et al., 2019; Orban et al., 2021b; Passarelli et al., 2021; Gamberini et al., 2020; Rolls et al., 2023d), this dorsal somatosensory stream may be characterized as an ‘action’ ‘where’ stream.

Another feature is that the somatosensory cortical areas do have connectivity directed towards motor (area 4), premotor (area 6), or mid-cingulate premotor cortex. This is a principle established in macaques (Rizzolatti and Sinigaglia, 2016), and presumably allows appropriate movements to be made to the somatosensory/ proprioceptive properties analyzed in each somatosensory / proprioceptive region.

6.1.8.3 Taste cortical regions

AVI and FOP3-5 are where in the HCP-MMP atlas (Section 1.12) the human primary taste cortex is located in the anterior dorsal (i.e. superior) insula and adjoining frontal operculum (Rolls, 2016c, 2015d, 2016g).

The taste inputs to these regions are received from the thalamus VPMpc (ventro-postero-medial nucleus pars parvocellularis) (Norgren, 1990; Pritchard et al., 1986). In primates it has been discovered that neurons in the primary taste cortex (in the rostro-dorsal insula and adjoining frontal operculum) have responses to the five primary taste stimuli sweet, salt, bitter, sour and glutamate (umami) (Yaxley et al., 1990; Scott et al., 1986a; Rolls et al., 1996c; Baylis and Rolls, 1991), with each neuron having a different profile of responses to this set of stimuli and thereby encoding information that increases approximately linearly with the number of neurons (Rolls et al., 2010a; Kadohisa et al., 2005a; Rolls and Treves, 2011). The primary taste cortex in macaques has onward connections to the orbitofrontal cortex (Baylis, Rolls and Baylis, 1995), and in this secondary taste cortical area, neurons have also

Dorsal somatosensory pathway: lateral view

Dorsal somatosensory pathway: medial view

Fig. 6.8 Dorsal somatosensory stream effective connectivity. The connectivity from the primary somatosensory cortex 3b partly via 1 and 2 to area 5 somatosensory regions 5m > 5L > 5mv is shown with green arrows. The onward connectivity of the 5mv to for example posterior parietal 7AL, 7Am and 7PC which have connectivity with intraparietal regions such as LIP is shown with red arrows. The width of the arrows reflects the effective connectivity with the size of the arrowheads reflecting the connectivity in each direction. The pathway in more detail is as follows, where > reflects an effective connectivity but does not exclude effects across levels:

(3b + 3a <<> 1 + 2) <<> 5m <<> 5L <<> 5mv <<> 7AL, 7Am and 7PC.

5mv also has connectivity to 6mp, TPOJ2 and the supracallosal anterior cingulate cortex p32pr, a32pr and a24pr. The abbreviations are listed in Section 1.12. (From Rolls, E.T., Deco, G., Huang, C.-C. and Feng, J. (2023) Prefrontal and somatosensory-motor cortex effective connectivity in humans. *Cerebral Cortex* doi: 10.1093/cercor/bhac391. Copyright © Oxford University Press.)

been discovered that respond to taste (Rolls, Yaxley and Sienkiewicz, 1990). In the primary taste cortex, feeding to satiety does not reduce the responses of neurons to the taste of the food eaten to satiety, providing evidence that the primary taste cortex represents what the taste is, independently of its reward value (Yaxley, Rolls and Sienkiewicz, 1988; Rolls, Scott, Sienkiewicz and Yaxley, 1988). In contrast, in the orbitofrontal cortex the responses of neurons decrease to zero to the food eaten to satiety, providing evidence that the reward value of the taste is represented in the orbitofrontal cortex (Rolls, Sienkiewicz and Yaxley, 1989d). A similar situation appears to hold in humans, in that feeding to satiety decreases orbitofrontal cortex activations to the food eaten to satiety (Kringelbach, O'Doherty, Rolls and Andrews, 2003), and the orbitofrontal cortex BOLD signal is correlated with the pleasantness of the taste, whereas in the insular taste cortex the BOLD signal is correlated with the intensity of the taste, and not with its pleasantness (Grabenhorst and Rolls, 2008).

However, the taste cortex is even more interesting than this, for it also represents the texture of food, which is a signal of somatosensory origin, in that some macaque neurons in the insula primary taste cortex respond to viscosity, others to rough texture, and others to the texture of fat in the mouth with responses related to the coefficient of sliding friction (Verhagen, Kadohisa and Rolls, 2004), which is how we have discovered that fat in the mouth is sensed (Rolls, Mills, Norton, Lazidis and Norton, 2018b; Rolls, 2016g), with similar encoding of texture as well as taste in the orbitofrontal cortex (Verhagen, Rolls and Kadohisa, 2003). A similar situation appears to hold in humans, in that the BOLD signal in the taste cortical areas can also be related to viscosity; and in some regions there is evidence that fat texture is represented (De Araujo and Rolls, 2004; Kringelbach, O'Doherty, Rolls and Andrews, 2003; Grabenhorst, Rolls, Parris and D'Souza, 2010b).

Part of the interest of these findings (Rolls et al., 2023f) is that they show how the insular and frontal opercular (FOP) regions do receive somatosensory inputs (Rolls et al., 2023f), which are needed if responses are to be found to oral texture stimuli such as the viscosity, roughness, and fat texture of food in the mouth (Rolls, 2020c). These discoveries, including that fat texture is sensed by the coefficient of sliding friction (Rolls et al., 2018b; Rolls, 2020c), help to provide a foundation for understanding the roles of the sensory qualities of food in the control of appetite and food intake (Rolls, 2016g,d, 2018a).

6.1.8.4 Connectivity of somatosensory to motor and premotor frontal cortical regions

Helpful descriptions of the connectivity of motor and premotor cortical regions, and their inputs from intraparietal sulcus and inferior parietal cortex regions for macaques have been provided elsewhere (Gerbella et al., 2017; Rizzolatti and Kalaska, 2013; Rizzolatti and Sinigaglia, 2016) (Fig. 15.1). In this research (Rolls et al., 2023f), the connectivity of these motor and premotor areas with other cortical regions is extended to humans, and in particular to cortical regions as defined in the HCP-MMP atlas (Glasser et al., 2016a; Huang et al., 2022). Highlights of the present results are that the area 6 premotor cortex regions have connectivity not only from postcentral somatosensory cortical regions such as 1,2,3 and 5, but also from parts of parietal area 7 and from the intraparietal regions (Rolls et al., 2023d). The inputs from the latter two parietal systems are likely to be important in functions such as visually guided actions in space (Gerbella et al., 2017; Rizzolatti and Kalaska, 2013; Rizzolatti and Sinigaglia, 2016; Gamberini et al., 2020; Fattori et al., 2017). The area 6 regions also receive from the mid-cingulate premotor regions (24dd, 24dv and 23c), which receive from the supracallosal anterior cingulate cortex and thereby provide a route for action-outcome learning and performance (Rolls et al., 2023c; Rolls, 2022b).

6.2 How computations are performed in the somatosensory system

6.2.1 Hierarchical computation in the somatosensory system

The operations performed in the hierarchically organised somatosensory system are interestingly similar to those in the visual system, and the computations involved may be similar, as follows. The principles of the computations, as for the visual system (Chapter 2), appear to be: convergence from stage to stage; larger receptive fields from stage to stage; responses to feature combinations generated at each stage, including at higher stages combinations of inputs received from different sensory systems, including vision and audition; the computations of shape representations that are invariant with respect to position, which is similar to complex cells in V1, and to what is computed in the inferior temporal visual cortex.

Neurons in area 3a, the primary somatosensory cortex, respond to the orientation of edges, and the receptive field organisation can be predicted from the responses to stimuli applied to different parts of the receptive field. This makes the neurons selective for the position of the edge. This is similar to the responses of simple cells in V1.

Neurons in area 3a have small receptive fields that respond to moving edges, but the direction can only be computed as perpendicular to the edge, because of the aperture problem. This is similar to the responsiveness of V1 neurons that respond to moving visual stimuli.

At the next stage of the hierarchy, in area 1, the receptive fields are larger, and respond to combinations of the inputs from V1, for example to curvature. This can only be achieved by having large receptive fields, and is similar to what can be found in V2.

In area 1 the aperture problem is solved for motion with the larger receptive fields enabling neurons to respond to global motion in a shape-invariant way. This corresponds to the computation performed in MT in the visual system.

Similar feature combination computation through the hierarchy occurs for the proprioceptive system. Neurons in area 3a respond to proprioceptive input signalling joint angle and muscle stretch, and although some combinations may be represented here, there may be more combination-sensitive neurons in area 2, which accordingly can respond to a position of the limb in space relative to the body, and to a particular reach direction. This appears to be further elaborated in area 5 which includes the parietal reach area, where neurons can be well tuned to the direction of reaching in space relative to the body.

Convergence with other sensory modalities also occurs, as in the visual system. In the somatosensory system, convergence with visual, auditory, and vestibular stimuli occurs in area 5, and more in area 7b (Delhaye et al., 2018). These neurons are active during reaching and grasping movements, appear to encode not just limb position but also target locations and motor actions. The coordinate frames in which representations are found is a topic of current interest, with the possible coordinate frames including limb position relative to the body, and visual and reaching coordinate frameworks needed including relative to the body (egocentric), relative to the head (egocentric); and relative to allocentric space (Rolls, 2020b).

6.2.2 Computations for pleasant touch and pain

There is considerable segregation of processing for pain and for positive touch from discriminative and proprioceptive somatosensory processing, even peripherally, with C fibres implicated in negative and positive somatosensory processing.

Partial segregation is maintained into the brain. There are nociceptive inputs to the insula somatosensory areas. However, the full affective value of pain inputs is more evident in the orbitofrontal cortex, damage to which reduces the affective components of pain.

Similarly, positively affective touch are especially represented in the orbitofrontal cortex.

The orbitofrontal cortex is especially involved in representing the reward value of stimuli (Chapter 11), and projects to the cingulate cortex where instrumental actions are chosen to obtain the rewards or avoid painful stimuli (Chapter 12). Subjective feelings of pleasure and pain may be especially related to computations in this system which specializes in reward valuation, and then goal directed instrumental action via its connectivity to the orbitofrontal cortex.

6.2.3 The mechanisms for somatosensory decision-making

The mechanisms for somatosensory and other types of decision-making are considered in Sections 6.1.7, 11.5.1, and B.6–B.8.

7 The auditory system

7.1 Introduction, and overview of computations in the auditory system

The auditory pathways are shown in Fig. 7.1a. The auditory nerves synapse in the cochlear nuclei in the brainstem, which connect to the medial superior olive which detects interaural time difference for auditory localization, and to the lateral superior olivary nucleus which detects interaural intensity differences for auditory localization. The olives project to the inferior colliculi in the midbrain where a map of auditory space is formed. The inferior colliculi project to the medial geniculate nucleus, which is the auditory thalamus, and this in turn projects to the primary auditory cortex in the superior part of the temporal lobe (Oertel and Doupe, 2013; Oertel and Wang, 2021).

Overview

1. Interaural time difference is decoded by delay lines in the medial superior olive. This is useful for left-right sound localisation, and for continuous waveforms is useful up to approximately 1 kHz, which is the maximum frequency with which peaks in the waveform can be detected, given the maximum firing rate of auditory neurons of approximately 1 kHz.
2. Interaural intensity difference is useful for left-right localisation above approximately 1 kHz, the frequency at which the wavelength is sufficiently short that the head starts to act as a baffle.
3. 3D sound localization is possible because we have a pinna that acts as a 3D asymmetric antenna, which performs spectro-temporal filtering that is different for different 3D spatial locations. This is useful for sounds with frequencies above several kHz, due to the size of the pinna; and a broad spectrum helps so that the different filtering performed at different frequencies can be utilised.
4. Because the ears are anchored to the head, the main representation of auditory space is in head-based coordinates. Because we may need to look at locations of sounds that are in head-centred space, there is a mapping of spatial visual inputs to head-centred space, as described in Section 3.4.1.
5. There is a representation of visual space that is for the allocentric position being viewed, and this is implemented by hippocampal spatial view cells as described in Chapter 9 and Section 3.4.3. It is predicted that there will be a representation of auditory space in the same world-based coordinates, but it has not been discovered yet. (This may seem implausible at first, but think of what happens when one rotates one's head while listening to individual singers in an opera or actors in a play: their correct positions in allocentric space remain constant, and this seems to apply to the sounds they make in the 'soundstage', as well as to their allocentric locations in visual space.)
6. There is evidence for dorsal and ventral auditory cortical pathways.

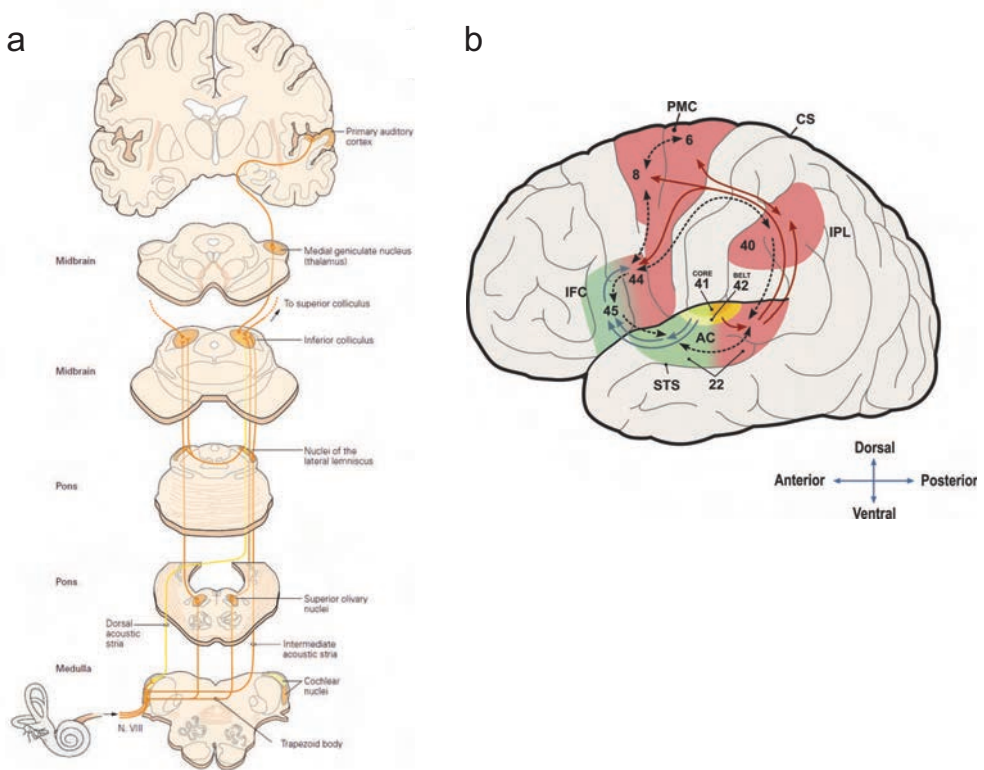

Fig. 7.1 a. The auditory pathways. b. Hierarchical organization of auditory cortical processing. The ventral auditory pathway is shown in green, and the dorsal auditory pathway in red. AC – auditory cortex; CS – central sulcus; IFC – inferior frontal cortex; IPL – inferior parietal lobule; PMC – premotor cortex; STS – superior temporal sulcus. For description, see text. (a. Reproduced from Oertel, D. and Doupe, A.J. (2013) The auditory central nervous system. Chapter 31 pp. 682–711 in Kandel, E.R. et al, 2013, Principles of Neuroscience, 5th Edition. McGraw-Hill: New York. © McGraw-Hill. b. Reprinted from Ina Bornkessel-Schlesewsky, Matthias Schlesewsky, Steven L. Small, and Josef P. Rauschecker (2015) Neurobiological roots of language in primate audition: common computational properties. *Trends in Cognitive Sciences* 19: 142–150. Copyright © Elsevier.)

7. The ventral auditory pathway appears to involve a series of hierarchical stages through the temporal lobe in the superior temporal gyrus. One projection is to the orbitofrontal cortex, where neurons are found that respond for example to the emotional expression in a voice. The ventral auditory pathway in the temporal lobe also projects to the inferior frontal gyrus (area 45), which in humans on the left is Broca's area, a frontal area involved in speech production.
8. The dorsal auditory pathway projects from the auditory cortex to the posterior superior temporal cortex, and then to the inferior parietal lobule (area 40), which in turn projects to the more dorsal part of the inferior frontal cortex (area 44). It is involved in sound localization, and perhaps in processing the dynamic aspects of sounds.

7.2 Auditory Localization

When a sound arises from the right, the right ear detects the sound earlier than the left ear. The difference in the time of arrival at the two ears is the interaural time delay (ITD). Given that the velocity of sound in air is 343 m/s, and the maximum distance between the ears, the time delays can be up to approximately 0.5 ms. For sine waves, nerve fibers can fire in phase

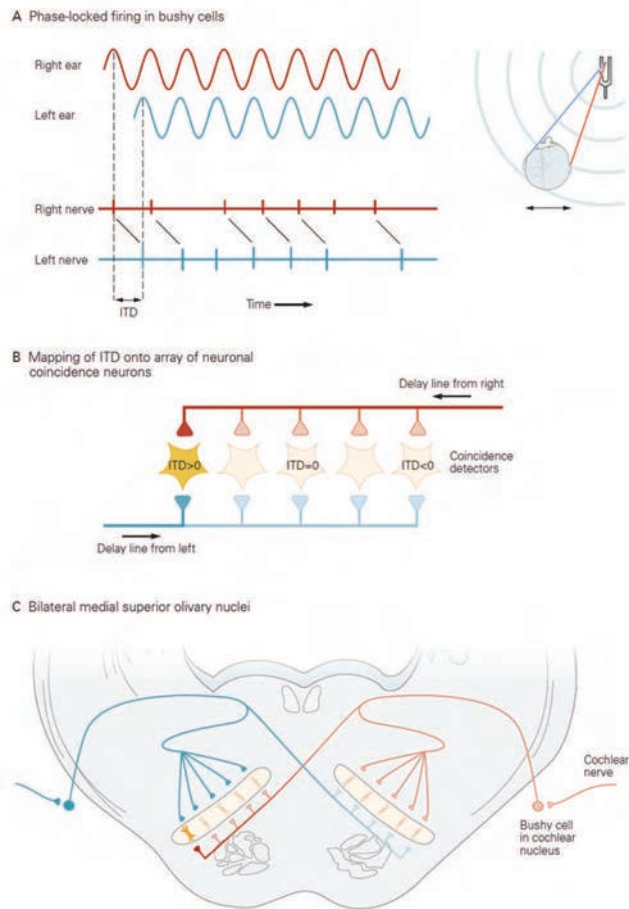

Fig. 7.2 Left-right sound localization. A. Interaural time differences are decoded to provide information about whether a sound source is to the left or right. B. Interaural time differences can be detected with delay lines. C. Mammals use delay lines for signals from the contralateral side to form a map in the superior olive of interaural time differences. (Reproduced from Oertel, D. and Doupe, A.J. (2013) *The auditory central nervous system*. Chapter 31 pp. 682–711 in Kandel, E.R. et al, 2013, *Principles of Neuroscience*, 5th Edition. McGraw-Hill: New York. © McGraw-Hill.)

with changes in the sound pressure as shown in Fig. 7.2A. This works up to about 1,000 Hz, which is as fast as the nerves can fire, even if they sometimes miss a beat.

In the medial superior olive, a very nice delay line system is set up to decode the time differences so that different neurons respond to different inter-aural time differences, as illustrated in Fig. 7.2B and C. The bitufted neurons of the medial superior olivary nucleus form a sheet that is contacted on the lateral face by bushy cells from the ipsilateral cochlear nucleus and on the medial face by bushy cells from the contralateral cochlear nucleus. On the ipsilateral side the branches of the bushy cell axons are of equal length and thus deliver synaptic currents to their targets in the medial superior olive simultaneously. On the contralateral side the branches deliver synaptic currents first to the anterior regions, closest to the midline, and then to progressively more posterior regions. When sounds arise from the right side, their early arrival at the right ear is compensated by progressively later arrival at neurons in the posterior region of the left medial superior olive (the mustard-colored cell is activated by a sound from the far right, as in Fig. 7.2B) (Oertel and Doupe, 2013). Thus each medial superior olive forms a map of where sounds arise in the contralateral hemifield.

This system is useful only for frequencies up to approximately 1 kHz, for the reasons described above. However, for frequencies above about 1 kHz, the head acts as a baffle, and sounds that are shadowed by the head reach the far ear with a smaller intensity. These intensity differences are decoded in the lateral superior olivary nucleus, to provide a way to detect left-right differences for high frequency sounds.

However, these two mechanisms implement only left-right localization, and provide no evidence about where the sound source is in front vs behind the listener, or in elevation. It is effectively a one-dimensional system.

Yet humans are quite good at 3D sound localization. 3D sound localization has many evolutionary advantages, but an aesthetic advantage was emphasized in a lecture given on 6 May 1972 that I attended at the Oxford Union by Karlheinz Stockhausen on electronic music. (That lecture is available on YouTube (Stockhausen, 1972).) Stockhausen described experiments he had performed on 3D music. He described that at the World Fair at Osaka in Japan he had made recordings in a spherical hall with 600 people on a metal grid across the middle of the inside of the sphere, with loudspeakers all the way round with 7 circles of speakers arranged in 10 columns vertically to create a sound-field above and below the listeners, with sounds coming potentially from any direction of azimuth or elevation. He described how this enabled him to experiment with 3D sound, which he considered an important aspect of electronic music.

Stockhausen then stated that he greatly regretted not being able to make recordings of the interesting musical effects that he created, because he did not have a 70 channel tape recorder. This started me thinking. How many channels of sound recording were actually needed? Were 70 channels needed? I reasoned that all the information from all the locations in space must be present at the tympanic membrane (the ear drum). I reasoned that therefore with a miniature microphone placed in the external auditory meatus close to the tympanic membrane (ear drum), it should be possible to record all the information that could be used by the brain to localize the source of the sound in space. I tested my hypothesis. I purchased some miniature electret microphones, and made recordings with these placed in my external auditory meatus very close to my tympanic membranes. The recordings were spectacular. When played back through headphones, I could localize the sound source to almost anywhere in 3D space. My hypothesis was that the asymmetric, almost helix-like, shape of the human pinna was acting as an asymmetric antenna that was filtering the sound depending on the direction of the sound source in 3D space. I quantified this by making polar frequency response measurements of the human head including the pinna, and published the results in the *Journal of Physiology* (Rolls, 1973) (available at <https://www.oxcns.org/papers>).

I realized the potential for making recordings of music, drama, etc using binaural ear canal recording, for then the exact sound heard by a listener in for example the position of the conductor of a piece of music could be recorded, and played back to the listener, with all the directional and room acoustics faithfully recorded. I therefore registered a UK provisional patent for the method in 1973. I also contacted the BBC Research Department, and demonstrated the system to members of the BBC Research Department at Kingswood Warren at the invitation of D.J.Meares in April 1974. As a result, the BBC broadcast 3D binaural intra-ear sound recordings every week or so for several years. (This recording method, although superb for playback using headphones or earphones, has limitations when listened to through stereo loudspeakers, for then the sound source is less clear, as a second localization occurs for the sound emanating from the loudspeakers.)

Since then, there has been much further research on 3D sound localization (Paul, 2009), with examples of the spectral filtering performed by the ear and head shown in Fig. 7.3. Neurons that encode the location of sounds in 3D space have been found in the ferret auditory cortex (Mrsic-Flogel et al., 2005), but a recent review of sound localization did not

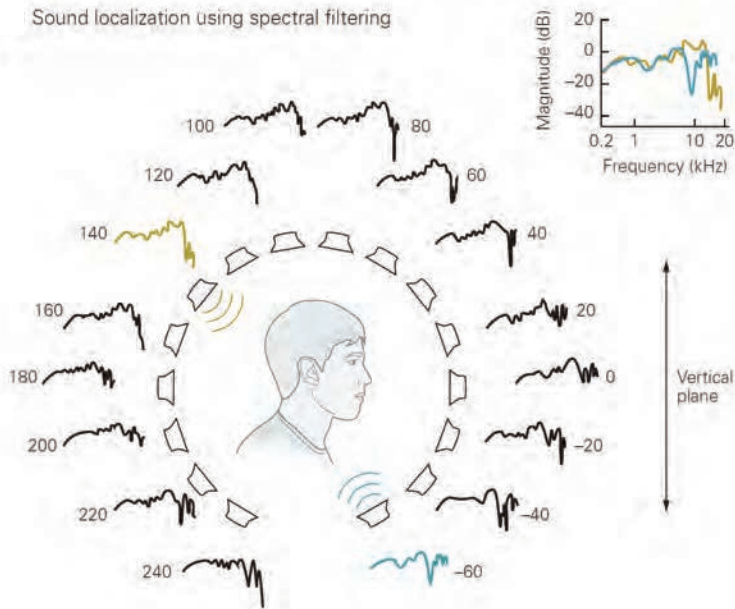

Fig. 7.3 3D sound localization using spectral filtering. When a noise that has equal energy at all frequencies over the human hearing range (white noise) is presented through a speaker, the ear, head, and shoulders cancel energy at some frequencies and enhance others. The amount of sound energy at each frequency at the ear canal is shown by the traces beside each speaker, which plot in decibels the power spectrum of sound that reaches the eardrum relative to the white noise that is produced by the speakers. For a white noise the power spectrum is flat. Note that by the time the noise has reached the bottom of the ear canal its spectrum is no longer flat. The small plot in the upper right compares spectral filtering of sounds coming from low in the front (blue) with sounds coming from behind and above the listener's head (brown). At high frequencies filtering by the ear introduces deep notches into spectra that vary depending on where the sounds arose. Sounds that lack energy at high frequencies and narrowband sounds are difficult to localize in the vertical plane. Spectral filtering also varies in the horizontal plane. (Data from D.Kistler and F.Wightman in Oertel, D. and Doupe, A.J. (2013) *The auditory central nervous system*. Chapter 31 pp. 682–711 in Kandel, E.R. et al, 2013, *Principles of Neuroscience*, 5th Edition. McGraw-Hill: New York. © McGraw-Hill.)

identify details of this 3D sound localization in primates including humans, although it did identify areas beyond the primary auditory cortex, in the auditory dorsal cortical stream, in the inferior parietal lobule, and in the dorsolateral prefrontal cortex, that are implicated in sound localization (van der Heijden et al., 2019).

7.3 Ventral and dorsal cortical auditory pathways

Rauschecker and colleagues, building on studies in primates, have described two hierarchical cortical streams of information transfer from auditory cortex (AC) which eventually reach prefrontal cortical regions (Rauschecker, 2012; Bornkessel-Schlesewsky et al., 2015). As illustrated in Fig. 7.1b, there are two streams of auditory processing, a ventral auditory stream (shown in green) that has been compared with the visual ventral stream of object-related processing, and a dorsal auditory stream (shown in red) that has been compared with the dorsal visual cortical stream.

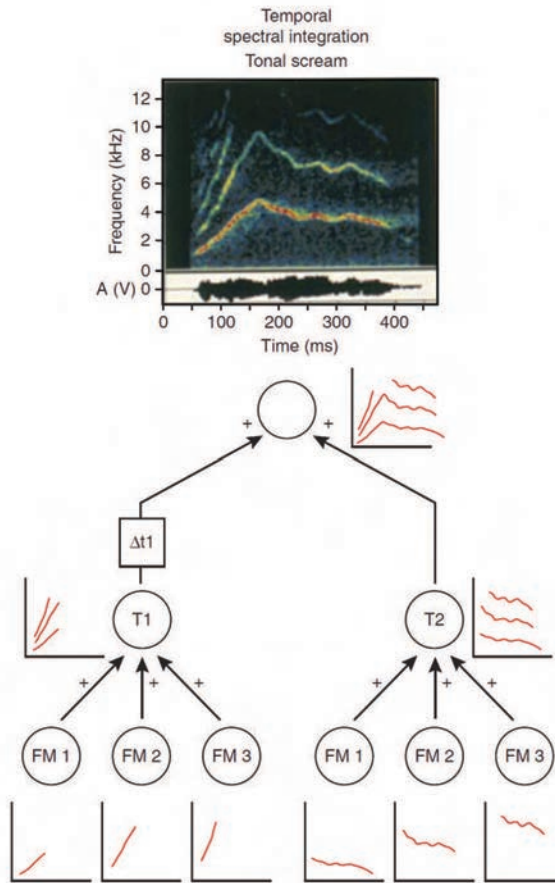

Fig. 7.4 Schematic of a feature hierarchy approach to building communication calls. Communication calls consist of elementary features, such as bandpass noise bursts or frequency-modulated (FM) sweeps. Harmonic calls, such as the vocal scream from the rhesus monkey repertoire depicted here by its spectrogram and time signal amplitude (A, measured as output voltage of a sound meter), consist of fundamental frequencies and higher harmonics. The neural circuitry for processing such calls is thought to consist of small hierarchical networks. At the lowest level, there are neurons serving as FM detectors tuned to the rate and direction of FM sweeps; these detectors extract each FM component (shown in cartoon spectrograms) in the upward and downward sweeps of the scream. The output of these FM detectors is combined nonlinearly at the next level: the target neurons T1 and T2 possess a high threshold and fire only if all inputs are activated. At the final level, a 'tonal-scream detector' is created by again combining output from neurons T1 and T2 nonlinearly. Temporal integration is accomplished by having the output of T1 pass through a delay line sufficient to hold up the input to the top neuron long enough that all inputs arrive at the same time. (Reproduced from J P Rauschecker and S K Scott (2009) Maps and streams in the auditory cortex: nonhuman primates illuminate human speech processing. *Nature Neuroscience* 12: 718–724. Copyright © Macmillan Publishers Ltd.)

7.4 The ventral cortical auditory stream

The first auditory cortical areas in primates are area 41, a core region, and area 42, a belt region (Pandya et al., 2015).

The ventral auditory stream involves projections to the anterior superior temporal cortex (aST, area 22), which in turn projects to the anterior and ventral parts of the inferior frontal gyrus (IFG, pars triangularis), area 45.

In non-human primates, the ventral stream subserves the recognition of successively more complex auditory objects, ranging from elementary auditory features (e.g., frequency-modulated (FM) sweeps or bandpass noise bursts) in the first auditory cortical areas, to species-specific vocalizations (monkey calls) in higher areas including the ventral prefrontal

Fig. 7.5 Orbitofrontal cortex neurons respond to socially relevant auditory stimuli. The responses of a mid-orbitofrontal cortex neuron to a set of different auditory stimuli. The mean firing rate (\pm SEM) in a 1 s period in which the sounds were made are shown. The neuron responded best to a deep vocalization which may have mimicked a 'grunt' call, second best to a hoot which is a communication call in macaques, and third best to the sound of a monkey lip-smacking, which is a form of social greeting. The 'No sound' condition shows the spontaneous firing rate of the neuron. (From Rolls, E. T., Critchley, H. D., Browning, A. S. and Inoue, K. (2006) Face-selective and auditory neurons in the primate orbitofrontal cortex. *Experimental Brain Research* 170: 74–87. © Springer-Verlag.)

cortex (Rauschecker and Scott, 2009; Romanski et al., 2005) and orbitofrontal cortex (Rolls, Critchley, Browning and Inoue, 2006a).

A feature hierarchy approach to how neurons with complex auditory properties could be formed is illustrated in Fig. 7.4 (Rauschecker and Scott, 2009).

Evidence for hierarchical processing of speech sounds relevant to language is that in humans, activations associated with the processing of short-timescale patterns (phonemes) are localized to the left mid-superior temporal gyrus, whereas activations associated with the integration of phonemes into temporally complex patterns (words) are localized to the left anterior superior temporal gyrus (DeWitt and Rauschecker, 2012) (see further Chapters 8 and 14).

In an area to which the superior temporal auditory cortex projects, the mid-orbitofrontal cortex areas 13 and 11, we discovered neurons that respond to primate vocalizations (Rolls, Critchley, Browning and Inoue, 2006a). An example is shown in Fig. 7.5, which shows a neuron that responded to the sound of lipsmacking (a social greeting) and a hoot (a contact call), as well as a deep vocalization like a grunt, all of which are important in macaque social communication (Cheney and Seyfarth, 2018). We relate the auditory neurons in this particular part of the auditory cortex hierarchy to decoding the emotional significance of vocalizations, for humans with damage to the orbitofrontal cortex and related areas were found to be impaired at identifying the emotional expression of different human vocalizations (Hornak, Rolls and Wade, 1996).

In the ventrolateral prefrontal cortex of macaques, some neurons respond to the sight of species-specific facial gestures, and to the auditory accompaniment, the vocalization (Roman-

ski et al., 2005). These auditory and visual inputs are being matched, for the neurons respond differently if the visual facial gestures and the auditory vocalization are incongruent (Diehl and Romanski, 2014). Neurons of this type may be important in identity processing and in the integration of multisensory communication information. This ventrolateral prefrontal cortex area includes area 12/47 (Plakke and Romanski, 2014), which is lateral orbitofrontal cortex (Rolls, 2019e).

For auditory short-term memory, the dorso-lateral prefrontal cortex becomes involved in the processing (Plakke and Romanski, 2014), as it does for working memory in other sensory modalities (Chapter 13).

7.5 The dorsal cortical auditory stream

The dorsal auditory stream in primates projects from the first auditory areas 41 and 42 to the posterior superior temporal (pST) cortex, and then to the inferior parietal lobule (IPL, area 40), which in turn projects to the more dorsal part of the inferior frontal gyrus (IFG pars opercularis, area 44), and also to premotor cortical area 6 (PMC) and to area 8 (Fig. 7.1b).

The dorsal auditory stream is implicated for example in the localization of sounds (Rauschecker and Scott, 2009; van der Heijden et al., 2019), and perhaps in processing the dynamic aspects of sounds (Rauschecker, 2012; Bornkessel-Schlesewsky et al., 2015).

So far, the known representations of auditory space are in head-based (egocentric) coordinates (which is natural, as the ears are anchored to the head), and there are mechanisms in the parietal lobe part of the dorsal visual system that match visual coordinates to this space (Oertel and Doupe, 2013), so that the eyes saccade to the source of a sound (see Chapter 3). However, I propose that there is an allocentric representation of auditory space analogous to the allocentric encoding of space ‘out there’ provided by spatial view cells (Rolls and Wirth, 2018) (see Chapter 9). For example, if the visual scene contains a waterfall in one part of the scene, and a noisy clock tower in another part of the scene, then both the visual and the auditory representations should remain locked in the same allocentric location in the scene when the head is rotated or the individual moves sideways to a different place. Congruency of object representations would thus be expected in visual and auditory space. It would be of interest to investigate this in the primate hippocampus and parahippocampal gyrus. When they are found, neurons coding in this way might be termed ‘allocentric sound location cells’.

7.6 Auditory cortical regions and connectivity in humans

It has become possible to understand much better the organisation of the human auditory cortical pathways by use of the Human Connectome Project - Multimodal Parcellation (HCP-MMP, Section 1.12), and measuring effective connectivity, complemented by functional connectivity and diffusion tractography (Section 1.13) with data from the Human Connectome Project, as described next (Rolls et al., 2023h). This has implications for understanding what is computed in different auditory cortical regions, and their connectivity to semantic and language systems involved at least in speech understanding.

Previous evidence for ventral and dorsal auditory streams in macaques, with some consistent evidence in humans, has been described (Rauschecker, 2018b; Rauschecker and Scott, 2009). A summary is that in humans a ventral auditory stream involves anterior auditory temporal cortical regions that connect via the anterior part of the temporal lobe to the inferior frontal gyrus including especially area 45 (Rauschecker, 2012) (Fig. 7.1). A dorsal auditory

stream was described as involving the posterior auditory cortical regions connecting via inferior parietal regions to premotor cortex 6, region 44, etc. (Rauschecker, 2012) (Fig. 7.1).

7.6.1 Early Auditory cortical regions

Schematic overviews of the effective connectivity of the human auditory cortical systems are shown in Figs. 7.6 and 7.7 (Rolls et al., 2023h). A simplified schematic organisation is that regions A1 and 52 > LBelt and MBelt > PBelt > A4. (Here > indicates ‘has effective connectivity to’, though some connectivity may cross levels of the hierarchy.) That part of the connectivity appears to be hierarchical.

In both humans and nonhuman primates, the auditory cortex is described as having core (corresponding to primary and primary-like auditory cortex), then belt (which surrounds the core), and then parabelt fields, all of which contain several subfields (Rauschecker, 2015; Van Essen and Glasser, 2018; Glasser et al., 2016a; van der Heijden et al., 2019; Rauschecker, 2018b,a; Erickson et al., 2017; Leaver and Rauschecker, 2016; DeWitt and Rauschecker, 2016; Bornkessel-Schlesewsky et al., 2015; DeWitt and Rauschecker, 2013; Ahveninen et al., 2013; Rauschecker, 2012; Rauschecker and Scott, 2009; Corcoles-Parada et al., 2019; Scott et al., 2017; Scott and Mishkin, 2016; Petkov et al., 2015; Munoz-Lopez et al., 2015; Karabanov et al., 2015; Scott et al., 2014; Kikuchi et al., 2014; Fukushima et al., 2014; Kravitz et al., 2013; Poremba et al., 2003; Romanski et al., 1999; Moerel et al., 2014; Morel et al., 1993; Rauschecker, 1998b,a; DeWitt and Rauschecker, 2012; Archakov et al., 2020; Rauschecker and Tian, 2000; DeWitt and Rauschecker, 2012; Rauschecker et al., 1995; Kaas and Hackett, 2000). Neurons in the core show responses with narrow tuning to tone frequency; belt neurons respond best to band-passed noise of a specific frequency and bandwidth; and parabelt neurons respond to increasingly complex sounds (Rauschecker, 2015; Leaver and Rauschecker, 2016; Tian et al., 2001).

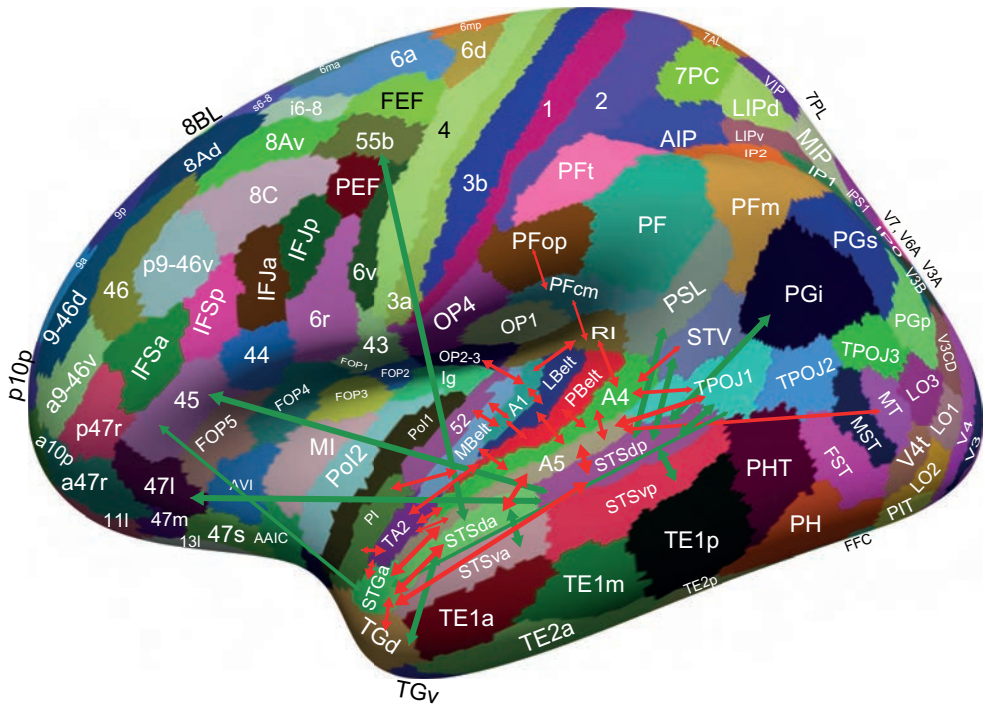

7.6.2 Ventral auditory cortical streams

After A4 there may be a split in the pathways in humans (Rolls et al., 2023h).

In one ventral stream, A4 has effective connectivity to anterior temporal lobe region TA2, and TA2 given its location is likely to be a ventral stream region (Fig. 7.6). TA2 has interesting connectivity to the parainsular region PI, which also receives visual and somatosensory inputs (Rolls et al., 2023f). TA2 has some effective connectivity to anterior temporal gyrus region STGa. However, STGa cannot be regarded as a region that mainly receives from TA2, for the connectivity to STGa from A5 is ten times stronger than that from TA2. TA2 also has effective connectivity to visual motion regions MT, MST, V6, V3A etc; and with region 1 (somatosensory cortex).

In a second ventral stream, A4 has effective connectivity to A5. A5 is higher in the hierarchy than A4, in that A4 receives from A1 and 52; and A5 receives from PBelt, LBelt, and A4 (Rolls et al., 2023h). A5 then connects to dorsal bank superior temporal sulcus (STS) regions STGa, STSda, and STSdp, which then have onward effective connectivity to TPOJ1, STV, PSL, TGv, TGD and PGI (Fig. 7.6), which are language-related regions (Rolls et al., 2022b).

The dorsal bank superior temporal sulcus regions (STSda and STSdp) also receive visual inputs about, for example, the movements made by the face and mouth during speaking, in that some neurons in these cortical regions of macaques respond perfectly to the small lip and mouth movements made by humans when they speak (Hasselmo, Rolls, Baylis and Nalwa, 1989b; Hasselmo, Rolls and Baylis, 1989a). We also discovered neurons in the same cortical regions that respond to auditory stimuli including vocalisation (Baylis, Rolls and Leonard, 1987), and indeed some neurons in this cortical region respond to both visual and auditory

Auditory system: lateral view

Fig. 7.6 Effective connectivity of human auditory cortical regions shown schematically. The widths of the lines and the size of the arrowheads indicate the magnitude and direction of the effective connectivity. Red arrows show the main auditory division connectivity, and green arrows further connectivity. A simplified schematic organisation is that region A1 > LBelt, MBelt and 52 > PBelt > A4 > A5 > STGa, STSda, STSdp > TPOJ1, STV, PGI. (Here > indicates has effective connectivity to, though some connectivity may cross levels of the hierarchy.) Somatosensory cortical regions have connectivity with A1, RI, TA2 etc. MT has connectivity to A5. TPOJ1, STV, PSL, STSdp and STSda are involved in language as analyzed elsewhere (Rolls et al., 2022b). Connections between early cortical auditory regions and area 44 in what may be a dorsal language related auditory stream are found. LBelt, PBelt, A4 and A5 have effective connectivity with MT/MST regions as indicated, and this may be part of a dorsal ‘where’ stream leading to intraparietal and area 7 regions. The abbreviations are listed in Section 1.12. (From Rolls, E. T., Rauschecker, J., Deco, G., Huang, C.-C. and Feng, J. (2023) Auditory cortical connectivity in humans. *Cerebral Cortex* 33: 6207-6227. doi: 10.1093/cercor/bhac496. Copyright © Oxford University Press.)

stimuli (Khandhadia et al., 2021; Belin, 2019). This makes these dorsal bank STS regions important for the decoding of articulator speech movements.

These dorsal bank STS regions are therefore important in linking motion-related changes in the sight of the face to the dynamically changing auditory input, and this is likely to be useful for identifying who in a group is making the vocalisation, in maximising the ability to decode information in noisy environments in order to understand speech, in maximizing the information in social signals by combining the auditory and visual components, etc. In the sense that this processing provides evidence about what the message is, this could be considered as a type of ventral stream ‘what’ semantic processing. This is developed further in Section 8.4 and in Chapter 14.

7.6.3 Dorsal auditory cortical streams

One stream here is the proposed dorsal ‘how’ stream for auditory processing related to language (Rauschecker, 2018b; Rauschecker and Scott, 2009) (Fig. 7.1). This auditory dorsal pathway is proposed to be involved in sensorimotor integration and control (Rauschecker, 2011), and in humans plays a role in speech production as well as categorization of phonemes

Fig. 7.7 Effective connectivity of human auditory cortical regions shown schematically. The widths of the lines and the size of the arrowheads indicate the magnitude and direction of the effective connectivity. Red arrows show the main auditory division connectivity, and green arrows further connectivity. A simplified schematic organisation is that region A1 > Lbelt, MBelt and 52 > PBelt > A4 > A5 > STGa, STSda, STSdp > TPOJ1, STV, PGI. (Here > indicates has effective connectivity to, though some connectivity may cross levels of the hierarchy.) Somatosensory cortical regions have connectivity with A1, RI, TA2 etc. MT has connectivity to A5. TPOJ1, STV, PSL, STSdp and STSda are involved in language as analyzed elsewhere (Rolls et al., 2022b). Connections between early cortical auditory regions and area 44 in what may be a dorsal language related auditory stream are found. Lbelt, Pbelt, A4 and A5 have effective connectivity with MT/MST regions as indicated, and this may be part of a dorsal 'where' stream leading to intraparietal and area 7 regions. The abbreviations are listed in Section 1.12. (From Rolls, E. T., Rauschecker, J., Deco, G., Huang, C.-C. and Feng, J. (2023) Auditory cortical connectivity in humans. *Cerebral Cortex* 33: 6207-6227. doi: 10.1093/cercor/bhac496. Copyright © Oxford University Press.)

during speech processing (Rauschecker, 2012). The pathway is from more posterior auditory cortex regions via the arcuate fasciculus to especially Broca's area 44, with inferior parietal and premotor cortices postulated as part of this dorsal stream network (Rauschecker, 2015). It has been suggested that this dorsal stream evolved as a substrate for sensorimotor processing, connecting sensory and motor cortical systems with each other and the basal ganglia (Rauschecker, 2018b; Archakov et al., 2020), thus permitting the learning of sequences and a foundation for both language and music (Rauschecker, 2018a).

Our diffusion tractography does show connections of P Belt, RI, A4 and A5 with Broca's area 44, and this may be how the dorsal 'how' language-related stream is reflected in our analysis (Rolls et al., 2023h). Corresponding effective or functional connectivity was not identified in our analysis (Rolls et al., 2023h), perhaps because it is functionally relatively

weak, or perhaps because the data were acquired in the resting state not during language production.

Considering the connectivity of Broca's area provides some additional relevant evidence to what are ventral vs dorsal language-related auditory streams. The anterior part of Broca's area, 45, in the inferior frontal gyrus pars triangularis, has more effective connectivity than the posterior part of Broca's area, 44, in the inferior frontal gyrus pars opercularis, with STGa, STSda and STSdp and related regions such as TGv (Rolls et al., 2023h, 2022b) which are anterior temporal lobe semantic regions (Rolls et al., 2022b). The diffusion tractography shows more connections of 44 than 45 with PBelt, A4, A5 and STSvp, and with premotor area 6 regions (Rolls et al., 2023h, 2022b). In addition to the hypotheses and this evidence that region 45 which is anterior in the frontal lobes is connected with anterior temporal lobe semantic systems (e.g. in the dorsal bank of the STS), and that region 44 more posteriorly in the frontal lobes is more connected with more posterior temporal lobe auditory regions involved in 'how' processing, it is further proposed that there is information flow from 45 to 44 as part of a route from semantic to language output in terms of speech production and articulation (Rolls et al., 2023h; Rauschecker, 2018b; Rauschecker and Scott, 2009; Rolls et al., 2022b).

A second dorsal auditory stream was found as follows (Rolls et al., 2023h). A4 and A5, and some earlier cortical regions, have effective connectivity to visual motion regions including MT and MST (Rolls et al., 2023h) which in turn have effective connectivity to intraparietal and thereby parietal area 7 regions (Fig. 7.7) (Rolls et al., 2023e). This analysis is supported by the functional connectivity, which is evident between A4, the PBelt etc and parietal 7AL, 7Am and 7PC; and is also supported by the diffusion tractography showing connections between similar regions (Rolls et al., 2023h). These auditory inputs to dorsal-stream parietal areas could be used to shift visual attention and eye position to a source of sound, to help track moving noisy objects such as flying birds and predators (e.g. alarm calls for eagles versus snakes (Seyfarth and Cheney, 2010)), or keeping track of the location of a predator when running away, and performing actions in the dark for objects that can be detected by their sound. This system may be involved not only in detecting the spatial location of sounds, but also to facilitate spatial attention including by moving the eyes and by top-down attentional space-based modulation in what is described for audition as the 'cocktail party' effect.

One point to note is that A4 and A5 are long regions that are likely in future to be subdivided into anterior and posterior parts. Similarly, at earlier stages of auditory processing, single-unit studies in macaques (Rauschecker et al., 1995) have shown that LBelt and PBelt can already be subdivided into subregions with mirror-symmetric target regions.

7.6.4 Other auditory system cortical connectivities

Another feature of the auditory cortical connectivity described here is the connectivity with somatosensory cortical areas, with, for example, connectivity from somatosensory cortical areas 1 and OP2-3 to auditory cortical regions A4 and A5 (Fig. 7.7); and the earlier auditory cortex regions have connectivity with the supracallosal anterior cingulate regions a24pr, a32pr, p24pr and p32pr (Rolls et al., 2023h) (Fig. 7.7) which have somatosensory/motor connectivity (Rolls et al., 2023i). This might relate to directing auditory attention to any touch to the body; to behaviors that might be performed before a highly developed visual system evolved; and to navigation / obstacle avoidance in the dark. Another type of somatosensory feedback may be needed in speech production, especially during early learning of articulation, where it may be crucial for the distinction between different types of consonants (Ohashi and Ostry, 2021).

In addition, there is evidence (Rolls et al., 2023h) for effective connectivity of some auditory cortical regions to the hippocampus, and to the scene-related ventromedial visual region VMV1 (Sulpizio et al., 2020), and the parahippocampal TF, with both types of connectivity involved in episodic memory (Rolls et al., 2023e, 2022a; Rolls, 2023c, 2022b). In addition, auditory cortical region A5 has connectivity with inferior frontal gyrus regions IFJa and IFSp, which are implicated in short-term working memory for the ventral streams (Plakke and Romanski, 2014; Passingham, 2021; Rolls et al., 2023f; Miller et al., 2018) (Chapter 13).

The auditory cortex connectivity with inferior parietal regions is primarily between the STS visual-auditory regions and PGi, with some connectivity also with PGs and PFm (Rolls et al., 2023h) (Fig. 7.7), all of which are visual inferior parietal regions linked considerably to ventral stream processing (Rolls et al., 2022b, 2023d). Inputs related to reward and punishment from, for example, the ventromedial prefrontal cortex (vmPFC) (10r, 10v, 10d) and orbitofrontal cortex (a47r) (Rolls et al., 2023c) reach STS auditory-visual cortical regions where objects, faces, and their semantic meaning are represented (Rolls et al., 2022b), rather than earlier stages of auditory cortical processing (Rolls et al., 2023h). Correspondingly, STS regions have effective connectivity with some orbitofrontal / vmPFC regions in which neurons respond to vocalisation and the face movements that produce them (Rolls, Critchley, Browning and Inoue, 2006a).

7.7 How the computations are performed in the auditory system

The computation of interaural time differences has been described, and the mechanisms for inter-aural intensity differences need not be complicated.

The computation of 3D sound location requires a relatively broad-band signal so that the spectrum can be evaluated. The most important effects are produced by the antenna effects of the pinna, for if the recordings are made from only two artificial pinnae, sound localization in 3D is reasonable. The helical shape of the pinnae is important, as that is asymmetric for sounds at different elevations. Because each individual's pinnae are slightly different shapes, learning in relation to one's own pinnae is needed for accurate sound localization. This is likely to be aided by craniotopic visual representations.

There is evidence for hierarchical processing across cortical areas in primates, and this is likely to proceed by building feature combination neurons from the features represented at the preceding stage. Competitive learning is the mechanism that I propose. This process is likely to be able to lead to neurons tuned to complex sounds including vocalizations that are found in the orbitofrontal and dorsolateral prefrontal cortex. It is likely that the anterior parts of the superior temporal gyrus are involved in this, as described in Chapter 8.

As in vision, there appears to be segregation of two types of computation, one more involved in spatial location and taking place in the dorsal auditory stream, and another computation more involved in analysis of what the sound is, its identity, in the ventral auditory system.

The value of auditory stimuli is represented in the orbitofrontal cortex, as shown by the findings that neurons there represent vocalizations with emotion-related significance, such as lip-smacking; but also by the finding that damage to the human orbitofrontal cortex impairs the ability to identify the emotional expression in the voice, but does not impair identification of sounds in general. Whether the mechanism for value representations for auditory stimuli is by pattern association learning with other reinforcers is not yet known.

8 The temporal cortex

8.1 Introduction and overview

The inferior temporal visual cortex is involved in invariant visual object recognition, as described in Chapter 2 (Rolls, 2021d).

The superior temporal cortex in its mid-part contains the auditory cortex, and the auditory belt cortex, as described in Chapter 7.

Behind the auditory cortex is Wernicke's area in the posterior part of the superior temporal gyrus, part of area 22, which is involved in phonological processing, and its functions are considered in Chapter 14.

The medial temporal lobe includes the parahippocampal gyrus and hippocampus involved in episodic memory, and this system is considered in Chapter 9.

The amygdala, a subcortical part of the anterior temporal lobe involved in emotion, is considered in Chapter 11.

In this Chapter, the focus is on *what* is computed in other parts of the temporal lobe, including the anterior parts of the temporal lobe (Fig. 8.1), which especially in humans are involved in semantic representations. Section 8.5 is about *how* these semantic representations may be set up.

In addition, in humans there is also a middle temporal gyrus, and its functions in face expression and gesture identification, and in theory of mind, are considered first.

8.2 Middle temporal gyrus and face expression and gesture

The cortex in the macaque superior temporal sulcus contains neurons that often combine object selectivity with a preference for moving visual stimuli, as described in Chapter 2. Some of these neurons in the middle to anterior part of the cortex in the superior temporal sulcus respond to moving heads and to face gesture, and some are tuned to face expression (Hasselmo, Rolls, Baylis and Nalwa, 1989b; Hasselmo, Rolls and Baylis, 1989a). With the great expansion of the human temporal lobe, this region may be in the middle temporal gyrus (see Fig. 8.1), which is not present in macaques, for with fMRI, activations are found here to face expression (Critchley et al., 2000).

In this context, it is of interest that a nearby part of the middle temporal gyrus has reduced functional connectivity with the ventromedial prefrontal cortex, precuneus, and posterior cingulate cortex in autism (Cheng, Rolls, Gu, Zhang and Feng, 2015). The reduced functional connectivity of this middle temporal gyrus area in autism spectrum conditions is of great interest, for some of the key typical symptoms of autism spectrum disorder are face processing and especially face expression processing deficits (Lai, Lombardo and Baron-Cohen, 2014), which will impair social and emotional communication (Rolls, 2014a). Further, in a meta-analysis of fMRI studies on the cortex in the superior temporal sulcus / along the middle temporal gyrus, a cluster of activations was identified that reflected motion processing, audio-visual correspondence (e.g. the sound and sight of an utterance), and face processing (Hein

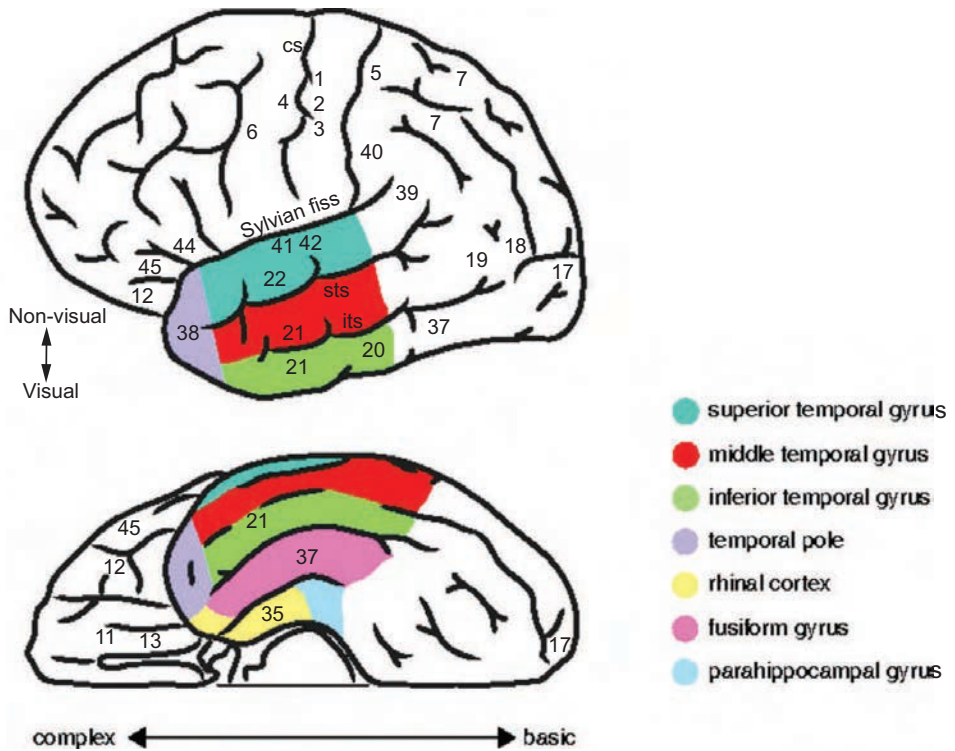

Fig. 8.1 Structures of the anterior temporal lobe of the human brain (in color). Above: lateral view; Below: ventral view. The axes indicate theoretical gradients of differential semantic processes. Along one axis, ventral structures contribute more to the processing of visual information (e.g. object concepts), and dorsolateral structures contribute more to the processing of non-visual information (e.g. abstract concepts, auditory concepts). Along the second axis, posterior structures contribute more to basic object representations, and anterior structures contribute more to the representation of complex conceptual, semantic, associations. Brodmann areas: 1,2,3 somatosensory cortex; 4 motor cortex; 5 superior parietal cortex; 6 premotor cortex; 7 inferior parietal cortex; 11, 13 medial orbitofrontal cortex; 17 primary visual (striate) cortex; 18, 19 prestriate visual cortical areas; 20 posterior inferior temporal cortex; 21 (anterior) inferior temporal cortex; 35 perirhinal cortex; 37 fusiform gyrus; 39 angular gyrus; 40 supramarginal gyrus; 41, 42 auditory cortex; 44 inferior frontal gyrus pars opercularis; 45 inferior frontal gyrus pars triangularis. cs central sulcus; its inferior temporal sulcus; sts superior temporal sulcus; Sylvian fiss Sylvian fissure / lateral sulcus. (Modified from Bonner, M.F. and Price, A.R. (2013) Where is the anterior temporal lobe and what does it do? *J. Neurosci* 33: 4213–4215.)

and Knight, 2008). The middle temporal gyrus region we identified with reduced functional connectivity in autism also has a more antero-dorsal band. Near this region, activations in the cortex in the superior temporal sulcus are related to speech processing (Hein and Knight, 2008). In addition, activations related to theory of mind were equally distributed over the anterior and posterior clusters (Hein and Knight, 2008). Thus the region that we identified with reduced functional cortical connectivity in autism spectrum disorder in the middle temporal gyrus / cortex in the superior temporal sulcus (Cheng, Rolls, Gu, Zhang and Feng, 2015) has functions related also to theory of mind and even speech processing. This is fascinating, given that there are major impairments of theory of mind and communication in autism spectrum disorder (Lai et al., 2014).

This processing stream in the superior temporal sulcus that performs processing important in social behavior is described further in Sections 2.4.9 and 2.5.3.

8.3 Semantic representations in the temporal lobe neocortex

Humans learn facts about items in the world, and group these items into useful categories and structures as semantic representations. This semantic knowledge is essential for many types of behavior and inferences. An example of a semantic representation might be a map of how cities are situated relative to each other, which could be built using many episodic memories of journeys to different cities. Each node in such a semantic representation might have a set of attributes associated with it, for example one city that was large, with skyscrapers, and beside the sea; whereas another city might have no skyscrapers, be far from the sea, and have a great University. Thus semantic representations, our knowledge about the world, involves a list of attributes or descriptors of each node, where a node might represent an individual person, a particular territory, or a certain type of object, such as a particular yacht or motor car. In the case of a territory, which is a semantic concept, the semantic attributes might include accumulated information, perhaps from many separate episodes, about where it is and its extent, who lives there, who the territory belongs to, whether it is well defended, whether the territory is fertile, prosperous, pleasant to live in, etc. The information used for semantic representations can be accumulated across all times.

Semantic memory is quite distinct from episodic memory, in which we might associate a particular person being in a particular place at a particular time, and that is what the hippocampus is involved in, as described in Chapter 9. Medial temporal lobe damage involving the hippocampus impairs episodic memory, but not previously learned semantic information. The learning of new semantic information is impaired by hippocampal damage, for the recall of episodic information is useful in building new semantic memories in the process of memory consolidation, as described in Chapter 9 (Rolls, 2022b). Semantic memories might be built using information recalled from many different episodic memories about many events each at particular times, as described in Section 9.2.3. Given that the formation of semantic memories is facilitated by the recall of episodic memory from the hippocampus (Section 9.2.8.5), it is proposed that an important contribution of the hippocampus to semantic memories (Section 9.2.8.5) is that pattern separation performed by the hippocampal system including the dentate granule cells (Rolls, 2016f), helps to reduce the correlations between the different semantic memories formed by hippocampus to neocortical recall. Correlations between the components of different semantic memories must be minimized, in order not to degrade the capacity of semantic memories (Ryom, Stendardi, Ciaramelli and Treves, 2023).

8.3.1 Neurophysiology of the medial temporal lobe, including concept cells

In one approach to semantic representations with macaque neurophysiology, two visual stimuli are repeatedly presented together with a short delay of a few seconds between them to set up paired associate learning, with the aim of studying semantic memory, which does involve the organisation of information in which simple associations may play a part. Neurons in the macaque perirhinal cortex were found to respond in relation to this type of visual paired associate learning (Miyashita and Chang, 1988; Fujimichi, Naya, Koyano, Takeda, Takeuchi and Miyashita, 2010; Miyashita, 2019). As described in Chapter 9, the perirhinal cortex is an area that receives multimodal information, and provides a gateway into the hippocampal episodic memory system, in which arbitrary multimodal associations that occur together need to be learned. However, the perirhinal cortex may be more a cortical area that is used in relation to hippocampal episodic memory function, and to recognition and long-term familiarity mem-

ory (Section 9.2.7), rather than the semantic system found more laterally and anteriorly in the human anterior temporal lobe.

Neurons that do respond to multimodal associations have been described in the human medial temporal lobe including the parahippocampal gyrus, and some have been described as ‘concept cells’ (Quian Quiroga, 2012; Quian Quiroga, Reddy, Kreiman, Koch and Fried, 2005; Quian Quiroga, 2023). For example, a neuron that responded to the sight of Jennifer Aniston or the sound of her voice also responded to other actors in the same movie, and the places with which they are associated (Quian Quiroga, 2012; Rey, Ison, Pedreira, Valentin, Alarcon, Selway, Richardson and Quian Quiroga, 2015; Quian Quiroga, Reddy, Kreiman, Koch and Fried, 2005; De Falco, Ison, Fried and Quian Quiroga, 2016). Object-place cells in macaques have some similar multi-attribute properties, in that they can be activated either by the object, or by the location in a viewed spatial scene, in object-location memory tasks (Rolls and Xiang, 2005, 2006; Rolls, 2023d). These neurons in macaques might accordingly also be described as ‘concept cells’ (Rolls, 2023c,d). Similar properties have been described for human hippocampal neurons, in a task in which a human was associated with the view of a place (Ison, Quian Quiroga and Fried, 2015). Some of these neurons can be described as representing the semantic properties of stimuli and appear to be quite widely distributed in the temporal lobe cortex (Rutishauser, 2019; Fried, Rutishauser, Cerf and Kreiman, 2014). In one study, the similarity of the neuronal responses to different concepts were closely related to the similarity of those concepts for individual participants (De Falco, Ison, Fried and Quian Quiroga, 2016). These findings are consistent with the evidence described in this section (8.3) that semantic representations are found in the temporal lobe cortex. Most of these recordings were made in the medial temporal lobe, and given the other evidence described below, these semantic representations may be especially in the temporal lobe neocortex. It is notable that many of the responses in these regions in humans were relatively small compared to those recorded in the macaque medial temporal lobe, though that could be related to the fact that the majority of these human recordings were made in patients with epilepsy.

Further evidence on what might be described as concept cells in macaques is as follows (Rolls, 2023d). When we discovered neurons in the macaque cortex in the anterior part of the superior temporal sulcus that responded to moving objects such as the sight of a head making or breaking social contact (Rolls, Baylis and Hasselmo, 1987; Hasselmo, Rolls and Baylis, 1989a; Hasselmo, Rolls, Baylis and Nalwa, 1989b), we also discovered nearby neurons that responded to auditory stimuli including vocalization (Rolls, Baylis and Hasselmo, 1987). The concept was that these two representations might be brought together in these cortical regions to form representations that could be activated by the sight of for example the lips moving to vocalize, and by the sound of the vocalization being made (Rolls et al., 1987). That has in fact now been shown to be the case, in that 76% of neurons in face patch AF in the cortex in the superior temporal sulcus were significantly influenced by the auditory component of a movie with faces that elicited neuronal responses, most often through enhancement of visual responses but sometimes in response to the auditory stimulus alone (Khandhadia, Murphy, Romanski, Bizley and Leopold, 2021). This type of neuron in macaques is thus multimodal, and can be activated by corresponding stimuli in the visual and auditory sensory modalities. That would appear to satisfy at least part of what a concept cell is (Rolls, 2023d). The concepts represented by these neurons in the third visual system are often about the social significance of stimuli (Pitcher and Ungerleider, 2021; Pitcher, Ianni and Ungerleider, 2019; Rolls, Deco, Huang and Feng, 2023e; Rolls, 2023a,d).

8.3.2 Neuropsychology

Semantic representations are about general conceptual knowledge about objects and events, including knowledge about their characteristic properties and behaviors, as well as knowledge about the words we use to name and describe objects and events in speech. In contrast, episodic memory encompasses memory for specific episodes or situations in one's life. Semantic representations are of factual knowledge divorced from any specific situational context, for example 'A scallop is an edible sea creature' (semantic) as opposed to 'I ate scallops for dinner yesterday evening' (episodic) (Patterson et al., 2007).

Patients with semantic dementia, a neurodegenerative disease affecting the anterior temporal lobe, and patients with a stroke in this region, have a deficit in semantic knowledge with a relative sparing of most other cognitive domains (Patterson et al., 2007). These patients have little trouble performing episodic recall tasks, visual perceptual tasks, or numerical tasks, and can even retain complex behaviors like performing novel musical pieces – yet they have a striking impairment on nearly all assessments of semantic knowledge. Damage to the left anterior temporal lobe is associated with a decline in object naming ability, providing evidence that it is specialized for the retrieval of unique entity concepts (Swanson et al., 2020).

Neurodegenerative damage to the temporal pole is associated with associative agnosia, semantic forms of primary progressive aphasia and semantic dementia (Mesulam, 2023). Object naming and word comprehension are critically dependent on the language-dominant (usually left) temporopolar region, whereas behavioral control and non-verbal object recognition display a more bilateral representation with a rightward bias (Mesulam, 2023). A first sign of left temporopolar dysfunction takes the form of taxonomic blurring where boundaries between categories are preserved but not boundaries between exemplars of a category (Mesulam, 2023), consistent with what is found in associative neural networks (Virasoro, 1989) which elucidate a mechanism by which these clinical symptoms arise.

8.3.3 Functional neuroimaging

There is evidence that parts of the temporal lobe represent amodal conceptual object knowledge in that they have supramodal representations and play a role in distinguishing between the conceptual representations of different objects (Fairhall and Caramazza, 2013a). In an fMRI study, human participants made category typicality judgments about pictured objects or their names. Activations to supramodal object categories (both the pictures of objects and their names) that reflected the similarity between the categories of objects were found in the posterior middle/inferior temporal gyrus and posterior cingulate/precuneus. Thus the middle/inferior temporal gyri are candidate regions for the amodal representation of the conceptual properties of objects (Fairhall and Caramazza, 2013a).

To investigate further the representations for different types of semantic knowledge, it was shown that access to knowledge of kinds of people (e.g. lawyer, nurse) produced selective activations in the left anterior temporal lobe, posterior middle temporal gyrus and the temporoparietal junction, precuneus, and medial prefrontal cortex (Fairhall and Caramazza, 2013b). For comparison, place-selective activations (e.g. bank, prison) were found in the parahippocampal gyrus and a connected region the retrosplenial cortex. Thus non-perceptual semantic representations about different types of object category appear to involve different parts of the temporal lobe (Fairhall and Caramazza, 2013b).

In an investigation of semantic knowledge about actions, it was found that the left lateral posterior temporal cortex encodes action representations that generalize across observed action scenes and written descriptions (Wurm and Caramazza, 2019). These temporal cortex regions thus are involved in general, conceptual, aspects of actions.

Verbs and nouns are fundamental units of language, and neuropsychological evidence

has shown that nouns and verbs can be damaged independently of each other (Hernandez et al., 2014). Also, neuroimaging studies have found regions that are particularly sensitive to a word's grammatical category (Tyler et al., 2008). The grammatical distinction between nouns and verbs is of fundamental importance, because a word's grammatical category determines the types of phrases in which it appears and the morphological transformations it undergoes. For example, 'The boy likes the candies' is correct, but not 'The likes boy the candies'. In another example, 'The boy liked the candies' is correct, but not 'The boyed like the candies'. The semantic-lexical properties of verbs and nouns that underlie their independence may be predication: a core lexical feature involved in binding constituent arguments (boy, candies) into a unified syntactic-semantic structure expressing a proposition (the boy likes the candies). To test whether the intrinsic 'predication-building' function of verbs is what drives the verb-noun distinction in the brain, verb-preferring regions with a localizer experiment including verbs and nouns were first identified. Then, the sensitivity of these regions to transitivity – an index measuring the tendency to select for a direct object – was measured (Hernandez et al., 2014). Transitivity is a verb-specific property lying at the core of its predication function. Neural activity in the left posterior middle temporal and inferior frontal gyri correlated with transitivity, indicating sensitivity to predication. This is evidence that grammatical class preference in the brain is driven by a word's function to build predication structures (Hernandez et al., 2014), and that the temporal lobe plays a key role in this.

Further evidence that temporal lobe semantic systems are involved in language is that left temporal cortex areas and the connected inferior frontal gyrus regions that include Broca's area in the inferior frontal gyrus are specifically involved when listening to syntactically ambiguous sentences such as 'The newspaper reported that bullying teenagers are a problem for the local school' (in which 'bullying teenagers' is syntactically ambiguous) (Campbell and Tyler, 2018). If an additional task was required, then other brain systems related to the task performance were engaged. Thus this temporal lobe - inferior frontal gyrus system may be specifically involved in syntactical processing of semantic information.

8.3.4 Brain stimulation

One type of study in humans possible in the course of surgery for clinical conditions has been electrical stimulation, to provide evidence on the types of function implemented in different parts of the temporal lobe. DeWitt and Rauschecker (2016) review findings from intraoperative stimulation mapping in 90 patients at 2754 cortical sites, extensively sampling the superior temporal gyrus (STG), supramarginal gyrus (SMG), middle temporal gyrus (MTG), and angular gyrus (AG) (Roux et al., 2015). Three findings emerge from the study. First, although the MTG was extensively surveyed, it was found to be uninvolved in auditory single-word comprehension, as indexed by performance on auditory word-to-picture matching (see Fig. 8.2A).

Second, although stimulation of several supramarginal / angular gyrus sites impaired comprehension, the dominant finding was for comprehension to be impaired by superior temporal gyrus stimulation (see Fig. 8.2A, inset).

Third, analysis of error types shows an anterior-oriented processing hierarchy within the superior temporal gyrus. Performance on auditory word-to-picture matching involves (i) auditory word-form recognition, (ii) retrieval of the word-form's semantic referents, and (iii) association of one of the referents to a visual depiction thereof. Roux et al. (2015) classified errors as either 'speech discrimination/word deafness errors', indicating a putative failure to resolve an auditory word-form from sensory input, or 'lexical-semantic errors', indicating putative failure to associate an accurately perceived word-form with a visual depiction of its semantic referent. Word-form analysis (transient word deafness) was associated with the

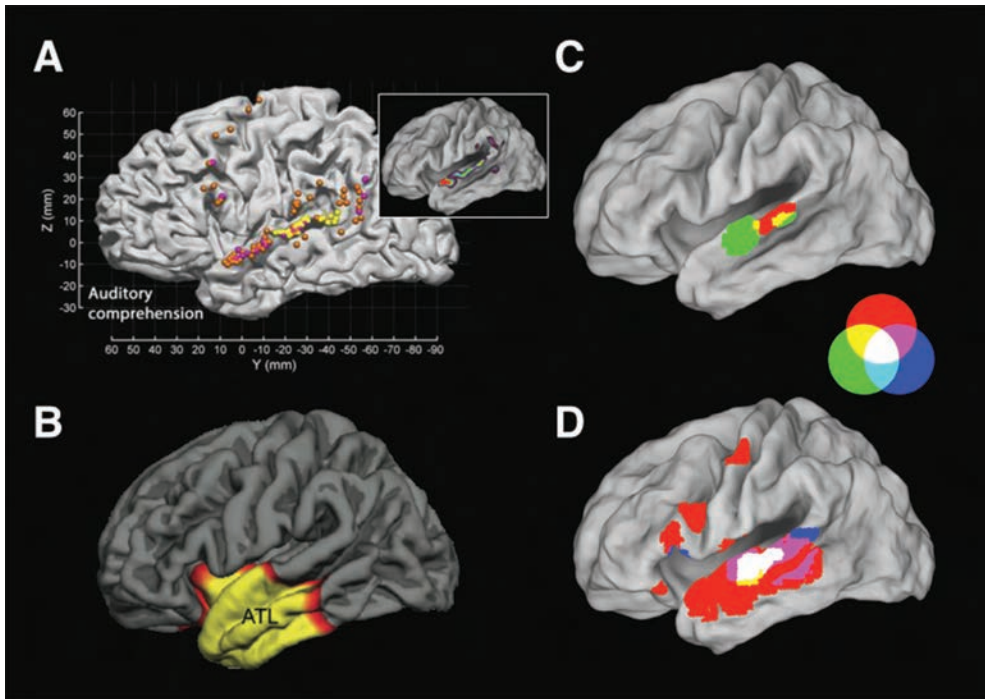

Fig. 8.2 Semantic retrieval in auditory single-word comprehension is associated with the integrity of anterior superior temporal gyrus (STG) function, as found in stimulation mapping (A, orange markers) and lesion-symptom mapping (B). Auditory word-form recognition is associated with mid-to-anterior STG, as found in stimulation mapping (A, yellow markers) and meta-analysis of functional imaging (C, D). The meta-analytic results depicted are RGB overlap maps for effects of repetition suppression for phonemes (C, red shading) and auditory words (C, green shading), as well as for tests of speech-related combination sensitivity (D, red shading), invariant representation (D, green shading) and areal specialization (D, blue shading). Notably, when a probability density function is estimated for the reported stimulation mapping foci (A), peak density is found along STG, excluding the most posterior aspect of STG, with the global peak in anterior STG (A, inset). Together, these results imply a processing hierarchy for phonemes, word-forms and semantic retrieval that extends along STG in an anterior-oriented gradient. (Reprinted from DeWitt, I. and Rauschecker, J.P. (2016) Convergent evidence for the causal involvement of anterior superior temporal gyrus in auditory single-word comprehension. *Cortex* 77: 164–166. © Elsevier Inc.)

mid-to-anterior superior temporal gyrus (Fig. 8.2A, yellow markers) while semantic retrieval (matching error) was associated with the anterior superior temporal gyrus (Fig. 8.2A, orange markers), indicating that anterior parts of the superior temporal gyrus are especially involved in semantic representations.

The parts of the anterior temporal implicated by all of this evidence in semantic processing are strongly connected with the inferior frontal gyrus ('Broca's area') by the uncinate fasciculus. This connection may enable syntactic operations performed in networks in the inferior frontal gyrus to utilize semantic representations in the anterior temporal lobe (see Section 14.5).

8.4 Connectivity and functions of the human temporal lobe regions related to semantics

In this section evidence is described on semantic systems in and connected to the temporal lobe (Rolls et al., 2022b). The evidence is based on use of the Human Connectome Project - Multimodal cortical Parcellation (HCP-MMP, Section 1.12), and measuring effective con-

nectivity, complemented by functional connectivity and diffusion tractography (Section 1.13) with data from the Human Connectome Project.

Brain areas involved in language and the connectivity between them is a topic of importance for understanding human brain function and in order to minimize language impairments during neurosurgery (Milton et al., 2021; Ding et al., 2016; Hickok and Poeppel, 2015, 2007; Bornkessel-Schlesewsky et al., 2015; DeWitt and Rauschecker, 2013; Rauschecker, 2012; Chang et al., 2015; Bouchard et al., 2013). Earlier views of Wernicke's area and its connections with Broca's area (Geschwind, 1970) have now been re-evaluated (Coslett and Schwartz, 2018) to produce new views on Wernicke's area (DeWitt and Rauschecker, 2013; Binder, 2017), Broca's area (Amunts and Zilles, 2012; Kelly et al., 2010; Gajardo-Vidal et al., 2021), their evolutionary origins (Rauschecker, 2018a), and neuropsychological and neuroimaging investigations of language systems (Kemmerer, 2015; Hagoort, 2017; Hagoort and Indefrey, 2014; Battistella et al., 2020; Friederici et al., 2017). In more recent research utilising the Human Connectome Project Multimodal Parcellation (HCP-MMP) atlas (Glasser et al., 2016a), 157 task-based fMRI studies were analyzed to identify brain regions in the HCP-MMP atlas related to semantics based on categorization of visual words and objects, and auditory words and stories, and the following regions were identified as part of the semantic network: 44, 45, 55b, IFJa, 8C, p32pr, SFL, SCEF, 8BM, STSdp, STSvp, TE1p, PHT and PBelt, and were shown to be interconnected with tractography (Milton et al., 2021).

In the research described next (Rolls et al., 2022b), community analysis was performed on the 360x360 effective connectivity matrix for the HCP-MMP cortical regions, and a community of 26 cortical regions was identified that included most of those or very similar regions to those noted above (Milton et al., 2021) related to language. Analyses were then performed on the connections, functional connectivity, and effective connectivity of these 26 left hemisphere cortical regions with the 360 cortical regions in the HCP-MMP atlas (Glasser et al., 2016a). A community analysis on the effective connectivity of these 26 language-related cortical regions identified the three groups of cortical language-related regions described next.

As background to the connectivity analyses of these three groups of language-related regions, the human temporal lobe semantic regions include cortical regions in the superior temporal sulcus and the adjacent temporal pole regions anteriorly and temporo-parieto-occipital regions posteriorly as illustrated in Figs. 8.3 and 8.4. These regions can be placed in their connectional context as follows. The inferior temporal visual cortex, illustrated in Fig. 2.23, has connectivity to the cortical regions in the ventral bank of the Superior Temporal Sulcus (STS) as illustrated in Fig. 2.24. The auditory cortical pathways and other cortical regions have connectivity to the cortical regions in the dorsal bank of the Superior Temporal Sulcus (STS) as illustrated in Figs. 7.7 and 2.25. Some of the functions of these cortical regions in the superior temporal sulcus in responding to socially relevant stimuli such as face expression, head motion, and vocalization have been described in Sections 2.5.3 and 2.5.2. Here these analyses are extended to show how the cortical regions in the superior temporal sulcus are parts of two much more extended systems that are termed here the Group 1 and Group 3 Semantic Regions involved in language (Rolls et al., 2022b). The Group 2 regions of this set include Broca's area regions 44 and 45 that are implicated in syntax, and are described in Chapter 14.

8.4.1 Group 1 semantic regions that include regions in the ventral bank of the Superior Temporal Sulcus

The cortical regions in this group identified by the community analysis are shown in Fig. 8.3 and consist of STSva STSvp TE1a TGd PGi 10v 9m 10pp 47s 8Av 8BL 9a and 9p (Rolls et al., 2022b). The Group 1 network includes inferior (ventral) regions of the cortex

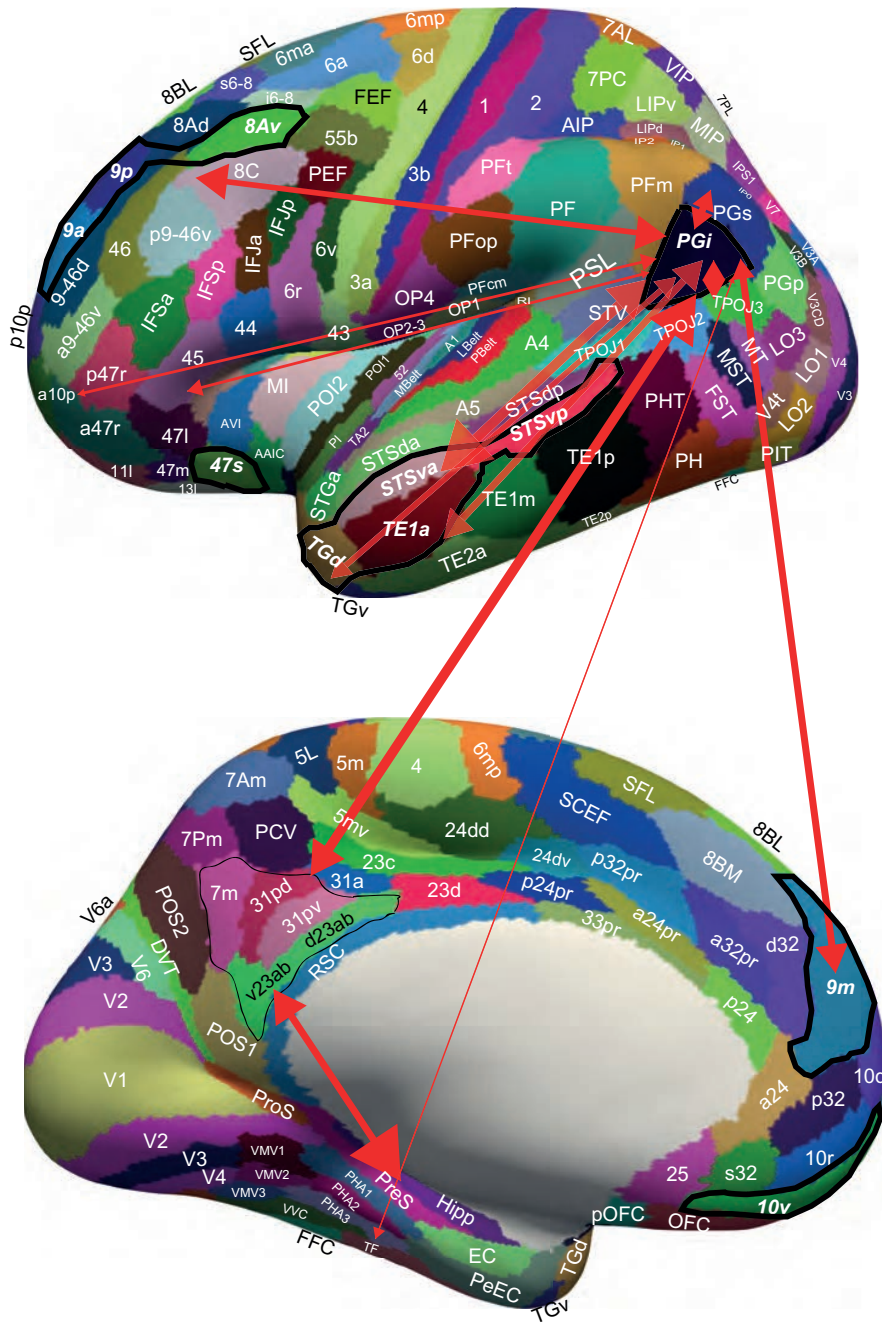

Fig. 8.3 Effective connectivity of region PGI chosen as an example of a Group 1 Semantic region with connectivity with the inferior STS stream, the posterior cingulate cortex, the frontal pole, and the dorsolateral prefrontal cortex. The Group 1 regions are indicated in bold italic font and are outlined in black (including PGI), and are: STSva STSvp TE1a TGD PGI 10v 9m 10pp 47s 8Av 8BL 9a 9p. The widths of the lines and the size of the arrowheads indicate the magnitude and direction of the effective connectivity. 7PM and IP1 connect to PGs which in turn connects to PGI, providing a route for PGI to receive visual motion information, and to connect that to areas such as STSva and STSvp. The thin black outline encloses the postero-ventral memory-related regions of the posterior cingulate cortex, which connect to the hippocampal system (Rolls et al., 2023i). The abbreviations are listed in Section 1.12. (From Rolls,E.T., Deco,G., Huang,C.-C. and Feng,J. (2022) The human language effective connectome. Neuroimage 258: 119352.)

in the Superior Temporal Sulcus (STS_{va} and STS_{vp}). The many different high-level cortical areas with which the Group 1 regions have connectivity indicate their roles in multimodal especially visual and value-related semantic representations.

The connectivity with inferior temporal visual cortex TE regions provides for transform-invariant visual representations of objects and faces as shown by discoveries in macaques (Rolls, 2021d,b; Perrett, Rolls and Caan, 1982; Booth and Rolls, 1998; Arcaro and Livingstone, 2021; Freiwald, 2020; Hesse and Tsao, 2020; Lehky and Tanaka, 2016) with complementary evidence from human neuroimaging (Kanwisher et al., 1997; Finzi et al., 2021; Collins and Olson, 2014).

The connectivity with inferior parietal cortex PG_i and to a smaller extent PGs regions may allow information about the visual motion of objects, such as a head turning away, or the eyes closing, or the lips moving, to convey a social signal such as a greeting (lip-smack) or threat, or when vocalizing, to reach STS areas (Rolls et al., 2023d). Indeed, it was discovered that single neurons in the macaque STS respond to face expression and also to face and head movement to encode the social relevance of stimuli (Hasselmo, Rolls, Baylis and Nalwa, 1989b; Hasselmo, Rolls and Baylis, 1989a). For example, a neuron might respond to closing of the eyes, or to turning of the head away from facing the viewer, both of which break social contact (Hasselmo et al., 1989b,a). Some neurons respond to the direction of gaze (Perrett et al., 1987). It was found that many of the neurons in the STS respond only or much better to moving faces or objects (Hasselmo et al., 1989a), whereas in the anterior inferior temporal cortex neurons were discovered that respond well to static visual stimuli, and are tuned for face identity (Perrett, Rolls and Caan, 1982; Rolls, 1984, 2000a; Rolls and Treves, 2011; Rolls, Treves, Tovee and Panzeri, 1997d; Rolls, Treves and Tovee, 1997b; Hasselmo, Rolls and Baylis, 1989a). It has been proposed that PG_i, with its inputs from PGs which has connectivity with superior parietal and intraparietal regions that encode visual motion, is part of this processing stream for socially relevant face-related information (Rolls et al., 2023d). Consistent with this, the effective connectivity is stronger from PG_i to STS regions (Rolls et al., 2022b). In humans, representations of this type could provide part of the basis for the development of systems to interpret the significance of such stimuli, including theory of mind. Consistent with this proposal, activations in the temporo-parietal junction region are related to theory of mind (DiNicola et al., 2020; Buckner and DiNicola, 2019; Schurz et al., 2017). Signals of this type are important in understanding the meaning of seen faces and objects, and indeed evidence about moving objects present in the STS may reach it from PGs and PG_i, which in turn receive connectivity from the intraparietal sulcus regions (Rolls et al., 2023d) in which neurons respond to visual motion and to grasping objects which are important in tool use (Maravita and Romano, 2018), which is another fundamental aspect of the meaning or semantics of stimuli.

Effective connectivity of the Group 1 regions with the frontal pole (10pp, 9m, 9a, 9p) regions implicated in planning and sequencing (Shallice and Cipolotti, 2018; Shallice and Burgess, 1996; Gilbert and Burgess, 2008) and prospective as well as retrospective memory (Underwood et al., 2015) is likely to provide information about the temporal order / sequence of events, which is important in interpreting causal interactions in the world (Rolls, 2021e).

Similarly, the connectivity via the parahippocampal TF region (Fig. 8.3) with the hippocampal system implicated in episodic memory (Dere et al., 2008; Ekstrom and Ranganath, 2018; Rolls, 2018b, 2021b; Moscovitch et al., 2016) is likely to be important in building semantic information about the meaning of events by enabling the memory of particular past events to be taken into account. The connectivity of the Group 1 regions with the postero-ventral parts of the posterior cingulate cortex which are implicated in episodic memory (Vann et al., 2009; Leech and Smallwood, 2019; Leech and Sharp, 2014; Rolls et al., 2023i) may, by providing a route to the hippocampal system, in a similar way be important in enabling the

Group 1 regions, especially those in the temporal lobe but also in the inferior parietal cortex (Davis et al., 2018; Papagno, 2018), to build semantic representations by taking particular previous episodes into account. Consistent with this, increasing activation of the angular gyrus in the parietal cortex and decreasing activation of the hippocampus occurs when episodic memories become incorporated into schemas (van der Linden et al., 2017).

The connectivity of the Group 1 regions with the orbitofrontal cortex (regions OFC and pOFC), pregenual anterior cingulate cortex (d32) and some ventromedial prefrontal cortex regions where reward value and emotion are represented (Grabenhorst and Rolls, 2011; Rolls et al., 2023c; Rolls, 2019c,e; Rolls et al., 2020a; Rolls, 2014a; Padoa-Schioppa and Conen, 2017; Cai and Padoa-Schioppa, 2012; Reber et al., 2017; Rolls, 2021h) provides another fundamental type of input for building semantic representations about people and objects.

The extensive connectivity of the Group 1 regions with the prefrontal cortex which is implicated in working memory and planning (Goldman-Rakic, 1996; Baddeley, 2021) (Chapter 13) is likely to enable semantic representations to be held online to facilitate planning, reasoning, and rearrangement of the order of components if a task fails (Rolls, 2020a).

8.4.2 Group 3 semantic regions that include regions in the dorsal bank of the Superior Temporal Sulcus

The cortical regions in Group 3 are shown in Fig. 8.4 and consist of A5 STGa STSda STSdp PSL STV and TPOJ1 (Rolls et al., 2022b).

The Group 3 network includes superior (or dorsal) parts of the cortex in the Superior Temporal Sulcus (STSda and STSdp) in the temporal lobe that have auditory as well as early visual inputs, continues up through the temporo-parietal junction (TPOJ1) into the Superior Temporal Visual region (STV) to the PeriSylvian Language area (PSL), and connects with inferior frontal gyrus areas IFSp and IFJp (rather than dorsolateral prefrontal cortex) and with areas 44 and 45 (Broca's area) (Fig. 8.4). Auditory region A5 (Chapter 7) is adjacent to STSdp.

Region TPOJ1 has robust effective connectivity with auditory association cortex, including A5, A4 and to some extent LBelt, PBelt and TA2 (Fig. 8.4).

The visual input is not from inferior temporal visual cortex (TE regions), but instead with some earlier visual cortical regions involved in motion processing (MST, MT, especially to STV and TPOJ1) and in face processing (the fusiform face cortex FFC and posterior inferior temporal cortex PIT). These inputs are likely to contribute to the neurons discovered in the STS that respond to biological motion such as moving parts of faces such as the lips and eyelids and to the head turning towards vs away from the viewer in object-based coordinates, and also to face expression (Hasselmo, Rolls, Baylis and Nalwa, 1989b; Hasselmo, Rolls and Baylis, 1989a). Activations to corresponding stimuli are found in similar posterior STS regions in humans (Critchley et al., 2000; Bellot et al., 2021). We proposed that this STS region is a third visual system that combines inputs from dorsal and ventral visual streams (Hasselmo, Rolls, Baylis and Nalwa, 1989b; Hasselmo, Rolls and Baylis, 1989a; Baylis, Rolls and Leonard, 1987), and this has recently received support (Pitcher and Ungerleider, 2021). Moreover, the same STS regions also contain neurons that respond to auditory stimuli including in some cases vocalization (Baylis, Rolls and Leonard, 1987). It is likely that neurons in these STS regions respond to combinations of auditory and synchronized visual stimuli such as vocalization and moving lips and are important in speech analysis by the viewer/hearer not only in noisy environments, but also to confirm who is speaking, and to learn associations between the sight of a person's face and the sound of their voice, which is part of what is required for the semantic representation of a person. Neurons of these types, including face expression, underlie the importance of this region in interpreting the social meaning of visual

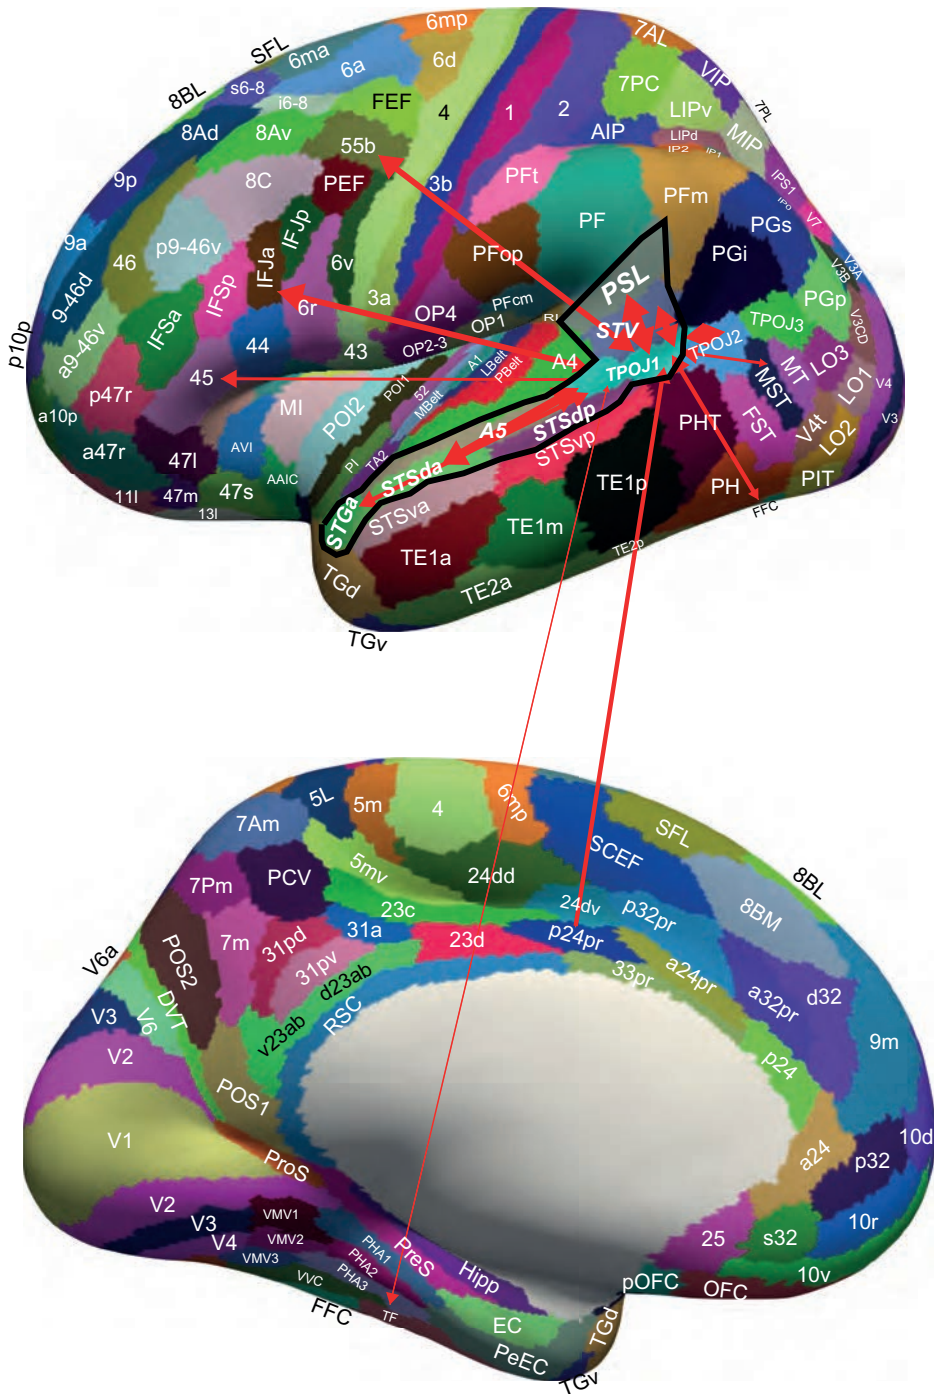

Fig. 8.4 Effective connectivity of region TPOJ1 chosen as an example of the typical effective connectivity of a Group 3 Semantic region with connectivity with a superior STS auditory-visual stream extending from STGA through STSda, A5, STSdp to TPOJ1. The Group 3 regions are indicated in bold italic font and are outlined in black, and are: A5 STGa STSda STSdp PSL STV TPOJ1. TPOJ1 also has effective connectivity with PSL, STV, TPOJ2, the inferior frontal gyrus IFJA and IFSp and 45, and with premotor area 55b and the midcingulate cortex p24pr. There is also effective connectivity with parahippocampal TF. The widths of the lines and the size of the arrowheads indicate the magnitude and direction of the effective connectivity. The abbreviations are listed in Section 1.12. (From Rolls, E.T., Deco, G., Huang, C.-C. and Feng, J. (2022) The human language effective connectome. *Neuroimage* 258: 119352.)

and auditory stimuli, which is a key part of semantic representations implemented in these STS regions, and that contribute to theory of mind, that is, of another individual's intentions and even thoughts.

Another type of influence on these Group 3 regions comes from somatosensory cortical areas, as is especially evident in the functional connectivity (Rolls et al., 2022b). The functional connectivity is not only with 1-3b and 5, but also with frontal opercular and insular cortex, and there is some evidence for this too in the effective connectivity, including with parietal PF which can be considered as the top of the somatosensory hierarchy (Rolls et al., 2023d) (Chapter 6). This may contribute to semantic representations of body image and the sense of self (Rolls et al., 2023d).

The effective connectivity of these Group 3 regions with the inferior frontal gyrus regions and with areas 44 and 45 is proposed to provide inputs to a set of attractor networks in these IFG regions (Rolls and Deco, 2015a), supported by the large number of recurrent collaterals onto each neuron in the inferior frontal gyrus (Elston, 2007; Elston et al., 2006), that are important in some particularly temporal aspects of speech production. Indeed, it is proposed that a set of attractor networks in these inferior frontal gyrus regions are linked by stronger forward than backwards connections, and so naturally implement a temporal trajectory or sequence through the series of attractors that implements by learning the sequential constraints that are a key part of syntax in languages in which word order is important in syntax (Rolls and Deco, 2015a). According to this theory of speech / language production, the biases for the content of what is in each attractor, e.g. the subject attractor=Jane, the verb attractor=jumps over, and the object attractor=John, come from the temporal lobe semantic regions being considered here, and the execution of the learned syntax comes from the temporally linked series of attractors for the parts of a sentence in the inferior frontal gyrus / Broca's area (Rolls and Deco, 2015a) (Section 14.5). The large extent of the inferior frontal gyrus with effective connectivity in humans (IFSp and IFJa, 44 and 45, 47l and 47s) with these temporal lobe semantic regions including TG is consistent with many sequential syntax-related order-dependent attractor networks in these inferior frontal regions, as it is likely that different attractor systems are required for the active vs passive voice and for different languages in which the word order is different (Rolls and Deco, 2015a).

The functions of each of these brain regions is a topic of great interest that is being facilitated by the use of the HCP-MMP atlas (Ekert et al., 2021a). For example, STSdp is implicated in the short-term retention of auditory representations that can be derived from either auditory or visual inputs. The left PeriSylvian Language (PSL) region may hold auditory representations of expected speech on-line until the spoken output is matched to the intended speech. TPOJ1 was not implicated in auditory or phonological short-term memory, but more in motor tasks (Ekert et al., 2021a).

8.5 The mechanisms for semantic learning in the human anterior temporal lobe

One approach to the computations involved in semantics is investigation in connectionist networks, which do not necessarily aim to be biologically plausible, but which can offer insight into what well-defined computations in networks can achieve.

In one such investigation, a deep linear network that displays many of the properties involved in learning semantic representations has been described (Saxe et al., 2019; McClelland et al., 2020). The network has one hidden layer, but is a linear network. It can therefore only compute what a network without a hidden layer can compute (because it is linear, see

Appendix B). However, the network, trained by backpropagation of error, does display interesting non-linear learning dynamics that are beyond what a network without a hidden layer shows. This enables the network to display properties found during semantic development such as the hierarchical differentiation of concepts through rapid developmental transitions, semantic illusions between such transitions, the emergence of item typicality and category coherence as factors controlling the speed of semantic processing, changing patterns of inductive projection over development, and the conservation of semantic similarity in neural representations across species. The network provides analytic insight into how the statistical structure of an environment can interact with nonlinear deep-learning dynamics to give rise to these properties, but the use of error back-propagation (Saxe et al., 2019; McClelland et al., 2020) is a problem in terms of biological plausibility.

Further evidence on semantic representations and how they may be learned is provided in Sections 14.2.4 and 14.4. Hypotheses and a model about how syntactic operations might be performed on semantic representations using a trajectory through a state space of cortical attractor networks are described in Section 14.5.

For semantic memory, different cortical regions may specialize in different attributes of a semantic memory. For example, an individual person might have attributes such as the sight of the face, the sound of the voice, the location where they work, etc. Semantic memories could be formed by coupling many such attractor networks together. An interesting issue arises though that if similar features are present in such compositional memories in the semantic representations of different individuals, this effectively increases the correlations between the items in the whole memory, and this can reduce somewhat the total memory capacity that might be expected (Ryom, Stendardi, Ciaromelli and Treves, 2023). This might occur if for example the sounds of the voices of several of the individuals are similar. How semantic representations are stored using coupled attractor networks each in a different brain region is a topic of current interest.

9 The hippocampus, memory, and spatial function

9.1 Introduction and overview

The hippocampus is involved in episodic memory, which is the memory of particular events in the recent past. An example would be where one was at dinner the preceding evening, who was there, and what one ate for dinner. The hippocampus has to be able to store this information in such a way that it is separate from the memory of what happened the day before. The hippocampus also needs to be able to recall this information, so that it can be used later by the brain to produce appropriate behavior and to help build neocortical semantic memories such as autobiographical memory (Chapter 8). Most episodic memories have a spatial component, and the order in which events happen is also often part of an episodic memory: and spatial and time sequence information is part of what is processed by the hippocampus. Perhaps because the hippocampus processes spatial information, it is also involved in some ways in spatial navigation.

The hippocampal system is extremely interesting to investigate as a brain system, because it has a distinctive set of neural networks, each with its own neural network architecture, which can be related to the computations performed by the hippocampal system.

The focus here is, as throughout this book, on the primate including human hippocampus, as the information processed in the rodent hippocampus is somewhat different. However, investigations of the architecture of the neural networks and how they operate has been performed considerably in rodents, and that information is described for it helps to build an understanding of hippocampal computation. Indeed, many studies in rodents help to test the theory of hippocampal computation that has been developed as described here.

9.1.1 Overview of what is computed by the hippocampal system

1. The hippocampus receives information from the ends of all sensory including spatial processing streams in the brain via the entorhinal cortex, area 28, the gateway to the hippocampus from the neocortex. There are as many backprojections from the hippocampus that return to the top ends of these cortical processing areas.
2. Damage to the human hippocampal system results in anterograde amnesia, in which new episodic memories cannot be formed, but in which previous memory including semantic memory (general knowledge) is relatively intact. The hippocampus may also be involved in prospective memory, of tasks that need to be performed, presumably because these also need the storage of sets of new particular items.
3. The hippocampus is also involved in navigation, but this may be in part when there is a need to store new items for the navigation in for example novel environments, at least in humans. Computations for navigation are described in Chapter 10.
4. The hippocampus contains allocentric (world-based) place cells in rodents and primates. In primates there are also spatial view cells that respond allocentrically to a location in space 'out there' at which the primate is looking. These spatial view cells are likely to be important in remembering what has been seen where in the environment, in that some

spatial view cells respond to a combination of spatial view and object in an ‘object-to-place in a scene’ memory task. The same is found in a ‘reward-to-place in a scene’ memory task. The spatial view neurons fire to a viewed location in space relatively independently of eye position, head direction, and the place where the individual is located, which is an important property of a memory system, for this enables correct recall of the object or reward at a viewed location in a scene even if the eye position, head direction, and place are different from when the learning took place. The location in a scene at which spatial view neurons fire can be updated for a few minutes by movements made in the dark, and this may be useful in selecting goals for navigation in the dark. This update by self-motion in for example the dark is referred to as idiothetic update.

5. The primate (including human) hippocampus may utilise information from ventral visual stream areas that respond to scenes to build hippocampal spatial scene representations. ‘Where’ hippocampal spatial scene representations are thus built by feature combinations in a ventromedial visual cortical stream that reaches the medial parahippocampal cortex (TH or PHA1-3) where spatial view neurons are found. In this situation, the route via the dorsal visual stream and parietal cortex areas to the hippocampal system from human parietal cortex region PGp (and via the retrosplenial scene area and posterior cingulate cortex (Rolls et al., 2023e)) (Section 3.5) is then used for the idiothetic update in the human medial parahippocampal gyrus scene area of where in the allocentric spatial scene we may be looking, for example in the dark or remembering, based on idiothetic information.
6. The primate (including human) hippocampus receives information about ‘what’ object or person is present via a ventrolateral visual cortical stream that reaches the hippocampus from the inferior temporal visual cortex via lateral parahippocampal gyrus region TF and perirhinal and entorhinal cortex.
7. The primate (including human) hippocampus receives information about the reward value or emotional component of episodic memory from the orbitofrontal cortex / ventromedial prefrontal cortex / pregenual anterior cingulate cortex. Consolidation of information from episodic memory into semantic memory in humans is likely to be influenced by the value component of episodic memory, which leads to enhanced rehearsal of episodic memories that are of potential value to the individual.
8. The primate (including human) hippocampus can then associate together the ‘what’, ‘where’ and value / emotional components to form an episodic event memory.
9. The human orbitofrontal cortex (region pOFC) has connectivity to the cholinergic basal forebrain cholinergic neurons that project to the neocortex. The anterior cingulate cortex and vmPFC have connectivity to the septal region which contains cholinergic neurons that project to the hippocampus. These pathways are implicated in memory consolidation in humans, in the context that basal forebrain neurons fire when rewarding, punishing, or novel stimuli are encountered and storage of events may be especially useful.
10. There are also time cells in at least the rodent hippocampus, each of which responds at different times in a delay period, so that they fire in a temporal sequence, which can be up to hundreds or more seconds long. These neurons, when associated with objects or places, are likely to enable the order in which the objects or places occurred to be recalled.
11. The primate hippocampus contains ‘whole body motion neurons’, which respond to head rotation (angular velocity), and in other cases to linear motion (translation, moving for example forwards). Similar neurons are present in the rodent medial entorhinal cortex, where they have been termed ‘speed cells’. They are likely to be involved in the memory of recent movements, and thus in idiothetic navigation.
12. The medial entorhinal cortex contains grid cells in rodents that fire with several peaks of firing as a rodent traverses places. In primates, there are spatial view grid cells, which are

likely to provide inputs to the spatial view cells found in the primate hippocampus. Different entorhinal cortex grid cells operate at different spatial scales. The lateral entorhinal cortex provides a route for object-related information from the ventral cortical systems to reach the hippocampus.

13. The presubiculum contains head direction cells, which use allocentric coordinates. They are found also in many other brain areas, and are likely to be important in navigation and in memory.
14. The perirhinal cortex, a stage before the entorhinal cortex on the route to and from the neocortex, is implicated in recognition memory, the ability to remember having seen an object in the recent past. It is also involved in long-term familiarity memory, with neurons responding with higher firing rates the more familiar a stimulus is.
15. This overview of what is represented in the hippocampal system summarizes evidence that is key to understanding *what* is computed in the hippocampus and connected structures, and *what* this computed information is used for in the hippocampus. *How* the computations are performed to make these representations, and *how* these representations are used in the hippocampus, are summarized in the next section, and are part of what is described in this Chapter.

9.1.2 Overview of how the computations are performed by the hippocampal system

1. A feature of the hippocampal network is that the CA3 system has a highly developed recurrent collateral system that enables it to associate together, operating as an autoassociation or attractor network, places / spatial views with objects. The single attractor network in CA3 enables any object to be associated with any place / spatial view in an episodic or event memory, and for the place to be recalled from the object, and the object from the place. This is completion of a memory in an autoassociation network.
2. The number of memories that can be stored in the hippocampus is determined largely by the number of recurrent collateral connections onto any one CA3 neuron (in the order of 12,000 in the rat) and the sparseness of the representation.
3. The dentate gyrus input to CA3 performs pattern separation of the inputs before CA3 to help achieve the relatively uncorrelated representations that help to achieve high memory capacity in CA3. The dentate granule cells perform this operation by competitive learning; by the low probability of contact of the dentate granule cell to CA3 connections (0.00015 in the rat: a granule cell makes 46 mossy fibre connections and there are 300,000 CA3 cells); and by neurogenesis with the new dentate granule cells helping to ensure that new memories are distinct from old memories by making new random connections to CA3 neurons. The dentate gyrus is the only part of cortex where new neurons can develop in adulthood, for here the premium is on selecting new random sets of neurons in CA3 for new memories distinct from previous memories, whereas elsewhere in cortex the information is stored in the synaptic weights and learned information would be lost if there was any turnover of neurons.
4. The CA1 which follows the CA3 prepares for the recall of memories, completed in CA3 by a partial retrieval cue, back to the neocortex. The CA1 has the architecture of a competitive network, useful for recoding the parts of an episodic memory necessarily represented as separate in CA3 for autoassociation in CA3.
5. Backprojections from the hippocampal system to neocortical areas have a large number of synapses onto each neocortical neuron to achieve high recall capacity of memories from

the hippocampus to the neocortex. This accounts for why there are as many backprojections as forward connections between adjacent cortical areas in a cortical hierarchy. For the recall to work efficiently, the backprojection synapses at one or more stages of the backprojection pathway must be associatively modifiable during the original learning.

6. Once set up in this way, the backprojection connections can also be used for top-down attentional control (see Chapter 13).
7. The medial entorhinal cortex appears to operate as a continuous attractor network that can perform path integration, updating the spatial representation based on motion signals (i.e. idiothetic update). The medial entorhinal cortex neurons reach the dentate and CA3, where competitive network learning can convert the grid cell representation into place cells by leading to different neurons learning combinations of the grid firing present at any one time in the entorhinal cortex. However, in humans the idiothetic update for changes in eye position, head direction, etc take place in the parietal cortex, with mechanisms considered in Section 3.5.
8. The lateral entorhinal cortex includes some neurons with slow ramping changes in firing rates over up to hundreds of seconds. Combinations of the firing of these neurons produced by competitive learning in the hippocampus can produce time cells. The theory for how this computation takes place can account for forward and reverse replay of temporal sequences of firing found in the hippocampus and related brain areas.

9.2 What is computed in the hippocampus

Any theory of the hippocampus must state at the systems level what is computed by the hippocampus. Some of the relevant evidence comes from the systems-level connections of the hippocampus (Section 9.2.1), from the effects of damage to the hippocampus (Section 9.2.2), and from the responses of neurons in the hippocampus during behavior (Section 9.2.4).

9.2.1 Systems-level anatomy

The main cortical connections of the hippocampus are shown in Fig. 9.1 (Rolls and Wirth, 2018), and in schematic form to show the nature of the network connectivity in Fig. 9.2 (Rolls, 2023c). These figures show that the primate hippocampus receives major inputs via the entorhinal cortex (area 28) (Garcia and Buffalo, 2020). These come from the highly developed parahippocampal gyrus (areas TF and TH) and also from the retrosplenial cortex, as well as the perirhinal cortex, and thereby from the ends of many processing streams of the cerebral association cortex, including the visual and auditory temporal lobe association cortical areas, the prefrontal cortex, and the parietal cortex (Van Hoesen, 1982; Amaral, Price, Pitkanen and Carmichael, 1992; Amaral, 1987; Witter, Groenewegen, Lopes da Silva and Lohman, 1989a; Suzuki and Amaral, 1994a; Witter, Wouterlood, Naber and Van Haeften, 2000b; Lavenex, Suzuki and Amaral, 2004; Johnston and Amaral, 2004; Witter, 2007; van Strien, Cappaert and Witter, 2009; Kondo, Lavenex and Amaral, 2009; Somogyi, 2010; Rolls, 2015b, 2018b; Garcia and Buffalo, 2020; Huang, Rolls, Hsu, Feng and Lin, 2021; Ma, Rolls, Huang, Cheng and Feng, 2022a; Rolls, Deco, Huang and Feng, 2022a, 2023e; Rolls, Wirth, Deco, Huang and Feng, 2023i; Rolls, Deco, Huang and Feng, 2023f,d,c; Rolls, 2023c). The hippocampus is thus by its connections potentially able to associate together object representations (from the temporal lobe visual and auditory areas) and spatial representations. In addition, the entorhinal cortex receives inputs from the amygdala, orbitofrontal cortex, and anterior cingulate cortex (Carmichael and Price, 1995b; Suzuki and Amaral, 1994a; Pitkanen et al., 2002; Stefanacci et al., 1996; Rolls, 2015b; Garcia and Buffalo, 2020; Huang et al., 2021; Ma et

Fig. 9.1 Cortical connections of the primate hippocampus. A medial view of the macaque brain is shown below, and a lateral view is above. The entorhinal cortex area 28 is the main entry for cortical connections to and from the hippocampus. The forward projections to the hippocampus are shown with large arrowheads, and the backprojections with small arrowheads. The main ventral stream connections to the hippocampus that convey information about objects, faces, etc are in blue, and the main dorsal stream connections that convey 'where' information about space and movements are in red. The ventral 'what' visual pathways project from the primary visual cortex V1 to V2, then V4, then posterior inferior temporal visual cortex (PIT), then anterior inferior temporal visual cortex (AIT), then perirhinal cortex (areas 35/36), and thus to entorhinal cortex. The dorsal 'where' visual pathways project from V1 to V2, then MT (middle temporal), then LIP (lateral intraparietal), then parietal area 7 (lateral) and medial (including the precuneus), then to posterior cingulate cortex areas 23/31 including the retrosplenial cortex (areas 29/30) and thus to parahippocampal gyrus (areas TF and TH), and then perirhinal and entorhinal cortex. Area 22 is superior temporal auditory association cortex. The hippocampus enables all the high order cortical regions to converge into a single network in the hippocampal CA3 region. Object information reaches the hippocampus from the temporal cortex parts of the ventral visual system. The parahippocampal place area (Epstein and Baker, 2019), and also the ventral visual stream, may provide visual scene information that drives hippocampal spatial view cells. The retrosplenial cortex (29,30) is the small region in primates including humans behind the splenium of the corpus callosum shaded grey: it is not necessarily homologous with what is termed retrosplenial cortex in rodents (Vann et al., 2009), which may also not have a homologous posterior cingulate cortex (Vogt, 2009). Connections involving the cingulate cortex are in green. Other abbreviations: as—arcuate sulcus; cs—central sulcus; ips—intraparietal sulcus; ios—inferior occipital sulcus; ls—lunate sulcus; sts—superior temporal sulcus. (Modified from Rolls, E. T. and Wirth, S. (2018) Spatial representations in the primate hippocampus, and their functions in memory and navigation. *Progress in Neurobiology* 171: 90–113.)

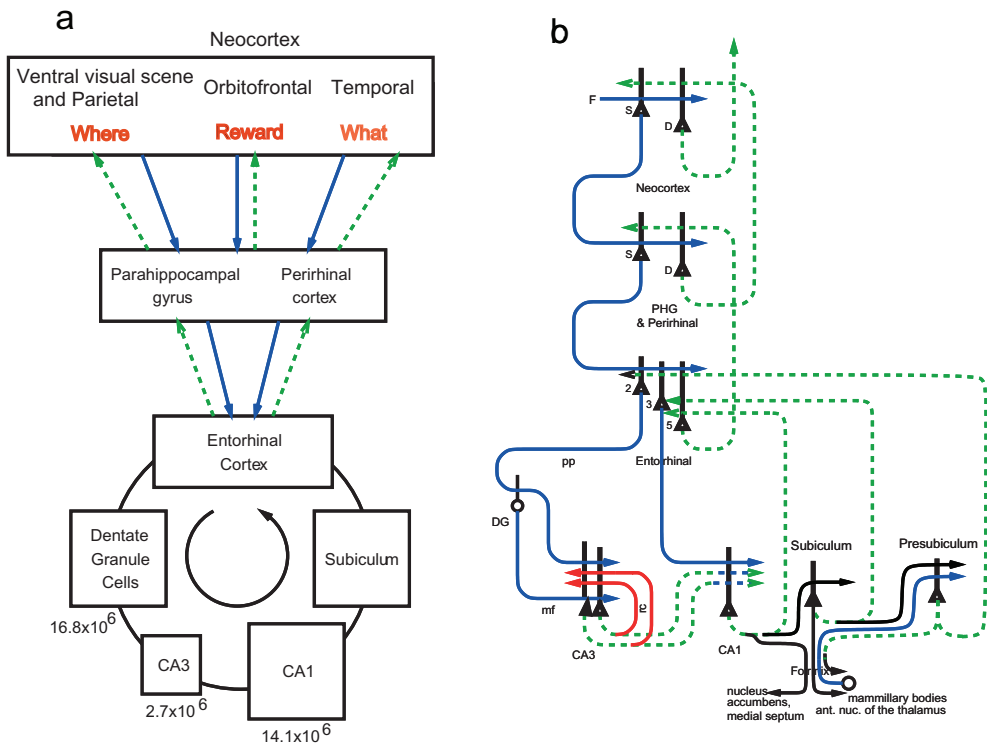

Fig. 9.2 The human / primate hippocampus receives neocortical input connections (blue) not only from the ‘what’ temporal lobe and ‘where’ parietal and ventral visual scene areas (orbitofrontal cortex, vmPFC, and anterior cingulate cortex) for episodic memory storage; and has return backprojections (green) to the same neocortical areas for memory recall. There is great convergence via the parahippocampal gyrus, perirhinal cortex, and dentate gyrus in the forward connections down to the single network implemented in the CA3 pyramidal cells, which have a highly developed recurrent collateral system (red) to implement an attractor episodic memory by associating the what, where and reward components of an episodic memory. a: Block diagram. b: Some of the principal excitatory neurons and their connections in the pathways. Time and temporal order are also important in episodic memory, and may be computed in the entorhinal-hippocampal circuitry (Rolls and Mills, 2019). Abbreviations - D: Deep pyramidal cells. DG: Dentate Granule cells. F: Forward inputs to areas of the association cortex from preceding cortical areas in the hierarchy. mf: mossy fibres. PHG: parahippocampal gyrus and perirhinal cortex. pp: perforant path. rc: recurrent collateral of the CA3 hippocampal pyramidal cells. S: Superficial pyramidal cells. 2: pyramidal cells in layer 2 of the entorhinal cortex. 3: pyramidal cells in layer 3 of the entorhinal cortex. The thick lines above the cell bodies represent the dendrites. The numbers of neurons in different parts of the hippocampal trisynaptic circuit in humans (Rogers Flattery et al., 2020) are shown in (a), and indicate very many dentate granule cells, consistent with expansion encoding and the production of sparse uncorrelated (pattern separated) representations prior to CA3. (From Rolls, E. T. (2023) Hippocampal spatial view cells for memory and navigation, and their underlying connectivity in humans. Hippocampus doi: 10.1002/hipo.23467.)

al., 2022a; Rolls et al., 2022a, 2023c,b; Rolls, 2023c), which could provide reward-related information to the hippocampus (Rolls, 2018b, 2022b, 2023c). The connections are analogous in the rat, although areas such as the temporal lobe and parietal lobe visual cortical areas are not well developed in rodents, and the parahippocampal gyrus may be represented by the dorsal perirhinal cortex (Burwell, Witter and Amaral, 1995).

Given that some topographic segregation is maintained in the afferents to the hippocampus in the perirhinal, parahippocampal, and entorhinal cortices (Amaral and Witter, 1989; Garcia and Buffalo, 2020; Huang, Rolls, Hsu, Feng and Lin, 2021; Ma, Rolls, Huang, Cheng and Feng, 2022a; Rolls, Deco, Huang and Feng, 2022a), it may be that these areas are able to subservise memory within one of these topographically separated areas, of for example visual object, or spatial, or olfactory information. In contrast, the final convergence afforded by the hippocampus into one network in CA3 (see Fig. 9.2) may be especially appropriate for

an episodic memory typically involving arbitrary associations between any of the inputs to the hippocampus, e.g. spatial, vestibular related to self-motion, visual object, olfactory, auditory, and reward (see below). There are also direct subcortical inputs from for example the amygdala and septum (Amaral, 1986; Rolls et al., 2023b).

The primary output from the hippocampus to neocortex originates in CA1 and projects to subiculum, entorhinal cortex, and parahippocampal structures (areas TF-TH) as well as prefrontal cortex (Van Hoesen, 1982; Delatour and Witter, 2002; Witter, 1993; van Haeften et al., 2003; Witter and Amaral, 2021; Huang et al., 2021; Ma et al., 2022a; Rolls et al., 2022a). The subiculum also projects via the fimbria/fornix to subcortical areas such as the mammillary bodies and anterior thalamic nuclei (see Fig. 9.2) (Bubb, Kinnavane and Aggleton, 2017). In addition to the projections originating in CA1, projections out of Ammon's horn also originate in CA3. Many researchers have reported that CA3 projects to the lateral and medial septal nuclei (Amaral and Witter, 1995; Risold and Swanson, 1997; Gaykema et al., 1991). The lateral septum also has projections to the medial septum (Jakab and Leranth, 1995), which in turn projects to subiculum and eventually entorhinal cortex (Amaral and Witter, 1995; Jakab and Leranth, 1995).

Developments in our understanding of the connections and connectivity of the human hippocampal system (Rolls, Deco, Huang and Feng, 2022a; Ma, Rolls, Huang, Cheng and Feng, 2022a; Huang, Rolls, Hsu, Feng and Lin, 2021; Rolls, Deco, Huang and Feng, 2023b; Rolls, 2023c, 2022b) are described in Section 9.2.8.

9.2.2 Evidence from the effects of damage to the hippocampus

Damage to the human hippocampus or some of its major connections such as the fornix can produce anterograde amnesia, which includes an inability to learn new information about events that happen after the damage, while leaving previous memories relatively intact (Corkin, 2002; Burgess et al., 2002; Smith and Milner, 1981; Petrides, 1985; Gaffan and Gaffan, 1991; Bubb et al., 2017). The initial discovery was made in the patient H.M. who was being treated for epilepsy (Scoville and Milner, 1957; Corkin, 2002). Right hippocampal damage is associated with spatial memory impairments (Smith and Milner, 1981; Crane and Milner, 2005). These discoveries have led to analysis of exactly which parts of the human medial temporal lobe are involved in memory, and how memory is implemented in the brain systems here, which include the hippocampus but also other structures.

Damage to the hippocampus or to some of its connections such as the fornix in monkeys produces deficits in learning about the places of objects and about the places where responses should be made (Buckley and Gaffan, 2000). For example, macaques and humans with damage to the hippocampal system or fornix are impaired in object–place memory tasks in which not only the objects seen, but where they were seen, must be remembered (Burgess et al., 2002; Crane and Milner, 2005; Gaffan, 1994; Gaffan and Saunders, 1985; Parkinson et al., 1988; Smith and Milner, 1981). Posterior parahippocampal lesions in macaques impair even a simple type of object–place learning in which the memory load is just one pair of trial-unique stimuli (Malkova and Mishkin, 2003). I further predict that a more difficult object-place learning task with non-trial-unique stimuli and with many object-place pairs would be impaired by neurotoxic hippocampal lesions. Neurotoxic lesions that selectively damage the primate hippocampus impair spatial scene memory (Murray et al., 1998), and spatial location memory (Waters, Basile and Murray, 2023), when for example environmental visual cues are used in foraging and navigation (Hampton, Hampstead and Murray, 2004; Lavenex, Amaral and Lavenex, 2006). Also, fornix lesions impair conditional left–right discrimination learning, in which the visual appearance of an object specifies whether a response is to be made to the left or the right (Rupniak and Gaffan, 1987). A comparable deficit is found in humans

(Petrides, 1985). Fornix sectioned monkeys are also impaired in learning on the basis of a spatial cue which object to choose (e.g. if two objects are on the left, choose object A, but if the two objects are on the right, choose object B) (Gaffan and Harrison, 1989a). Monkeys with fornix damage are also impaired in using information about their place in an environment. For example, Gaffan and Harrison (1989b) found learning impairments when which of two or more objects the monkey had to choose depended on the position of the monkey in the room.

Rats with hippocampal lesions are impaired in using environmental spatial cues to remember particular places (Cassaday and Rawlins, 1997; Martin et al., 2000; O'Keefe and Nadel, 1978; Jarrard, 1993; Kesner et al., 2004; Kesner and Rolls, 2015), to utilize spatial cues or bridge delays (Kesner, 1998; Kesner and Rolls, 2001; Rawlins, 1985; Kesner et al., 2004; Kesner and Rolls, 2015), or it has been argued to perform relational operations on remembered material (Eichenbaum, 1997). The evidence from rats is further considered in Section 9.4, where tests of the theory are described (Kesner and Rolls, 2015).

In humans, functional neuroimaging and neuronal recording show that the hippocampal system is activated by allocentric spatial including scene processing (Burgess, 2008; Chadwick et al., 2013; Hassabis et al., 2009; Maguire, 2014; Zeidman and Maguire, 2016; Mormann et al., 2017; Tsitsiklis et al., 2020) and by object-spatial episodic memory (Ison et al., 2015; Staresina et al., 2019).

One way of relating the impairment of spatial processing to other aspects of hippocampal function is to note that this spatial processing involves a snapshot type of memory, in which one whole scene must be remembered at a particular time. This memory may then be a special case of episodic memory, which involves an arbitrary association of a particular set of events which describe a past episode (Rolls, 2008e, 2010b; Kesner and Rolls, 2015). Further, the non-spatial tasks impaired by damage to the hippocampal system may be impaired because they are tasks in which a memory of a particular episode or context rather than of a general rule is involved (Gaffan et al., 1984). Further, the deficit in paired associate learning in humans may be especially evident when this involves arbitrary associations between words, and when they elicit spatial imagery, for example window – lake (Clark et al., 2018). Consistent with this, single neurons in the human hippocampus may respond not only to the sight or name of a film star, but also to objects associated with them, such as a bicycle (Quian Quiroga, Reddy, Kreiman, Koch and Fried, 2005; Fried, Rutishauser, Cerf and Kreiman, 2014; Rolls, 2015c; Bausch, Niediek, Reber, Mackay, Bostrom, Elger and Mormann, 2021; Rutishauser, Reddy, Mormann and Sarnthein, 2021). The right (spatial) vs left (word) specialization of function in the human hippocampus (Crane and Milner, 2005; Burgess et al., 2002; Amit, 1989; Bonelli et al., 2010; Sidhu et al., 2013), associated in humans with a less well developed hippocampal commissural system, could be related to the fact that arbitrary associations between words and places are not required.

It is suggested that the reason why the hippocampus is used for the spatial and non-spatial types of memory described above, and the reason that makes these two types of memory so analogous, is that the hippocampus contains one stage, the CA3 stage, which acts as an autoassociation memory. It is suggested that an autoassociation memory implemented by the CA3 neurons equally enables whole (spatial) scene or episodic memories to be formed, with a snapshot quality that depends on the arbitrary associations that can be made and the short temporal window which characterises the synaptic modifiability in this system (Rolls, 1990a,b, 1987, 1990b, 1989e, 2016b, 2018b). The hypothesis is that the autoassociation memory enables arbitrary sets of concurrent neuronal firings, representing for example the spatial context where an episode occurred, the people present during the episode, and what was seen during the episode, to be associated together and stored as one event. (The associations are arbitrary in the sense that any representation within CA3 may be associated with any other

representation in CA3.) The issue of the types of item, e.g. spatial, for which this type of associativity is hippocampus-dependent is considered below. Later recall of that episode from the hippocampus in response to a partial cue can then lead to reinstatement of the activity in the neocortex that was originally present during the episode. The theory described here shows how the episodic memory could be stored in the hippocampus, and later retrieved from the hippocampus and thereby to the neocortex using backprojections.

It is now evident that recognition memory (tested for example in primates by the ability to recognise a sample visual stimulus in a delayed match to sample task) is not impaired by hippocampal damage, produced for example by neurotoxic lesions (Murray et al., 1998; Baxter and Murray, 2001b,a; Waters et al., 2023). As shown below in Section 9.2.7, perirhinal cortex lesions do impair visual recognition memory in this type of task.

The extensive literature on the effects of hippocampal damage in rats is considered in Section 9.4 and by Kesner and Rolls (2015), in particular the parts of it that involve selective lesions to different subregions of the hippocampus and allow the theory described here to be tested.

The theory described here is intended to be as relevant to rodents as to primates including humans, the main difference being that the spatial representation used in the hippocampus of rats is about the place where the rat is, whereas the spatial representation in primates including humans includes a representation of space “out there”, as represented by spatial view cells (see Section 9.2.4).

9.2.3 Episodic memories need to be recalled from the hippocampus, and can be used to help build neocortical semantic memories

The information about episodic events recalled from the hippocampus could be used to help form semantic memories (Rolls, 1990a,b, 1989e,f; Treves and Rolls, 1994). For example, remembering many particular journeys could help to build a geographic cognitive map in the neocortex. The hippocampus and neocortex would thus be complementary memory systems, with the hippocampus being used for rapid, ‘on the fly’, unstructured storage of information involving activity potentially arriving from many areas of the neocortex; while the neocortex would gradually build and adjust, on the basis of much accumulating information, the semantic representation (Rolls, 1990b; Treves and Rolls, 1994; McClelland et al., 1995). A view close to this in which a hippocampal episodic memory trace helps to build a neocortical semantic memory has also been developed by Moscovitch et al. (2005).

What I mean by an episodic memory of the type in which the hippocampus could be involved is described further next (Rolls and Kesner, 2006b; Kesner and Rolls, 2015; Rolls, 2018b). A hippocampus-dependent episodic memory is unstructured in the sense that the information is stored as an association between representations such as spatial location, objects, and position in a temporal sequence. An episodic memory could be a single event capturing what happens in a time period in the order of 1–10 s (for example a memory of who was present at one’s fifth birthday, what they were wearing, where they sat, where the party was, etc), or a sequence of events with some information about the temporal order of the events. A hippocampus-dependent episodic memory includes spatial and/or temporal e.g. sequence information. All this is in contrast to a neocortical semantic memory which might utilize many such episodic memories, for example of separate train journeys, to form a neocortical topological ‘cognitive’ map. Such a semantic memory might need to benefit from information about exceptions, which contributes to the type of structure needed for a semantic memory. For example we may be told that a bat, although it flies, is not a bird because it is a mammal which nurses its young, and this information allows restructuring of a semantic representation of what constitutes a bird beyond the simple association and

generalization from limited experience that birds fly. Because this active restructuring is an important part of semantic memory that may frequently benefit from language, I propose that semantic memories are best formed during waking using thought and reasoning, and not during sleep (Rolls, 2016b). Indeed, I propose that episodic events that are recalled actively in this way from the hippocampus can become incorporated into neocortical representations and thus consolidated into semantic including autobiographical memories (Section 9.2.8.5). If episodic material (such as where and with whom one had dinner three days ago) is not recalled in this way, then it will be gradually overwritten in hippocampal memory in a process of forgetting as new sparse distributed representations are added to the store, in the way that has been analyzed quantitatively (Section B.19).

To make the distinction between an episodic memory in the hippocampus and a semantic memory in the temporal lobe neocortex (Section 8.3) clear, I now provide an example. An association could be built in the hippocampus by synaptic weight modification between coactive neurons some of which represented an individual and others of which represented the place where the individual was located at a particular time. That would form a single memory in an attractor memory network of the type implemented in hippocampal CA3 (Rolls, 1987, 2018b; Kesner and Rolls, 2015). Such a neuron or neurons that have learned this association could be activated later to recall with completion the whole memory by either a location recall cue or a recall cue provided of the individual. This is an object (or person) with place memory for an event at a particular time. These cells, given that the hippocampus is implicated in episodic memory which must be learned as a single event at a particular time, could be set up rapidly, even on a single trial. This memory at a particular time must be kept separate from episodic memories of even quite similar events but at different times. Recall of such recalled episodic representations from the hippocampus to the neocortex could help to build up a semantic memory in the neocortex that would contain knowledge about which spatial locations in the world are associated with which individuals or groups. Such a semantic memory would benefit from recalling a number of episodic memories, for that would establish which individuals were regularly seen in particular locations, which is semantic knowledge, as contrasted with single event episodic memories in the hippocampus. The semantic memory is not about events at a particular time, but in contrast can benefit from many event episodic memories made at particular times. The semantic memory is all the information accumulated across time about the locations, for example. This type of semantic representation would be the representation of a territory in the brain. This semantic representation in the temporal neocortex (Chapter 8) would enable all the properties of each territory to be learned, in contrast to hippocampal cells that would represent a single instance of an occasion at a particular time in which the individual or group was in a particular place. Such neurons with these semantic properties in the temporal neocortex might be termed ‘territory cells’. Such neocortical semantic representations would be of the attributes or properties that are associated with a particular individual, group, or object etc. Such ‘semantic cells’ (in this case representing a territory) are likely, in that semantic cells (which were termed ‘concept cells’) have been recorded in the human temporal cortex, and might respond to many of the attributes of for example Jennifer Aniston (Quian Quiroga, 2012; Rey, Ison, Pedreira, Valentin, Alarcon, Selway, Richardson and Quian Quiroga, 2015; Quian Quiroga, Reddy, Kreiman, Koch and Fried, 2005; De Falco, Ison, Fried and Quian Quiroga, 2016; Bausch, Niediek, Reber, Mackay, Bostrom, Elger and Mormann, 2021; Rutishauser, Reddy, Mormann and Sarnthein, 2021). ‘Concept cells’ can be activated whenever a concept is brought to mind, including in a memory task (Bausch et al., 2021). As noted in Section 8.3.1, object-location cells in macaques have some similar multi-attribute properties to ‘concept cells’ in humans, in that they can be activated either by the object, or by the location, in object-location memory tasks

(Rolls and Xiang, 2005, 2006; Rolls, 2023d). These neurons in macaques might accordingly also be described as ‘concept cells’ (Rolls, 2023c,d).

Moreover, computationally a semantic memory involves associating all the attributes or descriptors of the node (e.g. the territory) obtained across all times in an interactive activation type of network, as shown in Section 14.4. In contrast, an episodic memory is formed in an attractor network in CA3 which associates for example a single location with an object or individual at a particular time, as shown below. It thus follows that the hippocampus could represent a unique location and object at a unique time, but the concept of a territory and all its attributes is a neocortical representation in the anterior temporal lobe (Sections 8.3, 14.4 and 14.2.4).

In summary, this systems-level analysis provides evidence that the hippocampus is involved in associating a viewed location or a place with an object or individual at a particular time. The temporal lobe neocortex is involved in semantic representations with all the attributes accumulated across time to provide a full description. Thus to take an example, a territory is a semantic representation in the temporal neocortex that can represent all of the locations and the individuals who lay claim to the land, which is how a territory is defined. Hippocampal learning instead is about associations between particular locations and particular objects or individuals that occur at a particular time. In line with the hypothesis that the hippocampus is involved in the memory of particular events, hippocampal damage in humans impairs the memory of events that happened for example earlier in the day, but not semantic memory. When these hippocampal episodic event memories are recalled from the hippocampus to the neocortex, the temporal lobe neocortex can accumulate the evidence from many such episodic memories to help form a semantic representation (Rolls, 2022b, 2023d). This is consistent with the evidence from anterograde amnesia produced by hippocampal damage that new semantic memories can only be formed in the neocortex if the hippocampus is present to form its single event memories. The semantic representations, such as a representation of a territory, are neocortical entities, in that they remain after hippocampal damage. Further, as shown in Section 8.3, it is neocortical damage that impairs semantic representations. Thus a territory, in our example, is a neocortical temporal lobe semantic entity and not a hippocampal episodic memory entity. Routes by which semantic information including that represented by concept cells can reach the hippocampus to become incorporated into an episodic memory have been described (Rolls, 2023d).

In contrast to my proposal above that episodic memories would best be recalled from the hippocampus during waking to help build useful structured neocortical semantic memories (Section 9.2.8.5), some have suggested that the transfer of information from the hippocampus to the neocortex occurs especially during sleep (Marr, 1971; Schwindel and McNaughton, 2011; Foster, 2017). (David Marr heard this suggested by Larry Weiskrantz in a Part 2 lecture at Cambridge in 1967.) Indeed, it has been shown that after learning in hippocampal-dependent tasks, neocortical representations may change (Schwindel and McNaughton, 2011). Although this has been interpreted as the transfer of memories from the hippocampus to the neocortex (Schwindel and McNaughton, 2011), it should be noted that if the hippocampal representation changes as a result of learning, then the altered representation in CA1 will, even with fixed synaptic connections back to neocortex, alter neocortical firing, with no learning or actual ‘transfer’ involved. (This occurs whenever one vector comprised by a population of neurons firing changes and influences another vector of neuronal firing through fixed connections.) Indeed, for the reasons given above, active transfer of episodic memories from the hippocampus to the neocortex to form semantic memories is more likely I propose during the guided construction and correction of semantic memories in the cortex during waking with value taken into account (Section 9.2.8.5).

The actual addition of new information to the neocortical semantic representation could

itself be fast, for example when one recalls a particular train journey, and incorporates information from that into a geographical representation. An additional property of hippocampal episodic memories is that when recalled to the neocortex they can be used flexibly for many types of behavioral output (because the information is back in the neocortex). I further note that rapid learning is not a unique feature of episodic memory, with for example the stimulus-reward learning and its reversal implemented in the primate orbitofrontal cortex possible in one trial (Thorpe, Rolls and Maddison, 1983; Rolls, 2014a, 2019e; Rolls, Vatansever, Li, Cheng and Feng, 2020e) (see also Chapter 11).

The quantitative evidence considered below (Section 9.3.5.1) and by Treves and Rolls (1994) on the storage capacity of the CA3 system indicates that episodic memories could be stored in the hippocampus for at least a considerable period. This raises the issue of the possible gradient of retrograde amnesia following hippocampal damage, and of whether information originally hippocampus-dependent for acquisition gradually becomes ‘consolidated’ in the neocortex and thereby becomes independent of the hippocampus over time (McGaugh, 2000; Debiec, LeDoux and Nader, 2002; Squire, Genzel, Wixted and Morris, 2015). The issue of whether memories stored some time before hippocampal damage are less impaired than more recent memories, and whether the time course is minutes, hours, days, weeks or years is a debated issue (Gaffan, 1993; Squire, 1992; Squire et al., 2015; Barry and Maguire, 2019). (In humans, there is evidence for a gradient of retrograde amnesia; in rats and monkeys, hippocampal damage in many studies appears to impair previously learned hippocampal-type memories, suggesting that in these animals, at least with the rather limited numbers of different memories that need to be stored in the tasks used, the information remains in the hippocampus for long periods.) If there is a gradient of retrograde amnesia related to hippocampal damage, then this suggests that information may be retrieved from the hippocampus if it is needed, allowing the possibility of incorporating the retrieved information into neocortical memory stores. If on the other hand there is no gradient of retrograde amnesia related to hippocampal damage, but old as well as recent memories of the hippocampal type are stored in the hippocampus, and lost if it is damaged, then again this implies the necessity of a mechanism to retrieve information stored in the hippocampus, and to use this retrieved information to affect neural circuits elsewhere (for if this were not the case, information stored in the hippocampus could never be used for anything). The current perspective is thus that whichever view of the gradient of retrograde amnesia is correct, information stored in the hippocampus will need to be retrieved and affect other parts of the brain in order to be used, and the current theory shows how the recall could be implemented.

The other major set of outputs from the hippocampus projects via the subiculum and fimbria/fornix system to the anterior nucleus of the thalamus (both directly and via the mammillary bodies), which in turn projects to the cingulate cortex (Bubb, Kinnavane and Aggleton, 2017). The mammillary bodies do provide a route for vestibular information to enter the hippocampal system. The posterior cingulate cortex and adjoining regions provides a pathway between some neocortical regions and the hippocampus, and, given that connectivity, are implicated in episodic memory (Section 12.3).

9.2.4 Systems-level neurophysiology of the primate including human hippocampus

9.2.4.1 Spatial view neurons

The systems-level neurophysiology of the hippocampus shows what information could be stored or processed by the hippocampus. To understand how the hippocampus works it is not sufficient to state just that it can store information – one needs to know what information.

Discoveries on the systems-level neurophysiology of the primate hippocampus are described next (Rolls and Xiang, 2006; Rolls and Wirth, 2018; Rolls, 2021f, 2023c) that provide a perspective relevant to understanding the function of the human hippocampus that is somewhat different from that provided by the properties of place cells in rodents, which have been reviewed elsewhere (McNaughton, Barnes and O'Keefe, 1983; O'Keefe, 1984; Muller, Kubie, Bostock, Taube and Quirk, 1991; Jeffery and Hayman, 2004; Jeffery, Anderson, Hayman and Chakraborty, 2004; Hartley, Lever, Burgess and O'Keefe, 2014; Howard and Eichenbaum, 2015; Knierim and Neunuebel, 2016) and compared with those in primates (Rolls and Wirth, 2018; Rolls, 2023d).

The primate hippocampus contains spatial cells that respond when the monkey looks at a certain part of space, for example at one quadrant of a video monitor while the monkey is performing an object–place memory task in which he must remember where on the monitor he has seen particular images (Rolls, Miyashita, Cahusac, Kesner, Niki, Feigenbaum and Bach, 1989c). Approximately 9% of the hippocampal neurons have such spatial view fields, and about 2.4% combine information about the position in space with information about the object that is in that position in space (Rolls et al., 1989c). The latter point shows that information from very different parts of the cerebral cortex (medial parahippocampal gyrus and parietal cortex for spatial information, and inferior temporal cortex for visual information about objects) is brought together onto single neurons in the primate hippocampus.

Spatial view cells are allocentric

The reference frames of spatial representations are important to define, in order to understand functions. An egocentric frame of reference (relative to the body or head) is useful for actions made in nearby space. An allocentric frame of reference (i.e. world-based coordinates) is useful for remembering the location of objects and rewards in the world, independently of where one is located or one's body or head orientation. Feigenbaum and Rolls (1991) analyzed whether the spatial view neurons utilize allocentric or egocentric spatial coordinates. They moved the video screen and the macaque relative to each other, and to different places in the room. 46% of the spatial view neurons had firing that occurred in the same position on the display, or in the laboratory, when the macaque was rotated or moved to a different place in the room. Thus these hippocampal cells had spatial representations in allocentric (i.e. world-based) and not in egocentric (relative to the body or head) coordinates (Feigenbaum and Rolls, 1991). 10% of the spatial neurons had firing that stayed in the same place relative to the monkey's body/head axis when the video monitor was displaced, or the macaque was rotated, or was displaced to a different place in the room. Thus 10% of the neurons represented space in egocentric coordinates, that is, relative to the head.

Spatial view cells and place cells in the primate hippocampus

In rats, place cells are found, which respond depending on the place where the rat is in a spatial environment (McNaughton, Barnes and O'Keefe, 1983; O'Keefe, 1984; Muller, Kubie, Bostock, Taube and Quirk, 1991). To analyze whether such cells might be present in the primate hippocampus, Rolls and O'Mara (1993) and Rolls and O'Mara (1995) recorded the responses of hippocampal cells when macaques were moved in a small chair or robot on wheels in a cue-controlled testing environment. The most common type of cell responded to the part of space at which the monkeys were looking, independently of the place where the monkey was. These were termed 'view' neurons, and in some cases it could be shown that the responses moved if the wall cues were moved (Rolls and O'Mara, 1995). As far as I know, nothing like this has been performed in humans. Some testing of this type, with several places from each of which the same parts of a scene are visible, might be practicable in humans, and would be of great interest for understanding human hippocampal function. We

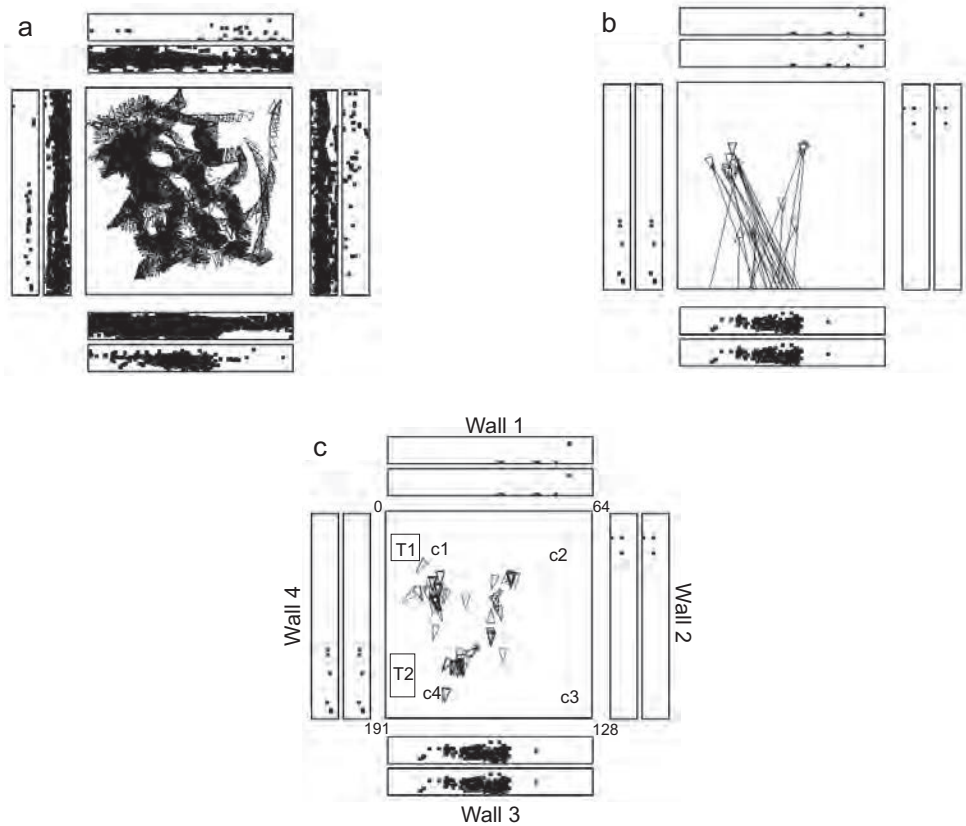

Fig. 9.3 Examples of the firing of a hippocampal spatial view cell when the monkey was walking around the laboratory and looking at the walls of the rich laboratory environment shown in Fig. 9.4. (a) The location in the rich environment at which the cell fired is indicated by the spots in the outer set of 4 rectangles in the Figure, each of which represents one of the walls of the room. There is one spot on the outer rectangle for each action potential. The base of the wall is towards the centre of each rectangle. The positions on the walls fixated during the recording sessions are indicated by points in the inner set of 4 rectangles, each of which also represents a wall of the room. The central square is a plan view of the room, with a triangle printed every 250 ms to indicate the position of the monkey, thus showing that many different places were visited during the recording sessions. (b) A similar representation of the same 3 recording sessions as in (a), but modified to indicate some of the range of monkey positions and horizontal gaze directions when the cell fired at more than 12 spikes/s. (c) A similar representation of the same 3 recording sessions as in (b), but modified to indicate more fully the range of places when the cell fired. The triangle indicates the current position of the monkey, and the line projected from it shows which part of the wall is being viewed at any one time while the monkey is walking. One spot is shown for each action potential. (After Georges-François, P., Rolls, E. T. and Robertson, R.G. (1999) Spatial view cells in the primate hippocampus: allocentric view not head direction or eye position or place. *Cerebral Cortex* 9: 197–212.)

also discovered that some other hippocampal neurons reflected place encoding, responding for example to the place where the macaque was located, to movement to a place, or to spatial view depending on the place where the monkey was located (Rolls and O'Mara, 1995). Primate hippocampal neurons that respond to place have also been described in virtual navigation tasks (Furuya, Matsumoto, Hori, Boas, Tran, Shimada, Ono and Nishijo, 2014; Wirth, Baraduc, Plante, Pinede and Duhamel, 2017).

Spatial view cells during active locomotion in the primate hippocampus and parahippocampal gyrus

Place cells fire best during active locomotion by the rat (Foster, Castro and McNaughton, 1989; Terrazas, Krause, Lipa, Gothard, Barnes and McNaughton, 2005). To investigate how primate hippocampal formation neurons fire during active locomotion, we recorded from sin-

gle hippocampal and parahippocampal neurons while monkeys moved themselves round by walking (or running) on all four legs in an open field test environment which was a 2.5m x 2.5m space within a large laboratory that provided a rich spatial environment including doors, windows, equipment, lab benches, etc (Fig. 9.4). The head could rotate in the horizontal plane, and where the monkey was looking in the horizontal and vertical planes as well as where he was facing was measured. We discovered in these investigations **hippocampal spatial view neurons** that responded significantly differently for different allocentric spatial views and had information about spatial view in their firing rate, but conveyed little information about eye position, head direction, or place (Georges-François, Rolls and Robertson, 1999; Robertson, Rolls and Georges-François, 1998; Rolls, Robertson and Georges-François, 1997a; Rolls, Treves, Robertson, Georges-François and Panzeri, 1998b; Rolls, 2023c). An example of such a hippocampal spatial view cell present in the primate hippocampus is shown in Fig. 9.3. The neuron fired primarily while the macaque looked at a part of Wall 3, as emphasized in Fig. 9.3b and c that show a spot on the representation in the Figure of the location on the wall where the monkey was looking when the firing rate was high. (It is emphasized that the monkey was viewing that location in the real rich laboratory environment, and that the spot in the Figure just shows where the monkey was looking in the real rich environment. Part of the rich real environment is illustrated in Fig. 9.6.) Fig. 9.3b illustrates the finding that the neuron responded while the monkey was looking from different places in the room at the spatial view field on Wall 3. The range of different places and head directions over which the neuron fired is illustrated in Fig. 9.3c. Analyses showed that this neuron responded to where the monkey was looking in space relatively independently of the place where the monkey was located, and of head direction and eye position. Moreover, the spatial view fields of the neuron were similar when the monkey was actively walking, and also when he was stationary but actively exploring with eye movements different parts of the spatial environment (Georges-François, Rolls and Robertson, 1999).

Spatial view cells are selective for spatial view much more than for place or head direction or eye position

The firing of a different hippocampal cell is provided in Fig. 9.4, to show with a different type of analysis, how the firing is related primarily to spatial view, rather than to place, or to head direction, or to eye position, or indeed just to the location towards which the monkey was facing (Georges-François, Rolls and Robertson, 1999). The highest firing of the cell, with the macaque at the place and with the head direction shown in Fig. 9.4a, occurred when the macaque looked 10° left. With the monkey in another place and with a different head direction, the highest firing was when the macaque was looking 30° right, but at the same spatial view (Fig. 9.4b). Fig. 9.4c shows the firing with the macaque at a different place (but the same head direction as in Fig. 9.4b), and the firing was now when the monkey looked approximately 30° left. The spatial view field was in the same location on Wall 1 as in Figs. 9.4a and b. Examples of video animations to illustrate the firing of macaque hippocampal spatial view neurons are provided with the Supplementary Material of Rolls and Wirth (2018) and Rolls (2023c) and are available at <https://www.oxcns.org/publications>.

These experiments show that it is the spatial view towards which the monkey looks that determines the neuronal responses, and not a particular place where the monkey was located, or head direction, or eye position, and this was confirmed with analyses of variance (Georges-François et al., 1999) and information theoretic analyses (Rolls, Treves, Robertson, Georges-François and Panzeri, 1998b). It was found that on average the spatial view cells encoded considerably more information about spatial view (0.47 bits) than about eye position (0.017 bits), head direction (0.005 bits), or place in the room (0.033 bits) (Georges-François

Hippocampal spatial view cells respond to a spatial view independently of place, head direction, and eye position

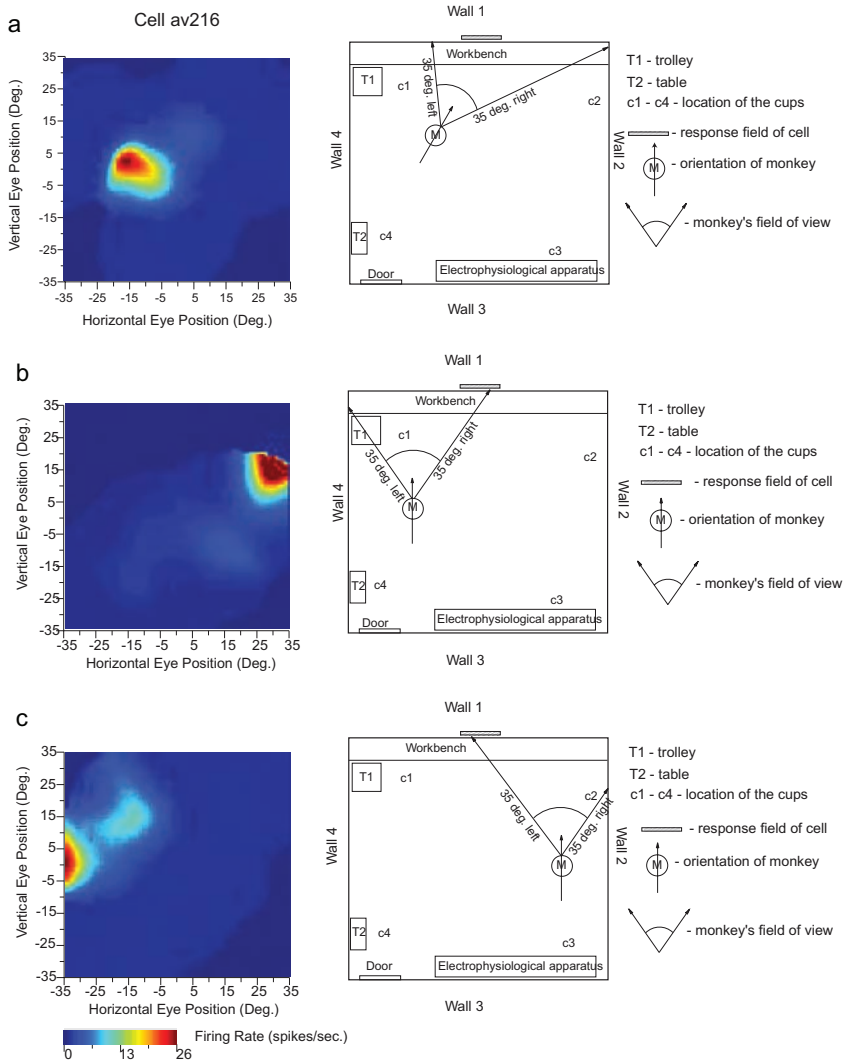

Fig. 9.4 Testing of a hippocampal spatial view neuron (av216) to show that it has allocentric encoding of a spatial view, and that the response does not depend on the place where the monkey is located, or on the allocentric bearing to the effective location in a scene, or on particular eye positions. The firing rate is shown as a function of the horizontal and vertical eye position, where positive values indicate right or up. The neuron responded when the monkey looked towards its view field (indicated with a hatched bar) relatively independently of place, eye position, or head direction. ANOVAs and information theory analyses performed on the same data cast in different ways confirmed this: for spatial view, the ANOVA was $p < 0.001$ with 0.217 bits in a 500 ms period for the average Shannon mutual information; for place $p = 0.9$ with 0.001 bits; for head direction $p = 0.5$ with 0.0 bits; and for eye position $p = 0.8$ with 0.006 bits. (Modified from Georges-François, P., Rolls, E. T. and Robertson, R.G. (1999) Spatial view cells in the primate hippocampus: allocentric view not head direction or eye position or place. *Cerebral Cortex* 9: 197–212. Note: Colored firing rate plots for the whole series of spatial view cell papers are provided in the .pdfs at <https://www.oxcns.org>.)

et al., 1999; Rolls et al., 1998b). This shows that the encoding by these primate hippocampal neurons may reflect some information about place etc but is primarily about spatial view.

Another example of a spatial view cell is shown in Fig. 9.5, for cell av083. In this case different vertical angles were investigated. In Fig. 9.5a it is shown that with the head horizontal the neuron responded when the eyes were elevated 15–30°. When the horizontal plane of

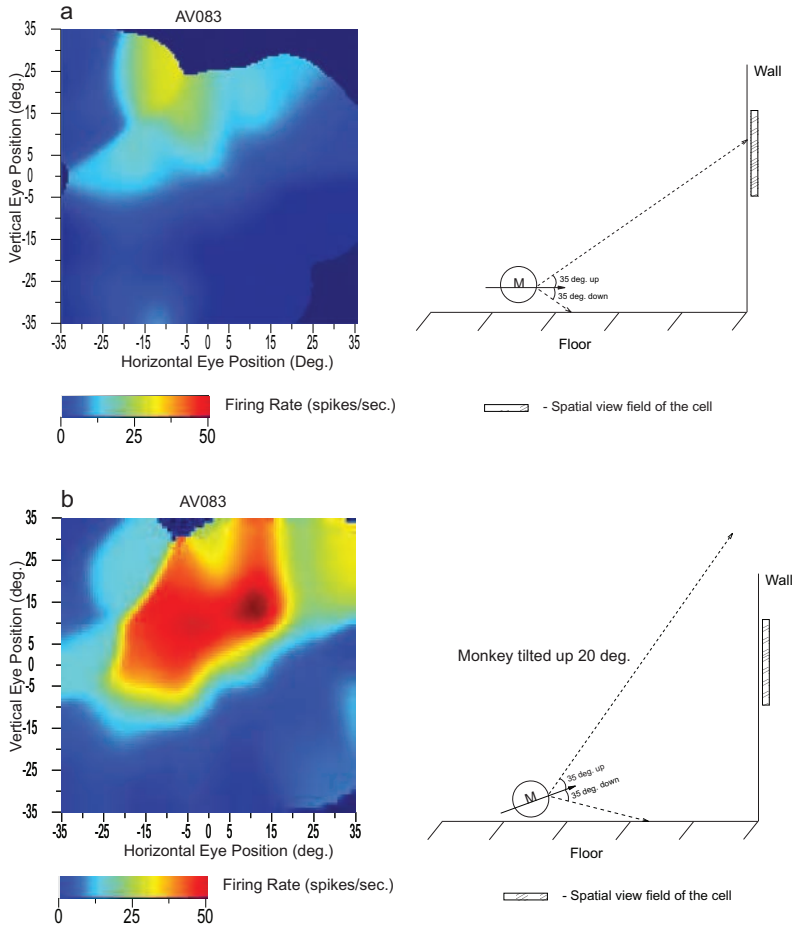

Fig. 9.5 Testing of another hippocampal spatial view neuron (av083) to show that it has allocentric encoding of a spatial view, in this case demonstrated in the vertical plane. The firing rate is shown as a function of the horizontal and vertical eye position, where positive values indicate right or up. The neuron responded when the monkey looked towards its view field (indicated with a hatched bar), independently of the egocentric angle of the spatial view field in the vertical plane. In (a) the head was in the horizontal plane, and some firing occurred when the monkey looked up very high. In (b) the monkey was tilted up 20°, and the neuron fired when the monkey looked up only a few degrees, and most of the spatial view field can be seen (if the eyes are moved to look at the correct allocentric position on the wall). This was confirmed in one-way ANOVAs, in which the several hundred firing rate and eye position data pairs used to construct (a,b) were sorted according to different hypotheses. When the data were sorted according to where the monkey was looking on the wall, the one-way ANOVA was significant at $P < 0.0001$, and the cell provided an average information (about spatial view) of 0.30 bits in a 500 ms epoch. When the same data were sorted according to eye position, the one-way ANOVA was not significant ($P \approx 0.09$), and the cell provided an average information (about eye position) of 0.03 bits in a 500 ms epoch. This analysis leads to the conclusion that the cell responded significantly differently for different allocentric spatial views and had information about spatial view in its firing rate, but did not respond differently just on the basis of eye position. The fact that the cell had different firings even though the monkey was in the same place indicates that the cell was not responding just on the basis of place. (Modified from Georges-François, P., Rolls, E. T. and Robertson, R.G. (1999) Spatial view cells in the primate hippocampus: allocentric view not head direction or eye position or place. *Cerebral Cortex* 9: 197–212. Note: Colored firing rate plots for the whole series of spatial view cell papers are provided in the .pdfs at <https://www.oxcns.org>.)

the monkey’s head was tilted up, the neuron responded when the eyes were less elevated, corresponding to the same allocentric position on the wall (Fig. 9.5b). Further data for the same cell are provided by Georges-François, Rolls and Robertson (1999). The analysis described for Fig. 9.5 shows that this spatial view cell codes for allocentric spatial view, in the vertical

Fig. 9.6 A hippocampal spatial view cell that responded to the spatial view of a trolley in the testing environment, including in this case when the macaque was very close to the place of the trolley. Left: the field of view of the macaque. Right: the firing Rate in spikes per second shown in color of the hippocampal spatial view neuron as a function of the horizontal and vertical eye position. (Modified from Rolls, E. T. (1996b) *The representation of space in the primate hippocampus, and its relation to memory*. Pp. 203–227 in: *Brain Processes and Memory*, eds. K.Ishikawa, J.L.McGaugh and H.Sakata. Elsevier: Amsterdam.)

plane, and not for eye position or position relative to the head or just where the monkey was facing.

The same types of investigation (Georges-François, Rolls and Robertson, 1999; Rolls, Robertson and Georges-François, 1997a; Robertson, Rolls and Georges-François, 1998; Rolls, Treves, Robertson, Georges-François and Panzeri, 1998b; Rolls, Xiang and Franco, 2005; Rolls and Xiang, 2005; Rolls and O’Mara, 1995; Feigenbaum and Rolls, 1991; Rolls, Miyashita, Cahusac, Kesner, Niki, Feigenbaum and Bach, 1989c; Rolls, 2023c) show that these primate hippocampal spatial view cells do not fire in relation to ‘facing direction’ (Mao, Avila, Caziot, Laurens, Dickman and Angelaki, 2021; Zhu, Lakshminarasimhan and Angelaki, 2023), though care is needed to show this because primates typically face and look at the location towards which they are navigating (Rolls, 2023d).

For humans there is now some evidence for medial temporal lobe neurons with properties like those of spatial view cells (Ekstrom, Kahana, Caplan, Fields, Isham, Newman and Fried, 2003; Miller, Neufang, Solway, Brandt, Trippel, Mader, Hefft, Merkow, Polyn, Jacobs, Kahana and Schulze-Bonhage, 2013; Tsitsiklis, Miller, Qasim, Inman, Gross, Willie, Smith, Sheth, Schevon, Sperling, Sharan, Stein and Jacobs, 2020; Donoghue, Cao, Han, Holman, Brandmeir, Wang and Jacobs, 2023), even though eye position has not usually been measured. For example, in the study by Ekstrom et al. (2003), some cells were found to represent views of landmarks. In a study of human medial temporal lobe neurons (in patients undergoing neurosurgery), it was found that in a virtual reality Treasure Hunt game, some neurons respond to the sight of remote locations rather than the subject’s own place (Tsitsiklis et al., 2020; Donoghue et al., 2023) (see Rolls (2023d)). Just like macaque spatial view cells, these neurons in humans respond when the spatial location is seen with different bearings (so they are not allocentric bearing to a landmark neurons, but spatial view neurons, see Section 9.3.15.2) (Donoghue et al., 2023). The locations in the human Treasure Hunt game were in at least some cases within the spatial environment. In the macaque testing, hippocampal spatial view neurons could respond when the macaque was distant from an effective part of the rich 3D environment of a large open laboratory, but also when the macaque was close to the effective part of the environment, as shown for a hippocampal neuron that responded to the part of the environment where there was a trolley, as illustrated in Fig. 9.6 (from Rolls (1996b)). The rich open laboratory testing environment is made evident in Figs. 9.4, 9.6, and 9.7. This is thus somewhat comparable to the way in which the human visual ‘spatial target’ neurons responded (Tsitsiklis et al., 2020; Donoghue et al., 2023).

The results described by Tsitsiklis, Miller, Qasim, Inman, Gross, Willie, Smith, Sheth, Schevon, Sperling, Sharan, Stein and Jacobs (2020) and Donoghue, Cao, Han, Holman, Brandmeir, Wang and Jacobs (2023) thus appear to confirm the presence of spatial view cells in humans, following their discovery in macaques (Georges-François, Rolls and Robertson, 1999; Rolls, Robertson and Georges-François, 1997a; Robertson, Rolls and Georges-François, 1998; Rolls, Treves, Robertson, Georges-François and Panzeri, 1998b; Rolls, Xiang and Franco, 2005c; Rolls and Xiang, 2005; Rolls and O'Mara, 1995; Feigenbaum and Rolls, 1991; Rolls, Miyashita, Cahusac, Kesner, Niki, Feigenbaum and Bach, 1989c; Rolls, 2023c). However, much work remains to be done on these neurons in humans, including testing whether these neurons signal the location of a reward or goal in space (Rolls and Xiang, 2005), routinely measuring eye position during the recordings, and measuring whether like spatial view cells in macaques they show idiothetic update, which is described below (Robertson et al., 1998).

Further evidence is that in humans some medial temporal lobe neurons reflect the learning of paired associations between views of places, and people or objects (Ison, Quian Quiroga and Fried, 2015; Rutishauser, Reddy, Mormann and Sarnthein, 2021) (just as in macaques (Rolls and Xiang, 2006)), and this shows that views of scenes are important for human hippocampal function. Consistent with these investigations, human functional neuroimaging studies do show hippocampal activation when scenes or parts of scenes are viewed, even when the human is fixed in one place for neuroimaging (Burgess, 2008; Zeidman and Maguire, 2016; Maguire, 2014; Chadwick et al., 2013, 2010; Hassabis et al., 2009; Brown et al., 2016; Epstein and Kanwisher, 1998; O'Keefe et al., 1998; Epstein and Baker, 2019). More evidence is that neurons in the human hippocampus respond differently to different types of scene (landscapes vs buildings), including in a scene-to-object recall association task in which the recall of the object representation in the entorhinal cortex is evident in the neuronal activity (Staresina, Reber, Niediek, Bostrom, Elger and Mormann, 2019). Some human hippocampal neurons also maintain their activity in a working memory task (Rutishauser et al., 2021).

Primate spatial view neurons are found not only in the hippocampus, but also in the parahippocampal gyrus (Georges-François, Rolls and Robertson, 1999; Robertson, Rolls and Georges-François, 1998; Rolls, Robertson and Georges-François, 1997a; Rolls, Treves, Robertson, Georges-François and Panzeri, 1998b). Consistently, in humans, neurons have been recorded in the parahippocampal gyrus that respond preferentially to viewed spatial scenes (Mormann, Kornblith, Cerf, Ison, Kraskov, Tran, Knieling, Quian Quiroga, Koch and Fried, 2017), though it was not possible to analyze whether the neurons respond preferentially to a part of a scene, which is an important property of spatial view neurons. But these observations do confirm that neurons in the parahippocampal gyrus do respond to viewed locations 'out there', rather than the place where the human is located, as shown also by Ekstrom et al. (2003). In human fMRI studies, the parahippocampal place (or scene) area is activated by spatial scenes (Epstein and Baker, 2019).

It is essential to measure the firing rate of a primate hippocampal cell with different head directions so that different spatial views can be compared, as testing with just one head direction (Matsumura et al., 1999) cannot provide evidence that will distinguish a place cell from a spatial view cell. These points will need to be borne in mind in future studies of hippocampal neuronal activity in primates including humans (Ekstrom et al., 2003; Fried et al., 1997; Kreiman et al., 2000; Tsitsiklis et al., 2020), and simultaneous recording of head position, head direction, and eye position, as described by Rolls and colleagues (Georges-François, Rolls and Robertson, 1999; Robertson, Rolls and Georges-François, 1998; Rolls, Robertson and Georges-François, 1997a; Rolls, Treves, Robertson, Georges-François and Panzeri, 1998b) will be needed. To distinguish spatial view from place cells it will be important to test neurons while the primate or human is in one place with all the different rich spatial views

visible from that place; and also to test the same neuron when the organism is in a different place, but at least some of the same spatial views are visible, as has been done in our primate single neuron recording (Georges-François, Rolls and Robertson, 1999; Robertson, Rolls and Georges-François, 1998; Rolls, Robertson and Georges-François, 1997a; Rolls, Treves, Robertson, Georges-François and Panzeri, 1998b; Rolls and Xiang, 2006). This type of factorial design is essential if any statement is presented about whether hippocampal neurons respond to spatial view, or place, or a combination of these (Rolls, 2023c,d).

It has been noted (Rolls, 2023d) that neurons that respond to combinations of the location being viewed and the place where the individual is located in what have been described as ‘mixed representations’ (Wirth et al., 2017; Tan et al., 2021; Wirth, 2023) might arise if training is incomplete, and not all views of a location have been seen from all places. If particular views are seen from only certain places, then hippocampal and related neurons would learn to respond to those views only from those places. Indeed, the evidence that hippocampal neurons learn to respond to particular combinations of the inputs that are present at the same time is likely to be key to understanding hippocampal function for this is ideally suited to episodic memory (Rolls, 2023c,d). Thus we cannot place weight on ‘mixed representations’ (for example of spatial view from only some places (Wirth et al., 2017; Wirth, 2023)) unless the training has allowed the set of spatial views analysed to be from all the places in the analysis with equal training or experience of all views from all places in the analysis (Rolls, 2023c,d).

Useful confirmation has also recently been obtained that relatively many macaque hippocampal neurons respond to the location “out there” in space (22% of neurons), compared to only 5% of hippocampal neurons that encode the place where the macaque is located (Mao, Avila, Caziot, Laurens, Dickman and Angelaki, 2021; Zhu, Lakshminarasimhan and Angelaki, 2023). Some neurons were classified as spatial view cells and others as ‘facing location’ cells, but the environment being viewed was simple (a cylindrical arena with a drain on the floor and two touchscreens with food on the walls), and more spatial view cells are likely to be found in a rich spatial environment such as the open lab that we used (Georges-François et al., 1999; Robertson et al., 1998; Rolls et al., 1997a, 1998b; Rolls and Xiang, 2006; Rolls et al., 2005c). Indeed the reason that we moved to a rich open lab visual environment was that we expected to find, and did find, more spatial view cells than in a relatively simple spatial environment with only 4 cues in the testing arena (Rolls and O’Mara, 1995). Some of the cells were described as responding to ‘facing direction’ (Mao et al., 2021; Zhu et al., 2023), but tests of the type illustrated in Figs. 9.3–9.6 were not reported to clearly dissociate spatial view from facing direction (Rolls, 2023d). In fact, spatial view cells in our testing environments were found to respond to where the macaque was looking in space, and not to the location towards which the individual was facing, by testing these specific hypotheses as illustrated in Figs. 9.4 and 9.5 (Georges-François, Rolls and Robertson, 1999; Rolls, Robertson and Georges-François, 1997a; Rolls and O’Mara, 1995). Further evidence is that in the dark, spatial view cells respond to a remembered spatial view location only when that location is being looked at, with facing location held constant, as illustrated in Fig. 9.7 (Robertson, Rolls and Georges-François, 1998).

In terms of brain computations, it of course makes sense for spatial view cells to respond to viewed locations in a natural scene that has many useful and clear landmarks, even if an individual is not facing those locations but is looking at them, because that information is useful, in the theory of the hippocampus presented here, for remembering where objects or individuals have been seen before in the environment (as described in this Chapter); and for navigation using landmarks as described in Section 9.3.15 (Rolls, 2021f, 2023d). Cells that respond to ‘facing direction’ (Mao et al., 2021; Zhu et al., 2023) would have little utility for memory and navigation, because primates including humans can search scenes with the eyes and need not face towards a particular location in order to find the location in space (Rolls,

2023d). Spatial view cells are in this sense invariant with respect to facing direction (Rolls, 2023d).

Spatial visual responses during navigation in a virtual environment

To test the nature of hippocampal cell activity in a context requiring that macaques compute a trajectory and move to a goal (at which a hidden reward was given) using visual landmarks, Wirth, Baraduc, Plante, Pinede and Duhamel (2017) measured hippocampal neuronal activity in a virtual environment - a star maze - in which animals navigated using a joystick. The test situation simulated a large environment (radius of 16 meters) and was presented on a large screen that covered 70 percent of the field of view in stereo to provide depth. The virtual environment created a perception of self-motion. The maze had 5 visual landmarks on the walls, and could be used to locate the position of a hidden reward located between two of the landmarks. It was found that 28% (53/189) of hippocampal cells fired when the animals looked at one or sometimes more than one of the visual landmarks, and thus had responses to a viewed location ‘out there’ in space. Of these view neurons, the responses of 83% were modulated by the position of the animal in the virtual reality environment. This is illustrated by the fact that the majority of cells responded to a landmark when it was viewed from one position only. In addition, 17% of the total population responded when the macaque was in one or more places in the virtual environment without significant modulation by where the animal was looking. Some hippocampal neurons also responded to body turns made during the navigation, and are likely to be whole body motion neurons, some of which respond to optic flow signals of head rotation (O’Mara, Rolls, Berthoz and Kesner (1994) and Section 9.2.4.2) which is the likely input signal given that there is no input from the vestibular system during virtual navigation.

The finding that many of the neurons that responded to the sight of landmarks did so mainly from certain places might have been because the navigational task constrained the individual to stay within the star maze, so that looking at some landmarks from some places, and with a particular view of the star maze in the foreground, might have not provided the opportunity for the landmarks to be seen in the same way from all places (Wirth et al., 2017; Rolls, 2023d), in contrast to the testing in an open field used by Rolls and colleagues (Rolls et al., 1997a; Robertson et al., 1998; Rolls et al., 1998b; Georges-François et al., 1999). Effectively, it could be that in a maze, in which only certain combinations of spatial view, place, body turn etc can occur, neurons can learn to respond only to whatever conjunctions of sensory input actually occur (Rolls, 2023d). Instead, in the real world and in an open field, neurons may be much better able to learn spatial view representations that are invariant with respect to place because each spatial view can be seen from many different places (Rolls, 2023d). In rodents, something like this does happen in a hairpin maze in which the places, head directions and views are constrained by the maze (Derdikman, Whitlock, Tsao, Fyhn, Hafting, Moser and Moser, 2009). This prevents the formation of the usual 2D grid cells in the medial entorhinal cortex found in open field environments, and instead results in grid cells firing at only some parts of the hairpin track being followed, and probably representing the few combinations of place, head direction and view afforded by the hairpin maze (Derdikman et al., 2009). Another and interesting possibility is that some of the macaque neurons (Wirth et al., 2017) only responded to a landmark when it was at a particular bearing, which is how an ‘allocentric bearing to a landmark’ cell would respond (see Section 9.3.15.2). Another possibility is that testing in the star maze emphasized looking at certain landmarks from certain places, as this is important for the navigation task (Wirth et al., 2017), so the type of combination representation just described of view, place, and head direction may have been formed because that was the sensory input provided in the star maze (Rolls, 2023d) (see Section 9.3.15).

If in the virtual reality navigation task the spatial topology of the star maze was retained, and the goal was retained, but new room cues were introduced, the macaque hippocampal neurons rapidly adapted to the five new room cues which replaced the previously learned room cues (Baraduc, Duhamel and Wirth, 2019). With the new environment, the ‘chart’ (or ‘map’) of the environment (Battaglia and Treves, 1998b) may be similar, because of the cues provided by the star maze and by the goal, and the new room cues may be associated onto the same chart (Rolls, 2023d). This parsimonious interpretation is consistent with the concept that remapping of hippocampal neurons in rodents (Schlesiger, Boubilil, Hales, Leutgeb and Leutgeb, 2018) occurs mainly when the spatial topology of the test environment is changed, for then the continuous attractor network that forms the ‘map’ or ‘chart’ (Samsonovich and McNaughton, 1997; Battaglia and Treves, 1998b) breaks because the links of coactive firing of neurons due to the closeness of the locations to which they respond is no longer present (see Section B.5). It seems likely that the spatial topology of the environment and of possible trajectories through it, the chart or map (Battaglia and Treves, 1998b), defined by the star maze and the goal, remained unchanged when the room cues were substituted (Baraduc, Duhamel and Wirth, 2019), so that no remapping was needed. Remapping occurs when the topology of the space is altered, for example when the shape of the arena is changed (Leutgeb, Leutgeb, Barnes, Moser, McNaughton and Moser, 2005a; Leutgeb, Leutgeb, Moser and Moser, 2006; Leutgeb and Leutgeb, 2007).

Virtual reality testing environments may not allow adequate separation of the different contributions to the firing of primate including human hippocampal spatial representations such as spatial view, place, head direction, and eye position if only a subset of combinations of these are available, and of course do not provide for any normal idiothetic (self-motion) inputs, but have allowed hippocampal neurons with spatial view fields, even if frequently modulated by place in ‘mixed representations’ (Rolls, 2023d), to be confirmed (Wirth et al., 2017). Further confirmatory investigations relating to spatial view cells are now available (Rolls, 2023d; Yang et al., 2023; Zhu et al., 2023; Corrigan et al., 2023). With these new investigations, the evidence is now very substantial that spatial view cells are a key representation in the primate including human hippocampus, in contrast to the emphasis on place cells that are found in rodents (Rolls, 2023d). This is leading to a re-evaluation of how episodic memory and navigation are performed in primates including humans (Rolls, 2023d).

A very interesting finding in the virtual reality task was that some hippocampal neurons that responded to looking at the room cues could start their firing just before that part of the scene had appeared when the macaque performed a joystick movement to view a new part of the scene (Wirth et al., 2017). This is another example of the evidence for idiothetic update of hippocampal view-responsive neurons that was discovered by Robertson, Rolls and Georges-François (1998), which is described next. Interestingly, this type of memory-related information about scenes may also be reflected in the responses of neurons in parietal cortex region LIP, which can also respond with a memory-related response to what is expected to be present in a location to which a saccade is made, with the coordinates in (at least) craniotopic and not retinal coordinates (Semework, Steenrod and Goldberg, 2018).

Idiothetic (self-motion) update of spatial view cells

If the view details are obscured by curtains and darkness, then some spatial view neurons (especially those in CA1 and less those in CA3) continue to respond when the monkey looks towards the spatial view field (see example in Fig. 9.7). This experiment (Robertson, Rolls and Georges-François, 1998; Rolls, Robertson and Georges-François, 1997a) shows that primate hippocampal spatial view neurons can be updated for at least short periods by idiothetic (self-motion) cues including eye position and head direction signals, and do not necessarily require the view details to be seen (which is different from inferior temporal cor-

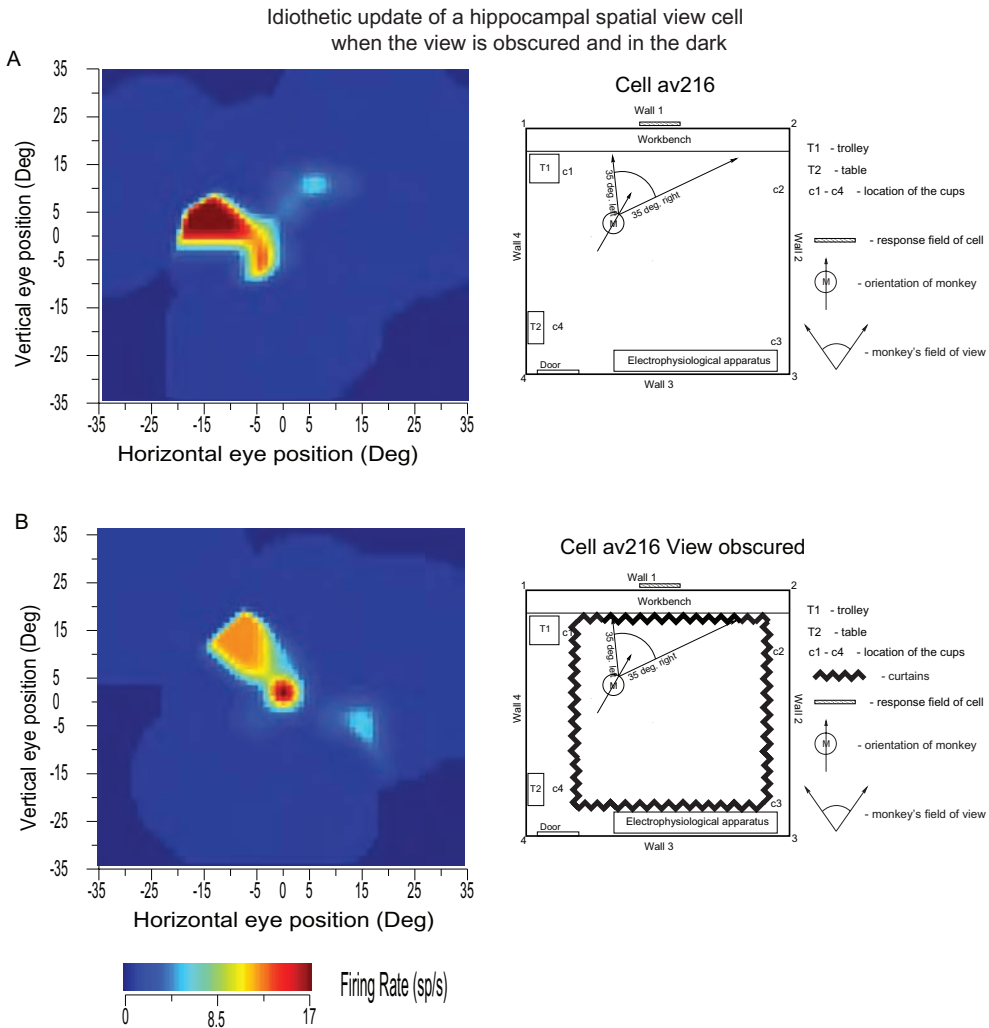

Fig. 9.7 Idiothetic update (by self-motion of the eyes) of the firing of a hippocampal spatial view cell. This cell fired when the macaque looked towards the effective spatial view even when the view was obscured with curtains. The firing is shown with the monkey stationary with his head facing in the direction indicated by the arrow when the curtains were drawn open (A) or were drawn closed (B). Left: firing rate of the cell in spikes/s is indicated by the color (a calibration bar in spikes/s is shown below) projected onto the monkey's field of view. The two-dimensional firing rate profile of the cell was smoothed for clarity using a 2-dimensional Gaussian spatial filter. The space adequately sampled by the eye movements of the monkey is indicated by light blue. The eye position in degrees is shown. Right: a plan view of the room to indicate the monkey's view of the wall is shown. M, position of the monkey. (After Robertson, R.G., Rolls, E. T. and Georges-François, P. (1998) Spatial view cells in the primate hippocampus: Effects of removal of view details. *Journal of Neurophysiology* 79: 1145-1156. © The American Physiological Society.)

tex object and face neurons). Consistent with this, a small drift is sometimes evident after a delay when the view details are obscured, consistent with inaccuracies in the temporal path integration of these signals, which is then corrected by showing the visual scene again.

This idiothetic update is likely to be important in navigation, especially in the dark, as described in Section 9.3.15, with some of the mechanisms for idiothetic update described in Section 3.4 (Rolls, 2021f).

Fig. 9.8 Whole body motion neuron in the macaque hippocampus. Activity of a neuron that increased its firing rate during backward linear translation, and decreased it during linear forward translation. The mean firing rate and its standard error are shown. These neurons responded to velocity, not just speed, in that their responses depended on the direction of motion (forward vs backward in this case; clockwise vs counterclockwise whole body motion for some other neurons, as well as on the speed of motion). Some could be activated if the view of the world was obscured so probably depended on vestibular input; others could be activated by optic flow without the body actually being moved. (Redrawn from O'Mara, S.M., Rolls, E.T., Berthoz, A. and Kesner, R.P. (1994) Neurons responding to whole-body motion in the primate hippocampus. *Journal of Neuroscience* 14: 6511-6523. © Society for Neuroscience.)

9.2.4.2 Whole body motion or speed neurons

Another type of neuron has been discovered in the primate hippocampus that responds to whole body motion (O'Mara, Rolls, Berthoz and Kesner, 1994), and these neurons could be involved in idiothetic update, and/or in memory, including for example body turns or distances travelled during navigation. Some of these neurons respond to linear motion (e.g. Fig. 9.8), and others to axial whole body rotation (both of which could be produced by sitting the macaque on a moving robot). Some of these neurons respond when the visual field is obscured, and thus respond on the basis of vestibular or proprioceptive inputs. Other neurons respond to rotation of the visual environment round the macaque, and thus encode motion by visual optic flow cues. Some neurons respond to both these types of input (O'Mara, Rolls, Berthoz and Kesner, 1994). The significance of these neurons is that they could be part of the way in which self-motion, i.e. idiothetic, cues are used to update the representation in the hippocampal formation of the current head direction, or the current position, and of the current spatial view, which is likely to be important in navigation, especially in the dark, as described in Section 9.3.15. These whole body motion neurons could also be useful in episodic memory, by encoding the movements that were taking place on a particular occasion.

This discovery of whole body motion cells in the macaque hippocampus (O'Mara, Rolls, Berthoz and Kesner, 1994) has been confirmed for the rat hippocampal system, in which 'speed cells' for linear motion have now been described in the medial entorhinal cortex (Kropff, Carmichael, Moser and Moser, 2015; Hinman, Brandon, Climer, Chapman and Haselmo, 2016). Experiments have now been performed in rodents to analyze whether 'speed cells' in fact respond to linear velocity as in macaques (in that some macaque whole body motion neurons code for motion direction, with the neuron illustrated in Fig. 9.8 responding to backwards linear motion; and others responding to forwards linear motion); whether there are direction-selective axial rotation cells as in macaques; and about the roles of vestibular, optic flow, or other inputs. Neurons were found that responded to angular or linear velocity in the rat medial entorhinal cortex, presubiculum, and parasubiculum (Spalla, Treves and Boccara, 2022), though the contributions of optic flow vs vestibular inputs were not investigated.

The inputs for whole body motion cells may reach the hippocampus via the mammillary body circuitry which receives inputs from the tegmental nuclei of Gudden (Dillingham et al., 2015; Cullen, 2019). This may provide one route for vestibular inputs, important of course in head direction representation, to reach the presubiculum, where head direction cells are found in primates (Robertson, Rolls, Georges-François and Panzeri, 1999) as well as in rodents (Wiener and Taube, 2005; Cullen and Taube, 2017). The mammillary bodies project to the anterior thalamic nuclei which in turn project to the cingulate and retrosplenial cortex, which in turn project into areas such as the subiculum, and thus can provide inputs to the hippocampal system (see Fig. 9.2 and Aggleton and Nelson (2015)).

The roles of whole body motion cells in navigation in humans and other primates are considered in Section 9.3.15 (Rolls, 2021f).

9.2.4.3 Spatial view grid cells in the primate entorhinal cortex

In the rodent entorhinal cortex, grid cells that represent places by hexagonal place grids and are involved in idiothetic update of place have been described (Moser, Rowland and Moser, 2015; Kropff and Treves, 2008). In macaques, a grid-cell like representation in the entorhinal cortex has been found, but the neurons have grid-like firing as the monkey moves the eyes across a spatial scene (Killian, Jutras and Buffalo, 2012; Rueckemann and Buffalo, 2017; Meister and Buffalo, 2018; Garcia and Buffalo, 2020). Similar competitive learning processes to those suggested for rodents (Rolls, Stringer and Elliot, 2006c) may transform these primate entorhinal cortex ‘spatial view grid cells’ into primate hippocampal spatial view cells, and may contribute to the idiothetic (eye movement-related) update of spatial view cells (Robertson, Rolls and Georges-François, 1998). The existence of spatial view grid cells in the entorhinal cortex of primates is predicted from the presence of spatial view cells in the primate CA3 and CA1 regions (Kesner and Rolls, 2015; Rueckemann and Buffalo, 2017). Moreover, some of these ‘spatial view grid cells’ have their responses aligned to the visual image (Meister and Buffalo, 2018), as predicted (Kesner and Rolls, 2015).

In the human entorhinal and cingulate cortex neurons with grid-like response properties are found (Jacobs, Weidemann, Miller, Solway, Burke, Wei, Suthana, Sperling, Sharan, Fried and Kahana, 2013; Nadasdy, Nguyen, Torok, Shen, Briggs, Modur and Buchanan, 2017), and there is neuroimaging evidence that is consistent with this (Nau, Navarro Schroder, Bellmund and Doeller, 2018b; Julian, Keinath, Frazzetta and Epstein, 2018). This is further evidence for the concept that representations of locations being viewed in space ‘out there’ is a key property of spatial representations in the hippocampal system of primates including humans.

9.2.4.4 Spatial view associated with object neurons in association memory

Primates have a highly developed ventral stream cortical visual system that utilises information from the fovea for object recognition, and a highly developed eye movement control system to bring the fovea to objects, using mechanisms described in Chapters 2 and 3 and elsewhere (Rolls, 2012d; Rolls and Webb, 2014). These developments enable primates to explore and remember information about what is present at locations seen ‘out there’ in the spatial environment without having to visit those places. Spatial view cells would accordingly be useful as part of a memory system by providing a representation of space that does not depend on where the primate is, and that could be associated with items such as objects or rewards in those viewed spatial locations. This could enable a monkey to remember where it had seen ripe fruit, or a human to remember where in a spatial scene he or she had seen a person. Primate hippocampal system spatial view neurons may therefore be important in forming memories of what has been seen and where it has been seen even on a single occasion, a key component of an episodic memory (Rolls, 2023c). Episodic memories of this type would be useful for spatial navigation or action in space.

Object AND Place-related activity

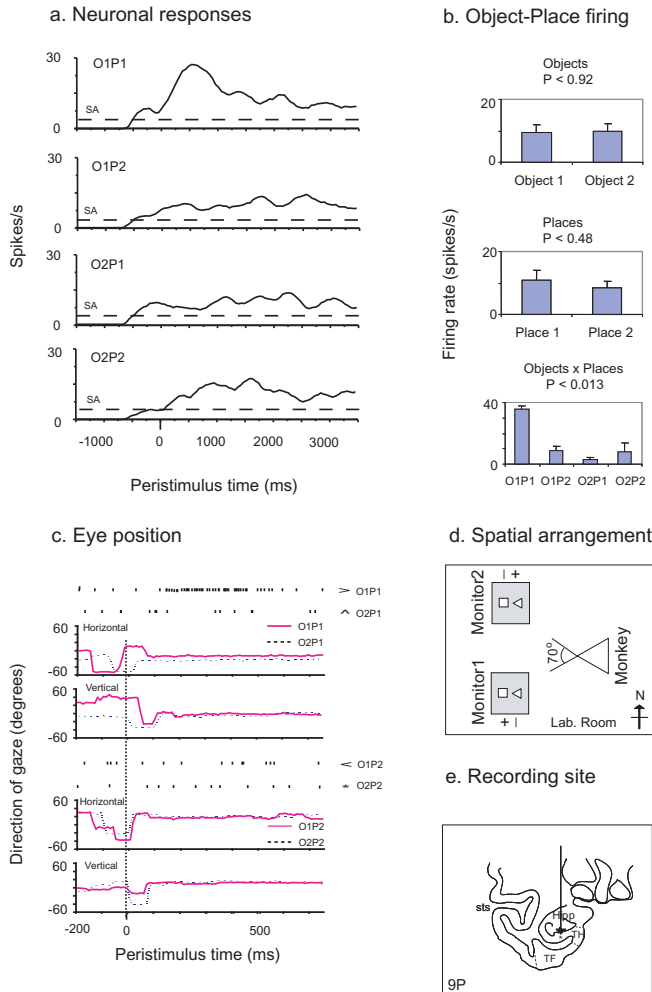

Fig. 9.9 Object–spatial view associations in the primate hippocampus. A hippocampal neuron (BL003c8a) with firing occurring to a particular combination of an object and place being viewed (Object 1–Place 1, O1P1). (a) Peristimulus time histograms showing the response of the neuron to each object–place combination. (b) The firing rate response of the neuron on different trials sorted according to the object that was shown on the trial, the place where the object was shown, and the combination of which object was shown with the place where it was shown. In the object*position bar histograms, O1P1 = Object 1 in Place 1, etc. The mean responses \pm sem are shown. (c) Trials to show the eye positions on 4 different trials. (d) Schematic diagram showing the spatial arrangement used in the Go–NoGo object–place combination task in this experiment. + indicates that a Go (lick) response to that object–place combination will be rewarded, and a minus that it will be punished. Only one object was shown on the screen at a time. The room was approximately 4 m x 4 m, and the distance of the monkey from the monitors was typically 1.5–2 m in the different experiments. The triangle labelled monkey shows the position of the monkey, and the angle shows the approximate angle subtended by the video display monitors. (e) The recording site of the neuron. Hipp–hippocampus; Prh–perirhinal cortex; rh–rhinal sulcus; sts–superior temporal sulcus; TE–inferior temporal visual cortex. 9P = 9 mm Posterior to the sphenoid reference. (After Rolls, E. T., Xiang, J.-Z. and Franco, L. (2005) Object, space and object-space representations in the primate hippocampus. *Journal of Neurophysiology* 94: 833–844. © The American Physiological Society.)

To investigate the fundamental question of whether object information, as well as spatial information, is provided in the primate hippocampus, single hippocampal neurons were recorded during an object–place memory task in which the monkeys had to learn associations between objects and where they were shown in an open laboratory (Rolls, Xiang and Franco, 2005c). Some neurons (10%) responded differently to different objects independently of lo-

cation; other neurons (13%) responded to the spatial view independently of which object was present at the location; and some neurons (12%) responded to a combination of a particular object and the place where it was shown in the room. An example of a neuron responding to a particular object–place combination is shown in Fig. 9.9. These results show that there are separate as well as combined, conjunctive, representations of objects and their locations in space in the primate hippocampus. This is a property required in an episodic memory system, for which association between objects and the places where they are seen, is prototypical. The results thus show that requirements for a human episodic memory system, separate and combined neuronal representations of objects and where they are seen “out there” in the environment, are present in the primate hippocampus (Rolls, Xiang and Franco, 2005c). These results have been confirmed in humans, in whom association learning between a spatial view and an object or person are reflected in the responses of medial temporal lobe neurons (Ison, Quian Quiroga and Fried, 2015) including hippocampal neurons (Staresina, Reber, Niediek, Bostrom, Elger and Mormann, 2019). When an object is recalled from a spatial scene, firing in the human entorhinal cortex, the route back to ventral stream visual cortical areas in humans (Rolls et al. (2023e), Section 9.2.8), is found to the recalled object (Staresina et al., 2019).

What may be a corresponding finding in rats is that some rat hippocampal neurons respond on the basis of the conjunction of location and odor (Wood et al., 1999). Results consistent with our object-place neurons in primates are that Diamond and colleagues have shown using the vibrissa somatosensory input for the ‘object’ system, that rat hippocampal neurons respond to object-place combinations, objects, or places, and there is even a reward-place association system in rats (Itskov et al., 2011) similar to that in primates. This brings the evidence from rats closely into line with the evidence from primates of hippocampal neurons useful for object-place episodic associative memory.

It has also been discovered that primate hippocampal neuronal activity is related to the recall of episodic memories. In a one-trial object–place recall task, images of an object in one position on a screen, and of a second object in a different position on the screen, were shown successively. Then one of the objects was shown at the top of the screen, and the monkey had to recall the position in which it had been shown earlier in the trial, and to touch that location (Rolls and Xiang, 2006). In addition to neurons that responded to the objects or places, a new type of neuronal response was found in which 5% of hippocampal neurons had spatial view-related responses when a spatial view was being recalled by an object cue, or vice versa (Rolls and Xiang, 2006; Kesner and Rolls, 2015) (see example in Fig. 9.10). This was like episodic memory, in that it was a one-trial object to spatial view location memory that was being learned and recalled. Consistent with this discovery, in humans, in an object-place recall task in virtual reality, some neurons during recall also reflect the recall of the location when the object recall cue is provided (Miller, Neufang, Solway, Brandt, Trippel, Mader, Hefft, Merkow, Polyn, Jacobs, Kahana and Schulze-Bonhage, 2013). In a complementary way, as noted above, when an object is recalled from a spatial scene, neuronal firing in the human hippocampus and entorhinal cortex is found that reflects the associative recall (Staresina, Reber, Niediek, Bostrom, Elger and Mormann, 2019).

9.2.4.5 Spatial view associated with reward neurons

The primate including human anterior hippocampus (which corresponds to the rodent ventral hippocampus) receives inputs from brain regions involved in reward processing such as the amygdala and orbitofrontal cortex (Carmichael and Price, 1995b; Suzuki and Amaral, 1994a; Pitkanen et al., 2002; Stefanacci et al., 1996; Rolls, 2015b; Rolls et al., 2022a, 2023c,b; Rolls, 2022b). To investigate how this affective input may be incorporated into primate hippocampal function, Rolls and Xiang (2005) recorded neuronal activity while macaques performed a

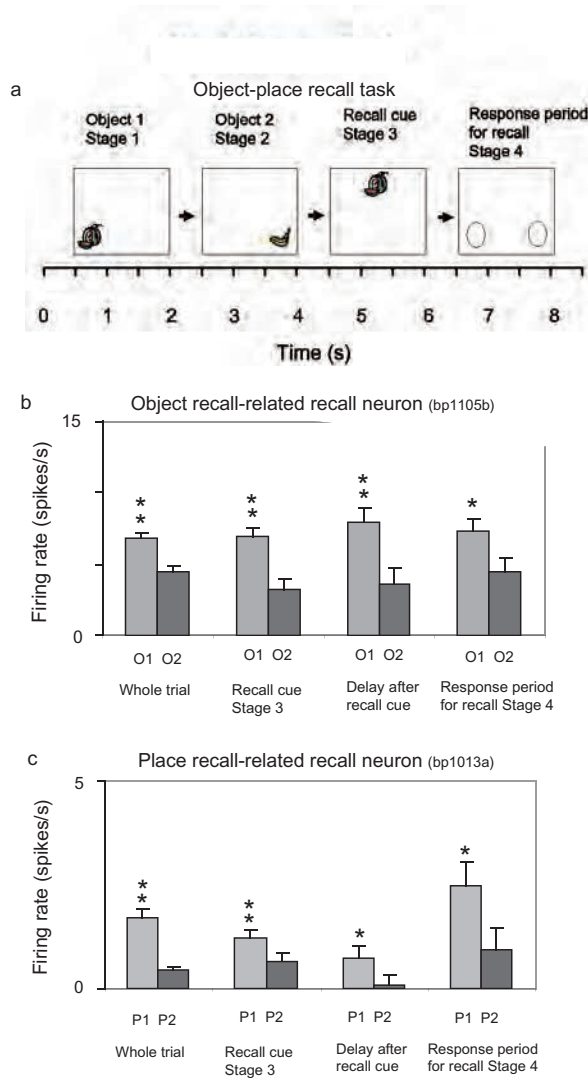

Fig. 9.10 Firing of hippocampal neurons in a one trial object-viewed location recall task. (a) In stage 1, object 1 was shown in a location on the screen being viewed, and in stage 2 object 2 was shown. In stage 3 one of the objects was shown at the top centre of the screen, and the monkey had to touch the location on the screen where that object had been shown in order to obtain a juice reward. (b) A neuron that was selective for object 1 (O1) responded even in stage 4 when the object was not visible but the object and its location had to be recalled. (c) A neuron that was selective for location 1 (P1) responded even in stage 4 when the object was not visible but the object and its location on the screen being viewed had to be recalled. The average firing rate in spikes/s across trials \pm sem is shown. ** $p < 0.01$; * $p < 0.05$. (Modified from Rolls, E. T. and Xiang, J-Z. (2006) Spatial view cells in the primate hippocampus, and memory recall. *Reviews in the Neurosciences* 17: 175-200.)

reward-place association task in which each spatial scene shown on a video monitor had one location which if touched yielded a preferred fruit juice reward, and a second location which yielded a less preferred juice reward. Each scene had different locations for the different rewards. Of 312 hippocampal neurons analyzed, 18% responded more to the location of the preferred reward in different scenes, and 5% to the location of the less preferred reward (Rolls and Xiang, 2005). An example of one of these neurons, responding to the place in each scene of a preferred reward, is shown in Fig. 9.11.

When the locations of the preferred rewards in the scenes were reversed, 60% of 44

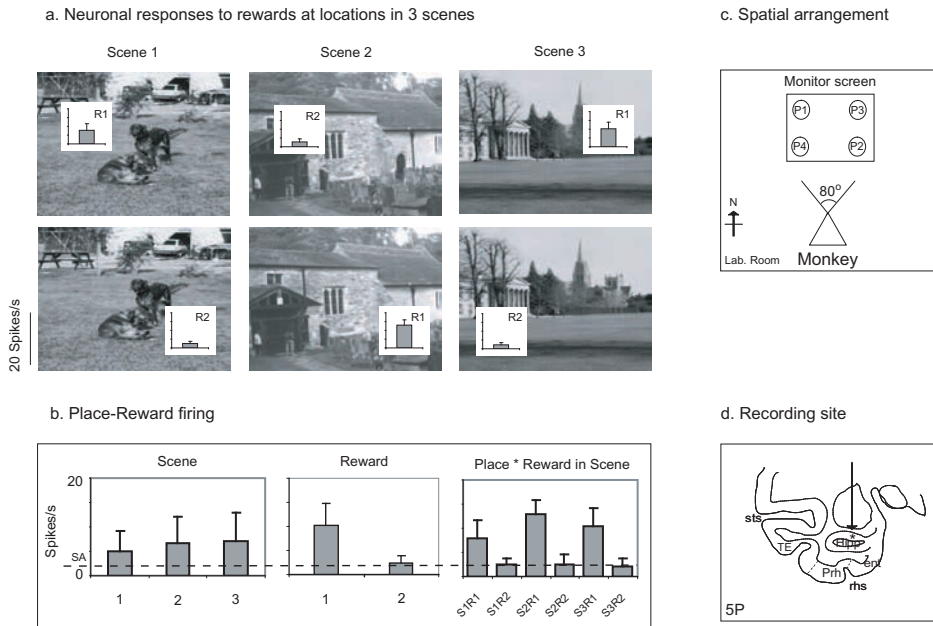

Fig. 9.11 Reward-spatial view associations in the primate hippocampus. A hippocampal neuron that encoded the particular rewards available at different locations in different scenes. On each trial the monkey could touch a circled location in the scene, and, depending on the location, received either a preferred juice reward or a less preferred reward. (a) Firing rate inserts to show the firing in 3 different scenes (S1–S3) of the locations associated with reward 1 (R1, preferred) and reward 2 (R2). The mean responses \pm sem are shown. SA, spontaneous firing rate. (b) The firing rates sorted by scene, by reward (1 vs 2), and by scene-reward combinations (e.g. scene 1 reward 1 = S1R1). (c) The spatial arrangement on the screen of the 4 spatial locations (P1–P4). (d) The recording site of the neuron. ent-entorhinal cortex; Hipp-hippocampal pyramidal cell field CA3/CA1 and dentate gyrus; Prh-perirhinal cortex; rhs-rhinal sulcus; sts-superior temporal sulcus; TE-inferior temporal visual cortex. (After Rolls, E. T., and Xiang, J.-Z. (2005) Reward-spatial view representations and learning in the primate hippocampus. *Journal of Neuroscience* 25: 6167–6174. © The Society for Neuroscience.)

neurons tested reversed the location to which they responded, showing that the reward-place associations could be altered by new learning in a few trials. The majority (82%) of these 44 hippocampal reward-place neurons tested did not respond to object-reward associations in a visual discrimination object-reward association task. Thus the primate hippocampus contains a representation of the reward associations of places “out there” being viewed, and this is a way in which affective information can be stored as part of an episodic memory, and how the current mood state may influence the retrieval of episodic memories (Rolls and Xiang, 2005). There is consistent evidence that rewards available in a spatial environment can influence the responsiveness of rodent place neurons (Tabuchi et al., 2003; Mizumori and Tryon, 2015).

In another type of task for which the primate hippocampus is needed, conditional spatial response learning, in which the monkeys had to learn which spatial response to make to different stimuli, that is, to acquire associations between visual stimuli and spatial responses, 14% of hippocampal neurons responded to particular combinations of visual stimuli and spatial responses (Miyashita, Rolls, Cahusac, Niki and Feigenbaum, 1989). The firing of these neurons could not be accounted for by the motor requirements of the task, nor wholly by the stimulus aspects of the task, as demonstrated by testing their firing in related visual discrimination tasks. These results showed that single hippocampal neurons respond to combinations of the visual stimuli and the spatial responses with which they must become associated in conditional response tasks, and are consistent with the computational theory described here according to which part of the mechanism of this learning involves associations between visual stimuli and spatial responses learned by single hippocampal neurons. In a following

study by Cahusac, Rolls, Miyashita and Niki (1993), it was found that during such conditional spatial response learning, 22% of this type of neuron analyzed in the hippocampus and parahippocampal gyrus altered their responses so that their activity, which was initially equal to the two new stimuli, became progressively differential to the two stimuli when the monkey learned to make different responses to the two stimuli (Cahusac, Rolls, Miyashita and Niki, 1993). These changes occurred for different neurons just before, at, or just after the time when the monkey learned the correct response to make to the stimuli, and are consistent with the hypothesis that when new associations between objects and places (in this case the places for responses) are learned, some hippocampal neurons learn to respond to the new associations that are required to solve the task. These discoveries were confirmed by Wirth, Yanike, Frank, Smith, Brown and Suzuki (2003).

This type of learning may well be relevant to navigation, in which behavioral responses such as a body turn may be needed when a particular visual stimulus identifying a place is seen (see Section 9.3.15).

9.2.5 Spatial view cells in primates including humans, and foveal vision

The discovery that many primate hippocampal neurons respond to the location being viewed ‘out there’, and not to the place where the individual is located (Rolls et al., 1989c; Feigenbaum and Rolls, 1991; Rolls and O’Mara, 1995; Rolls et al., 1997a; Robertson et al., 1998; Rolls et al., 1998b; Georges-François et al., 1999; Rolls et al., 2005c; Rolls and Xiang, 2005, 2006), is now confirmed by a number of other investigations (Wirth, Baraduc, Plante, Pinede and Duhamel, 2017; Corrigan, Gulli, Doucet, Borna, Abbass, Roussy, Rogelio and Martinez-Trujillo, 2023; Mao, Avila, Caziot, Laurens, Dickman and Angelaki, 2021; Zhu, Lakshminarasimhan and Angelaki, 2023; Yang, Chen and Naya, 2023; Tan, Ng, Owens, Libedinsky and Yen, 2021), with consistent findings in humans (Tsitsiklis, Miller, Qasim, Inman, Gross, Willie, Smith, Sheth, Schevon, Sperling, Sharan, Stein and Jacobs, 2020; Donoghue, Cao, Han, Holman, Brandmeir, Wang and Jacobs, 2023) (see Rolls (2023c), Rolls (2023d) and Rolls and Wirth (2023)). Further properties of primate hippocampal neurons are described by Rolls and Xiang (2006), Rolls and Wirth (2018), Rolls (2021f), Rolls (2023c), and papers in the Special Issue of *Hippocampus* (2023, issue 5) on View Representations cited by Rolls (2023d), and are fundamental to understanding what is computed in the primate including human hippocampal system.

The difference between a representation of an object and the representation of a spatial scene is considered in Section 2.8.14. That discussion is important for understanding the difference between object representations, and scene representations, and how spatial view cells are important in representing scenes. The idiothetic update of spatial view cells provides further evidence that they are involved in scene representations, for it shows that their representation is in a spatial reference frame.

The very interesting similarities and differences of these primate hippocampal spatial representations, which are influenced by the highly developed primate visual system, from the more place-related representations found in rodents, are considered by Rolls and Wirth (2018) and Rolls (2023d). Ways in which ventral visual stream processing of scenes (Epstein and Baker, 2019) may contribute to the formation of hippocampal spatial view cells are described in Sections 2.8.14 and 9.2.8 (Rolls, Tromans and Stringer, 2008f; Rolls, 2021f, 2023c; Rolls, Deco, Huang and Feng, 2023e; Rolls, 2023d). A key factor is the primate (including human) fovea, which provides for high spatial resolution at the fovea as described next (Rolls, 2023d).

To investigate the difference in what is analysed by the primate and rodent visual systems,

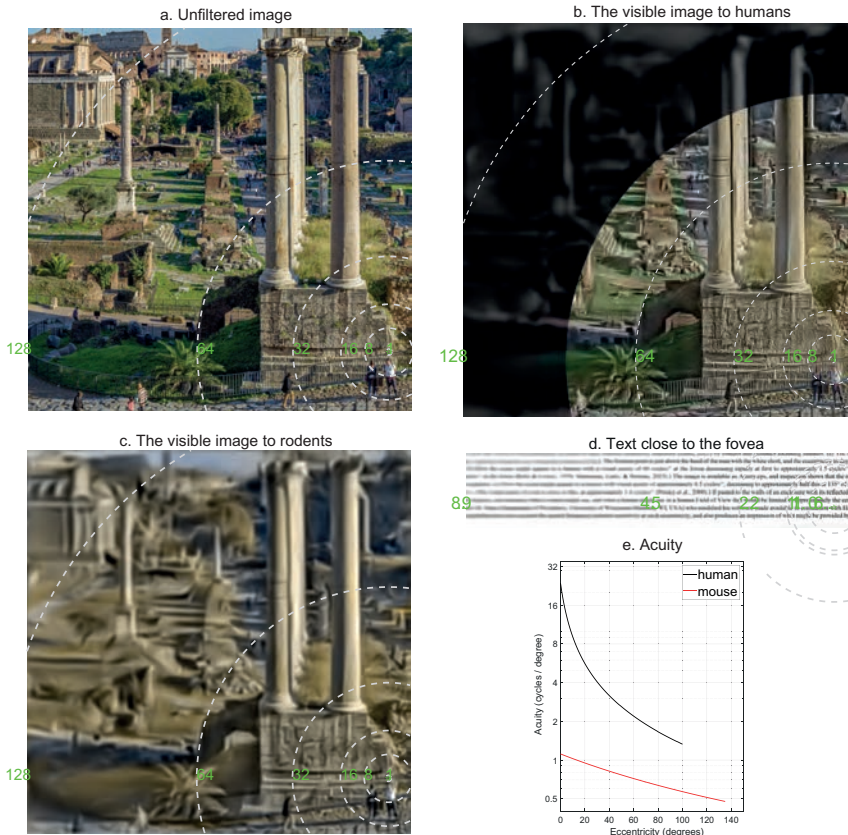

Fig. 9.12 Illustration of how the world is seen differently in terms of their contrast sensitivity functions (Haun, 2021) by rodents and primates including humans. (a) The unfiltered image which has 4096x4096 pixel resolution. The fixation point is just above the head of the man with the white shirt, and the eccentricity in degrees of different parts of the scene is indicated by the scale for the circles. (b) How the scene might appear to a human with a visual acuity of 60 cycles/° at the fovea decreasing rapidly at first to approximately 1.5 cycles/° at 90°. Note that in humans and other primates with forward facing eyes little can be seen beyond 90° of eccentricity from the fovea, which is indicated by the darker region in the figure. (A macaque has a visual acuity of approximately 54 cycles/° at the fovea (Rolls and Cowey, 1970; Srinivasan et al., 2015).) Inspection of the figure shows that the resolution of the filtered image at the fovea is sufficient for face recognition. (c) How the scene might appear to a mouse with visual acuity of approximately 0.5 cycles/°, decreasing to approximately half this at 135° of eccentricity (Prusky et al., 2000; van Beest et al., 2021). (The visual acuity of a rat is close to this, at approximately 1.6 cycles/° (Prusky et al., 2000).) If pasted to the walls of an enclosure with its reflected image too, the visual angle subtended would be approximately 256°, and indicates what a rodent might see, and what a human might see in a human Field of View that would be limited to approximately the central 180° (90° left and right.) (d) To emphasise how the visual acuity keeps increasing in primates close to the fovea, text is shown to be readable in only about the central 3° around the fovea (i.e. to a radius of 1.5°, with the region shown extending to 8.9°.) (e) Acuity for humans and mice. Collaboration with Professor Andrew M. Haun (Department of Psychiatry, University of Wisconsin-Madison, WI, USA) who modified his software made available in connection with Haun (2021) at <https://osf.io/8xf9w/> is warmly acknowledged. The algorithm takes into account the spatial frequency contrast sensitivity at each eccentricity, and also produces an impression of what might be provided by the rodent colour system. The filtered images in (b-d) show what exceeds the contrast sensitivity threshold at each eccentricity. (After Rolls, E. T. 2023 Hippocampal spatial view cells, place cells, and concept cells: view representations. Hippocampus doi: 10.1002/hipo.23536)

a scene was filtered with the contrast sensitivity function of humans and mice (Haun, 2021), with the results illustrated in Fig. 9.12. The following points can be made. First, the field of view of the rodent is large, approximately 270° (135° each way from the centre), whereas in humans and other primates with forward facing eyes little is visible beyond 90° from the fovea, with calibration circles provided at 64° and 128° in Fig. 9.12, and the invisible region for primates shown as dark in Fig. 9.12. Second, the spatial resolution for the whole of the field of view is poor in rodents, whereas humans have a very high resolution fovea (with

approximately 60 cycles/° for the acuity), which, as illustrated in Fig. 9.12b when expanded, is sufficient for face recognition and reading text. The implication for the rodent is that what is analysed by the rodent visual system might be sufficient to process a few, well spread out, visual landmarks to help form rodent place fields (or at least reset them) based on what is visible in the environment, as proposed by De Araujo, Rolls and Stringer (2001) (see Fig. 9.34). The implication for humans and other primates is that very high resolution is available close to the fovea that can enable great detail in a scene available over a relatively small visual angle to be used to associate particular objects or faces or rewards (which as illustrated in Fig. 9.12b might subtend 1° or less) with their location in a scene. This is completely in line with the theory (Rolls, 1989b, 1999c, 2023c,a) and evidence (Rolls and Xiang, 2006, 2005; Rolls et al., 2005c) that an important function of primate including human hippocampal spatial view cells is to participate in forming associations between objects including faces, rewards etc and their location in a scene.

The visual system of primates including humans thus supports this key function in episodic memory, by providing sufficient resolution at the fovea for objects etc together with sufficient resolution more peripherally to represent scenes and landmarks. Further, the high visual spatial resolution of the fovea in primates that provides the ability to use fine detail in a distant scene is also very valuable for navigation that is guided by distant viewed landmarks, for it enables even somewhat similar distant landmarks to be distinguished and used as guides for navigation (Rolls, 2021f, 2023c,d). In contrast, with the relatively poor spatial resolution available in the rodent visual system, rodents could not easily perform object in scene or reward in scene memory for a small object or reward in a large scene, because the rodent visual acuity is too poor to recognise a small object in a very large scene, and learn the location of the small object in the scene.

It is therefore proposed that a key and fundamental difference between the primate including human and rodent hippocampus is that rodents have a poor visual system that cannot implement the memory for where a small object or reward is in a large scene, a key property of primate including human episodic memory (Rolls, 2023d). Instead, rodents are dominated by the place where they are located, given their reliance on somatosensory vibrissa twitching and local olfactory cues, and a visual system that can mainly support place representations of where the individual is located using computations described by De Araujo et al. (2001) and illustrated in Fig. 9.34 in Section 9.3.11. Rodent egocentric visual cells in their hippocampal system may be useful for obstacle avoidance (Rolls, 2023d).

9.2.6 Head direction cells in the presubiculum

Head direction cells found in rats (Ranck, 1985; Taube et al., 1990a, 1996; Muller et al., 1996; Wiener and Taube, 2005) and in primates (Robertson, Rolls, Georges-François and Panzeri, 1999) respond maximally when the animal's head is facing in a particular preferred direction. An example of a primate head direction cell recorded in the presubiculum of the monkey is shown in Fig. 9.13. Similar cells are found in the rat pre-/post-subiculum, but also in a number of connected structures including the anterior thalamic nuclei (Taube et al., 1996; Wiener and Taube, 2005). The firing rate of these cells is a function of the head direction of the monkey, with a response that is typically 10–100 times larger to the optimal as compared to the opposite head direction. The mean half-amplitude width of the tuning of the cells was 76 degrees. The response of head direction cells in the presubiculum was not influenced by the place where the monkey was, there being the same tuning to head direction at different places in a room, and even outside the room. The response of these cells was also independent of the 'spatial view' observed by the monkey, and also of eye position (where the monkey was looking). The cells maintain their tuning for periods of at least several minutes when the

Fig. 9.13 Head direction cell in the primate presubiculum. Polar response plots of the firing rate (in spikes/s) when the monkey was stationary at different positions (shown at the 0 on the firing rate scale) in (and one outside) the room are shown. The monkey was rotated to face in each direction. The mean response of the cell from at least 4 different firing rate measurements in each head direction in pseudorandom sequence are shown. c1–c3: cups to which the monkey could walk on all fours to obtain food. Polar firing rate response plots are superimposed on an overhead view of the square room to show where the firing for each plot was recorded. The plot at the lower left was taken outside the room, in the corridor, where the same head direction firing was maintained. (After Robertson, R.G., Rolls, E. T., Georges-Francois, P. and Panzeri, S. (1999) Head direction cells in the primate pre-subiculum. *Hippocampus* 9: 206–219. © Wiley-Liss.)

view details are obscured or the room is darkened (Robertson, Rolls, Georges-François and Panzeri, 1999).

This representation of head direction could be useful together with the hippocampal spatial view cells and whole body motion cells found in primates in a number of spatial and memory functions. One is path integration for head direction, the process by which in the absence of visual input one's head direction is updated based on idiothetic, that is self-motion, signals reflecting recent movements or movement 'paths'. The memory mechanism required is an integration over time of self-motion signals produced by for example vestibular inputs or motor commands. Neuronal network computational mechanisms by which this memory function may be performed are described in Section B.5.5. Another memory function for which head direction cells may be important is in episodic memory. An episodic memory might include for example the fact that one had turned right by 90 degrees in the dark, and was therefore facing towards a particular spatial view, which one could later recall. Another spatial / memory function in which head direction cells are implicated is in updating using path integration one's representation of the place where one is located. Indeed, place cells in rats may be updated in the dark through an effect of head direction cells in rotating the place map, and normally the place cell and head direction maps are kept in alignment (Leutgeb, Leutgeb, Treves, Meyer, Barnes, McNaughton, Moser and Moser, 2005b; Wiener and Taube, 2005; Yoganarasimha, Yu and Knierim, 2006).

Self-organizing continuous attractor neural networks that can perform path integration

from velocity signals are described in Section B.5.5 and include head direction from head velocity (Stringer, Trappenberg, Rolls and De Araujo, 2002b; Stringer and Rolls, 2006); place from whole body motion (Stringer, Trappenberg, Rolls and De Araujo, 2002b; Stringer, Rolls, Trappenberg and De Araujo, 2002a); and spatial view from eye and whole body motion (Stringer, Rolls and Trappenberg, 2004, 2005; Rolls and Stringer, 2005) using it is now thought the dorsal visual system (Rolls, 2020b). Path integration of head direction is reflected in the firing of neurons in the presubiculum, and mechanisms outside the hippocampus, perhaps in the dorsal tegmental nucleus (Taube, Muller and Ranck, 1990b; Sharp, 1996; Bassett and Taube, 2005; Dillingham, Frizzati, Nelson and Vann, 2015; Cullen and Taube, 2017; Cullen, 2019), probably implement path integration for head direction.

Indeed, one function of the mammillary body circuitry may be to introduce a head direction signal from the tegmental nuclei of Gudden via the anterior thalamic nuclei to the hippocampal circuitry (Dillingham et al., 2015). This may provide one route for vestibular inputs, important of course in head direction representation, to reach the presubiculum, where head direction cells are found in primates (Robertson, Rolls, Georges-François and Panzeri, 1999) as well as in rodents (Wiener and Taube, 2005). Indeed, the anterior thalamic nuclei project to the cingulate and retrosplenial cortex, which in turn project into areas such as the subiculum, and thus can provide inputs to the hippocampal system about for example head direction (see Fig. 9.2 and Aggleton and Nelson (2015)).

Further, there is now evidence that the dorsal visual system leading to the parietal cortex area 7a, and thereby to the retrosplenial and cingulate cortex, which in turn connect via the parahippocampal gyrus to the hippocampus (Fig. 9.1) is one way in which spatial representations are updated idiothetically for use by the hippocampal system (Section 3.4) (Rolls, 2020b, 2021f; Rolls et al., 2023e,d; Rolls, 2023c).

9.2.7 Perirhinal cortex, recognition memory, and long-term familiarity memory

The functions of the perirhinal cortex are different to those of the hippocampus, and are reviewed here partly because the perirhinal cortex (areas 35 and 36) provides ventral stream afferents to the hippocampus via the entorhinal cortex (area 28) (Rolls et al., 2022a, 2023e; Rolls, 2023c), and partly to show that the computations performed in it are different to hippocampal computations. The location of the perirhinal cortex is shown in Fig. 9.16.

The perirhinal cortex is involved in recognition memory in that damage to the perirhinal cortex produces impairments in recognition memory tasks in which several items intervene between the sample presentation of a stimulus and its presentation again as a match stimulus (Malkova, Bachevalier, Mishkin and Saunders, 2001; Zola-Morgan, Squire, Amaral and Suzuki, 1989; Zola-Morgan, Squire and Ramus, 1994). In macaques, damage to the perirhinal cortex rather than to the hippocampus produces deficits in recognition memory measured in a delayed match to sample task with intervening stimuli (Murray, Baxter and Gaffan, 1998; Baxter and Murray, 2001b,a; Buckley and Gaffan, 2006; Waters, Basile and Murray, 2023). Further, damage to the perirhinal cortex rather than to the hippocampus is believed to underlie the impairment in recognition memory found in amnesia in humans associated with medial temporal lobe damage (Buckley and Gaffan, 2000, 2006).

Neurophysiologically, it has been shown that many inferior temporal cortex (area TE) neurons (Rolls, 2016b, 2012d, 2021d), which provide visual inputs to the perirhinal cortex (Suzuki and Amaral, 1994a,b), respond more to the first, than to the second, presentation of a stimulus in a running recognition task with trial-unique stimuli (Baylis and Rolls, 1987). In this running recognition task (originally developed for neurophysiology by Rolls, Perrett, Caan and Wilson (1982d)), there is typically a presentation of a novel stimulus, and after

Fig. 9.14 Perirhinal cortex neurons in primates are involved in short-term memory. 'Resetting' of perirhinal cortex neuronal responses between trials in a short-term memory task (delayed match to sample). Neuronal responses are larger to the sample than the match presentation of a particular image within a trial, and are large to the sample on the next trial ('Trial B') even if it is the same image that has just been shown a few seconds earlier as the match image on the preceding trial. * = $p < 0.01$ and ** = $p < 0.005$ in a Wilcoxon post-hoc test. The mean and sem of the responses across neurons are shown. (After Hölscher, C. and Rolls, E. T. (2002) Perirhinal cortex neuronal activity is actively related to working memory in the macaque. *Neural Plasticity* 9: 41–51.)

a delay which may be in the order of minutes or more and in which other stimuli may be shown, the stimulus is presented again as 'familiar', and the monkey can respond to obtain food reward. Many inferior temporal cortex neurons responded more to the 'novel' than to the 'familiar' presentation of a stimulus, where 'familiar' in this task reflects a change produced by seeing the stimulus typically once (or a few times) before. (A small proportion of neurons respond more to the familiar (second) than to the novel (first) presentation of each visual stimulus.) In the inferior temporal cortex this memory spanned up to 1–2 intervening stimuli between the first (novel) and second (familiar) presentations of a given stimulus (Baylis and Rolls, 1987), and when recordings are made more ventrally, towards and within the perirhinal cortex, the memory span increases to several or more intervening stimuli (Wilson et al., 1990; Brown and Xiang, 1998; Xiang and Brown, 1998). The implication is that the inferior temporal visual cortex can implement a very simple form of recognition memory in which neurons respond more to the first compared to a second presentation of a stimulus with 1–2 intervening stimuli, and that the same rather simple type of recognition process can extend over more intervening stimuli as one moves towards the perirhinal cortex. The underlying mechanism could be a type of habituation or adaptation which is partly stimulus-specific because neurons in these regions can have different responses to different stimuli. For comparison, very few primate hippocampal neurons have activity related to recognition memory (Rolls, Cahusac, Feigenbaum and Miyashita, 1993).

The perirhinal cortex is directly or closely connected with a number of other brain regions involved in the long-term recognition memory for visual stimuli. Relatively far forward in the *orbitofrontal cortex*, in area 11, neurons are activated by novel visual stimuli (Rolls, Browning, Inoue and Hernadi, 2005a), and activations in humans are produced by novel visual stimuli (Frey and Petrides, 2002). The responses of these neurons decrease over on average 5 presentations of a novel stimulus, and may be related to long-term memory in that the responses do not occur to a stimulus that was shown as novel 24 h earlier (Rolls, Browning, Inoue and Hernadi, 2005a). Using the running recognition memory task, Rolls, Perrett, Caan and Wilson (1982d) discovered a population of neurons that responded to familiar vis-

ual stimuli and were related to long-term memory at the anterior border of the thalamus, in a region that is at the border of the *ventral anterior thalamic nucleus (VA)* and the reticular nucleus of the thalamus (see also Wilson and Rolls (1990c); cf. Bubb et al. (2017)). Neurons that were also activated in a running recognition memory task by familiar stimuli and that may be related to these thalamic neurons were described by Xiang and Brown (2004) in a *ventromedial prefrontal cortex* region that they termed PFCvm, and a ventrolateral prefrontal region that they termed PFCo. Wilson and Rolls (1993) showed that the activity of some neurons in the amygdala was related to stimulus novelty (with memory spans of 2–10 intervening other stimuli) and of others to familiarity in monkeys performing recognition memory tasks. Wilson and Rolls (1990c) described neuronal responses related to novel visual stimuli in the *substantia innominata and diagonal band of Broca*. These neurons, also activated in other memory tasks (Wilson and Rolls, 1990b,a), may be the cholinergic neurons that project to the cerebral cortex and that may, by providing acetylcholine to the cerebral cortex, help in the consolidation of memories by the release of acetylcholine at the time that a memory is being formed in the neocortex. Consistent with this, cholinergic basal forebrain lesions produce severe learning impairments in learning visual scenes and in object-reward associations (Easton, Ridley, Baker and Gaffan, 2002), and damage to the cholinergic basal forebrain neurons is implicated in Alzheimer’s disease (Whitehouse et al., 1982; Bierer et al., 1995; Fernandez-Cabello et al., 2020). The neurophysiological evidence of Wilson and Rolls (1990c), Wilson and Rolls (1990b) and Wilson and Rolls (1990a) indicates that these *basal forebrain neurons* do change their firing rate during different types of association memory and recognition tasks, and thus the phasic release of acetyl choline to the cortex at the time of memory formation may be important to consolidation, by facilitating LTP (Bear and Singer, 1986; Hasselmo and Sarter, 2011; Zaborszky et al., 2018) (see Section 9.2.8.5).

This interconnected perirhinal cortex / orbitofrontal cortex system may thus be involved in setting up neurons that respond differently to novel and familiar stimuli and thereby implement recognition memory (see also Section 11.3.7 on the ventromedial prefrontal cortex and memory), and may also influence the operation of other memory systems by influences on the basal forebrain cholinergic neurons which have widespread connections to the cerebral cortex (Zaborszky et al., 2018).

A second type of memory in which the perirhinal cortex is involved is the short-term memory for visual stimuli. In a task typically performed with non-trial-unique stimuli, a delayed matching-to-sample task with up to several intervening stimuli, some perirhinal cortex neurons respond more to the match stimulus than to the sample stimulus (Miller et al., 1993). Many other neurons in this task respond more to the sample (‘novel’) than to the match (‘familiar’) presentations of the stimuli. There is active engagement of the perirhinal cortex in this delayed matching-to-sample task, in that the response of these neurons is always larger to the sample than to the match stimulus, even if the stimulus shown as the sample has been seen just seconds ago on a previous trial (Hölscher and Rolls, 2002), as shown in Fig. 9.14. Thus this short-term memory in the perirhinal cortex is actively reset at the start of the next trial (Hölscher and Rolls, 2002).

A third type of memory in which the perirhinal cortex is implicated is paired associate learning (a model of semantic long-term memory), which is represented by a population of neurons in a restricted part of area 36 where the neuronal responses may occur to both members of a pair of pictures separated by a delay used in the paired association task (Miyashita et al., 1998, 1996) (see also Section 8.3.1). The learning of this task may be facilitated by the short-term memory-related firing that follows the first member of the pair during the delay period (Hirabayashi et al., 2013). Another very plausible function for these associations across time is not semantic memory but instead view invariant learning, which can be helped

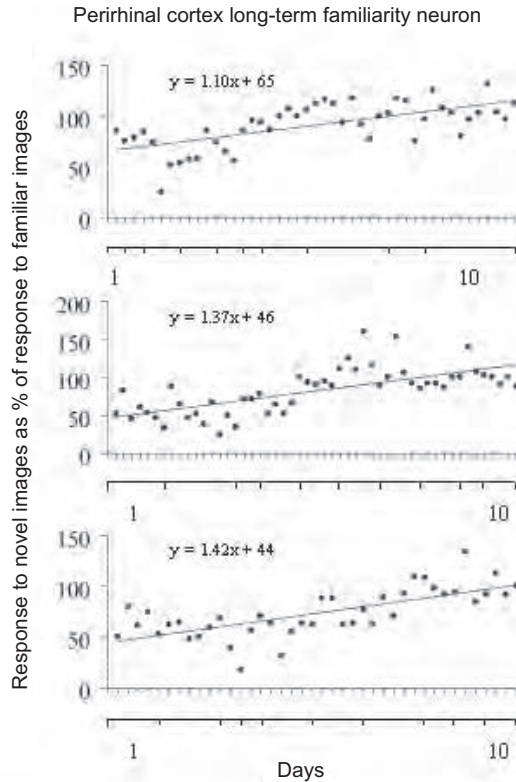

Fig. 9.15 Perirhinal cortex neurons in primates are involved in long-term familiarity memory. The average response of each neuron (shown by a full circle) to a set of 15 novel visual stimuli introduced on day 1 is shown as a proportion of the neuron's response to a very familiar set of stimuli. In each experiment on a neuron, each visual stimulus was shown for approximately 13 1-s periods. Several neurons were analyzed on some days. Thus in the order of 500 exposures to each stimulus in the novel set were required before the response to the initially novel set of stimuli was as large as to the already very familiar set of stimuli. Each stimulus was an image of an object presented on a video monitor. The 3 separate graphs are for 3 separate replications of the whole experiment. (After Hölscher, C., Rolls, E. T. and Xiang, J.-Z. 2003. Perirhinal cortex neuronal activity related to long-term familiarity memory in the macaque. *European Journal of Neuroscience* 18: 2037–2046. © Federation of European Neuroscience Societies and John Wiley & Sons.)

by associations across time (Rolls, 2021d), as described in Chapter 2, and which may be impaired by perirhinal cortex lesions (Buckley, Booth, Rolls and Gaffan, 2001).

Evidence that the perirhinal cortex is involved in a fourth type of memory, long-term familiarity memory, comes from a neuronal recording study in which it was shown that perirhinal cortex neuronal responses in the rhesus macaque gradually increase in magnitude to a set of stimuli as that set is repeated for 400 presentations each 1.3 s long (Hölscher, Rolls and Xiang, 2003). The single neurons were recorded in the perirhinal cortex in monkeys performing a delayed matching-to-sample task with up to 3 intervening stimuli, using a set of very familiar visual stimuli used for several weeks. When a novel set of stimuli was introduced, the neuronal responses were on average only 47% of the magnitude of the responses to the familiar set of stimuli. It was shown in eight different replications in three monkeys that the responses of the perirhinal cortex neurons gradually increased over hundreds of presentations of the new set of (initially novel) stimuli to become as large as to the already familiar stimuli. Examples of three replications are shown in Fig. 9.15, and the recording sites were in the perirhinal cortex as indicated in Fig. 9.16 (see Hölscher, Rolls and Xiang (2003)). The mean

number of 1.3 s presentations to induce this effect was 400 occurring over 7–13 days. These results show that perirhinal cortex neurons represent the very long-term familiarity of visual stimuli (Hölscher, Rolls and Xiang, 2003).

A representation of the long-term familiarity of visual stimuli may be important for many aspects of social and other behavior. For example, long-term familiarity is likely to be a cue about which objects belong to one, who are members of your family, who are members of your social group vs strangers, and which house or village or territory is yours, i.e. about ownership (Hölscher, Rolls and Xiang, 2003; Rolls, Franco and Stringer, 2005b). Indeed, this enhanced processing of highly familiar stimuli by the perirhinal cortex which provides major inputs to the hippocampus is likely to lead to enhanced processing by hippocampal spatial memory systems of information about one's own spatial home environment, which may be adaptive, as individuals spend most of their time there, and may need to defend the environment in which they live which could be enhanced by good spatial knowledge of their home environment.

Indeed, an important aspect of territoriality is a sense of ownership, that the territory belongs to oneself, or to someone else, and it has been proposed that this aspect of territoriality is related to long-term familiarity implemented in the perirhinal cortex (Hölscher, Rolls and Xiang, 2003; Rolls, Franco and Stringer, 2005b). More generally, ownership can be considered to be a semantic attribute of an object, territory, etc. The ownership could signify that we own it, or that someone else owns it. Long-term familiarity is a cue to ownership, but does not in itself encode the attribute about who owns it. A neighbour's garden may be very familiar, but one does not own that territory. So familiarity is a cue, but not all the information needed to specify ownership. The way in which semantic knowledge about for example a territory in the anterior temporal lobe may incorporate attributes such as ownership and familiarity is described in Sections 8.3, 14.2.4, and 14.4.

Another important property of the perirhinal cortex long-term familiarity neurons is that they encode the degree of familiarity of stimuli, as shown by their gradual build-up of responsiveness over 10 days of testing in which the stimuli were seen hundreds of times (Fig. 9.15). This is likely to be important in the build-up of a sense of ownership, for example whether a recently taken territory belongs to you.

Part of the impairment in temporal lobe amnesia may be related to the difficulty of building representations of the degree of familiarity of stimuli in which these perirhinal cortex neurons are implicated. This perirhinal long-term familiarity memory system could also account for the responses of the familiarity neurons discovered in the anterior thalamic region (Rolls et al., 1982d), via the hippocampal–subiculum–fornix–mammillary body–mammillothalamic tract route to the anterior thalamic nuclei, as well as by the direct route from the subiculum via the fornix to the anterior thalamic nuclei (Bubb et al., 2017). This route is involved in memory, in that amnesia can result from damage to the fornix (Gaffan and Gaffan, 1991) and anterior thalamus (Bubb et al., 2017; O'Mara and Aggleton, 2019). The computational roles of these subcortical pathways in memory in primates is not clear. Fornix section will deafferent the hippocampus of cholinergic input, and that will impair memory. It is not surprising if neurons in these diencephalic regions have responses that are similar to those of hippocampal neurons, because of the anatomical connectivity (O'Mara and Aggleton, 2019). The mammillary bodies are likely to be an important relay for vestibular input related to head direction cells (Dillingham et al., 2015). The anterior thalamic nucleus route reaches the cingulate cortex, and that leads me to suggest that this may be part of an evolutionarily early route to enable the hippocampus to influence action (Rolls, 2019c), in which the hippocampal system is implicated as shown by its neuronal activity in conditional spatial responses made to visual stimuli (Cahusac, Miyashita and Rolls, 1989; Miyashita, Rolls, Cahusac, Niki and Feigenbaum, 1989; Cahusac, Rolls, Miyashita and Niki, 1993).

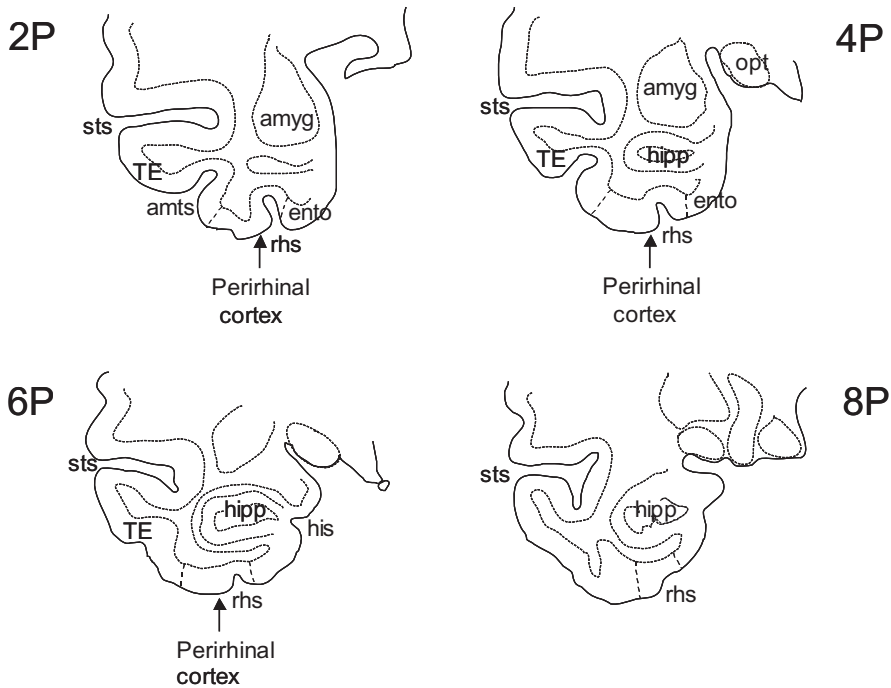

Fig. 9.16 The locations of the perirhinal cortex (areas 35 and 36 in and near the banks of the rhinal sulcus), the entorhinal cortex (area 28), and the hippocampus in macaques. The coronal (transverse) sections are at different distances behind (P, posterior to) an anatomical marker, the sphenoid bone, which is approximately at the anterior–posterior position of the optic chiasm and anterior commissure. amts—anterior middle temporal sulcus; amyg—amygdala; ento—entorhinal cortex; hipp—hippocampus; his—hippocampal sulcus; opt—optic tract; rhs—rhinal sulcus; sts—superior temporal sulcus; TE—inferior temporal visual cortex.

However, in primates the hippocampal backprojection pathways to the neocortex probably provide the main route by which the hippocampus is involved computationally in memory, by implementing memory recall.

It has been shown that long-term familiarity memory for the perirhinal cortex can be modelled by neurons with synapses with a small amount of long-term potentiation which occurs at every presentation of a given stimulus, but which also incorporate hetero-synaptic long-term depression to make the learning self-limiting (Rolls, Franco and Stringer, 2005b).

A fifth type of memory in which the perirhinal cortex is implicated is in tasks in which the stimuli to be discriminated are made up of a small number of features that are combined in different combinations. The features in each stimulus are thus highly overlapping, and the task requires setting up different representations of the different but highly overlapping feature conjunctions in a low-dimensional feature space. This is very different to object representations as they typically occur in the world, in which each object is a particular combination of features from a very high-dimensional feature space, so that the representations of different objects in general have much less overlap in feature space, and the inferior temporal visual cortex can form object representations by forming neurons that respond to different combinations of features from a high-dimensional feature space. In any case, it is argued that perirhinal cortex lesions impair the discrimination between stimuli according to how ambiguous they are in terms of their degree of overlap of a few features (Bussey and Saksida, 2005; Buckley and Gaffan, 2006; Bussey et al., 2002, 2003, 2005). (However, a more mnemonic than perceptual case is made by Hampton (2005) based on the evidence for delay-dependent deficits produced by perirhinal cortex lesions in recognition memory tasks, and reversal-learning impairments which reflect a more associative than perceptual role for

the perirhinal cortex.) In the extreme case, such a stimulus set might require A+, B+, but AB- (where A+ means that A is rewarded), which requires a non-linear discrimination. One way to solve such memory problems is to add a further layer to an existing object representation network, where further combinations of what is represented at earlier layers can be formed. This is equivalent to adding a fifth layer to the VisNet architecture described in Chapter 2, and adding such an additional layer, which might correspond to adding a perirhinal cortex layer to an inferior temporal cortex layer, does, as expected, help a network to solve the class of problem where the stimuli consist of different highly overlapping combinations of a small number of features (Cowell et al., 2006). However, when we recorded in the primate perirhinal cortex, we did not find much evidence for very specifically tuned object neurons, but did find that neuronal activity is related to short-term perceptual memory (Hölscher and Rolls, 2002). In the light of this, and the fact that inferior temporal visual cortex neurons do provide very good invariant representations of objects which are complex combinations of features (Rolls, 2012d; Rolls and Treves, 2011), the possibility is suggested that one function of the perirhinal cortex may be to provide a visual short-term memory, which is usually required for the tasks such as oddity with multiple distracters that led to the conjunctive / configural hypothesis (Bussey et al., 2005). Consistently, the visual short-term memory capability of the perirhinal cortex is probably important also for its role in delayed paired-associate learning (Fujimichi, Naya, Koyano, Takeda, Takeuchi and Miyashita, 2010; Miyashita, 2019).

It then becomes a somewhat semantic issue about whether one considers that the perirhinal cortex is involved in object perception as well as in memory (Bussey and Saksida, 2005; Buckley and Gaffan, 2006; Ferko et al., 2022). My own view is that the perirhinal cortex can be thought of as involved in the memory for and discrimination between stimuli when the stimuli are composed of a small number of features with different combinations of features for different stimuli, so that in this way, and perhaps in other ways, the stimuli, which could be objects, are ambiguous. The perirhinal cortex may thus contribute in these special cases, and may be considered to be starting the pattern separation computations that are important in hippocampal computation, as described below. These special cases should be distinguished from object perception that occurs with normal objects in the world, in which each object is composed of a combination of features drawn from a high-dimensional feature space. Object representation in this sense is implemented in the anterior inferior temporal visual cortex, as shown by evidence described in Chapter 2 and Appendix C.

The perirhinal cortex, by receiving from the inferior temporal visual cortex, and perhaps by performing further conjunction learning to that already implemented by the anterior inferior temporal visual cortex (see Chapter 2), thus has visual representations of objects, and some at least of the perirhinal cortex neurons have view-invariant representations.

Another factor that distinguishes the perirhinal cortex is that the perirhinal cortex receives forward inputs from other modalities, including auditory, olfactory and somatosensory (Suzuki and Amaral, 1994a,b; Rolls et al., 2022a, 2023e). This may enable the perirhinal cortex by combining these multimodal inputs to build representations that reflect the convergence of more than visual inputs. The perirhinal cortex, via its projections to the lateral entorhinal cortex and via the lateral perforant path, could thus introduce object information into the hippocampus for object–place associations. The parahippocampal gyrus, in which cells with spatial information are present in macaques (Rolls, Xiang and Franco, 2005c; Rolls and Xiang, 2006), could via connections to the medial entorhinal cortex introduce spatial information into the hippocampus (Section 9.2.8.1), and there is evidence consistent with this in rodents (Hargreaves et al., 2005). In contrast to the perirhinal cortex, the final convergence afforded by the hippocampus into one network in CA3 (see Fig. 9.2) may enable the hippocampus proper to implement an event or episodic memory typically involving arbit-

Fig. 9.17 Example of the streamlines showing hippocampal connections using diffusion tractography imaging for a single participant from the Human Connectome Project dataset. The tractography is from a transparent view through the brain, with parasagittal and axial slices of the human brain overlaid to show the trajectory of the pathways in the context of the brain. Voxels in the left hippocampus were seeded for the case illustrated. Streamlines from the hippocampus reach local areas such as the entorhinal and perirhinal cortex, and the parahippocampal gyrus (violet). But in addition streamlines reach more distant areas, including early visual cortical areas bilaterally via the (dorsal) hippocampal commissure (purple, pink); and the parietal cortex (yellow), the orbitofrontal cortex (magenta), the anterior cingulate cortex via the cingulum just above the corpus callosum (light green), and the anterior thalamus and mammillary bodies via the fornix (light blue). The hippocampus is shown in white with slight opacity, and appears small posteriorly just because it rotates laterally. (S - superior/inferior; L - left/right; A - anterior/posterior). (From Huang,C-C., Rolls,E.T., Hsu,C-C.H., Feng,J. and Lin,C-P. (2021) Extensive cortical connectivity of the human hippocampal memory system: beyond the ‘what’ and ‘where’ dual stream model. *Cerebral Cortex* 31: 4652-4669.)

rary associations between any of the inputs to the hippocampus, e.g. spatial, visual object, olfactory, and auditory (see below).

9.2.8 Connectivity of the human hippocampal system

The connections and connectivity of the human hippocampal system have been investigated (Rolls et al., 2022a; Ma et al., 2022a; Huang et al., 2021; Rolls, 2023c, 2022b) using the methods introduced in Section 1.13 and using the HCP-MMP atlas (Section 1.12), and these discoveries, which are leading to new conceptual advances in our understanding of the human hippocampal memory system, are described next. The investigations utilize effective connectivity, functional connectivity, and anatomical connections analyzed with diffusion tractography. The figures in this series of investigations in this book mainly show effective connectivity, but the results that are obtained with diffusion tractography are illustrated for the hippocampus in Fig. 9.17. Connections between the human hippocampus and the lateral and anterior temporal lobe cortex, the orbitofrontal cortex, the anterior cingulate cortex via the cingulum, the retrosplenial cortex, the parietal cortex, and early cortical visual regions are illustrated.

9.2.8.1 A ventromedial visual cortical stream to the hippocampus for visual scene representations

Connectivity is directed to the human hippocampus from a medial posterior part of the parahippocampal gyrus PHA1-3 (which corresponds to TH in macaques) and the adjoining ventromedial visual areas (VMV1-3) (Rolls et al., 2022a, 2023e) (Fig. 9.18). This parahippocampal / VMV region (Sulpizio et al., 2020) is a parahippocampal place area (or Parahippo-

Fig. 9.18 Effective connectivity of the human Ventromedial Visual Cortical Stream which reaches the parahippocampal gyrus PHA1–PHA3 regions via ventromedial (VMV) and Ventral Visual Complex (VVC) and ProSriate regions: schematic overview. Visual scenes are represented in the anterior parts of VMV and the posterior parts of PHA1–PHA3 in what is the Parahippocampal Scene Area PSA (sometimes called the Parahippocampal Place Area, PPA) (Sulpizio et al., 2020). The retrosplenic scene area is in a band of cortex in the Prostriate cortex PRoS and Dorsal Visual Transitional cortex DVT that is posterior to region RSC (Sulpizio et al., 2020). The occipital scene area is in V3CD and borders V4 (Sulpizio et al., 2020). The green arrow shows how the Ventromedial Visual Stream provides ‘where’ input about locations in scenes to the hippocampal memory system from the medial parahippocampal gyrus PHA1–PHA3 region (which corresponds to TH in macaques). The connectivity from PGp to PHA regions is suggested to be involved in idiothetic update of locations in scenes. The widths of the lines and the size of the arrowheads indicate the magnitude and direction of the effective connectivity. The abbreviations are listed in Section 1.12. (From Rolls, E. T. (2023) Hippocampal spatial view cells for memory and navigation, and their underlying connectivity in humans. Hippocampus doi: 10.1002/hipo.23467.)

campal Scene Area, PSA, as it responds to viewed scenes not the place where the individual is located) (Sulpizio et al., 2020; Natu et al., 2021; Kamps et al., 2016; Epstein and Kanwisher, 1998; Epstein and Baker, 2019; Epstein and Julian, 2013; Epstein, 2008, 2005). My proposal is that the Parahippocampal Scene Area is a route via which hippocampal spatial view cells receive their information about and selectivity for locations in scenes. This direct route (Rolls et al., 2022a, 2023e) is complemented by connectivity via the posterior cingulate cortex (Rolls et al., 2023i) (Section 12.3).

The ‘Ventromedial Visual Stream’ pathway shown in Fig. 9.18 summarizes how in humans visual information reaches the parahippocampal gyrus PHA1 – PHA3 regions via ventromedial (VMV1-3) and Ventral Visual Complex (VVC) regions (Rolls et al., 2023e). In this stream there is effective connectivity from $V1 > V2 > V3 > V4$. Then V2, V3 and V4 have effective connectivity to the VMV regions, which in turn have effective connectivity to

PHA1-3, which in turn have effective connectivity directed to the hippocampal system (Fig. 9.18, green arrow) (Rolls et al., 2023e). In addition, V2 has effective connectivity to the transitional visual areas DVT (Dorsal Transitional Visual area) and ProS (the ProStriate region), which in humans are where in the HCP-MMP atlas (Glasser et al., 2016a; Huang et al., 2022) the retrosplenial place area is located (Sulpizio et al., 2020); and these regions in turn have effective connectivity to the PHA1-3 parahippocampal regions (Fig. 9.18) (Rolls et al., 2023e). In humans, the occipital place area OPA is located in V3CD, V3B, and IPO (Sulpizio et al., 2020) (Fig. 9.18).

It is proposed that scene representations are built using combinations of ventral visual stream features that when overlapping in space are locked together by associative learning and can form a continuous attractor network to encode a visual scene (Rolls et al., 2008f; Stringer et al., 2005; Rolls et al., 2023d; Rolls and Stringer, 2005) using spatial view cells (Rolls and Wirth, 2018; Georges-François et al., 1999; Rolls et al., 1998b; Robertson et al., 1998; Rolls et al., 1997a; Tsitsiklis et al., 2020; Wirth et al., 2017; Rolls, 2022b, 2023c) in the parahippocampal scene (or place) area referred to above, which in turn connects to the hippocampus to provide the ‘where’ component of episodic memory (Rolls et al., 2022a, 2023d). This connectivity to the hippocampal scene system is considered further elsewhere (Rolls et al., 2023d, 2022a; Rolls, 2022b, 2023c, 2022b). It is proposed below that a contribution of the dorsal visual stream to scene processing is to provide idiothetic update of spatial view representations.

At first sight, this Ventromedial Visual Cortical Stream for ‘where’, scene, representations, may seem like an unusual proposal. The proposal is that ‘where’ information, about locations in scenes that are encoded by hippocampal spatial view cells, reaches the hippocampus from the Parahippocampal Scene Area in PHA1-3 and VMV1-3, which has much connectivity with early ventral visual stream cortical areas. Indeed faces are represented near to the Parahippocampal Scene Area in the fusiform gyrus FFC (Pitcher et al., 2019; Natu et al., 2021; Weiner et al., 2017); ideograms (or logograms) of words are represented just lateral to faces in the visual word form area in the fusiform gyrus (Yeatman and White, 2021; Dehaene et al., 2005; Dehaene and Cohen, 2011; Caffarra et al., 2021); and cortical regions that represent objects are nearby and project forward into the inferior temporal visual cortical areas involved in invariant visual object recognition (Grill-Spector et al., 2006; Rolls, 2021b,d). However, scenes are likely to be represented by spatially contiguous scene features that become associated together in the correct topological arrangement because of the statistics of the inputs (Rolls, Tromans and Stringer, 2008f; Stringer, Rolls and Trappenberg, 2005), and thus visual scene representations are likely to be formed from visual features of the type that are represented in ventral stream visual areas.

Highly relevant to these points is that spatial view cells are found in the macaque parahippocampal gyrus as well as the hippocampus (Georges-François et al., 1999; Rolls et al., 1998b; Robertson et al., 1998; Rolls et al., 1997a, 2005c; Rolls and Xiang, 2005; Rolls, 2023c). Indeed, it is proposed and likely that many of the neurons in the Parahippocampal Scene (Place) Area are spatial view cells, and that this is how scenes are represented in the primate including human brain.

These findings are supported by tract-tracing studies in macaques (Kravitz, Saleem, Baker, Ungerleider and Mishkin, 2013; Kravitz, Saleem, Baker and Mishkin, 2011), though more cortical regions are distinguished in the human brain, and the advantage of studying the connectivity in humans with a parcellation such as the HCP-Multimodal Parcellation (Glasser et al., 2016a; Huang et al., 2022) is that we are now dealing with identifiable systems in humans that other studies (fMRI, lesion etc) in humans can directly relate to by reference to the HCP-Multimodal Parcellation, and that the connectivity in humans relates to the strength

of connections in both directions between every pair of cortical regions, not only to whether anatomical connections can be traced.

9.2.8.2 The roles of the parietal cortex in the idiothetic update of hippocampal and parahippocampal spatial view cells and scene representations

What has just been proposed in Section 9.2.8.1 raises the question of the role of the parietal cortex, traditionally regarded as the brain region involved in ‘where’ representations (Ungerleider and Mishkin, 1982; Pitcher and Ungerleider, 2021), in the responses of hippocampal (and parahippocampal gyrus) spatial view cells. As shown in Figs. 3.12 and 9.18, the hippocampal system does receive input from parietal cortex visual regions (Rolls et al., 2023d, 2022a; Ma et al., 2022a; Huang et al., 2021; Rolls et al., 2023e). Inputs are also received via the visuo-motor parts of the posterior cingulate cortex (Rolls et al., 2023i; Baker et al., 2018) (Section 12.3).

In more detail, the effective connectivity of the human Dorsal Visual Cortical Stream is shown in Fig. 3.12 (Rolls et al., 2023e). There is effective connectivity from parietal cortex regions to the parahippocampal scene area, as illustrated in Fig. 3.12. Strong effective connectivity is directed from inferior parietal region PGp to the Parahippocampal Scene Areas (PSA) in PHA1-3 (Figs. 3.12 and 9.18) (Rolls et al., 2023d). PGp receives its inputs from parietal area 7 regions and intraparietal regions (Fig. 3.12) (Rolls et al., 2023e) involved in visual motion analysis and in coordinate transforms from retinal to head-based and then to world-based (allocentric) coordinates (Snyder et al., 1998; Rolls, 2020b; Salinas and Sejnowski, 2001). These coordinate transforms are fundamental for self-motion update of scene representations, so that the spatial view neurons in the parahippocampal scene area can represent where in a scene the individual is looking independently of eye position, head direction, and even the place of the head in the environment, when the view details are obscured or in the dark (Robertson et al., 1998; Rolls, 2020b, 2023c). Given these two lines of evidence, it is proposed that the parietal cortex has the role of idiothetic update of the scene representations in the Parahippocampal Scene Area and thereby in the hippocampus (Rolls et al., 2023e,d; Rolls, 2023c).

Thus the hypothesis is that the ‘where’ scene representations in the human ventromedial visual stream are built by combinations of ventral stream spatial features, and the viewed position in the scene is idiothetically updated by coordinate transforms to the allocentric level of scenes (Rolls, 2020b, 2023c) by the parietal cortex inputs to the Parahippocampal Scene Area (Rolls et al., 2023e,d; Rolls, 2023c). Optic flow is a signal that can be used in idiothetic update, and in addition it is known that optic flow regions such as V3, V6 and the MT+ complex have functional (Sherrill et al., 2015; Rolls et al., 2023e) and effective (Rolls et al., 2023e) connectivity with regions involved in navigation such as the hippocampus, retrosplenial cortex, and posterior parietal cortex, and that optic flow activates regions that are close to cortical scene regions in the occipital, retrosplenial, and parahippocampal scene regions (Sulpizio et al., 2020).

It is emphasized in this approach that the ‘path integration’ that is required for idiothetic update in humans and other primates involves eye position as well as head direction and the place where the individual is located, and much takes place in the dorsal visual system regions in the cortex in the intraparietal sulcus and area 7 (Rolls, 2020b; Rolls et al., 2023d). The mechanisms by which these coordinate transforms are implemented in the parietal cortex (Rolls, 2020b) are considered in Section 3.5. A real problem with hypothesizing that path integration of any type occurs within the hippocampus is that the energy landscape of any continuous attractor network representation of place or spatial view in the hippocampus that utilised idiothetic update (Stringer, Rolls and Trappenberg, 2005; Rolls and Stringer, 2005;

Stringer, Rolls, Trappenberg and De Araujo, 2002a) would be so distorted by association with the ‘what’ and reward information used for episodic memory that it would be very poor at path integration, as the energy landscape would be too bumpy because of the associations (cf. Spalla, Cornacchia and Treves (2021)).

What has been proposed is thus that the primate including human hippocampal ‘where’ system has two components or parts. One is a ventromedial visual cortical stream scene system with spatial view cells formed by visual feature components locked together in the correct spatial arrangement using overlapping receptive fields and associatively modified synapses of recurrent collaterals of the pyramidal cells that learn from the statistics of the neuronal activity how close the features are in the scene (Rolls et al., 2008f; Stringer et al., 2005). This is located in ventral visual stream areas such as the ventromedial visual areas VMV1-3 and the parahippocampal scene area (Rolls et al., 2022a, 2023e). The second component is the dorsal visual stream areas extending into the intraparietal sulcus areas such as LIP, VIP and MIP, area 7, and PGp (in the HCP-MMP atlas (Glasser et al., 2016a; Huang et al., 2022)), which are involved in idiothetic update of spatial view cells by computing representations of allocentric view that are invariant with respect to retinal position, eye position, head direction, and the place where the individual is located (Rolls et al., 2023d; Rolls, 2020b; Rolls et al., 2023e).

The connectivity from the hippocampus and parahippocampal gyrus to the parietal cortex may further provide a route for allocentric locations in space with associations with rewards, goals, or objects and remembered using hippocampal mechanisms to produce navigation and visuo-motor actions in space that require transforms to egocentric coordinates (Rolls et al., 2023d).

To be clear, this organisation in primates including humans is completely different to anything envisaged for rodents, in which place cells and navigational strategies involving idiothetic update of place representations that can be used in the dark and that might take place at least in part in the hippocampus are invoked (O’Keefe, 1990; Burgess and O’Keefe, 1996; McNaughton, Barnes, Gerrard, Gothard, Jung, Knierim, Kudrimoti, Qin, Skaggs, Suster and Weaver, 1996; Samsonovich and McNaughton, 1997; Royet, Zald, Versace, Costes, Lavenne, Koenig and Gervais, 2000; Bicanski and Burgess, 2018; Edvardsen, Bicanski and Burgess, 2020). In contrast, primates have a highly developed foveate visual system in which eye position, head direction, and even place need to be idiothetically updated for visual scene updates, and this takes place largely in the dorsal visual stream leading to the parietal cortex (Rolls, 2020b) (Chapter 3). This is one example in which the systems-level brain organisation of primates including humans is different from that of rodents (Section 19.10).

9.2.8.3 Ventrolateral visual stream ‘What’ inputs to the human hippocampal system

To add to the recently developing understanding of human hippocampal system inputs, Fig. 9.19 shows the ventrolateral visual stream in humans progressing via $V1 > V2 > V4 >$ Fusiform Face Cortex FFC (which contains representations of faces, objects and even words in the visual word form area laterally) $>$ the anterior inferior temporal visual cortex TE regions (Rolls et al., 2023e) where invariant representations of objects and faces are built (Rolls, 2000a, 2021b,d). This pathway provides ‘what’ inputs to the hippocampal memory system via parahippocampal area TF, which is lateral and anterior to the scene area in PHA1-3 (Fig. 9.19) (Rolls et al., 2023e).

Fig. 9.19 also illustrates some of the reward-related inputs to the human hippocampal system with green arrows, and these are considered next.

Fig. 9.19 Effective connectivity of the Ventrolateral Visual Stream which reaches inferior temporal cortex TE regions in which objects and faces are represented (red arrows): schematic overview. One of the red arrows shows how the Ventrolateral Visual Stream provides ‘what’ input to the hippocampal memory system via parahippocampal gyrus TF to perirhinal PeEc connectivity from FFC, PH, TE1p, TE2a and TE2p. The green arrows show how reward regions of the orbitofrontal cortex, vmPFC (pOFC, 10r, 10v) and pregenual anterior cingulate (a24 and p32), and punishment/non-reward regions of the lateral orbitofrontal cortex (47m) have effective connectivity with the hippocampus (Hipp), entorhinal cortex (EC), and perirhinal cortex (PeEc). The Ventrolateral Visual Stream also provides input to the semantic language system via TgD. The Ventrolateral Visual Stream also has connectivity to the inferior parietal visual regions PFm, PGs and PGI as indicated by two red arrows. The widths of the lines and the size of the arrowheads indicate the magnitude and direction of the effective connectivity. The abbreviations are listed in Section 1.12. (From Rolls, E. T. (2023) Hippocampal spatial view cells for memory and navigation, and their underlying connectivity in humans. Hippocampus doi: 10.1002/hipo.23467.)

9.2.8.4 Reward value / emotion-related inputs to the human hippocampus

First, reward value and emotion-related inputs reach the human hippocampal system from the orbitofrontal cortex, ventromedial prefrontal cortex, and anterior cingulate cortex partly via the perirhinal and entorhinal cortex (Figs. 9.19 and 11.28) (Rolls et al., 2022a; Ma et al., 2022a; Rolls et al., 2023c,e), and perhaps even more directly (Huang et al., 2021). This important route for reward to gain access to the human hippocampus in addition to ‘what’ and ‘where’ inputs is shown in the hippocampal schematic connection diagram in Fig. 9.2, which shows how reward value information could be associated with ‘where’ spatial view cell activity in hippocampal CA3, if not before.

The connectivity for these reward value and emotion-related inputs to reach the human hippocampus is shown in more detail in Figs. 9.19 and 11.28 (Rolls et al., 2023c,e). The sensory/perceptual cortical regions on the left of Fig. 11.28 provide visual, taste, olfactory and auditory input not coded in terms of their reward value to the orbitofrontal cortex (Rolls, 2019e,f, 2021b). The representation of these signals in the orbitofrontal cortex is in terms of their reward value, as shown by stimulus-reward learning and reversal; and by satiation which selectively reduces the reward value (Rolls, 2019f; Grabenhorst and Rolls, 2011; Rolls, Cheng and Feng, 2020a; Rolls, 2021h; Rolls, Vatanserver, Li, Cheng and Feng, 2020e; Hornak, O'Doherty, Bramham, Rolls, Morris, Bullock and Polkey, 2004; Hornak, Bramham, Rolls, Morris, O'Doherty, Bullock and Polkey, 2003; Hornak, Rolls and Wade, 1996; Rolls, Hornak, Wade and McGrath, 1994a; Berlin, Rolls and Kischka, 2004; Thorpe, Rolls and Maddison, 1983). Reward is represented especially in the human medial orbitofrontal cortex, and punishment and non-reward in the lateral orbitofrontal cortex (Rolls, 2019f,e; Rolls, Cheng and Feng, 2020a; Grabenhorst and Rolls, 2011). The medial and lateral orbitofrontal cortex have effective connectivity to the pregenual anterior cingulate cortex, in part via the ventromedial prefrontal cortex (vmPFC) (Fig. 11.28) (Rolls et al., 2023c). The medial and lateral orbitofrontal cortex, and the vmPFC, then have effective connectivity with the hippocampal system (perirhinal and entorhinal cortex, and perhaps directly with the hippocampus) (Figs. 9.19 and 11.28) (Rolls et al., 2023c). The memory-related part of the posterior cingulate cortex provides additional connectivity between these reward-related regions and the hippocampal system (Rolls et al., 2023i, 2022a).

These neural connectivity investigations provide clear evidence on how reward value and emotion-related information can reach the human hippocampal system. It is proposed that in the hippocampus, including in CA3, reward value information can be associated with spatial view information to enable the reward and emotional aspects of episodic memory to become part of the episodic memory (Rolls et al., 2023c; Rolls, 2022b). The return pathways from the hippocampus to the orbitofrontal cortex, pregenual anterior cingulate cortex, and vmPFC shown in Figs. 9.19, 11.28 and 9.2 provide a route for the reward and emotional value of an episodic memory to be recalled back from the hippocampus to the orbitofrontal and anterior cingulate cortex and vmPFC (Treves and Rolls, 1994; Rolls and Treves, 1994; Rolls, 1995b, 2021b), from which it can influence other brain regions involved in actions (Rolls, 2021b; Rolls et al., 2020a, 2023c).

This connectivity described in humans also shows how a key component of navigation, the goal or reward towards which the navigation is directed, reaches the human hippocampal system, where navigation may be guided by a remembered sequence of spatial view locations encoded by spatial view cells (Rolls et al., 2023c; Rolls, 2021f,b).

9.2.8.5 Human hippocampal system and orbitofrontal / ventromedial prefrontal cortex connectivity involved in memory consolidation

The orbitofrontal cortex and pregenual anterior cingulate cortex have connectivity (yellow in Fig. 11.28) directed to the human cholinergic basal nucleus of Meynert which projects to the neocortex, and septal region which projects to the hippocampus, and these pathways are proposed to influence memory consolidation including consolidation into long-term semantic memory (Rolls et al., 2023c; Rolls, 2022b). It is proposed (Rolls, 2022b) that the orbitofrontal cortex, ventromedial prefrontal cortex (vmPFC), and anterior cingulate regions do not perform spatial computations, but influence them and memory by introducing reward inputs to the hippocampus which are key parts of episodic memory and navigation, and also by influencing the cholinergic system in the septal region that projects to the hippocampus, and in the basal forebrain that projects to the neocortex (Rolls et al., 2023c; Rolls, 2022b), and which are implicated in the synaptic mechanisms involved in memory consolidation (Newman et al.,

2012; Hasselmo and Sarter, 2011; Giocomo and Hasselmo, 2007; Hasselmo and Giocomo, 2006; Hasselmo and McGaughy, 2004; Hasselmo, 1999; Hasselmo and Bower, 1993). This new approach to memory consolidation, which is related to the effective connectivity of the orbitofrontal cortex, vmPFC and anterior cingulate with the hippocampal system directly and via the cholinergic brainstem nuclei (Rolls et al., 2023c) is described next.

Damage to the human vmPFC can impair memory, especially the ability to retrieve vivid autobiographical and episodic memories (McCormick et al., 2018; Bonnici and Maguire, 2018; Barry et al., 2018; Rosenbaum et al., 2014; Moscovitch et al., 2016; Preston and Eichenbaum, 2013; Gilboa and Marlatte, 2017). There is a reduced frequency of mind-wandering; and a reduced focus on future-oriented thoughts and an increased focus on present-related thought (McCormick et al., 2018; Ciaramelli and Treves, 2019). These patients have an inability to initiate internal reflections, including mental visualizations of extended events. In contrast, patients with hippocampal damage seem able to initiate mental events but they are devoid of visual representations of scenes (McCormick et al., 2018; Bonnici and Maguire, 2018). Hippocampal damage seems to particularly impair the spatial coherence of scenes, whereas vmPFC damage leads to a difficulty constructing scenes in a broader sense, with the prediction of what should be in a scene, and the monitoring or integration of the scene elements being particularly compromised (De Luca, McCormick, Mullally, Intraub, Maguire and Ciaramelli, 2018). Schemas can be defined as adaptable associative networks of knowledge extracted over multiple similar experiences (and are an important component of long-term semantic memory (van der Linden, Berkers, Morris and Fernandez, 2017; Farzanfar, Spiers, Moscovitch and Rosenbaum, 2023)), and patients with vmPFC damage appear to have problems in facilitating new encoding by memory schemas, with patients with confabulation (Rosenbaum et al., 2014) having difficulty in reinstating schemas (Ghosh et al., 2014; Ghosh and Gilboa, 2014). The vmPFC is also activated during the learning of new schemas (Gilboa and Marlatte, 2017). (In contrast with the vmPFC, the hippocampus is implicated more in single event memory in which details of the context are encoded (Moscovitch et al., 2016).)

Although the term vmPFC has been used to describe the region implicated in the memory deficits (McCormick et al., 2018; Bonnici and Maguire, 2018), this is not a very precise description, and in fact the overlap of the lesions that produce these problems is in the pregenual anterior cingulate cortex (De Luca, McCormick, Mullally, Intraub, Maguire and Ciaramelli, 2018), and it is activation in the pregenual and supragenual anterior cingulate cortex that precedes activation of the hippocampus during the recall of remote autobiographical memory (McCormick and Maguire, 2021).

The connectivity of the orbitofrontal cortex, vmPFC and pregenual anterior cingulate cortex that connects these reward and punishment emotion-related systems with the hippocampal system is described in Sections 9.2.8.4 and 11.3.10 (Fig. 11.28). A considerable part of the output of the human medial and lateral orbitofrontal cortex value / emotion system is thus directed towards the hippocampal system for memory (Fig. 11.28 (Rolls et al., 2023c)). It is proposed that this connectivity provides a key input about reward / punishment value for the hippocampal episodic memory system, adding to the ‘what’, ‘where’, and ‘when’ information that are also key components of episodic memory. Damage to the vmPFC / anterior cingulate cortex system is likely to contribute to episodic memory impairments produced by damage to these OFC/ vmPFC / ACC regions by impairing a key component of episodic memory, the reward / punishment / emotional value component. Such damage would impair the value information reaching the hippocampal system for storage, and also for later retrieval. Indeed, if one of the possible inputs such as the reward input used for hippocampal memory retrieval by completion in the CA3 attractor network was missing, that would be expected to im-

pair memory retrieval (Treves and Rolls, 1994; Rolls, 2018b; Treves and Rolls, 1991; Rolls, 2021b).

One of the great puzzles of the hippocampal episodic memory system is that hippocampal damage impairs not only episodic memory (the memory for particular events at a particular place and time), but also the learning of new semantic memories, that is knowledge about the world, facts, etc. Already existing semantic memory may show little impairment. A well-known example is that HM, who had bilateral medial temporal lobe damage which included large parts of the hippocampus, could not learn his way to his new house after the bitemporal surgery, but could remember his way to the house he lived in before the surgery. He could never learn who his doctors were (Corkin, 2002). There is much consistent evidence that hippocampal damage can impair new semantic learning (Duff et al., 2019). Why is the hippocampal episodic memory system so importantly involved in learning new semantic information? The new findings on the connectivity of the orbitofrontal cortex / vmPFC / anterior cingulate cortex system with the hippocampus (Rolls et al., 2023c) considered above lead to a new proposal.

During our daily lives, hundreds of events occur to us. We see many people and objects in many places. Some of these events will be associated with some value representation, for example if one of the people is a close friend, who perhaps tells us something useful about a scientific experiment. Most of the daily episodic events will have no value association. In any case, many of these episodic events are stored ‘on the fly’ in unstructured form in the hippocampus.

Later, when we are not faced with a barrage of incoming information in different episodes, we may have time to reflect on the events of the day. During that recall, the object/people and spatial but also value representations will be recalled by the hippocampus, with activation of neocortical areas that originally provided the object/person, spatial, and value information to the hippocampus for episodic memory storage as described above. If the recalled episodic memory during this time of reflection contains no value component, that is, is not useful to us, or is not very novel as signalled by the orbitofrontal cortex (Rolls et al., 2005a, 2020a; Rolls, 2019e,f), we are likely to think no more about those ‘insignificant’ events with no value/novelty association. However, if there is a reward/punishment/emotional/novelty component, then we are likely to keep thinking about the whole episode, and what we might learn from that episodic event. It is argued that the prolonged reflection on, and thinking about, episodic events with value associations, is key to learning new semantic memories which are only likely to be formed if they have some utility as reflected in orbitofrontal cortex / vmPFC processing. In reflecting on the episodic events, we try to incorporate them into our knowledge base, including schemas (van der Linden, Berkers, Morris and Fernandez, 2017) and adjust our knowledge base as necessary, that is, to learn new semantic information in neocortical areas such as the anterior temporal lobe, temporo-parietal junction, and angular gyrus (Bonner and Price, 2013; Rolls, 2021b; Rolls et al., 2022b; van der Linden et al., 2017; Farzanfar et al., 2023).

The proposal thus is that if an episodic event has a value component (including a potential value component) as signalled by the vmPFC / anterior cingulate cortex / orbitofrontal cortex, then that value information is likely to make us process the recalled episodic events deeply, and incorporate new information from the hippocampal episodic event into our neocortical knowledge / semantic memory. Evidence supporting this approach is that the depth of processing makes a large difference to how well a memory is encoded and stored (Craik and Tulving, 1975; Xue, 2018). Indeed, I propose that one key factor that influences the depth of processing and the storage of memory, and its conversion into a semantic representation with depth, is the reward value associated with the event, which reflects the utility of that event for long-term memory storage. I propose that the depth of processing tends to remain shallow for

daily events with no reward value or emotional component, and that if the event has reward value, we are far more likely to think about the ramifications of the event in depth, and to make use of the event in developing semantic representations and schemas. This provides a clear and testable hypothesis about how episodic memory can be so important in forming new semantic memories; and indeed accords the orbitofrontal cortex / vmPFC / pregenual anterior cingulate cortex a key role in influencing how the operation of episodic memory is related to the formation of new semantic memories, by allowing value to influence the processing and thereby the consolidation. Further support for the approach is that there is increasing acceptance that the vmPFC ‘helps refine hippocampal representations to form efficient concept spaces that are tuned based on goal relevance’ (Morton and Preston, 2021).

In addition, the medial orbitofrontal cortex (pOFC region) is the only cortical region in humans found to have effective connectivity directed to the basal forebrain magnocellular nucleus of Meynert (yellow in Fig. 11.28 (Rolls et al., 2023c)), which contains cholinergic neurons that project to the neocortex in humans (Mesulam, 1990; Zaborszky et al., 2018, 2008). The human pregenual anterior cingulate cortex (with subgenual 25 and 10r) in humans has effective connectivity directed to the septal nuclei (yellow in Fig. 11.28 (Rolls et al., 2023c)), which contains cholinergic neurons that project to the hippocampus in humans (Mesulam, 1990; Zaborszky et al., 2018, 2008). These pregenual anterior cingulate regions are likely to be important influences on septal neurons, for the only other cortical regions found with substantial effective connectivity to the human septal region (Rolls et al., 2023c) are the hippocampus, subiculum, and v23ab which is part of the posterior cingulate cortex also implicated in episodic memory (Rolls et al., 2023i). In accordance with this, it is proposed that the damage in humans to the orbitofrontal and anterior cingulate cortex regions that impairs episodic memory (Ciaramelli et al., 2019; McCormick et al., 2018) arises in part because of the reduced release of acetylcholine to reward / punishing / salient stimuli, which may impair long-term synaptic potentiation and thus memory storage in both the hippocampus and neocortex (Zaborszky et al., 2018; Newman et al., 2012; Hasselmo and Sarter, 2011; Giacomo and Hasselmo, 2007; Hasselmo and Giacomo, 2006; Rolls, 2021b).

Indeed, it has been discovered that different magnocellular neurons in the basal nucleus which are probably cholinergic respond to reinforcing (rewarding, or punishing), or novel, stimuli (Wilson and Rolls, 1990a,b,c), all represented in the orbitofrontal cortex (Rolls et al., 2005a; Rolls, 2019f,e). Cholinergic activation by these types of ‘salient’ stimuli can be utilised to enhance memory storage when these rewarding, punishing, or novel stimuli are encountered, which is evolutionarily adaptive by facilitating memory storage when rewarding, punishing, or novel environmental situations are encountered (Rolls and Deco, 2015b; Rolls, 2021b). Consistent with these proposals, depletion of acetylcholine in the forebrain by cholinergic lesions impairs scene memory (Easton, Ridley, Baker and Gaffan, 2002), and in the neocortical / hippocampal system (by depletion in the inferior temporal cortex and fornix transection) also impairs spatial scene memory in macaques (Browning, Gaffan, Crosson and Baxter, 2010).

In terms of the different effects of vmPFC and hippocampal damage on mind-wandering (McCormick et al., 2018; Ciaramelli and Treves, 2019), it is to be expected that damage to the orbitofrontal cortex region will impair neocortically mediated effects because the pOFC region has effective connectivity to the nucleus basalis which in turns connects to neocortical regions where it influences cortical excitability, learning, and thereby semantic memory consolidation (Fig. 11.28) (Rolls et al., 2023c). vmPFC lesions that influence the cholinergic nucleus basalis to neocortex system would thus be expected to impair long-term memory consolidation and remote memory including the use and development of schemata.

The view proposed here is therefore that there is not a major memory system / network

in the vmPFC that processes schemata, but that instead the vmPFC can modulate the use and generation of such schemata because of alteration of neocortical function produced by altering the nucleus basalis input to the neocortex. The normal function of this pOFC to nucleus basalis system is proposed, based on the above evidence, to release acetylcholine into the neocortex to facilitate its storage and processing functions when rewarding, punishing, or novel stimuli are encountered, which are important times when consolidation of memory in the neocortex may be useful, to facilitate the memory and semantic processing about those events. In contrast, as expected, damage to the hippocampus impairs mind-wandering about events in ‘recent’ memory (in the order of the last 6 months) (McCormick et al., 2018; Ciaramelli and Treves, 2019), and if vmPFC damage extends to the pregenual anterior cingulate cortex this hippocampal episodic memory system may also be impaired, because the pregenual anterior cingulate cortex has effective connectivity to the cholinergic septal region, as does the hippocampus, and this system is expected in a comparable way to modulate when the hippocampus stores episodic memory (Fig. 11.28) (Rolls et al., 2023c).

In summary, the following proposals are made in a new approach to memory consolidation in the brain (Rolls, 2022b), and show how better understanding of the connectivity of the human brain is leading to better understanding of what is computed in different brain regions, which in turn has implications for how the computations are performed, including in this case the roles of cholinergic systems.

1. The reward / punishment value system in the human orbitofrontal cortex and regions to which it projects including the vmPFC and pregenual anterior cingulate cortex have effective connectivity with the hippocampus, and provide an important value / emotion-related component of episodic memory used by the hippocampus in addition to ‘what’, ‘where’, and ‘when’ components.
2. Damage to the human vmPFC and anterior cingulate cortex may impair episodic memory implemented by the hippocampal system because it impairs this important component, value information. That may leave the memory system less anchored in goals, and therefore perhaps results in thinking less about the future.
3. Damage to the human orbitofrontal cortex, pregenual anterior cingulate cortex, and vmPFC may also impair activation of brain regions to which they connect, the basal forebrain cholinergic system which connects to the neocortex, and the cholinergic medial septal nuclei which project to the hippocampus, and thereby impair memory consolidation in the neocortex and hippocampus, leading to weaker memories, and thereby to confabulation, a key memory change that follows the medial prefrontal damage.
4. The value / utility component of hippocampal episodic memory representations dependent on the human orbitofrontal cortex / vmPFC / pregenual anterior cingulate cortex may influence the extent to which value-related episodic memories are repeatedly recalled and used in further processing. Greater depth of processing driven by an orbitofrontal cortex / vmPFC / pregenual anterior cingulate cortex value component of a recalled hippocampal episodic event memory is more likely to activate neocortical semantic representations and schemas which then are modified to incorporate new evidence from the episodic event. It is proposed that this is an important way in which the formation or correction of semantic memories depends on the operation of the hippocampal episodic memory system including its value component (Rolls, 2022b).

9.3 How computations are performed in the hippocampal system

Given the systems-level hypothesis that the primate hippocampus is involved in episodic memory, and the neurophysiological evidence about what is represented in the primate hippocampus (described in Section 9.2), we now consider *how* the hippocampus performs its computations. The computations include storing memories that often have a spatial or temporal component, and that can be formed rapidly, and later recalled back to the neocortex. A feature of the theory of hippocampal computation is that it is guided importantly by the neuronal network internal connectivity and synaptic modifiability of the hippocampus that enables it to store and retrieve many memories. Another feature of the theory is that it provides what I think is the only quantitative approach to how memories are retrieved from the hippocampus for later use in the neocortex. The computational theory of the hippocampus is described in this section (9.3), and has been developed in many papers (Rolls, 1989a, 1990b, 1989e,f, 1987; Treves and Rolls, 1994; Rolls, 1990a,b; Treves and Rolls, 1991, 1992; Rolls, 1996d; Rolls and Treves, 1998; Rolls, Stringer and Trappenberg, 2002; Stringer, Rolls and Trappenberg, 2005; Rolls and Stringer, 2005; Rolls and Kesner, 2006b; Rolls, Stringer and Elliot, 2006c; Kesner and Rolls, 2015; Rolls, 2016b, 2018b, 2021f). Ways in which the primate hippocampus could be involved in navigation are described in Section 9.3.15 (Rolls, 2021f).

9.3.1 Historical development of the theory of the hippocampus

Many scientists are interested in how the theory was developed, and a brief account is now provided. Some other approaches to hippocampal computation are considered in Section 9.7.

The theory was preceded by work of Marr (1971) who developed a mathematical model, which although not applied to particular networks within the hippocampus and dealing with binary neurons and binary synapses which utilised heavily the properties of the binomial distribution, was important in utilizing computational concepts. The model was assessed by Willshaw and Buckingham (1990) and Willshaw, Dayan and Morris (2015)¹¹, who showed that Marr's model did not require any recurrent collateral effect. Early work of Gardner-Medwin (1976) showed how progressive recall could operate in a network of binary neurons with binary synapses.

Rolls (1987) described a theory of the hippocampus that had been presented to the Dahlem conference in 1985 on the Neural and Molecular Bases of Learning in which the CA3 neurons operated as an autoassociation memory to store episodic memories including object and place memories, and could operate using **pattern completion** to recall the whole memory from any part. Rolls (1987) also proposed that the dentate granule cells operated as a preprocessing stage for this by performing **pattern separation** so that the mossy fibres could act to set up different representations for each memory to be stored in the CA3 cells. Rolls (1987) proposed that the CA1 cells operate as a recoder for the information recalled from the CA3

¹¹Marr (1971) showed how a network with recurrent collaterals could complete a memory using a partial retrieval cue, and how sparse representations could increase the number of memories stored. The analysis of these auto-association or attractor networks was developed by Kohonen (1977) and Hopfield (1982), and the value of sparse representations was quantified by Treves and Rolls (1991). Marr (1971) did not specify the functions of the dentate granule cells vs the CA3 cells vs the CA1 cells (which were addressed in the Rolls (1989) papers (see e.g. Rolls (1990b) and Rolls (1990b)) and by Treves and Rolls (1992) and Treves and Rolls (1994)), nor how retrieval to the neocortex of hippocampal memories could be produced, for which a theory was developed by Rolls (1990b) and made quantitative by Treves and Rolls (1994). In addition, Treves and Rolls (1994) and Rolls and Treves (1998) have argued that approaches to neurocomputation which base their calculations on what would happen in the tail of an exponential, Poisson, or binomial distribution are very fragile.

cells to a partial memory cue, so that the recalled information would be represented more efficiently to enable recall, via the backprojection synapses, of activity in the neocortical areas similar to that which had been present during the original episode¹². This theory was developed further (Rolls, 1989a, 1990b, 1989e,f, 1990a,b), including further details about how the backprojections could operate (Rolls, 1990b, 1989e), and how the dentate granule cells could operate as a competitive network and could further produce *pattern separation* by using the very diluted connectivity of the dentate to CA3 neuron mossy fibre synapses (Rolls, 1989a, 1990b, 2013b, 2016f, 2021i). Quantitative aspects of the theory were then developed with Alessandro Treves, who brought the expertise of theoretical physics applied previously mainly to understand the properties of fully connected attractor networks with binary neurons (Amit, 1989; Hopfield, 1982) to bear on the much more diluted connectivity of the recurrent collateral connections found in real biological networks (e.g. 2% between CA3 pyramidal cells in the rat), in networks of neurons with graded (continuously variable) firing rates, graded synaptic strengths, and sparse representations in which only a small proportion of the neurons is active at any one time, as is found in the hippocampus (Treves, 1990; Treves and Rolls, 1991). These developments in understanding quantitatively the operation of more biologically relevant recurrent networks with modifiable synapses were applied quantitatively to the CA3 region (Treves and Rolls, 1991), and to the issue of why there are separate mossy fibre and perforant path inputs to the CA3 cells of the hippocampus (Treves and Rolls, 1992). This whole model of the hippocampus was described in more detail, and a quantitative treatment of the theory of recall by backprojection pathways in the brain was formulated (Treves and Rolls, 1994; Rolls and Treves, 1994).

The speed of operation of the CA3 system, and of the cortico-cortical recall backprojections, was addressed in a number of developments (Battaglia and Treves, 1998b; Panzeri, Rolls, Battaglia and Lavis, 2001; Simmen, Rolls and Treves, 1996a; Treves, 1993). Rolls (1995b) produced a simulation of the operation of the major parts of the hippocampus from the entorhinal cortex through the dentate, CA3, and CA1 cells back to the hippocampus, which established the quantitative feasibility of the whole theory, and raised a number of important issues considered below, including the role of topography within parts of the hippocampal internal connectivity. The simulation also emphasized some of the advantages, for a system that must store many different memories, of a binary representation, in which for any one memory the neurons were either firing or not, as opposed to having continuously graded firing rates. The simulation by Rolls (1995b) also showed how recall, if not perfect at the stage of the CA3 cells, was improved by associative synapses at subsequent stages, including the connections of the CA3 cells to the CA1 cells, and the connections of the CA1 cells to the entorhinal cortex cells.

The theory has been developed further (Stringer, Rolls and Trappenberg, 2005; Rolls, Tromans and Stringer, 2008f; Rolls, 2010b; Webb, Rolls, Deco and Feng, 2011; Rolls and Webb, 2012; Rolls, 2012b, 2013c,b; Kesner and Rolls, 2015; Rolls, 2015a, 2016f,b, 2018b; Rolls and Wirth, 2018; Rolls and Mills, 2019; Rolls, 2020b, 2021d,f, 2022b), as described below.

¹²McNaughton and Morris (1987) at about the same time suggested that the CA3 network might be an autoassociation network, and that the mossy fibre to CA3 connections might implement 'detonator' synapses. However, the concepts that the diluted mossy fibre connectivity might implement selection of a new random set of CA3 cells for each new memory, and that a direct perforant path input to CA3 was needed to initiate retrieval, were introduced by Treves and Rolls (1992). The theory of CA1 and of backprojections to the neocortex for memory recall were introduced by Rolls (1990b). Contributions by Levy (1989); McNaughton (1991); Hasselmo et al. (1995); McClelland et al. (1995); and many others, are described below.

Fig. 9.20 An example of a CA3 neuron from the hippocampus. The thick extensions from the cell body or soma are the dendrites, which form an extensive dendritic tree receiving in this case approximately 12,000 synapses. The axon is the thin connection leaving the cell. It divides into a number of collateral branches. Two axonal branches can be seen in the plane of the section to travel to each end of the population of CA3 cells. One branch (on the left) continues to connect to the next group of cells, the CA1 cells. The junction between the CA3 and CA1 cells is shown by the two arrows. The diagram shows a camera lucida drawing of a single CA3 pyramidal cell intracellularly labelled with horseradish peroxidase. DG, dentate gyrus. The small letters refer to the different strata of the hippocampus. (Reproduced from Norio Ishizuk, Janet Weber and David G. Amaral (1990) Organization of intrahippocampal projections originating from CA3 pyramidal cells in the rat. *Journal of Comparative Neurology* 295: 580–623. Copyright © Wiley-Liss, Inc.)

Tests of the theory including analysis of the functions of different subregions of the hippocampus are described in Section 9.4 and by Rolls and Kesner (2006b) and Kesner and Rolls (2015).

9.3.2 Hippocampal circuitry

Figs. 9.2 on page 318, 9.20, 9.21 and 9.22 show diagrams of hippocampal circuitry that is described next, based on many sources (Amaral, Ishizuka and Claiborne, 1990; Storm-Mathiesen, Zimmer and Ottersen, 1990; Amaral and Witter, 1989; Amaral, 1993; Naber, Lopes da Silva and Witter, 2001; Lavenex, Suzuki and Amaral, 2004; Witter, Wouterlood, Naber and Van Haeften, 2000b; Johnston and Amaral, 2004; Witter, 2007; van Strien, Cappaert and Witter, 2009; Kondo, Lavenex and Amaral, 2009).

Projections from the entorhinal cortex layer 2 reach the granule cells (of which there are 10^6 in the rat) in the dentate gyrus (DG), via the perforant path (pp) (Witter, 1993).

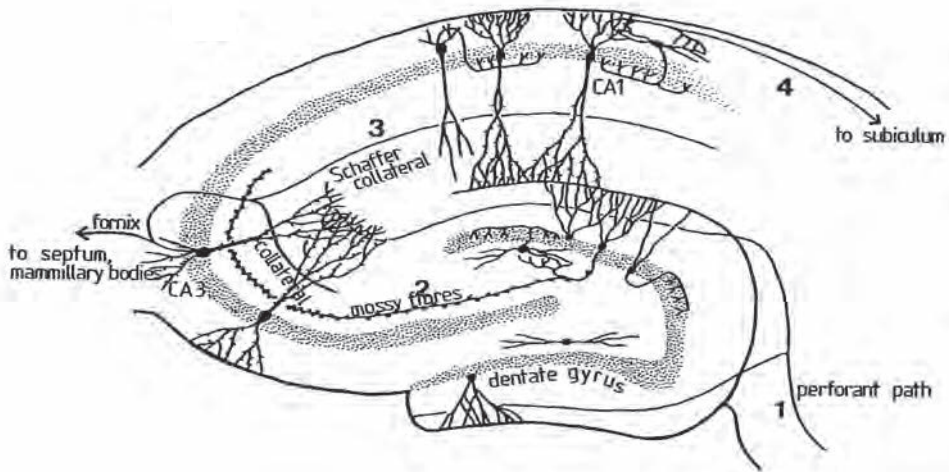

Fig. 9.21 Representation of connections within the hippocampus. Inputs reach the hippocampus through the perforant path (1) which makes synapses with the dendrites of the dentate granule cells and also with the apical dendrites of the CA3 pyramidal cells. The dentate granule cells project via the mossy fibres (2) to the CA3 pyramidal cells. The well-developed recurrent collateral system of the CA3 cells is indicated. The CA3 pyramidal cells project via the Schaffer collaterals (3) to the CA1 pyramidal cells, which in turn have connections (4) to the subiculum.

In the dentate gyrus there is a set of inhibitory interneurons that provide recurrent inhibition between the granule cells. (In addition, there are some excitatory interneurons in the hilus that interconnect granule cells.) The granule cells project to CA3 cells via the mossy fibres (mf), which provide a sparse but possibly powerful connection to the 3×10^5 CA3 pyramidal cells in the rat. Each CA3 cell receives approximately 50 mossy fibre inputs, so that the sparseness of this connectivity is thus 0.005%. By contrast, there are many more – probably weaker – direct perforant path inputs also from layer 2 of the entorhinal cortex onto each CA3 cell, in the rat in the order of 4×10^3 . The largest number of synapses (about 1.2×10^4 in the rat) on the dendrites of CA3 pyramidal cells is, however, provided by the (recurrent) axon collaterals of CA3 cells themselves (rc) (see Fig. 9.23). It is remarkable that the recurrent collaterals are distributed to other CA3 cells throughout the hippocampus (Amaral and Witter, 1989, 1995; Amaral, Ishizuka and Claiborne, 1990; Ishizuka, Weber and Amaral, 1990; Witter, 2007), so that effectively the CA3 system provides a single network, with a connectivity of approximately 2% between the different CA3 neurons given that the connections are bilateral.

The CA3–CA3 recurrent collateral system is even more extensive in macaques than in rats (Kondo, Lavenex and Amaral, 2009). This is a clear indication that in primates there is recurrent collateral connectivity within a hemisphere to provide for a single autoassociation / attractor network in the primate CA3. Interestingly, the left and right CA3 neurons in humans are not connected across the midline, so the human has two hippocampi (which doubles the number of memories that can be stored), whereas the rat has a single hippocampus. The neurons that comprise CA3, in turn, project to CA1 neurons via the Schaffer collaterals. In addition, projections that terminate in the CA1 region originate in layer 3 of the entorhinal cortex (see Fig. 9.2).

Some of the neuron numbers in different parts of the circuitry in humans are shown in Fig. 9.2 (Rogers Flattery et al., 2020). Very important for humans would be an estimate of the number of synapses that the CA3 recurrent collaterals make on each CA3 neuron, for that sets the limit on the memory capacity of the hippocampal system, as shown below.

A CA2 group of cells lies between CA3 and CA1. CA2 neurons do not have highly

Fig. 9.22 Functional canonical microcircuit of the hippocampal cortex. Recurrent collateral connections (rc) are shown as a loop back to a particular population of cells, of which just one neuron is shown. (From Rolls, E. T. (2016) *Cerebral Cortex: Principles of Operation*. Oxford University Press: Oxford.)

Fig. 9.23 The numbers of connections onto each CA3 cell from three different sources in the rat. (After Treves, A. and Rolls, E. T. (1992) Computational constraints suggest the need for two distinct input systems to the hippocampal CA3 network. *Hippocampus* 2: 189–199. © Churchill Livingstone Inc; and Rolls, E. T. and Treves, A. (1998) *Neural Networks and Brain Function*. Oxford University Press: Oxford.)

developed recurrent collaterals that mix with CA3 recurrent collaterals. CA2 does act to dis-inhibit CA1, where it may act as a general facilitator on CA1 of learning about its CA3 inputs about ‘what’, ‘when’ and reward associations, for which CA1 uses competitive learning. The CA2 neurons are influenced by oxytocin (Tirko, Eyring, Carcea, Mitre, Chao, Froemke and Tsien, 2018), and may play a role in the facilitating effects that social interactions have on memory (Oliva, 2022). In this context, CA2 has been proposed to play a role in the facilitation of memories of events that might be relevant to territoriality (Wirth et al., 2021).

9.3.3 Medial entorhinal cortex, spatial processing streams, and grid cells

The entorhinal cortex (area 28) provides inputs to the hippocampus, as well as receiving the outputs of the hippocampus (Garcia and Buffalo, 2020), so its operation is considered briefly first. The medial (/posterior) entorhinal cortex receives spatial inputs from the dorsal ‘spatial’ processing streams via the parahippocampal gyrus, and provides a route for these to enter the hippocampus; and for the return routes from the hippocampus to send backprojections back via the parahippocampal gyri to the dorsal ‘spatial’ processing streams (the red pathways in Fig. 9.2). The lateral (/anterior) entorhinal cortex receives inputs from the ventral ‘object’ processing streams via the perirhinal cortex, and provides a route for these to enter the hippocampus; and for the return routes from the hippocampus to send backprojections back via the perirhinal cortex to the ventral ‘object’ processing streams (the blue pathways in Fig. 9.2).

The entorhinal cortex performs interesting computations in its own right. In the rodent medial entorhinal cortex, there are grid cells, which have regularly spaced peaks of firing in an environment, so that as a rat runs through an environment, a single neuron increases then decreases its firing a number of times as the rat traverses the environment (Hafting et al., 2005; Moser et al., 2015). Each grid cell responds to a set of places in a spatial environment, with the places to which a cell responds set out in a regular grid. Different grid cells have different phases (positional offsets) and grid spacings or frequencies (Hafting, Fyhn, Molden, Moser and Moser, 2005; Giocomo, Moser and Moser, 2011; Moser, Rowland and Moser, 2015; Kropff and Treves, 2008). The grid cell system appears to provide ring continuous attractors that would be useful for spatial path integration (computing position based on self-motion) (Giocomo et al., 2011; Moser et al., 2014a; Zilli, 2012).

One attractive theory is that different temporal delays in the neural circuitry of the medial entorhinal cortex are related to different temporal adaptation time courses and result in the different sizes of spatial grids that are found in the rodent medial entorhinal cortex (Kropff and Treves, 2008; Soldatkina, Schonsberg and Treves, 2022).

An interesting computational issue is how the grid cells present in the medial entorhinal cortex (Hafting, Fyhn, Molden, Moser and Moser, 2005; Moser, Rowland and Moser, 2015) might help to generate hippocampal place cells in rodents. We have proposed that this could be performed by competitive learning, implemented in the dentate granule cells (or beyond) in the hippocampal system (Rolls, Stringer and Elliot, 2006c). Each grid cell responds to a set of places in a spatial environment, with the places to which a cell responds set out in a regular grid. Different grid cells have different phases (positional offsets) and grid spacings or frequencies (Hafting, Fyhn, Molden, Moser and Moser, 2005; Giocomo, Moser and Moser, 2011; Moser, Rowland and Moser, 2015; Kropff and Treves, 2008). We have simulated the dentate granule cells as a system that receives as inputs the activity of a population of grid cells as the animal traverses a spatial environment, and have shown that the competitive net builds dentate-like place cells from such entorhinal grid cell inputs (Rolls, Stringer and Elliot, 2006c). This occurs because the combination of entorhinal cortex grid cells that are co-active when the animal is in one place become associated together by the action of the competitive net. Each dentate cell represents primarily one place because the dentate representation is kept sparse, thus helping to implement symmetry-breaking. Simulations to demonstrate this are shown next. The operation of competitive nets is described in Section B.4, and the anatomical connectivity is that of a competitive net, with the entorhinal inputs making synaptic connections onto the dendrites of the dentate granule cells, as shown in Figs. 9.2 and 9.21.

Fig. 9.24a and b show examples of two 2D entorhinal cortex (EC) grid cells (with frequencies of 4 and 7 cycles along the X axis) (Rolls, Stringer and Elliot, 2006c). As in the

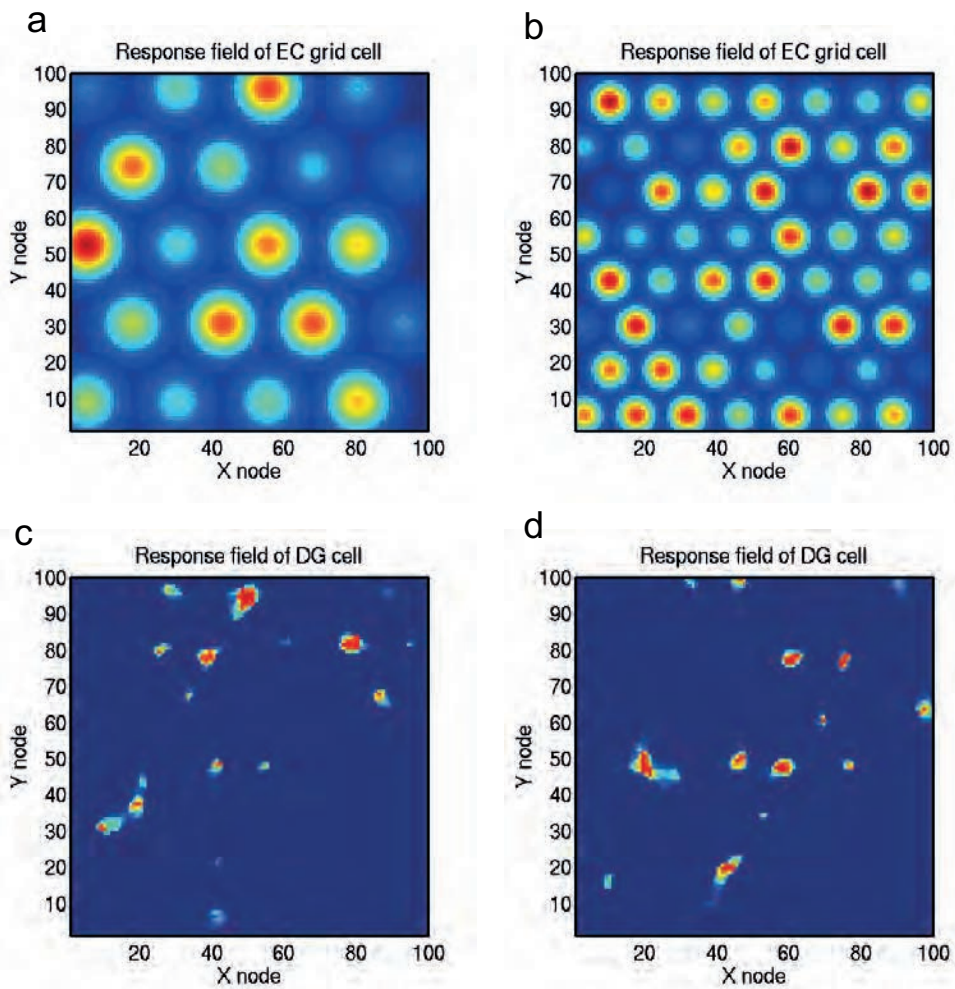

Fig. 9.24 Simulation of competitive learning in the dentate gyrus to produce place cells from the entorhinal cortex grid cell inputs. (a and b) Firing rate profiles of two entorhinal cortex (EC) grid cells with frequencies of 4 and 7 cycles. (c and d) Firing rate profiles of two dentate gyrus (DG) cells with no training. (After Rolls, E. T., Stringer, S.M. and Elliot, T. (2006) Entorhinal cortex grid cells can map to hippocampal place cells by competitive learning. *Network: Computation in Neural Systems* 17: 447–465. © Informa UK Limited.)

neurophysiological recordings (Hafting et al., 2005), the firing peaks occur at the vertices of a grid of equilateral triangles. Fig. 9.24c and d show the firing rate profiles of two dentate gyrus (DG) cells without training. Multiple peaks in the response profiles are evident, and this shows that the contrast enhancement and the competitive interactions in the DG layer were not sufficient without training and thereby synaptic modification to produce place-like fields in DG.

Fig. 9.25a and b show the firing rate profiles of two Dentate Granule cells after training with the Hebb rule. This type of relatively small 2D place field was frequently found in the simulations. This result shows that competitive learning was sufficient to produce place-like fields in the dentate granule cells. Fig. 9.25c and d show the firing rate profiles of two DG cells after training with the trace rule, which is a modified form of Equation B.32 on page 873 that has a short-term memory trace of previous neuronal activity as specified in Equation 2.3 on page 110. The use of the trace rule is intended to test the concept that by keeping neurons

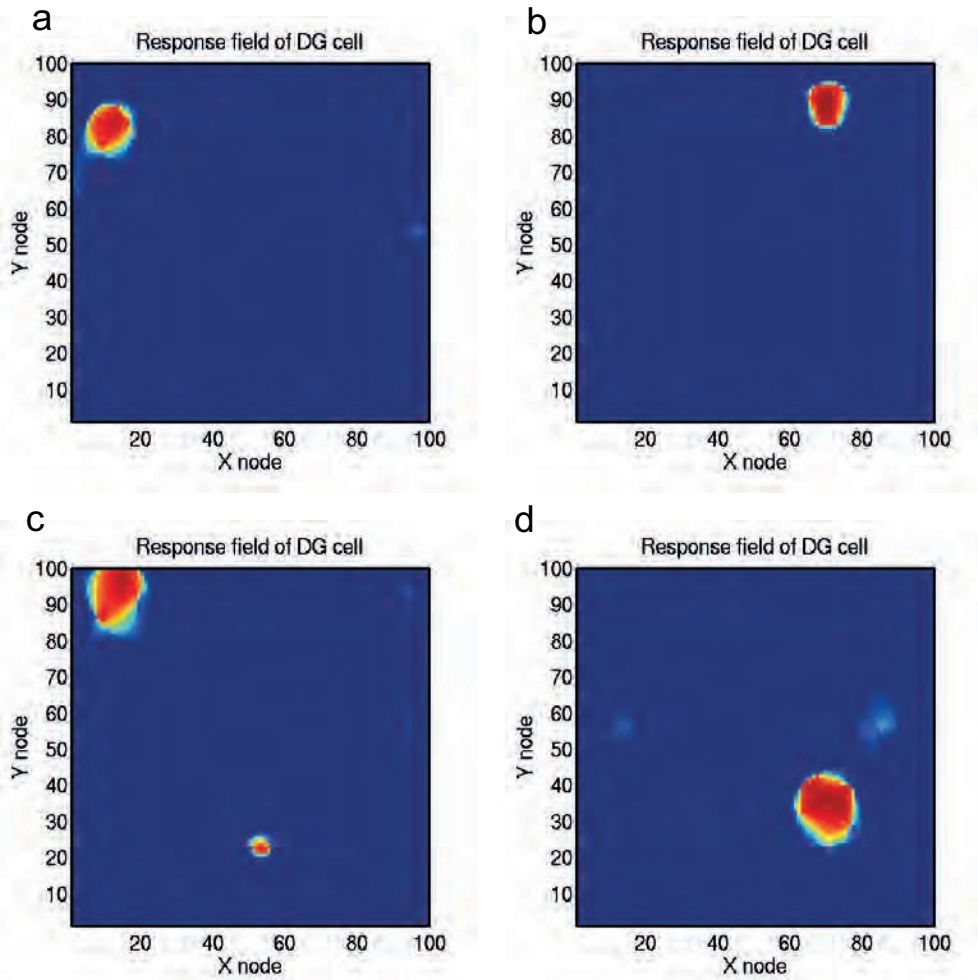

Fig. 9.25 Simulation of competitive learning in the dentate gyrus (DG) to produce place cells from the entorhinal cortex grid cell inputs. (a and b) Firing rate profiles of two DG cells after training with the Hebb associative synaptic modification rule. (c and d) Firing rate profiles of two DG cells after training with the trace rule with $\eta = 0.8$. (After Rolls, E. T., Stringer, S.M. and Elliot, T. (2006) Entorhinal cortex grid cells can map to hippocampal place cells by competitive learning. *Network: Computation in Neural Systems* 17: 447–465. © Informa UK Limited.)

in a modifiable state for a short time after strong activation (using for example the long time constant of NMDA receptors) the inputs from places near to a recently visited place where the activity of the neuron was high will tend to become associated onto the same postsynaptic neuron, thereby enlarging the place field. In the simulations, the place fields tended to be larger with the trace than with the purely associative Hebb rule shown in Equation 9.8 (Rolls, Stringer and Elliot, 2006c).

Although the Dentate Granule cells illustrated had one main place field, some remaining grid-like firing was sometimes evident in the place fields with both Hebb and trace rule training, and indeed is evident in Fig. 9.25c and d. These are also characteristics of dentate granule cells recorded under the same conditions as the EC grid cell experiments (E. Moser, personal communication). These results were found only with training, with untrained networks showing repeating peaks of firing in large parts of the space as illustrated in Fig. 9.24c and d. These results show that competitive learning can account for the mapping of 2D grid cells in the en-

torhinal cortex to 2D place cells in the dentate gyrus / CA regions (Rolls, Stringer and Elliot, 2006c). The sparseness of the dentate cell representation, set by the feedback inhibitory neurons in the dentate gyrus, sets the number of place fields that are typically found in the dentate granule cells. The role of competitive learning in forming dentate granule cells with single or multiple place fields (Rolls, Stringer and Elliot, 2006c) has been confirmed (Si and Treves, 2009; Soldatkina, Schonsberg and Treves, 2022).

In the macaque entorhinal cortex, there is evidence for spatial view grid cells, which have peaks and troughs of firing for different viewed locations in space (Killian et al., 2012; Rueckemann and Buffalo, 2017; Meister and Buffalo, 2018; Garcia and Buffalo, 2020). These may be the equivalent of rodent grid cells, but now involved in the continuous representation of visual space, which is so developed in primates. In the human entorhinal and cingulate cortex neurons with grid-like response properties are found (Jacobs, Weidemann, Miller, Solway, Burke, Wei, Suthana, Sperling, Sharan, Fried and Kahana, 2013; Nadasdy, Nguyen, Torok, Shen, Briggs, Modur and Buchanan, 2017), and there is neuroimaging evidence that is consistent with this (Nau, Navarro Schroder, Bellmund and Doeller, 2018b; Julian, Keinath, Frazzetta and Epstein, 2018). This is further evidence for the concept that representations of locations being viewed in space ‘out there’ is a key property of spatial representations in the hippocampal system of primates including humans.

9.3.4 Lateral entorhinal cortex, object processing streams, and the generation of time cells in the hippocampus

As noted above, the lateral entorhinal cortex is involved in representing object information, and provides a route for inputs from the ventral processing streams to reach the hippocampus, and for return pathways from the hippocampus back to the ventral processing streams (Hargreaves et al., 2005; Witter, 1993; Knierim et al., 2014; Huang et al., 2021; Rolls et al., 2022a; Ma et al., 2022a; Rolls et al., 2023e).

However, in addition the lateral entorhinal cortex may play a special role in the generation of timing information, which becomes strongly represented as time cells especially in CA1, as described in Section 9.3.7.4. Although some cells with time-related information are present in the medial entorhinal cortex (Kraus, Brandon, Robinson, Connerney, Hasselmo and Eichenbaum, 2015), in the lateral entorhinal cortex, temporal information is robustly encoded across time scales from seconds to many minutes within neuronal populations in freely foraging rats (Tsao, Sugar, Lu, Wang, Knierim, Moser and Moser, 2018). In the lateral entorhinal cortex, the neurons that encode time have rather long firing rate timescales in which the firing of individual neurons may ramp down towards zero over many minutes, and in some cases may ramp or jump up from low rates to these high rates before starting another decrease in firing over a long period (Tsao et al., 2018), as illustrated in Fig. 9.26b.

9.3.4.1 The theory of the generation of time in the brain, and of hippocampal time cells

The encoding of the time-related information in the hippocampus appears to use a firing rate code, in that different CA1 hippocampal neurons have short periods of firing at different times in a delay period, and thus reflect which temporal part of the task is current (Macdonald, Lepage, Eden and Eichenbaum, 2011). An example is shown in Fig. 9.26c (Kraus et al., 2013). Some hippocampal neurons in both CA3 and CA1 fire to combinations of time and object or place (Eichenbaum, 2017; Salz et al., 2016; Howard and Eichenbaum, 2015; Eichenbaum, 2014), thus reflecting associations of objects and places with time which enable the sequence of places and/or objects to be remembered (Rolls and Mills, 2019).

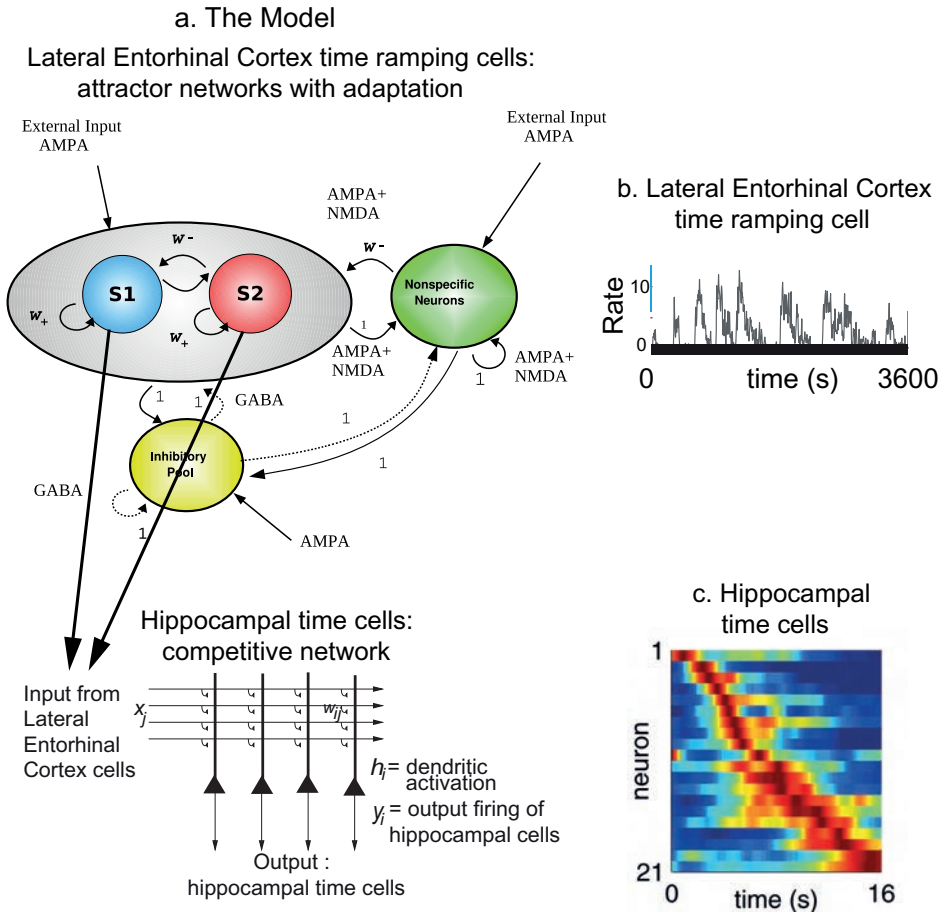

Fig. 9.26 The generation of time in the hippocampal memory system. Model of the lateral entorhinal cortex temporal cells and hippocampal time cells. a. The lateral entorhinal cortex is modelled as an integrate-and-fire attractor neuronal network. The excitatory neurons are divided into two selective populations or pools S1 and S2 either of which can sustain a high firing rate attractor state because of strong synaptic connections w_+ within each population. The inhibitory neurons ensure that only one population, S1, or S2, can be active at any one time. In the model, there are three such attractor networks for the lateral entorhinal cortex, each with different time constants for the synaptic depression that occurs in the recurrent collaterals of the attractors networks (indicated by recurrent arrows), so that nets 1–3 tend to cycle with different periods (long, medium, and short). The S1 and S2 pools of all three lateral entorhinal cortex attractor networks send their outputs to a competitive network in the hippocampus (e.g. in CA1 or in the dentate gyrus). The competitive network learns to respond to combinations of the outputs of the lateral entorhinal cortex, and forms thereby hippocampal time cells, as shown in the simulations. b. Example of a lateral entorhinal cortex time ramping cell recorded in the rat by Tsao et al. (2018). The firing rate is in spikes/s. These neurons are characterized by slow ramping changes in their firing rates with a long time period. c. Hippocampal time cells recorded in the rat by Kraus et al (2013). Each neuron of the 21 shown has a high firing rate for a short period of time during a 16 s interval during which the rat was running on a treadmill. The firing rate is indicated by the color with low rates blue, and high rates red/brown. (From Rolls, E. T. and Mills, P. (2019) The generation of time in the hippocampal memory system. *Cell Reports* 28: 1649–1658. [b from Albert Tsao, Jorgen Sugar, Li Lu, Cheng Wang, James J. Knierim, May-Britt Moser, and Edvard I. Moser (2018) Integrating time from experience in the lateral entorhinal cortex. *Nature* 561: 57–62. © Springer Nature. c from Benjamin J. Kraus, Robert J. Robinson, John A. White, Howard Eichenbaum, and Michael E. Hasselmo (2013) Hippocampal ‘Time Cells’: Time versus Path Integration. *Neuron* 78: 1092. © Elsevier Inc.]

Rolls and Mills (2019) proposed that ramping time cells in the lateral entorhinal cortex can be produced by synaptic adaptation, and demonstrated this in an integrate-and-fire attractor network model. They proposed that competitive networks in the hippocampal system can convert these entorhinal cortex time ramping cells into hippocampal time cells, and demonstrated this in a competitive network (Fig. 9.26). Rolls and Mills (2019) proposed that this

conversion is necessary to provide orthogonal hippocampal time representations to encode the temporal sequence of events in hippocampal episodic memory, and supported that with analytic arguments.

The theory proposed for the lateral entorhinal cortex temporal encoding cells, with their very slow ramping firing rate time courses that may gradually decrease, or increase, over often very many seconds, is that this is implemented by attractor networks with adaptation with a time course of many seconds (Rolls and Mills, 2019). The adaptation considered here is synaptic adaptation or depression that reflects the amount of neuronal activity, but neuronal adaptation is an alternative. The network is set up so that within a network, one attractor is typically active, but as the synapses of its neurons adapt, its firing rate gradually decreases, resulting in less inhibition via inhibitory interneurons on another attractor population in the same net, which can then rise into activity as it is not showing adaptation at that stage. The result is that two (or more) attractor populations within a single network keep cycling into high firing rate attractor states with a period determined approximately by the time constant of the adaptation / depression process.

The theory is that within the lateral entorhinal cortex there are at least three different networks with different time constants for the adaptation (Rolls and Mills, 2019), with the longer time constant networks deeper in the entorhinal cortex, consistent with the empirical evidence (Kropff and Treves, 2008). This enables different time periods to be spanned. The theory also is that the different networks, each with their own characteristic time constant and cycling period, are weakly interconnected with synapses that with their weak effects help to keep the different lateral entorhinal cortex networks influencing each other in the interests of mild synchrony helping to produce robust and reliable coding, because the different networks are interacting weakly (Section B.9) (Rolls, 2016b).

The theory then is that this very temporally broad encoding of time, in terms of the temporal dynamics of each cell, and by the very distributed representation because many different neurons or neuronal populations have their own gradual time courses, is converted into a temporally discrete code, by allocating neurons in the hippocampus to learn combinations of the firing of many different lateral entorhinal cortex cells (Rolls and Mills, 2019) (Fig. 9.26). The hippocampal time code is much more time discrete, and is therefore much better suited to making associations between this discrete and sparse time cell code with object representations in the hippocampus. The hippocampal / dentate gyrus network that is proposed to learn these different combinations is a competitive network. By forming neurons that respond differently to different combinations of the different time courses of different populations of entorhinal cortex neurons, a time-unique code suitable for sequential memory can be formed in the hippocampus. This is completely analogous to our theory that a competitive network is used to convert medial entorhinal cortex grid cell firing into hippocampal place cell firing (Rolls et al., 2006c), suitable in a parallel way for object-place associations, and reflecting it is suggested the conservatism in brain design (Rolls, 2016b). The overall architecture is illustrated in Fig. 9.26.

9.3.4.2 The model of lateral entorhinal cortex temporal cells and hippocampal time cells

The theory was tested, illustrated, and analyzed in a simulation that provided a model shown in Fig. 9.26 with biologically plausible characteristics (Rolls and Mills, 2019). The lateral entorhinal cortex was modelled as three networks, each with an integrate-and-fire attractor neuronal network with synaptic adaptation in the recurrent collateral synapses (Rolls and Deco, 2016). In the model as simulated, there are three such attractor networks for the lateral entorhinal cortex, each with different time constants for the synaptic depression that occurs in

the recurrent collaterals of the attractor networks, so that Nets 1–3 tend to cycle with different periods (long, medium, and short).

The synaptic depression mechanism used for the recurrent collateral connections between the neurons in each specific pool, i.e. within S1 or within S2, following Dayan and Abbott (2001) and Deco and Rolls (2005c), was as follows. The probability of transmitter release P_{rel} was decreased after each presynaptic spike by a factor $P_{\text{rel}} = P_{\text{rel}} \cdot f_D$ with $f_D = 0.999$. Between presynaptic action potentials the release probability P_{rel} was updated by

$$\tau_P \frac{dP_{\text{rel}}}{dt} = P_0 - P_{\text{rel}} \quad (9.1)$$

with $P_0 = 1$ and $\tau_P = 25$ s.

Each lateral entorhinal cortex network was a biophysically realistic attractor network, so that the properties of receptors, synaptic currents and the statistical effects related to the probabilistic spiking of the neurons could be part of the model (Brunel and Wang, 2001; Rolls and Deco, 2010) with synaptic adaptation (Rolls and Mills, 2019; Deco and Rolls, 2005c). The S1 and S2 pools of all three lateral entorhinal cortex attractor networks send their outputs to a competitive network in the hippocampus (e.g. in CA1 or in the dentate gyrus) (Fig. 9.26). The competitive network learns to respond to combinations of the outputs of the lateral entorhinal cortex, and forms thereby hippocampal time cells, as shown in the simulations. A description of the operation and properties of competitive networks, together with demonstration simulation software, is provided with this book (see Appendices B and D). The fully connected 2-layer lateral entorhinal cortex (LEC) / hippocampal model has the architecture of a competitive network. There is an input layer of 6 LEC temporal cell populations (S1 and S2 from Nets 1–3) with feedforward associatively modifiable synaptic connections onto an output layer of 20 hippocampal cells (Fig. 9.26).

9.3.4.3 Operation of the entorhinal-hippocampal time generation network

Fig. 9.27a shows a simulation of the lateral entorhinal cortex model with an intermediate value for the time constant of the synaptic adaptation set by $f_D=0.99960$ for Net 2. The firing rates in Nets 1–3 are shown, and within each network, the firing rates of the population of neurons in S1 and S2 are shown. For Net 1, the value of $f_D=0.99972$, producing a longer time constant for the synaptic depression and longer cycle times for the firing of Net 1. For Net 3, the value of $f_D=0.99800$, producing a shorter time constant for the synaptic depression and shorter cycle times for the firing of Net 3.

Fig. 9.27b shows the firing of the hippocampal (e.g. CA1) neurons in the same simulation. The hippocampal neurons have been sorted so that the neuron that fires first in the sequence is in the top row. Each vertical yellow line represents firing by a hippocampal neuron. The first 100 s of the simulation is shown.

Fig. 9.27c shows the simulation of the firing of the hippocampal (e.g. CA1) neurons as illustrated in Fig. 9.27b, but now for the full 1000 s of the simulation. An interesting point emerges, that the hippocampal neurons come back into activity again later on. This is also found by neurons recorded in the lateral entorhinal cortex (Tsao, Sugar, Lu, Wang, Knierim, Moser and Moser, 2018). However, Fig. 9.27c also shows that a reasonable approximation of the 120 s sequence repeats later on in the time period of 1000 s. This is evidence that the whole system is generating a time signature that is reasonably stable over the whole 1000 s time period, in that components of the sequence are replayed later on in time. This ‘replay’ is more evident in the simulations for shorter time periods described by Rolls and Mills (2019).

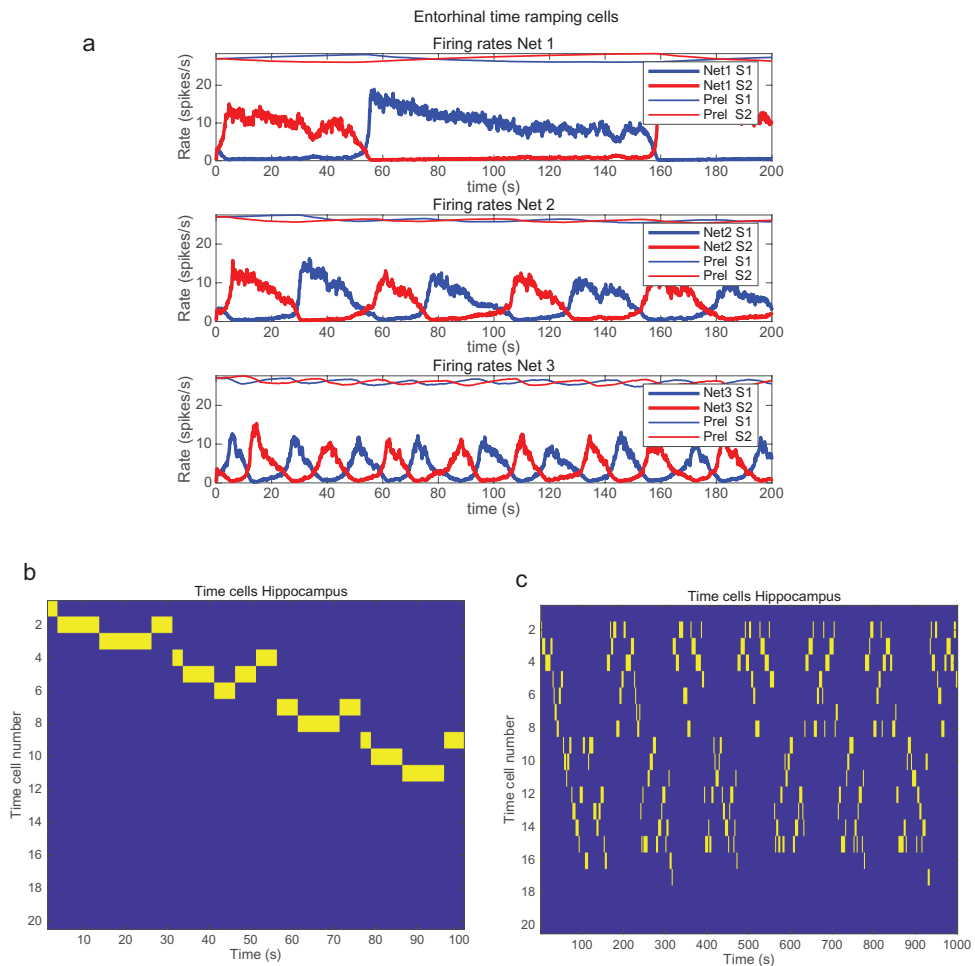

Fig. 9.27 The generation of time in the hippocampal memory system. Simulation of the model with a long value for the time constant set by $fD=0.99960$ for Net 2. a. The firing rates in Nets 1–3 are shown, and within each network, the firing rates of the population of neurons in S1 and S2 are shown. In addition the value of the variable P_{tel} for pools S1 and S2 is shown, scaled so that a value of $P_{tel}=1$ is shown as 30 on the y axis. For Net 1, the value of $fD=0.99972$, producing a longer time constant for the synaptic depression and longer cycle times for the firing of Net 1. For Net 3, the value of $fD=0.99800$, producing a shorter time constant for the synaptic depression and shorter cycle times for the firing of Net 3. The first 200 s period of a 600 s simulation in which similar firing continued is shown. b,c. The firing of the hippocampal neurons in the same simulation. The hippocampal neurons have been sorted so that the neuron that fires first in the sequence is in the top row. Each vertical yellow line represents firing by a hippocampal neuron. The first 100 s of the simulation is shown in (b), and the full 1000 s of the simulation is in (c). The whole 1000 s of the simulation shows that although the neurons may be synchronised to be in a particular order at the start of the simulation (or potentially by an external event), the neurons have further time-ordered bursts of firing later in time. (From Rolls, E. T. and Mills, P. (2019) The generation of time in the hippocampal memory system. *Cell Reports* 28: 1649–1658.)

9.3.4.4 Forward and reverse replay of temporal sequences by the time generation system

To investigate whether the forward and reverse replay illustrated in Fig. 9.27 is a robust emergent property of this neuronal architecture, we ran the same competitive network simulations, but for the lateral entorhinal cortex replaced the firing of the integrate-and-fire neurons with precisely generated waveforms, for example square waves as shown in Fig. 9.28a (Rolls and Mills, 2019). An example of the perfect play and reverse replay that resulted is shown in Fig. 9.28b.

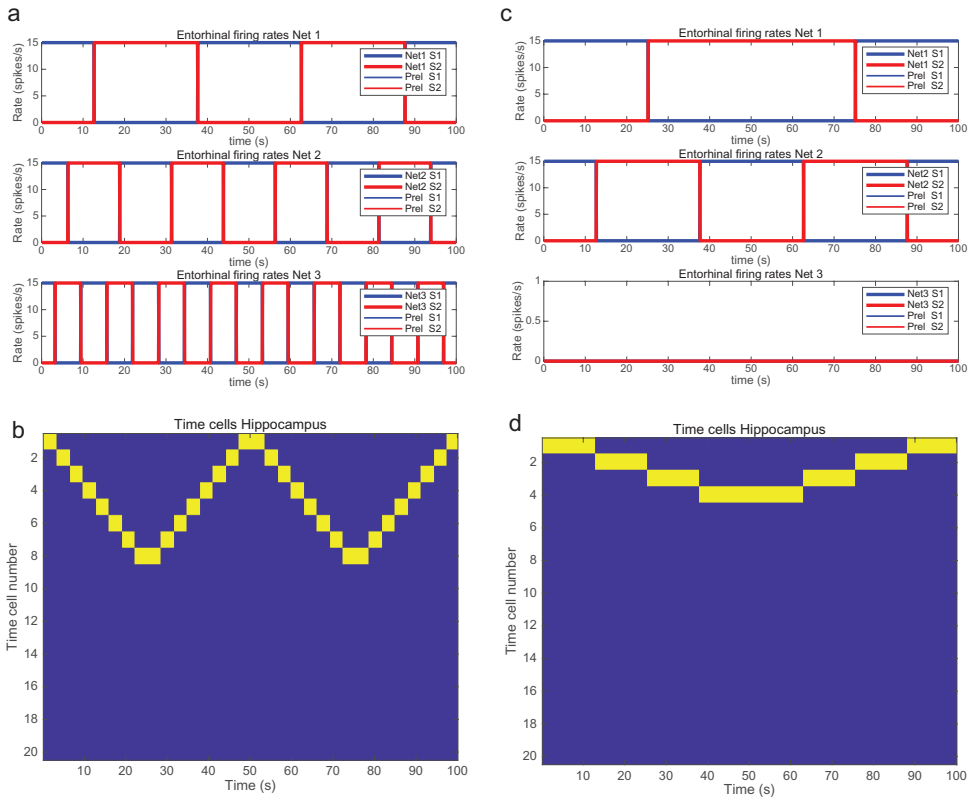

Fig. 9.28 The generation of time in the hippocampal memory system. Simulations to show how replay and reverse replay can be generated. a. Simulated square waves for the lateral entorhinal cortex for Nets 1–3, with a frequency of 2 for Net 1, 4 for Net 2, and 8 for Net 3. b. The hippocampal neurons produced by the lateral entorhinal cortex firing in (a) have been sorted so that the neuron that fires first in the sequence is in the top row. Each vertical yellow line represents firing by a hippocampal neuron. After the initial sequence in which 8 neurons come into successive firing, from 0–25 s, there is a period of reverse replay from 25–50 s. This is followed by a repetition of the initial forward sequence from 50–75 s; and this is followed by reverse replay of the sequence from 75–100 s. c. Simulated square waves for the lateral entorhinal cortex for Nets 1–2, with a frequency of 1 for Net 1, 2 for Net 2, and no firing for Net 3. d. The hippocampal neurons produced by the lateral entorhinal cortex firing in (c) have been sorted so that the neuron that fires first in the sequence is in the top row. After the initial sequence in which 4 neurons come into successive firing, from 0–50 s, there is a period of reverse replay from 50–100 s. (From Rolls, E. T. and Mills, P. (2019) The generation of time in the hippocampal memory system. *Cell Reports* 28: 1649–1658.)

We explained the mechanism using Fig. 9.28c, d with a simplified system in which only Nets 1 and 2 of the entorhinal cortex are active (Fig. 9.28c). Fig. 9.28d shows that Neuron 1 had learned to respond to the combination of Net 1 population S1 firing, and Net 2 population S1 firing. Neuron 2 had learned to respond to Net 1 S1 and Net 2 S2. Neuron 3 had learned to respond to Net 1 S2 and Net 2 S2. Neuron 4 had learned to respond to Net 1 S2 and Net 2 S1. It is now possible to see that these combinations of firing in Nets 1 and 2 then occur in reverse sequence, generating the reverse replay in the hippocampal neurons. Only four neurons are needed to encode the combinations of firing in Nets 1 and 2, and no other hippocampal neurons have learned to respond, because this is a competitive network (see Section B.4).

This provides a computational account for the frequently studied and observed ‘reverse replay’ recorded from hippocampal neurons in rodents (Foster and Wilson, 2006; Foster, 2017; Berners-Lee, Feng, Silva, Wu, Ambrose, Pfeiffer and Foster, 2022). The account provided here is that ‘reverse replay’ may be a simple or mechanistic but emergent property of a set of coupled timers of the type found in the lateral entorhinal cortex which is then recoded into or-

thogonal categories using combinations of the timers learned by a competitive network in the hippocampus. The replay and reverse replay described here are at the same rate as in the original sequence, because they are controlled by the time ramping cells of the lateral entorhinal cortex. We propose that the much more rapid replay and reverse replay described so far in the hippocampus, occurring over sometimes 200 ms for the whole sequence, may be playback from the recurrent collateral CA3 attractor network, which once it has been presented with replay and reverse replay temporal sequences, may play them back at high speed determined primarily by the synaptic delay time constants in the recurrent collateral CA3–CA3 attractor network (Sompolinsky and Kanter, 1986; Rolls, 2016b) (see Section B.6).

This research advances understanding of how the computations are performed in the entorhinal–hippocampal system (Rolls and Mills, 2019). The research shows how temporal encoding could be formed in the lateral entorhinal cortex; how this code is not suitable for an associative episodic memory system of the type implemented in the hippocampus; and how time cells found in the hippocampus could be produced, with an appropriately sparse and orthogonal representation of time for use in a hippocampal memory system that can associate place and/or time with objects to encode and later retrieve episodic memories, in which CA1 is especially implicated (Kesner and Rolls, 2015) (see Section 9.3.7.4).

It has been suggested that learning temporal sequences of events is an important function of the hippocampus which may be useful in remembering the sequence of events in an episodic memory (Kesner and Rolls, 2015; Buzsaki and Tingley, 2018), and this research shows how synaptic adaptation taking place over time in the lateral entorhinal cortex can then lead to neurons that are appropriate for learning temporal sequences in for example CA1 of the hippocampus (see Section 9.3.7.4). The research also shows how forward and reverse replay can be generated in the brain. The hypothesis is that recall to the neocortex can be in the correct temporal sequence as a result of the hippocampal system mechanisms described here, using the hippocampal to neocortical backprojection system described in Section 9.3.8. The reverse replay described may be a mechanistic consequence of the way in which the memory of temporal sequences is implemented in the brain. Whether the fast reverse replay observed neurophysiologically performs a useful function such as the transfer of information to the neocortex for consolidation (Foster and Wilson, 2006; Foster, 2017; Berners-Lee et al., 2022) is an open issue in the light of the mechanisms described here that generate it as a side effect. Alternative mechanisms that are likely to be involved in memory consolidation are described in Section 9.2.8.5 (Rolls, 2022b).

Part of the interest of this computational approach to how time cells are formed in the hippocampus by competitive learning of inputs from the lateral entorhinal cortex, is that the mechanism is very similar to that involved in transforming medial entorhinal cortex grid cells into dentate and hippocampal place cells. This probably reflects reuse of the same computational mechanism to perform computations using different types of input, and is an example of how evolution often works by reusing similar neural operations to perform different functions and computations (Rolls, 2016b).

9.3.5 CA3 as an autoassociation memory

9.3.5.1 Arbitrary associations, and pattern completion in recall

CA3 recurrent collaterals form a single attractor network

The architecture of the CA3 neurons is shown in Figs. 9.2 and 9.21. There is a highly developed CA3 to CA3 recurrent collateral system forming a single network (see Section 9.3.2).

Moreover, many of the synapses in the hippocampus show associative modification as shown by long-term potentiation, and this synaptic modification appears to be involved in

Fig. 9.29 The architecture of an attractor or autoassociation neural network. The architecture of a discrete attractor neural network used for storing discrete patterns is the same as that of a continuous attractor neural network (CANN) used for storing continuous, e.g. spatial, patterns (see further Sections B.3 and B.5).

learning (Morris, 2003, 1989; Morris et al., 2003; Lynch, 2004; Nakazawa et al., 2003, 2004; Andersen et al., 2007; Wang and Morris, 2010; Jackson, 2013; Siegelbaum and Kandel, 2013; Takeuchi et al., 2014) (Section 1.6). On the basis of the evidence summarized above, Rolls has proposed that the CA3 stage acts as an autoassociation memory that enables episodic memories to be formed and stored in the CA3 network, and that subsequently the extensive recurrent collateral connectivity allows for the retrieval of a whole representation to be initiated by the activation of some small part of the same representation (the cue) (Rolls, 1987, 1989a, 1990b, 1989f, 1990a,b). The crucial synaptic modification for this is in the recurrent collateral synapses. (A description of the operation of autoassociative networks is provided in Section B.3 and by Hertz et al. (1991) and Rolls and Treves (1998). The architecture of an autoassociation network is shown in Fig. 9.29.)

Rolls' theory presented at the Dahlem conference in 1985 (Rolls, 1987) is that because the CA3 operates effectively as a single network because of its long-range recurrent collaterals that extend throughout the CA3 region, it can allow arbitrary associations between inputs originating from very different parts of the cerebral neocortex to be formed (Rolls, 1987, 1989a, 1990b, 1989f, 1990a,b). These might involve associations between information originating in the temporal visual cortex about the presence of an object, and information originating in the parietal cortex about where it is. I note that although there is some spatial gradient in the CA3 recurrent connections, so that the connectivity is not fully uniform (Ishizuka et al., 1990; Witter, 2007), nevertheless the network will still have the properties of a single interconnected autoassociation network allowing associations between arbitrary neurons to be formed, given the presence of many long-range connections which overlap from different CA3 cells. It is very interesting indeed that in primates (macaques), the associational projections from CA3 to CA3 travel extensively along the longitudinal axis, and overall the radial, transverse, and longitudinal gradients of CA3 fiber distribution, clear in the rat, are much more subtle in the nonhuman primate brain (Kondo, Lavenex and Amaral, 2009). The implication is that in primates, the CA3 network operates even more as a single network than in rodents.

The autoassociation or attractor memory is different from pattern association memory, in which a visual stimulus might become associated with a taste by associative synaptic modification. Later presentation of the visual stimulus would retrieve the taste representation. However, presentation of the taste would not retrieve the visual representation, and this

is an important and fundamental difference between autoassociation and pattern association, as described in detail in Appendix B. Pattern association memories generalize, and auto-association memories complete incomplete representations. Further, competitive networks can generalize, but may not complete perfectly depending on what input is being clamped into the network (Appendix B).

Tests of the attractor hypothesis of CA3 operation based on the effects of CA3 lesions or CA3 NMDA knockouts on pattern completion are described in Section 9.4 (Kesner and Rolls, 2015). Another type of test of the autoassociation (or attractor) hypothesis for CA3 has been to train rats in different environments, e.g. a square and a circular environment, and then test the prediction of the hypothesis that when presented with an environment ambiguous between these, hippocampal neurons will fall into an attractor state that represents one of the two previously learned environments, but not a mixture of the two environments. Evidence consistent with the hypothesis has been found (Wills, Lever, Cacucci, Burgess and O’Keefe, 2005). In a particularly dramatic example, it has been found that within each theta cycle, hippocampal pyramidal neurons may represent one or other of the learned environments (Jezek, Henriksen, Treves, Moser and Moser, 2011). This was measured by recording in an ambiguous environment, in which it was found that the CA3 representation ‘flickered’ between two possible environments. This is an indication, predicted by Rolls and Treves (1998) (page 118), that autoassociative memory recall can take place sufficiently rapidly to be complete within one theta cycle (120 ms), and that theta cycles could provide a mechanism for a fresh retrieval process to occur after a reset caused by the inhibitory part of each theta cycle, so that the memory can be updated rapidly to reflect a continuously changing environment, and not remain too long in an attractor state.

Storage capacity

We have performed quantitative analyses of the storage and retrieval processes in the CA3 network (Treves and Rolls, 1991, 1992). We have extended previous formal models of autoassociative memory (Amit, 1989) by analyzing a network with graded response neurons, so as to represent more realistically the continuously variable rates at which neurons fire, and with incomplete connectivity (Treves, 1990; Treves and Rolls, 1991). We have found that in general the maximum number p_{\max} of firing patterns that can be (individually) retrieved is proportional to the number C^{RC} of (associatively) modifiable recurrent collateral synapses per neuron, by a factor that increases roughly with the inverse of the population sparseness a^p of the neuronal representation. The sparseness a^p of the representation can be measured, by extending the binary notion of the proportion of neurons that are firing, as

$$a^p = \frac{(\sum_{i=1}^N y_i/N)^2}{\sum_{i=1}^N y_i^2/N} \quad (9.2)$$

where y_i is the firing rate of the i th neuron in the set of N neurons (Treves and Rolls, 1991; Rolls and Treves, 1998; Rolls and Deco, 2002; Franco, Rolls, Aggelopoulos and Jerez, 2007). More precisely, Treves and Rolls (1991) and Rolls, Treves, Foster and Perez-Vicente (1997c) have shown that such a network with graded patterns does operate efficiently as an auto-associative network, and can store (and recall correctly) a number of different patterns p as follows

$$p \approx \frac{C^{\text{RC}}}{a^p \ln(\frac{1}{a^p})} k \quad (9.3)$$

where C^{RC} is the number of synapses on the dendrites of each neuron devoted to the recurrent collaterals from other neurons in the network, and k is a factor that depends weakly on the detailed structure of the rate distribution, on the connectivity pattern, etc., but is roughly in the order of 0.2–0.3. For example, for $C^{RC} = 12,000$ and $a^p = 0.02$ (realistic estimates for the rat), p_{max} is calculated to be approximately 36,000. This analysis emphasizes the utility of having a sparse representation in the hippocampus, for this enables many different memories to be stored. Third, in order for most associative networks to store information efficiently, heterosynaptic long term depression (Fazeli and Collingridge, 1996) (as well as LTP) is required (Rolls and Treves, 1990; Treves and Rolls, 1991) (see Section B.3). Simulations that are fully consistent with the analytic theory are provided by Simmen, Treves and Rolls (1996b) and Rolls, Treves, Foster and Perez-Vicente (1997c).

We have also indicated how to estimate I , the total amount of information (in bits per synapse) that can be retrieved from the network. (Information theory applied to what is represented in the brain is described in Appendix C.) I is defined with respect to the information i_p (in bits per cell) contained in each stored firing pattern, by subtracting the amount i_l lost in retrieval and multiplying by p/C^{RC} :

$$I \approx \frac{p}{C^{RC}}(i_p - i_l) \quad (9.4)$$

The maximal value I_{max} of this quantity was found (Treves and Rolls, 1991) to be in several interesting cases around 0.2–0.3 bits per synapse, with only a mild dependency on parameters such as the sparseness of coding a^p .

We may then estimate (Treves and Rolls, 1992) how much information has to be stored in each pattern for the network to efficiently exploit its information retrieval capacity I_{max} . The estimate is expressed as a requirement on i_p :

$$i_p > a^p \ln\left(\frac{1}{a^p}\right) \quad (9.5)$$

As the information content i_p of each stored pattern depends on the storage process, we see how the retrieval capacity analysis, coupled with the notion that the system is organized so as to be an efficient memory device in a quantitative sense, leads to a constraint on the storage process.

A number of points deserve comment. First, if it is stated that a certain number of memories is the upper limit of what could be stored in a given network, then the question is sometimes asked, what constitutes a memory? The answer is precise (Section B.3). Any one memory is represented by the firing rates of the population of neurons that are stored by the associative synaptic modification, and can be correctly recalled later. The firing rates in the primate hippocampus might be constant for a period of for example 1 s in which the monkey was looking at an object in one position in space; synaptic modification would occur in this time period (cf. the time course of LTP, which is sufficiently rapid for this); and the memory of the event would have been stored. The quantitative analysis shows how many such random patterns of rates of the neuronal population can be stored and later recalled correctly. If the rates were constant for 5 s while the rat was at one place or the monkey was looking at an object at one position in space, then the memory would be for the pattern of firing of the neurons in this 5-s period. (The pattern of firing of the population refers to the rate at which each neuron in the population of CA3 neurons is firing.)

Second, the question sometimes arises of whether the CA3 neurons operate as an attractor network. An attractor network is one in which a stable pattern of firing is maintained once it has been started. Autoassociation networks trained with modified Hebb rules can store the number of different memories, each one expressed as a stable attractor, indicated in Equation

B.15. However, the hippocampal CA3 cells do not necessarily have to operate as a stable attractor: instead, it would be sufficient for the present theory if they can retrieve stored information in response to a partial cue initiating retrieval. The partial cue would remain on during recall, so that the attractor network would be operating in the clamped condition (Rolls and Treves, 1998) (see Section B.3). The completion of the partial pattern would then provide more information than entered the hippocampus, and the extra information retrieved would help the next stage to operate. Demonstrations of this by simulations that are fully consistent with the analytic theory are provided by Rolls (1995b), Simmen, Treves and Rolls (1996b), and Rolls, Treves, Foster and Perez-Vicente (1997c).

Third, in order for most associative networks to store information efficiently, heterosynaptic long term depression (as well as LTP) is required (Rolls and Treves, 1990; Treves and Rolls, 1991; Rolls, 1996c). Without heterosynaptic LTD, there would otherwise always be a correlation between any set of positively firing inputs acting as the input pattern vector to a neuron. LTD effectively enables the average firing of each input axon to be subtracted from its input at any one time, reducing the average correlation between different pattern vectors to be stored to a low value (Rolls, 1996c) (see Section B.3).

Fourth, the firing of CA3 cells is relatively sparse, and this helps to decorrelate different population vectors of CA3 cell firing for different memories (Rolls, 2013c,b). (Sparse representations are more likely to be decorrelated with each other (Appendices B and C).) Evidence on the sparseness of the CA3 cell representation in rats includes evidence that CA3 cell ensembles may support the fast acquisition of detailed memories by providing a locally continuous, but globally orthogonal spatial representation, onto which new sensory inputs can rapidly be associated (Leutgeb and Leutgeb, 2007). In the macaque hippocampus, in which spatial view cells are found, for the representation of 64 locations around the walls of the room, the mean single cell sparseness a^s was 0.34, and the mean population sparseness a^p was 0.33 (Rolls, Treves, Robertson, Georges-François and Panzeri, 1998b; Rolls and Treves, 2011). For comparison, the corresponding values for macaque inferior temporal cortex neurons tuned to objects and faces were 0.77 (Franco, Rolls, Aggelopoulos and Jerez, 2007; Rolls and Treves, 2011); for taste and oral texture neurons in the insular cortex the population sparseness was 0.71; for taste and oral texture neurons in the orbitofrontal cortex was 0.61; and for taste and oral texture neurons in the amygdala was 0.81 (Rolls and Treves, 2011). Thus the evidence is that the hippocampal CA3 / pyramidal cell representation is more sparse in macaques than in neocortical areas and the amygdala, and this is consistent with the importance in hippocampal CA3 of using a sparse representation to produce a large memory capacity. Although the value of a for the sparseness of the representation does not seem especially low, it must be remembered that these are graded firing rate representations, and the graded nature appears to increase the value of a (Rolls and Treves, 2011). Moreover, these values were obtained in just one spatial environment, and if measured over many spatial environments, might be more sparse. A further analysis of how to interpret these sparseness measures is provided in Section C.3.1.1, and their potential utility in better understanding hippocampal representations in humans is described by Rolls (2023d).

Fifth, given that the memory capacity of the hippocampal CA3 system is limited, it is necessary to have some form of forgetting in this store, or another mechanism, to ensure that its capacity is not exceeded. (Exceeding the capacity can lead to a loss of much of the information retrievable from the network.) Heterosynaptic LTD could help this forgetting, by enabling new memories to overwrite old memories (Rolls, 1996c) (see Section B.19). The limited capacity of the CA3 system does also provide one of the arguments that some transfer of information from the hippocampus to neocortical memory stores may be useful (see Treves and Rolls (1994)). Given its limited capacity, the hippocampus might be a useful store for only a limited period, which might be in the order of days, weeks, or months. This period may well

depend on the acquisition rate of new episodic memories. If the animal were in a constant and limited environment, then as new information is not being added to the hippocampus, the representations in the hippocampus would remain stable and persistent. These hypotheses have clear experimental implications, both for recordings from single neurons and for the gradient of retrograde amnesia, both of which might be expected to depend on whether the environment is stable or frequently changing. They show that the conditions under which a gradient of retrograde amnesia might be demonstrable would be when large numbers of new memories are being acquired, not when only a few memories (few in the case of the hippocampus being less than a few hundred) are being learned.

The potential link to the gradient of retrograde amnesia is that the retrograde memories lost in amnesia are those not yet consolidated in longer term storage (in the neocortex). As they are still held in the hippocampus, their number has to be less than the storage capacity of the (presumed) CA3 autoassociative memory. Therefore the time gradient of the amnesia provides not only a measure of a characteristic time for consolidation, but also an upper bound on the rate of storage of new memories in CA3. For example, if one were to take as a measure of the time gradient in the monkey, say, 5 weeks (about 50,000 min) (Squire, 1992) and as a reasonable estimate of the capacity of CA3 in the monkey e.g $p = 50,000$, then one would conclude that there is an upper bound on the rate of storage in CA3 of not more than one new memory per minute, on average. (This might be an average over many weeks; the fastest rate might be closer to 1 per s, see Treves and Rolls (1994).) These quantitative considerations are consistent with the concept described in Section 9.2.3 that retrieval of episodic memories from the hippocampus for a considerable time after they have been stored would be useful in helping the neocortex to build a semantic memory (Rolls, 1990a, 1989f, 1990b,a; Treves and Rolls, 1994; Moscovitch et al., 2005; McClelland et al., 1995; Rolls, 2022b).

Recall and Completion

A fundamental property of the autoassociation model of the CA3 recurrent collateral network is that the recall can be symmetric, that is, the whole of the memory can be retrieved from any part. For example, in an object–place autoassociation memory, an object could be recalled from a place retrieval cue, and vice versa. This is not the case with a pattern association network. If for example the CA3 activity represented a place / spatial view, and perforant path inputs with associative synapses to CA3 neurons carried object information (consistent with evidence that the lateral perforant path (LPP) may reflect inputs from the perirhinal cortex connecting via the lateral entorhinal cortex (Hargreaves et al., 2005)), then an object could recall a place, but a place could not recall an object.

Another fundamental property is that the recall can be complete even from a small fragment. Thus, it is a prediction that when an incomplete retrieval cue is given, CA3 may be especially important in the retrieval process. Tests of this prediction are described in Section 9.4. Further evidence for pattern completion has been observed using imaging with voltage-sensitive dye in the CA3 region of a rat hippocampal slice. Following the induction of long-term potentiation from two stimulation sites activated simultaneously, stimulation at either of the two sites produced the whole pattern of activation that could be produced from both stimulation sites before LTP, thus demonstrating pattern completion in CA3 (Jackson, 2013).

CA3 as a short term attractor memory

Another fundamental property of the autoassociation model of the CA3 recurrent collateral network is that it can implement a short-term memory by maintaining the firing of neurons using the excitatory recurrent collateral connections. A stable attractor can maintain one memory active in this way for a considerable period, until a new input pushes the attractor to represent a new location or memory (see Section B.3). For example, if one place were

being held in a CA3 place short-term memory, then if the rat moved to a new place, the CA3 representation would move to represent the new place, and the short-term memory held in the CA3 network would be lost. It is thus predicted that when the hippocampus is used as a short-term memory with ongoing neuronal activity used to represent the short-term memory, then maintenance of the memory will be very dependent on what happens in the delay period. If the animal is relatively isolated from its environment and does not move around in a well-defined spatial environment (as can be achieved by placing a vertical cylinder / bucket around a rat in the delay period), then the memory may be maintained for a considerable period in the CA3 (and even updated by idiothetic, self-motion, inputs as described below). However, the CA3 short-term memory will be very sensitive to disruption / interference, so that if the rat is allowed to move in the spatial environment during the delay period, then it is predicted that CA3 will not be able to maintain correctly the spatial short-term memory. In the circumstances where a representation must be kept active while the hippocampus (or inferior temporal visual cortex or parietal cortex) must be updating its representation to reflect the new changing perceptual inputs, which must be represented in these brain areas for the ongoing events to have high-level representations, the prefrontal cortex is thought computationally to provide an off-line buffer store, see Section 13.6.1.

The predictions are thus that if there is no task in a delay period (and no need for an off-line buffer store), the hippocampus may be sufficient to perform the short-term memory function (such as remembering a previous location), provided that there is little distraction in the delay period. On the other hand, short-term memory deficits are predicted to be produced by prefrontal cortex lesions if there are intervening stimuli in a delay period in a task. However, the order of items in a hippocampal episodic memory is important, and the mechanism for this is proposed to be the lateral entorhinal cortex / CA1 system that generates time cells, which can then be associated with objects or places to remember the order of the items (see Sections 9.3.4 and 9.3.7.4).

9.3.5.2 Continuous, spatial, patterns and CA3 representations: hippocampal charts

The fact that spatial patterns, which imply continuous representations of space, are represented in the hippocampus has led to the application of continuous attractor models to help understand hippocampal function. This has been necessary, because space is inherently continuous, because the firing of place and spatial view cells is approximately Gaussian as a function of the distance away from the preferred spatial location, because these cells have spatially overlapping fields, and because the theory is that these cells in CA3 are connected by Hebb-modifiable synapses. This specification would inherently lead the system to operate as a continuous attractor network. Such models have been developed with the hippocampus in mind (Samsonovich and McNaughton, 1997; Battaglia and Treves, 1998b; Rolls, Stringer and Trappenberg, 2002; Stringer, Trappenberg, Rolls and De Araujo, 2002b; Stringer, Rolls, Trappenberg and De Araujo, 2002a; Stringer and Rolls, 2002; Stringer, Rolls and Trappenberg, 2004, 2005; Stringer and Rolls, 2006) and are described next (see for detailed description Section B.5).

A class of network that can maintain the firing of its neurons to represent any location along a continuous physical dimension such as spatial position, head direction, etc. is a 'continuous attractor' neural network (CANN). It uses excitatory recurrent collateral connections between the neurons (as are present in CA3) to reflect the distance between the neurons in the state space of the animal (e.g. place or head direction). These networks can maintain the bubble of neural activity constant for long periods wherever it is started to represent the current state (head direction, position, etc) of the animal, and are likely to be involved in many aspects

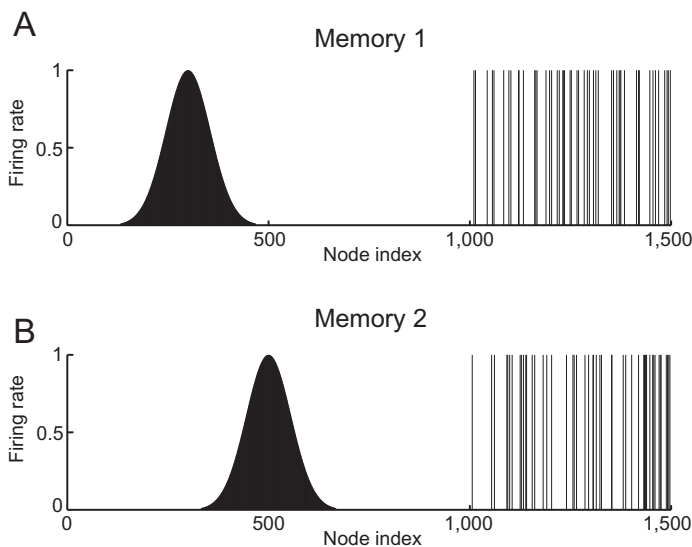

Fig. 9.30 An attractor network can associate continuous spatial patterns with discrete sets of neurons firing to represent for example objects. This provides a basis for the hippocampal CA3 network to associate spatial locations with objects or people. The types of firing patterns stored in continuous attractor networks are illustrated for the patterns present on neurons 1–1,000 for Memory 1 (when the firing is that produced when the spatial state represented is that for location 300), and for Memory 2 (when the firing is that produced when the spatial state represented is that for location 500). The continuous nature of the spatial representation results from the fact that each neuron has a Gaussian firing rate that peaks at its optimal location. This particular mixed network also contains discrete representations that consist of discrete subsets of active binary firing rate neurons in the range 1,001–1,500. The firing of these latter neurons can be thought of as representing the discrete events that occur at the location. Continuous attractor networks by definition contain only continuous representations, but this particular mixed network can store mixed continuous and discrete representations, and is illustrated to show the difference of the firing patterns normally stored in separate continuous attractor and discrete attractor networks. For this particular mixed network, during learning, Memory 1 is stored in the synaptic weights, then Memory 2, etc, and each memory contains a part that is continuously distributed to represent physical space, and a part that represents a discrete event or object. (After Rolls, E. T., Stringer, S.M. and Trappenberg, T.P. (2002) A unified model of spatial and episodic memory. *Proceedings of the Royal Society B* 269: 1087–1093. © The Royal Society.)

of spatial processing and memory, including spatial vision. Global inhibition is used to keep the number of neurons in a bubble or packet of actively firing neurons relatively constant, and to help to ensure that there is only one activity packet. Continuous attractor networks can be thought of as very similar to autoassociation or discrete attractor networks (see Appendix B), and have the same architecture, as illustrated in Fig. 9.29. The main difference is that the patterns stored in a CANN are continuous patterns, with each neuron having broadly tuned firing which decreases with for example a Gaussian function as the distance from the optimal firing location of the cell is varied, and with different neurons having tuning that overlaps throughout the space. Such tuning is illustrated in Fig. 9.30. For comparison, autoassociation networks normally have discrete (separate) patterns (each pattern implemented by the firing of a particular subset of the neurons), with no continuous distribution of the patterns throughout the space (see Fig. 9.30). A consequent difference is that the CANN can maintain its firing at any location in the trained continuous space, whereas a discrete attractor or auto-association network moves its population of active neurons towards one of the previously learned attractor states, and thus implements the recall of a particular previously learned pattern from an incomplete or noisy (distorted) version of one of the previously learned patterns. The energy landscape of a discrete attractor network (see Section B.3, Hopfield (1982)) has separate energy minima, each one of which corresponds to a learned pattern, whereas the energy landscape of a continuous attractor network is flat, so that the activity packet remains stable with continuous firing wherever it is started in the state space. (The state space refers

to the set of possible spatial states of the animal in its environment, e.g. the set of possible places in a room.) Continuous attractor networks and their application to memory systems in the hippocampus are reviewed next with details in Section B.5, as they are very likely to apply to the operation of systems with spatial representations and recurrent connections, such as the CA3 neurons. Continuous attractor networks have been studied by for example Amari (1977), Zhang (1996), and Stringer, Trappenberg, Rolls and De Araujo (2002b).

One key issue in such continuous attractor neural networks is how the synaptic strengths between the neurons in the continuous attractor network could be learned in biological systems, and it has been shown that associative synaptic modification while navigating the environment can implement this, because the spatial representations of nearby locations overlap and therefore become associatively linked (see Section B.5.3 and Stringer, Trappenberg, Rolls and De Araujo (2002b)).

A second key issue in such continuous attractor neural networks is how the bubble of neuronal firing representing one location in the continuous state space should be updated based on non-visual cues to represent a new location in state space (Section B.5.5). This is essentially the problem of path integration: how a system that represents a memory of where the agent is in physical space could be updated based on idiothetic (self-motion) cues such as vestibular cues (which might represent a head velocity signal), or proprioceptive cues (which might update a representation of place based on movements being made in the space, during for example walking in the dark). Examples of classes of neurons that can be updated idiothetically include head direction cells in rats (Muller et al., 1996; Ranck, 1985; Taube et al., 1996, 1990a; Bassett and Taube, 2005) and primates (Robertson, Rolls, Georges-François and Panzeri, 1999), which respond maximally when the animal's head is facing in a preferred direction and can be updated by head rotation in the dark; place cells in rats (O'Keefe, 1984; Markus et al., 1995; O'Keefe and Dostrovsky, 1971; McNaughton et al., 1983; Muller et al., 1991; Jeffery and Hayman, 2004; Jeffery et al., 2004) that fire maximally when the animal is in a particular location and can be updated by running in a particular direction in the dark; and spatial view cells in primates that respond when the monkey is looking towards a particular location in space (Georges-François, Rolls and Robertson, 1999; Robertson, Rolls and Georges-François, 1998; Rolls, Robertson and Georges-François, 1997a; Rolls, Treves, Robertson, Georges-François and Panzeri, 1998b; Rolls, 2023c) and can be updated by eye movements in the dark (Robertson, Rolls and Georges-François, 1998).

Path integration is described in Section B.5.5, using as an example the update of a head direction representation by a head velocity signal. For example, a proposal about how the synaptic connections from idiothetic inputs to a continuous attractor network can be learned with some biological plausibility, in that the network can be trained by a self-organizing process, was introduced by Stringer, Trappenberg, Rolls and De Araujo (2002b). The mechanism associates a short-term memory trace of the firing of the neurons in the attractor network reflecting recent movements in the state space (e.g. of places), with an idiothetic velocity of movement input (see Fig. B.28). This has been applied to head direction cells (Stringer, Trappenberg, Rolls and De Araujo, 2002b; Stringer and Rolls, 2006), rat place cells (Stringer, Trappenberg, Rolls and De Araujo, 2002b; Stringer, Rolls, Trappenberg and De Araujo, 2002a), and primate spatial view cells (Stringer, Rolls and Trappenberg, 2004, 2005; Rolls and Stringer, 2005). These attractor networks provide a basis for understanding cognitive maps, and how they are updated by learning and by self-motion. The implication is that to the extent that path integration of place or spatial view representations is performed within the hippocampus itself, then the CA3 system is the most likely part of the hippocampus to be involved in this, because it has the appropriate recurrent collateral connections. Consistent with this, Whishaw and colleagues (Wallace and Whishaw, 2003; Maaswinkel et al., 1999; Whishaw et al., 2001) have shown that path integration is impaired by hippocampal lesions.

Part of the neural mechanism for the updating of place by path integration may be in the entorhinal cortex (McNaughton, Battaglia, Jensen, Moser and Moser, 2006; Soldatkina, Schonsberg and Treves, 2022) (see Section 9.3.3). Head direction cells are present in the entorhinal cortex, where grid cells (see Section 9.3.6) are also present (Giocomo et al., 2011; Moser et al., 2014b, 2015), and indeed where some cells respond to combinations of grid and head direction (Leutgeb, Leutgeb, Treves, Meyer, Barnes, McNaughton, Moser and Moser, 2005b; Sargolini, Fyhn, Hafting, McNaughton, Witter, Moser and Moser, 2006). Such combination cells in the entorhinal cortex may be part of the mechanism by which the place map is kept in register with the head direction map. The rodent medial entorhinal cortex grid cells are a strong candidate for path integration over distance and direction travelled, for the repeating nature of the grid (see Section 9.3.6 for details and Fig. 9.24) is likely to be a reflection of a continuous attractor cycling once round its ring for every peak observed. The simplification this offers is that the path integration need be learned only once, as it is just an integration over self-movement, and can be used then in any environment (Soldatkina, Schonsberg and Treves, 2022). Consistent with this, grid cells are relatively little influenced by the details of the visual cues in the environment in which the rat is tested, apart from the rotation of the whole grid by the head direction cells, which can be set by the environment (Hafting, Fyhn, Molden, Moser and Moser, 2005; Fyhn, Molden, Witter, Moser and Moser, 2004; Sargolini, Fyhn, Hafting, McNaughton, Witter, Moser and Moser, 2006). Thus path integration for place may be performed by grid cells in the rodent entorhinal cortex (Giocomo et al., 2011; Moser et al., 2015; Kropff and Treves, 2008; Zilli, 2012; Moser et al., 2014b,a; Soldatkina et al., 2022).

The summary of path integration in the context of grid cells provided by McNaughton et al. (2006) was not self-organizing, that is, the appropriate synaptic strengths for the model to perform the path integration did not become specified as a result of movements in the environment. Self-organizing continuous attractor neural networks that can perform path integration from velocity signals are described in Section B.5.5 and include head direction from head velocity (Stringer, Trappenberg, Rolls and De Araujo, 2002b; Stringer and Rolls, 2006); place from whole body motion (Stringer, Trappenberg, Rolls and De Araujo, 2002b; Stringer, Rolls, Trappenberg and De Araujo, 2002a); and spatial view from eye and whole body motion (Stringer, Rolls and Trappenberg, 2004, 2005; Rolls and Stringer, 2005). Models such as these provide a basis for understanding the principles of operation of medial entorhinal cortex grid cells (Giocomo, Moser and Moser, 2011; Moser, Rowland and Moser, 2015; Kropff and Treves, 2008; Moser, Roudi, Witter, Kentros, Bonhoeffer and Moser, 2014b; Moser, Moser and Roudi, 2014a; Soldatkina, Schonsberg and Treves, 2022).

This leaves open the question of where idiothetic update is performed for where one is looking in space. Is this in the primate medial entorhinal cortex, where spatial view grid cells are found (Killian, Jutras and Buffalo, 2012; Meister and Buffalo, 2018; Garcia and Buffalo, 2020)? The evidence described in Section 3.4 indicates that the dorsal visual stream leading into the parietal cortex area 7a performs much of the self-motion update for visual spatial representations, by using the different mechanism of gain modulation (Rolls, 2020b).

A third key issue is how stability in the bubble of activity representing the current location can be maintained without much drift in darkness, when it is operating as a memory system. A solution is described in Section B.5.6 (Stringer, Trappenberg, Rolls and De Araujo, 2002b).

A fourth key issue is considered in Section B.5.8 in which networks are described that store both continuous patterns and discrete patterns (see Fig. 9.30). These networks can be used to store for example the location in (continuous, physical) space where an object (an item with a discrete representation) is present (Rolls, Stringer and Trappenberg, 2002). *This type of mixed attractor in which discrete representations of objects and continuous representations of space can be combined is important for understanding the operation of the CA3 region*

of the hippocampus in episodic memory, in which discrete object and continuous spatial representations must be combined.

A fifth key issue is the capacity of a continuous attractor network for storing many different environments each with many places. It turns out that the capacity is high, for each environment has its own chart of connected set of places, and the charts for different environments are quite uncorrelated with each other (Battaglia and Treves, 1998b) (Section B.5.4). Although the capacity of a continuous attractor network for charts is high, because each chart is relatively uncorrelated with other charts, the capacity is nevertheless more than 100 times lower than for the number of discrete items that can be stored in an attractor network such as CA3 in the hippocampus (Battaglia and Treves, 1998b; Treves, 2016). The smaller number of charts or maps than discrete items is related to a reduction of approximately 0.3 caused by changing from discrete to continuous, spatial, representations; and to the fact that each chart includes many places (Treves, 2016; Papp and Treves, 2008; Cerasti and Treves, 2013; Soldatkina, Schonsberg and Treves, 2022). But that might still mean in the order of 100 charts in the rat hippocampus (Soldatkina et al., 2022).

Continuous attractor networks provide a way to understand spatial maps and charts. The topology of a 2D space through which trajectories have been followed is represented by the connection strengths between neurons, which are high if the neurons are often coactive because they are close together in a space (Stringer, Rolls, Trappenberg and De Araujo, 2002a; Stringer, Rolls and Trappenberg, 2004, 2005; Rolls and Stringer, 2005). In this situation, *remapping* of hippocampal neurons (Schlesiger, Boubilil, Hales, Leutgeb and Leutgeb, 2018) occurs mainly when the spatial topology of the test environment is changed, for then the continuous attractor network that forms the map or chart (Battaglia and Treves, 1998b) breaks because the synaptic links formed by coactive firing of neurons due to the closeness of the places to which they respond are no longer applicable (see Section B.5). Then remapping results in a new chart or map being formed for the new space, and after remapping a new arbitrary set of neurons learns to represent the topology of the space in a new chart. The well established concept of a ‘map’ or ‘chart’ (Samsonovich and McNaughton, 1997; Battaglia and Treves, 1998b) (also used in *The Hippocampus as a Cognitive Map* (O’Keefe and Nadel, 1978; O’Keefe, 1990)) has also had the term ‘schema’ applied to it (Baraduc, Duhamel and Wirth, 2019). If the map or chart remains with the same spatial topology, but changes are made that do not affect the topology such as introducing different room cues with the shape of the arena (a star maze) and the goal remaining unchanged, then no remapping need occur in the continuous attractor network map or chart, as has been found (Baraduc, Duhamel and Wirth, 2019). A continuous attractor network or chart is of course just a series of locations that overlap with each other, and thus the parsimonious interpretation of the result (Baraduc, Duhamel and Wirth, 2019) is that the topology of the spatial map or chart of the star maze and goal was not altered by substituting new room cues onto the same chart or topological space. Remapping occurs when the topology of the space is altered, for example when the shape of the arena is changed (Leutgeb, Leutgeb, Barnes, Moser, McNaughton and Moser, 2005a; Leutgeb, Leutgeb, Moser and Moser, 2006; Leutgeb and Leutgeb, 2007). The hippocampus may store in a continuous attractor network a representation of views or places as they are encountered and perhaps associated with objects and rewards and body turns in what is usually termed a chart (Samsonovich and McNaughton, 1997; Battaglia and Treves, 1998b). A schema more usually refers to a full semantic representation in neocortical semantic regions that contains all the information about the cognitive representation (for example about a territory) that may have been obtained over many particular episodes, with the hippocampus contributing because it can store information about particular episodes (Rolls, 2022b; Farzanfar, Spiers, Moscovitch and Rosenbaum, 2023).

Overall, it is argued that the CA3 region is likely to be involved in associating a relatively continuous spatial representation with an object representation as an episodic memory computation, and not with performing a continuous attractor-based idiothetic update of the spatial representation, which latter may be performed by the entorhinal cortex (Rolls, 2013c) and by the dorsal visual system (Rolls, 2020b) (Section 3.5). Consistent with this view, it has been argued that the bumpiness of the CA3 representation of space is more consistent with episodic memory storage, than with spatial path integration using the CA3 system as a continuous attractor network implementing path integration (Cerasti and Treves, 2013; Stella, Cerasti and Treves, 2013).

9.3.5.3 The dynamics of the recurrent network

The analysis described above of the capacity of a recurrent network such as the CA3 considered steady-state conditions of the firing rates of the neurons. The question arises of how quickly the recurrent network would settle into its final state. With reference to the CA3 network, how long does it take before a pattern of activity, originally evoked in CA3 by afferent inputs, becomes influenced by the activation of recurrent collaterals? In a more general context, recurrent collaterals between the pyramidal cells are an important feature of the connectivity of the cerebral neocortex. How long would it take these collaterals to contribute fully to the activity of cortical cells? If these settling processes took in the order of hundreds of ms, they would be much too slow to contribute usefully to cortical activity, whether in the hippocampus or in the neocortex (Rolls and Deco, 2002; Panzeri, Rolls, Battaglia and Lavis, 2001; Rolls, 1992a, 2003, 2016b).

It has been shown that if the neurons are treated not as McCulloch-Pitts neurons that are simply ‘updated’ at each iteration, or cycle of time steps (and assume the active state if the threshold is exceeded), but instead are analyzed and modelled as ‘integrate-and-fire’ neurons in real continuous time, then the network can effectively ‘relax’ into its recall state very rapidly, in one or two time constants of the synapses (Treves, 1993; Rolls and Treves, 1998; Battaglia and Treves, 1998b; Panzeri, Rolls, Battaglia and Lavis, 2001). This corresponds to perhaps 20 ms in the brain. One factor in this rapid dynamics of autoassociative networks with brain-like ‘integrate-and-fire’ membrane and synaptic properties is that with some spontaneous activity, some of the neurons in the network are close to threshold already before the recall cue is applied, and hence some of the neurons are very quickly pushed by the recall cue into firing, so that information starts to be exchanged very rapidly (within 1–2 ms of brain time) through the modified synapses by the neurons in the network. The progressive exchange of information starting early on within what would otherwise be thought of as an iteration period (of perhaps 20 ms, corresponding to a neuronal firing rate of 50 spikes/s), is the mechanism accounting for rapid recall in an autoassociative neuronal network made biologically realistic in this way. Further analysis of the fast dynamics of these networks if they are implemented in a biologically plausible way with ‘integrate-and-fire’ neurons is provided in Section B.6.4, in Appendix A5 of Rolls and Treves (1998), by Treves (1993), by Battaglia and Treves (1998b), and by Panzeri, Rolls, Battaglia and Lavis (2001).

9.3.5.4 Memory for sequences

One possibility that has been considered previously is that sequences might be stored in an attractor network such as CA3 by assuming that each ‘cycle’ round the recurrent collaterals might be a step in a sequential memory (Hopfield, 1982; Kleinfeld, 1986; Sompolinsky and Kanter, 1986). In practice, that does not work well, for the continuous dynamics of integrate-and-fire attractor networks results in them performing the recall in approximately 1.5 time constants of the recurrent collateral synapses, about 15 ms (Battaglia and Treves, 1998a). Moreover, such a system would be very expensive in terms of memory capacity, in that each

cycle round the recurrent collateral loop on a discrete update scenario would use up one of the available memories in the network. Consideration of such systems is therefore left to Section B.3.3.10.

Probably the most likely way for the hippocampus to encode sequences to encode the order of items in a memory is to use the time cells generated in the entorhinal cortex to hippocampal system, described in Sections 9.3.4 and 9.3.7.4, and associate a particular time in the sequence with for example a place or object (Rolls and Mills, 2019). This would enable the temporal order to be recalled correctly. This system is known to act over time periods of the order of up to many hundreds of seconds. The evidence described in Section 9.3.7.4 suggests that this is implemented by the time cells in CA1.

9.3.5.5 The dilution of the CA3 recurrent collateral connectivity enhances memory storage capacity and pattern completion

Fig. 9.23 shows that in the rat, there are approximately 300,000 CA3 neurons, but only 12,000 recurrent collateral synapses per neuron. The dilution of the connectivity is thus $12,000 / 300,000 = 0.04$. The connectivity is thus not complete, and complete connectivity in an auto-association network would make it simple, for the connectivity between the neurons would then be symmetric (i.e. the connection strength from any one neuron to another is matched by a connection of the same strength in the opposite direction), and this guarantees energy minima for the basins of attraction that will be stable, and a memory capacity that can be calculated (Hopfield, 1982). We have shown how this attractor type of network can be extended to have similar properties with diluted connectivity, and also with sparse representations with graded firing rates (Treves and Rolls, 1991; Treves, 1990, 1991b; Rolls and Webb, 2012; Webb, Rolls, Deco and Feng, 2011).

However, the question has been asked about whether there are any advantages to diluted autoassociation or attractor networks compared to fully connected attractor networks (Rolls, 2012b). One biological property that may be a limiting factor is the number of synaptic connections per neuron, which is 12,000 in the CA3-CA3 network just for the recurrent collaterals (see Fig. 9.23). The number may be higher in humans, allowing more memories to be stored in the hippocampus than order 12,000. I note that the storage of a large number of memories may be facilitated in humans because the left and right hippocampus appear to be much less connected between the two hemispheres than in the rat, which effectively has a single hippocampus in that the CA3 neurons are connected by commissural connections. In humans, with effectively two separate CA3 networks, one on each side of the brain, the memory storage capacity may be doubled, as the capacity is set by the number of recurrent collaterals per neuron in each attractor network. In humans, the right hippocampus may be devoted to episodic memories with spatial and visual components, whereas the left hippocampus may be devoted to memories with verbal / linguistic components, i.e. in which words may be part of the episode (e.g. who said what to whom and when) (Amit, 1989; Bonelli et al., 2010; Sidhu et al., 2013).

The answer that has been suggested to why the connectivity of the CA3 autoassociation network is diluted (and why neocortical recurrent networks are also diluted), is that this may help to reduce the probability of having two or more synapses between any pair of randomly connected neurons within the network, which it has been shown greatly impairs the number of memories that can be stored in an attractor network, because of the distortion that this produces in the energy landscape (Rolls, 2012b) (Section B.3.4). In more detail, the hypothesis proposed is that the diluted connectivity allows biological processes that set up synaptic connections between neurons to arrange for there to be only very rarely more than one synaptic connection between any pair of neurons. If probabilistically there were more than one connection between any two neurons, it was shown by simulation of an autoassociation attractor

network that such connections would dominate the attractor states into which the network could enter and be stable, thus strongly reducing the memory capacity of the network (the number of memories that can be stored and correctly retrieved), below the normal large capacity for diluted connectivity. Diluted connectivity between neurons in the cortex thus has an important role in allowing high capacity of memory networks in the cortex, and helping to ensure that the critical capacity is not reached at which overloading occurs leading to an impairment in the ability to retrieve any memories from the network (Rolls, 2012b). The diluted connectivity is thus seen as an adaptation that simplifies the genetic specification of the wiring of the brain, by enabling just two attributes of the connectivity to be specified (e.g. from a CA3 to another CA3 neuron chosen at random to specify the CA3 to CA3 recurrent collateral connectivity), rather than which particular neuron should connect to which other particular neuron (Rolls, 2012b; Rolls and Stringer, 2000). Consistent with this hypothesis, there are NMDA receptors with the genetic specification that they are NMDA receptors on neurons of a particular type, CA3 neurons (as shown by the evidence from CA3-specific vs CA1-specific NMDA receptor knockouts) (Nakazawa et al., 2002, 2003, 2004; Rondi-Reig et al., 2001). A consequence is that the vector of output neuronal firing in the CA3 region, i.e. the number of CA3 neurons, is quite large (300,000 neurons in the rat). The large number of elements in this vector may have consequences for the noise in the system, as we will see below.

The role of dilution in the connectivity of the CA3 recurrent collateral connectivity includes enabling this large number of separate memories to be recalled from any part of each memory, that is, in pattern completion (Rolls, 2012b) (Section B.3.4).

The dilution of the CA3-CA3 recurrent collateral connectivity at 0.04 may be greater dilution than that in a local neocortical area, which is in the order of 0.1 (Rolls, 2012b). This is consistent with the hypothesis that the storage capacity of the CA3 system is at a premium, and so the dilution is kept to a low value (i.e. great dilution), as then there is lower distortion of the basins of attraction and hence the memory capacity is maximized (Rolls, 2012b) (Section B.3.4).

9.3.5.6 Noise and stability produced by the diluted connectivity and the graded firing rates in the CA3-CA3 attractor network

Many processes in the brain are influenced by the noise or variability of neuronal spike firing (Rolls and Deco, 2010; Faisal, Selen and Wolpert, 2008; Deco, Rolls, Albantakis and Romo, 2013). The action potentials are generated in a way that frequently approximates a Poisson process, in which the spikes for a given mean firing rate occur at times that are essentially random (apart from a small effect of the refractory period), with a coefficient of variation of the interspike interval distribution (CV) near 1.0 (Rolls and Deco, 2010). The sources of the noise include quantal transmitter release, and noise in ion channel openings (Faisal, Selen and Wolpert, 2008). The membrane potential is often held close to the firing threshold, and then small changes in the inputs and the noise in the neuronal operations cause spikes to be emitted at almost random times for a given mean firing rate. Spiking neuronal networks with balanced inhibition and excitation currents and associatively modified recurrent synaptic connections can be shown to possess a stable attractor state where neuron spiking is approximately Poisson too (Amit and Brunel, 1997; Miller and Wang, 2006). The noise caused by the variability of individual neuron spiking which then affects other neurons in the network can play an important role in the function of such recurrent attractor networks, by causing for example an otherwise stable network to jump into a decision state (Wang, 2002; Deco and Rolls, 2006; Rolls and Deco, 2010). Attractor networks with this type of spiking-related noise are used in the brain for memory recall, and for decision-making, which in terms of the neural mechanism are effectively the same process. Noise in attractor networks is useful for

memory and decision-making, for it makes them non-deterministic, and this contributes to new solutions to problems, and indeed to creativity (Rolls and Deco, 2010) (Section 18.2).

To investigate the extent to which the diluted connectivity affects the dynamics of attractor networks in the cerebral cortex (which includes the hippocampus), we simulated an integrate-and-fire attractor network taking decisions between competing inputs with diluted connectivity of 0.25 or 0.1 but the same number of synaptic connections per neuron for the recurrent collateral synapses within an attractor population as for full connectivity (Rolls and Webb, 2012). The results indicated that there was less spiking-related noise with the diluted connectivity in that the stability of the network when in the spontaneous state of firing increased, and the accuracy of the correct decisions increased. The decision times were a little slower with diluted than with complete connectivity. Given that the capacity of the network is set by the number of recurrent collateral synaptic connections per neuron, on which there is a biological limit, the findings indicate that the stability of cortical networks, and the accuracy of their correct decisions or memory recall operations, can be increased by utilizing diluted connectivity and correspondingly increasing the number of neurons in the network (which may help to smooth the noise), with little impact on the speed of processing of the cortex. Thus diluted connectivity can decrease cortical spiking-related noise, and thus enhance the reliability of memory recall, which includes completion from a partial recall cue (Rolls and Webb, 2012).

Representations in the neocortex and in the hippocampus are often distributed with graded firing rates in the neuronal populations (Rolls and Treves, 2011) (Appendix C). The firing rate probability distribution of each neuron to a set of stimuli is often exponential or gamma (Rolls and Treves, 2011) (Section C.3.1). These graded firing rate distributed representations are present in the hippocampus, both for place cells in rodents and for spatial view cells in the primate (O'Keefe and Speakman, 1987; O'Keefe, 1979; McNaughton, Barnes and O'Keefe, 1983; Rolls, Robertson and Georges-François, 1997a; Rolls, Treves, Robertson, Georges-François and Panzeri, 1998b; Georges-François, Rolls and Robertson, 1999; Rolls and Treves, 2011). In processes in the brain such as memory recall in the hippocampus or decision-making in the neocortex that are influenced by the noise produced by the close to random spike timings of each neuron for a given mean rate, the noise with this graded type of representation may be larger than with the binary firing rate distribution that is usually investigated.

In integrate-and-fire simulations of an attractor decision-making network, we showed that the noise is indeed greater for a given sparseness of the representation for graded, exponential, than for binary firing rate distributions (Webb, Rolls, Deco and Feng, 2011). The greater noise was measured by faster escaping times from the spontaneous firing rate state when the decision cues are applied, and this corresponds to faster decision or reaction times. The greater noise was also evident as less stability of the spontaneous firing state before the decision cues are applied. The implication is that spiking-related noise will continue to be a factor that influences processes such as decision-making, signal detection, short-term memory, and memory recall and completion (including in the CA3 network) even with the quite large networks found in the cerebral cortex. In these networks there are several thousand recurrent collateral synapses onto each neuron. The greater noise with graded firing rate distributions has the advantage that it can increase the speed of operation of cortical circuitry (Webb, Rolls, Deco and Feng, 2011). The graded firing rates also by operating in a non-linear network effectively increase the sparseness of the representation, and this itself provides a pattern separation effect (Webb, Rolls, Deco and Feng, 2011). The non-linearity is present in the NMDA threshold for synaptic modification, as well as in the threshold for firing of a neuron.

9.3.5.7 Pattern separation of CA3 cell populations encoding different memories

For the CA3 to operate with high capacity as an autoassociation or attractor memory, the sets of CA3 neurons that represent each event to be stored and later recalled need to be as uncorrelated from each other as possible. Correlations between patterns reduce the memory capacity of an autoassociation network (Marr, 1971; Kohonen, 1977, 1989; Kohonen, Oja and Lehtio, 1981; Sompolinsky, 1987; Rolls and Treves, 1998; Boboeva, Brasselet and Treves, 2018; Rolls, 2023d; Ryom, Stendardi, Ciaramelli and Treves, 2023), and because storage capacity is at a premium in an episodic memory system, there are several mechanisms that reduce the correlations between the firing of the population vectors of CA3 neuron firing each one of which represents a different event to be stored in memory. In the theoretical physics approach to the capacity of attractor networks, it is indeed assumed that the different vectors of firing rates to be stored are well separated from each other, by drawing each vector of firing at random, and by assuming very large (infinite) numbers of neurons in each pattern (Hopfield, 1982; Rolls and Treves, 1998) (Section B.3).

We have proposed that there are several mechanisms that help to achieve this pattern separation, namely the mossy fibre pattern separation effect produced by the small number of connections received by a CA3 neuron from mossy fibers which dominate the CA3 cell firing; the expansion recoding, and the sparse representation provided by the dentate granule cells that form the mossy fiber synapses; and the sparseness of the CA3 cell representation. Neurogenesis of dentate granule cells is a fifth potential contributor to achieving pattern separation of CA3 cell firing. These five mechanisms are described here, and elsewhere (Rolls, 2013c,b, 2016f, 2021i). It is remarked that some of this architecture may be special to the hippocampus, and not found in the neocortex, because of the importance of storing and retrieving large numbers of (episodic) memories in the hippocampus. The neocortex in contrast is more concerned with building new representations for which competitive learning is more important, and thus neocortical circuitry does not use a mossy fibre system to produce new random sets of neurons activated.

9.3.5.8 Mossy fibre inputs to the CA3 cells

We hypothesize that the mossy fibre inputs force efficient information storage by virtue of their strong and sparse influence on the CA3 cell firing rates (Rolls, 1987, 1990b, 1989f; Treves and Rolls, 1992). (The strong effects likely to be mediated by the mossy fibres were also emphasized by McNaughton and Morris (1987) and McNaughton and Nadel (1990).) We hypothesize that the mossy fibre input appears to be particularly appropriate in several ways. First of all, the fact that mossy fibre synapses are large and located very close to the soma makes them relatively powerful in activating the postsynaptic cell. (This should not be taken to imply that a CA3 cell can be fired by a single mossy fibre EPSP.)

Second, the firing activity of dentate granule cells appears to be very sparse (Jung and McNaughton, 1993; Leutgeb and Leutgeb, 2007) and this, together with the small number of connections on each CA3 cell, produces a sparse signal, which can then be transformed into an even sparser firing activity in CA3 by a threshold effect¹³. The hypothesis is that the

¹³For example, if only 1 granule cell in 100 were active in the dentate gyrus, and each CA3 cell received a connection from 50 randomly placed granule cells, then the number of active mossy fibre inputs received by CA3 cells would follow a Poisson distribution of average $50/100 = 1/2$, i.e. 60% of the cells would not receive any active input, 30% would receive only one, 7.5% two, little more than 1% would receive three, and so on. (It is easy to show from the properties of the Poisson distribution and our definition of sparseness, that the sparseness of the mossy fibre signal as seen by a CA3 cell would be $x/(1+x)$, with $x = C^{MF} a_{DG}$, assuming equal strengths for all mossy fibre synapses. C^{MF} is the number of mossy fibre connections to a CA3 neuron, and a_{DG} is the sparseness of the representation in the dentate granule cells.) If three mossy fibre inputs were required to fire a CA3 cell and these

mossy fibre sparse connectivity solution performs the appropriate function to enable learning to operate correctly in CA3 (Treves and Rolls, 1992; Cerasti and Treves, 2010, 2013; Soldatkina, Schonsberg and Treves, 2022). The perforant path input would, the quantitative analysis shows, not produce a pattern of firing in CA3 that contains sufficient information for learning (Treves and Rolls, 1992).

Third, non-associative plasticity of mossy fibres (Brown et al., 1989, 1990b) might have a useful effect in enhancing the signal-to-noise ratio, in that a consistently firing mossy fibre would produce non-linearly amplified currents in the postsynaptic cell, which would not happen with an occasionally firing fibre (Treves and Rolls, 1992). This plasticity, and also learning in the dentate, would also have the effect that similar fragments of each episode (e.g. the same environmental location) recurring on subsequent occasions would be more likely to activate the same population of CA3 cells, which would have potential advantages in terms of economy of use of the CA3 cells in different memories, and in making some link between different episodic memories with a common feature, such as the same location in space.

Fourth, with only a few, and powerful, active mossy fibre inputs to each CA3 cell, setting a given sparseness of the representation provided by CA3 cells would be simplified, for the EPSPs produced by the mossy fibres would be Poisson distributed with large membrane potential differences for each active mossy fibre. Setting the average firing rate of the dentate granule cells would effectively set the sparseness of the CA3 representation, without great precision being required in the threshold setting of the CA3 cells (Rolls, Treves, Foster and Perez-Vicente, 1997c). Part of what is achieved by the mossy fibre input may be setting the sparseness of the CA3 cells correctly, which, as shown above and in Section B.3, is very important in an autoassociative memory store.

Fifth, the non-associative and sparse connectivity properties of the mossy fibre connections to CA3 cells may be appropriate for an episodic memory system that can learn very fast, in one trial. The hypothesis is that the sparse connectivity would help arbitrary relatively uncorrelated sets of CA3 neurons to be activated for even somewhat similar input patterns without the need for any learning of how best to separate the patterns, which in a self-organizing competitive network would take several repetitions (at least) of the set of patterns. The mossy fibre solution may thus be adaptive in a system that must learn in one trial, and for which the CA3 recurrent collateral learning requires uncorrelated sets of CA3 cells to be allocated for each (one-trial) episodic memory. The hypothesis is that the mossy fibre sparse connectivity solution performs the appropriate function without the mossy fibre system having to learn by repeated presentations how best to separate a set of training patterns (see further Section 9.4).

The argument based on information suggests, then, that an input system with the characteristics of the mossy fibres is essential during learning, in that it may act as a sort of (unsupervised) teacher that effectively strongly influences which CA3 neurons fire based on the pattern of granule cell activity. This establishes an information-rich neuronal representation of the episode in the CA3 network (Treves and Rolls, 1992; Rolls, 2013b; Kesner and Rolls, 2015; Rolls, 2016f). The perforant path input would, the quantitative analysis shows, not produce a pattern of firing in CA3 that contains sufficient information for learning (Treves and Rolls, 1992; Soldatkina, Schonsberg and Treves, 2022).

The particular property of the small number of mossy fibre connections onto a CA3 cell, approximately 46 (see Fig. 9.23), is that this has a randomizing effect on the representations set up in CA3, so that they are as different as possible from each other (Rolls, 1990b, 1989e; Treves and Rolls, 1992). (This means for example that place cells in a given environment are well separated to cover the whole space.) The result is that any one event or episode will set

were the only inputs available, we see that the activity in CA3 would be roughly as sparse, in the example, as in the dentate gyrus.

up a representation that is very different from other events or episodes, because the set of CA3 neurons activated for each event is random. This is then the optimal situation for the CA3 recurrent collateral effect to operate, for it can then associate together the random set of neurons that are active for a particular event (for example an object in a particular place), and later recall the whole set from any part. It is because the representations in CA3 are unstructured, or random, in this way that large numbers of memories can be stored in the CA3 autoassociation system, and that interference between the different memories is kept as low as possible, in that they are maximally different from each other (Hopfield, 1982; Treves and Rolls, 1991).

This is a key difference from the neocortex, in which new representations should be learned at each stage of the hierarchy that usefully combine information received from earlier cortical stages in the hierarchy. The difference then for the neocortex is that it uses competitive learning for the forward inputs to produce information-enhanced firing of the cortical pyramidal cells (Rolls, 2021c). In contrast, the hippocampus randomly allocates CA3 cells to new memories, to make each memory as different as possible from earlier memories.

The requirement for a small number of mossy fibre connections onto each CA3 neuron applies not only to discrete (Treves and Rolls, 1992) but also to spatial representations, and some learning in these connections, whether associative or not, can help to select out the small number of mossy fibres that may be active at any one time to select a set of random neurons in the CA3 (Cerasti and Treves, 2010). Any learning may help by reducing the accuracy required for a particular number of mossy fibre connections to be specified genetically onto each CA3 neuron. The optimal number of mossy fibres for the best information transfer from dentate granule cells to CA3 cells is in the order of 35–50 (Treves and Rolls, 1992; Cerasti and Treves, 2010). The mossy fibres also make connections useful for feedforward inhibition in CA3 (Acsady et al., 1998), which is likely to be useful to help in the sparse representations being formed in CA3.

On the basis of these points, it has been predicted that the mossy fibres may be necessary for new learning in the hippocampus, but may not be necessary for recall of existing memories from the hippocampus. Experimental evidence consistent with this prediction about the role of the mossy fibres in learning has been found in rats with disruption of the dentate granule cells (Lassalle et al., 2000) (see Section 9.4).

I have hypothesized that non-associative plasticity of mossy fibres (Brown et al., 1989, 1990b) might have a useful effect in enhancing the signal-to-noise ratio, in that a consistently firing mossy fibre would produce nonlinearly amplified currents in the postsynaptic cell, which would not happen with an occasionally firing fibre (Treves and Rolls, 1992). This plasticity, and also learning in the dentate, would also have the effect that similar fragments of each episode (e.g. the same environmental location) recurring on subsequent occasions would be more likely to activate the same population of CA3 cells, which would have potential advantages in terms of economy of use of the CA3 cells in different memories, and in making some link between different episodic memories with a common feature, such as the same location in space. Consistent with this, dentate neurons that fire repeatedly are more effective in activating CA3 neurons (Henze et al., 2002).

As acetylcholine does turn down the efficacy of the recurrent collateral synapses between CA3 neurons (Hasselmo et al., 1995; Giocomo and Hasselmo, 2007), then cholinergic activation also might help to allow external inputs rather than the internal recurrent collateral inputs to dominate the firing of the CA3 neurons during learning, as the current theory proposes. If cholinergic activation at the same time facilitated LTP in the recurrent collaterals (as it appears to in the neocortex), then cholinergic activation could have a useful double role in facilitating new learning at times of behavioral activation, when presumably it may be

particularly relevant to allocate some of the limited memory capacity to new memories (see Section 9.2.8.5).

9.3.5.9 Perforant path inputs to CA3 cells initiate recall in CA3 and contribute to generalization

By calculating the amount of information that would end up being carried by a CA3 firing pattern produced solely by the perforant path input and by the effect of the recurrent connections, we have been able to show (Treves and Rolls, 1992) that an input of the perforant path type, alone, is unable to direct efficient information storage. Such an input is too weak, it turns out, to drive the firing of the cells, as the ‘dynamics’ of the network is dominated by the randomizing effect of the recurrent collaterals. This is the manifestation, in the CA3 network, of a general problem affecting storage (i.e. learning) in all autoassociative memories. The problem arises when the system is considered to be activated by a set of input axons making synaptic connections that have to compete with the recurrent connections, rather than having the firing rates of the neurons artificially clamped into a prescribed pattern (Rolls, 2021c).

An autoassociative memory network needs afferent inputs also in the other mode of operation, i.e. when it retrieves a previously stored pattern of activity. We have shown (Treves and Rolls, 1992) that the requirements on the organization of the afferents are in this case very different, implying the necessity of a second, separate, input system, which we have identified with the perforant path input to CA3. In brief, the argument is based on the notion that the cue available to initiate retrieval might be rather small, i.e. the distribution of activity on the afferent axons might carry a small correlation, $q \ll 1$, with the activity distribution present during learning. In order not to lose this small correlation altogether, but rather transform it into an input current in the CA3 cells that carries a sizable signal – which can then initiate the retrieval of the full pattern by the recurrent collaterals – one needs a large number of associatively modifiable synapses. This is expressed by the following formulas that give the specific signal S produced by sets of associatively modifiable synapses, or by non-associatively modifiable synapses: if C^{AFF} is the number of afferents per cell,

$$S_{\text{ASS}} \approx \frac{\sqrt{C^{\text{AFF}}}}{\sqrt{p}} q \quad (9.6)$$

$$S_{\text{NONASS}} \approx \frac{1}{\sqrt{C^{\text{AFF}}}} q \quad (9.7)$$

Associatively modifiable synapses are therefore needed, and are needed in a number C^{AFF} of the same order as the number of concurrently stored patterns p , so that small cues can be effective; whereas non-associatively modifiable synapses – or even more so, non-modifiable ones – produce very small signals, which decrease in size the larger the number of synapses. In contrast with the storage process, the average strength of these synapses does not now play a crucial role. This suggests that the perforant path system is the one involved in relaying the cues that initiate retrieval.

The concept is that to initiate retrieval, a numerically large input (the perforant path system, see Fig. 9.23) is useful so that even a partial cue is sufficient (see Equation 17 of Treves and Rolls (1992)); and that the retrieval cue need not be very strong, as the recurrent collaterals (in CA3) then take over in the retrieval process to produce good recall (Treves and Rolls, 1992). In this scenario, the perforant path to CA3 synapses operate as a pattern associator, the quantitative properties of which are described in Section B.2. If an incomplete recall cue is provided to a pattern association network using distributed input representations, then most of the output pattern will be retrieved, and in this sense pattern association networks generalize

between similar retrieval patterns to produce the correct output firing, and this generalization performed at the perforant path synapses to CA3 cells helps in the further completion produced by the recurrent collateral CA3-CA3 autoassociation process.

In contrast, during storage, strong signals, in the order of mV for each synaptic connection, are provided by the mossy fibre inputs to dominate the recurrent collateral activations, so that the new pattern of CA3 cell firing can be stored in the CA3 recurrent collateral connections (Treves and Rolls, 1992).

Before leaving the CA3 cells, it is suggested that the three major classes of excitatory input to the CA3 cells (recurrent collateral, mossy fibre, and perforant path, see Fig. 9.2) could be independently scaled, by virtue of the different classes of inhibitory interneuron which receive their own set of inputs, and end on different parts of the dendrite of the CA3 cells (cf. for CA1 Buhl et al. (1994) and Gulyas et al. (1993)). This possibility is made simpler by having these major classes of input terminate on different segments of the dendrites. Each of these inputs, and the negative feedback produced through inhibitory interneurons when the CA3 cells fire, should for optimal functioning be separately regulated (Rolls, 1995b), and the anatomical arrangement of the different types of inhibitory interneuron might be appropriate for achieving this.

9.3.6 Dentate granule cells

The theory is that the dentate granule cell stage of hippocampal processing which precedes the CA3 stage acts in a number of ways to produce during learning the sparse yet efficient (i.e. non-redundant) representation in CA3 neurons that is required for the autoassociation to perform well (Rolls, 1989a, 1990b, 1989f; Treves and Rolls, 1992; Rolls and Kesner, 2006b; Rolls, 2013b; Kesner and Rolls, 2015; Rolls, 2016f). An important property for episodic memory is that the dentate by acting in this way would perform pattern separation (or orthogonalization), enabling the hippocampus to store different memories of even similar events, and this prediction has been confirmed as described in Section 9.4. By *pattern separation* I mean that the correlations between different memory patterns represented by a population of neurons become reduced (Rolls, 2013b, 2016f).

9.3.6.1 The dentate cells as a competitive network

The first way in which the dentate granule cell stage helps to produce during learning the sparse yet efficient (i.e. non-redundant) representation in CA3 neurons is that the perforant path – dentate granule cell system with its Hebb-like modifiability is suggested to act as a competitive learning network to remove redundancy from the inputs producing a more orthogonal, sparse, and categorised set of outputs (Rolls, 1987, 1989a, 1990b, 1989f, 1990a,b). Competitive networks are described in Section B.4. The non-linearity in the NMDA receptors may help the operation of such a competitive net, for it ensures that only the most active neurons left after the competitive feedback inhibition have synapses that become modified and thus learn to respond to that input (Rolls, 1989a) (see Section B.4.9.3). If the synaptic modification produced in the dentate granule cells lasts for a period of more than the duration of learning the episodic memory, then it could reflect the formation of codes for regularly occurring combinations of active inputs that might need to participate in different episodic memories. Because of the non-linearity in the NMDA receptors, the non-linearity of the competitive interactions between the neurons (produced by feedback inhibition and non-linearity in the activation function of the neurons) need not be so great (Rolls, 1989a) (see Section B.4). Because of the feedback inhibition, the competitive process may result in a relatively constant number of strongly active dentate neurons relatively independently of the number

of active perforant path inputs to the dentate cells. The operation of the dentate granule cell system as a competitive network may also be facilitated by a Hebb rule of the form:

$$\delta w_{ij} = \alpha y_i (x_j - w_{ij}) \quad (9.8)$$

where δw_{ij} is the change of the synaptic weight w_{ij} that results from the simultaneous (or conjunctive) presence of presynaptic firing x_j and postsynaptic firing or activation y_i , and α is a learning rate constant that specifies how much the synapses alter on any one pairing (see Rolls (1989a) and Appendix B). Incorporation of a rule such as this which implies heterosynaptic long-term depression as well as long-term potentiation (Levy and Desmond, 1985; Levy et al., 1990) makes the sum of the synaptic weights on each neuron remain roughly constant during learning (Oja, 1982; Rolls and Deco, 2002; Rolls and Treves, 1998; Rolls, 1989a) (see Section B.4).

This functionality could be used to help build dentate gyrus and hippocampal place cells in rats from the grid cells present in the medial entorhinal cortex (Hafting et al., 2005; Moser et al., 2015), as described in Section 9.3.3 (Rolls, Stringer and Elliot, 2006c).

As described above, in primates, there is evidence that there is a grid-cell like representation in the entorhinal cortex, with neurons having grid-like firing as the monkey moves the eyes across a spatial scene (Killian, Jutras and Buffalo, 2012; Meister and Buffalo, 2018). Similar competitive learning processes may transform these entorhinal cortex ‘spatial view grid cells’ into hippocampal spatial view cells, and may help with the idiothetic (produced in this case by movements of the eyes) update of spatial view cells (Robertson, Rolls and Georges-François, 1998). The presence of spatial view grid cells in the entorhinal cortex of primates (Killian et al., 2012) is of course predicted from the presence of spatial view cells in the primate CA3 and CA1 regions (Rolls and Xiang, 2006). Further support for this type of representation of space being viewed ‘out there’ rather than where one is located as for rat place cells is that neurons in the human entorhinal cortex with spatial view grid-like properties have now been described (Jacobs, Weidemann, Miller, Solway, Burke, Wei, Suthana, Sperling, Sharan, Fried and Kahana, 2013).

The importance of transforming from a grid cell representation in the entorhinal cortex to a place cell representation (or in primates a spatial view cell representation) in the hippocampus is considered quantitatively next. At least one important function this allows is the formation of memories, formed for example between an object and a place or a viewed spatial location, which is proposed to be a prototypical function of the hippocampus that is fundamental to episodic memory (Rolls, 1996d; Rolls and Treves, 1998; Rolls and Kesner, 2006b; Rolls and Xiang, 2006). For the formation of such object–place memories in an associative network (in particular, an autoassociative network in the CA3 region of the hippocampus), the place must be made explicit in the representation, and moreover, for high capacity, that is the ability to store and retrieve many memories, the representation must be sparse. By made explicit, I mean that information can be read off easily from the firing rates of the neurons, with different places producing very different sets of neurons firing, so that different representations are relatively orthogonal. The entorhinal cortex representations are not only not sparse (in the simulations of Rolls, Stringer and Elliot (2006c), the sparseness a^P was 0.54), but in addition the typical overlap between the sets of firing of the neuronal populations representing two different places was high (with a mean cosine of the angle or normalized dot product of 0.540). In contrast, the sparseness of the representations formed in the dentate granule cells with Hebb rule training was 0.024, and a typical cosine of the angle was 0.000. (Low values of this measure of sparseness, a^P , defined in Equation 9.2, indicate sparse representations. The cosine of the angle between two vectors takes the value 1 if they point in the same direction, and the value 0 if they are orthogonal, as described in Appendix A.) These sparse and orthogonal representations are what is required for high capacity storage

of object and place, object and reward, and of in general episodic, memories, and this is the function, I propose, of the mapping from entorhinal cortex to hippocampal cells for which Rolls, Stringer and Elliot (2006c) produced a computational model. This concept maps well onto utility in an environment, for it is the place where we are located or at which we are looking in the world with which we wish to associate objects or rewards, and this is made explicit in the dentate granule cell / hippocampal representation (Rolls, 1999c; Rolls et al., 2005c; Rolls and Xiang, 2005; Rolls and Kesner, 2006b; Rolls and Xiang, 2006; Kesner and Rolls, 2015). In contrast, the medial entorhinal cortex may represent self-motion space in a way that is suitable for idiothetic path integration in *any* environment. Any association of an object with a grid cell representation would not be useful, because no unique place or spatial location would be involved.

9.3.6.2 Separation of overlapping inputs

The second way in which the dentate granule cell stage acts to produce during learning the sparse yet efficient (i.e. non-redundant) representation in CA3 neurons is also a result of the competitive learning hypothesized to be implemented by the dentate granule cells (Rolls, 1987, 1989a, 1990b, 1989f, 1990a,b, 1994b). It is proposed that this allows overlapping (or very similar) inputs to the hippocampus to be separated, in the following way (see also Rolls (1996d)). Consider three patterns B, W, and BW, where BW is a linear combination of B and W. (To make the example very concrete, we could consider binary patterns where B=10, W=01 and BW=11.) Then the memory system is required to associate B with reward, W with reward, but BW with punishment. Without the hippocampus, rats might have more difficulty in solving such problems, particularly when they are spatial, for the dentate / CA3 system in rodents is characterized by being implicated in spatial memory. However, it is a property of competitive neuronal networks that they can separate such overlapping patterns, as has been shown elsewhere (Rolls and Treves, 1998; Rolls, 1989a) (see Section B.4); normalization of synaptic weight vectors is required for this property. It is thus an important part of hippocampal neuronal network architecture that there is a competitive network that precedes the CA3 autoassociation system. Without the dentate gyrus, if a conventional autoassociation network were presented with the mixture BW having learned B and W separately, then the autoassociation network would produce a mixed output state, and would therefore be incapable of storing separate memories for B, W and BW. It is suggested therefore that competition in the dentate gyrus is one of the powerful computational features of the hippocampus, and that could enable it to help solve spatial pattern separation tasks. Consistent with this, rats with dentate gyrus lesions are impaired at a metric spatial pattern separation task (Gilbert, Kesner and Lee, 2001; Goodrich-Hunsaker, Hunsaker and Kesner, 2005) (see Section 9.4). The recoding of grid cells in the entorhinal cortex (Hafting et al., 2005; Moser et al., 2015) into small place field cells in the dentate granule cells that was modelled by Rolls, Stringer and Elliot (2006c) can also be considered to be a case where overlapping inputs must be recoded so that different spatial components can be treated differently.

It is noted that Sutherland and Rudy's configural learning hypothesis was similar, but was not tested with spatial pattern separation. Instead, when tested with for example tone and light combinations, it was not consistently found that the hippocampus was important (O'Reilly and Rudy, 2001; Sutherland and Rudy, 1991). I suggest that application of the configural concept, but applied to spatial pattern separation, may capture part of what the dentate gyrus acting as a competitive network could perform, particularly when a large number of such overlapping spatial memories must be stored and retrieved.

9.3.6.3 Low contact probability of dentate with CA3 neurons

The third way in which the dentate gyrus is hypothesized to contribute to the sparse and relatively orthogonal representations in CA3 arises because of the very low contact probability in the mossy fibre–CA3 connections, and has been explained above in Section 9.3.5.8 and by Treves and Rolls (1992).

9.3.6.4 Dentate mossy fibre synapses to CA3 cells are strong

A fourth way is that as suggested and explained above in Section 9.3.5.8, the dentate granule cell–mossy fibre input to the CA3 cells may be powerful and its use particularly during learning would be efficient in forcing a new pattern of firing onto the CA3 cells during learning.

9.3.6.5 Expansion recoding

Fifth, expansion recoding can decorrelate input patterns, and this can be performed by a stage of competitive learning with a large number of neurons (Appendix B). A mechanism like this appears to be implemented by the dentate granule cells, which are numerous (10^6) in the rat, compared to 300,000 CA3 cells, have associatively modifiable synapses (required for a competitive network), and strong inhibition provided by the inhibitory interneurons. This may not represent expansion of numbers relative to the number of entorhinal cortex cells, but the principle of a large number of dentate granule cells, with competitive learning and strong inhibition through inhibitory interneurons, would produce a decorrelation of signals like that achieved by expansion recoding (Rolls, 2013b).

9.3.6.6 Neurogenesis of dentate granule cells

Sixth, adult neurogenesis in the dentate gyrus may perform the computational role of facilitating pattern separation for new patterns, by providing new dentate granule cells with new sets of random connections to CA3 neurons (Rolls, 2010b; Aimone, Deng and Gage, 2010; Aimone and Gage, 2011; Johnston, Shtrahman, Parylak, Goncalves and Gage, 2016; Toda, Parylak, Linker and Gage, 2019). Consistent with the dentate spatial pattern separation hypothesis reviewed here, in mice with impaired dentate neurogenesis, spatial learning in a delayed non-matching-to-place task in the radial arm maze was impaired for arms that were presented with little separation, but no deficit was observed when the arms were presented farther apart (Clelland et al., 2009). Consistently, impaired neurogenesis in the dentate also produced a deficit for small spatial separations in an associative object-in-place task (Clelland et al., 2009).

The dentate granule cell / mossy fiber system may be one of the few places in the mammalian brain where neurogenesis may occur, because here the proposed computational role of the dentate granule cells is just to select new subsets of CA3 neurons for new learning. That is, the dentate granule cells, according to the theory, do not store the information, which instead is stored by the modification that then occurs in the CA3–CA3 recurrent collateral synapses between the selected CA3 neurons. In contrast, in most other brain areas where memories are stored and learning occurs, the learning is implemented by synaptic modification of the neurons in the circuit, and any loss of existing neurons and replacement by new neurons would result in loss of the learning or memory (Rolls, 2016b, 2021c).

9.3.7 CA1 cells

9.3.7.1 Associative retrieval at the CA3 to CA1 (Schaffer collateral) synapses

The CA3 cells connect to the CA1 cells by the Schaeffer collateral synapses. The following arguments outline the advantage of this connection being associatively modifiable, and apply

independently of the relative extent to which the CA3 or the direct entorhinal cortex inputs to CA1 drive the CA1 cells during the learning phase.

The amount of information about each episode retrievable from CA3 has to be balanced off against the number of episodes that can be held concurrently in storage. The balance is regulated by the sparseness of the coding. Whatever the amount of information per episode in CA3, one may hypothesize that the organization of the structures that follow CA3 (i.e. CA1, the various subicular fields, and the return projections to neocortex shown in Fig. 9.2) should be optimized so as to preserve and use this information content in its entirety. This would prevent further loss of information, after the massive but necessary reduction in information content that has taken place along the sensory pathways and before the autoassociation stage in CA3. We have proposed (Treves and Rolls, 1994; Treves, 1995; Schultz and Rolls, 1999) that the need to preserve the full information content present in the output of an autoassociative memory requires an intermediate recoding stage (CA1) with special characteristics. In fact, a calculation of the information present in the CA1 firing pattern, elicited by a pattern of activity retrieved from CA3, shows that a considerable fraction of the information is lost if the synapses are non-modifiable, and that this loss can be prevented only if the CA3 to CA1 synapses are associatively modifiable. Their modifiability should match the plasticity of the CA3 recurrent collaterals. The additional information that can be retrieved beyond that retrieved by CA3 because the CA3 to CA1 synapses are associatively modifiable is strongly demonstrated by the hippocampal simulation described by Rolls (1995b), and quantitatively analyzed by Schultz and Rolls (1999).

9.3.7.2 Recoding in CA1 to facilitate retrieval to the neocortex

An additional factor is that if the total amount of information carried by CA3 cells is redistributed over a larger number of CA1 cells, less information needs to be loaded onto each CA1 cell, rendering the code more robust to information loss in the next stages. For example, if each CA3 cell had to code for 2 bits of information, e.g. by firing at one of four equiprobable activity levels, then each CA1 cell (if there were twice as many as there are CA3 cells) could code for just 1 bit, e.g. by firing at one of only two equiprobable levels. Thus the same information content could be maintained in the overall representation while reducing the sensitivity to noise in the firing level of each cell. In fact, there are more CA1 cells (4×10^5) than CA3 cells in (SD) rats. There are even more CA1 cells (4.6×10^6) in humans (and the ratio of CA1 to CA3 cells is greater). The CA1 cells may thus provide the first part of the expansion for the return projections to the enormous numbers of neocortical cells in primates, after the bottleneck of the single network in CA3, the number of neurons in which may be limited because it has to operate as a single network.

Another argument on the operation of the CA1 cells is also considered to be related to the CA3 autoassociation effect. In this, several arbitrary patterns of firing occur together on the CA3 neurons, and become associated together to form an episodic or 'whole scene' memory. It is essential for this operation that several different sparse representations are present conjunctively in order to form the association. Moreover, when completion operates in the CA3 autoassociation system, all the neurons firing in the original conjunction can be brought into activity by only a part of the original set of conjunctive events. For these reasons, a memory in the CA3 cells consists of several different simultaneously active ensembles of activity. To be explicit, the parts A, B, C, D and E of a particular episode would each be represented, roughly speaking, by its own population of CA3 cells, and these five populations would be linked together by autoassociation. It is suggested that the CA1 cells, which receive these groups of simultaneously active ensembles, can detect the conjunctions of firing of the different ensembles that represent the episodic memory, and allocate by competitive learning neurons to represent at least larger parts of each episodic memory (Rolls, 1987, 1989a, 1990b, 1989f,

1990a,a,b). In relation to the simple example above, some CA1 neurons might code for ABC, and others for BDE, rather than having to maintain independent representations in CA1 of A, B, C, D, and E. This implies a more efficient representation, in the sense that when eventually after many further stages, neocortical neuronal activity is recalled (as discussed below), each neocortical cell need not be accessed by all the axons carrying each component A, B, C, D and E, but instead by fewer axons carrying larger fragments, such as ABC, and BDE; or even ABCDE. This process is performed by competitive networks, which self-organize to find categories in the input space, where each category is represented by a set or combination of simultaneously active inputs (Rolls and Deco, 2002; Rolls and Treves, 1998; Rolls, 2000b) (see Section B.4).

Concerning the details of operation of the CA1 system, I note that although competitive learning may capture part of how it is able to recode, the competition is probably not global, but instead would operate relatively locally within the domain of the connections of inhibitory neurons. This simple example is intended to show how the coding may become less componential and more conjunctive in CA1 than in CA3, but should not be taken to imply that the representation produced becomes more sparse. An example of what might be predicted follows. Given that objects and the places in which they are seen may be associated by learning in the hippocampus, we might predict that relatively more CA3 neurons might be encoding either objects or places (the components to be associated), and relatively more CA1 neurons might be encoding conjunctive combinations of objects and places. Although object, spatial view, and object-spatial view combination neurons have been shown to be present in the primate hippocampus during a room-based object-spatial view task (Rolls, Xiang and Franco, 2005c), the relative proportions of the types of neuronal response in CA3 vs CA1 have not yet been analyzed.

The conjunctive recoding just described applies to any one single item in memory. Successive memory items would be encoded by a temporal sequence of such conjunctively encoded representations. To the extent that CA1 helps to build conjunctively encoded separate memory items, this could help a sequence of such memories (i.e. memory items) to be distinct (i.e. orthogonal to each other). This may be contrasted with successive memory items as encoded in CA3, in which there might be more overlap because each memory would be represented by its components, and some of the components might be common to some of the successive memory items. Episodic memory has been used here to refer to the memory of a single event or item. It can also be used to describe a succession of items that occurred close together in time, usually at one place. CA1 could help the encoding of these successive items that are parts of a multi-item episodic memory by making each item distinct from the next, due to the conjunctive encoding of each item. These arguments suggest that the CA1 could be useful in what is described as temporal pattern separation in Section 9.4.

9.3.7.3 CA1 inputs from CA3 vs direct entorhinal inputs

Another feature of the CA1 network is its double set of afferents, with each of its cells receiving most synapses from the Schaeffer collaterals coming from CA3, but also a proportion (about 1/6 – Amaral et al. (1990)) from direct perforant path projections from the entorhinal cortex. Such projections appear to originate mainly in layer 3 of entorhinal cortex (Witter et al., 1989b), from a population of cells only partially overlapping with that (mainly in layer 2) giving rise to the perforant path projections to DG and CA3. This suggests that it is useful to include in CA1 not only what it is possible to recall from CA3, but also the detailed information present in the retrieval cue itself (Treves and Rolls, 1994).

Another possibility is that the perforant path input provides the strong forcing input to the CA1 neurons during learning, and that the output of the CA3 system is associated with this forced CA1 firing during learning (McClelland, McNaughton and O'Reilly, 1995). During

recall, an incomplete cue could then be completed in CA3, and the CA3 output would then produce firing in CA1 that would correspond to that present during the learning. This suggestion is essentially identical to that of Treves and Rolls (1994) about the backprojection system and recall, except that McClelland et al. (1995) suggest that the output of CA3 is associated at the CA3 to CA1 (Schaeffer collateral) synapses with the signal present during training in CA1, whereas in the theory of Treves and Rolls (1994) the output of the hippocampus consists of CA1 firing which is associated in the entorhinal cortex and earlier cortical stages with the firing present during learning, providing a theory of how the correct recall is implemented at every backprojection stage though the neocortex (see Section 9.3.8). There is evidence that the CA3 inputs to CA1 are much stronger than the entorhinal cortex inputs to CA1 (Zhao, Hsu and Spruston, 2022; Zhao, Wang, Spruston and Magee, 2020) (and N. Spruston, personal communication, 2022), so the theory of McClelland, McNaughton and O'Reilly (1995) about CA1 does not receive support.

9.3.7.4 CA1 time cells and sequence memory for objects and odors

Time cells each of which fires at a different time in a temporal sequence are found in CA3 and especially in CA1 (Macdonald et al., 2011; Eichenbaum, 2017; Salz et al., 2016; Howard and Eichenbaum, 2015; Eichenbaum, 2014). An example is shown in Fig. 9.26c (Kraus et al., 2013). These neurons are likely to be involved in remembering the order of events and temporal sequences, in that some hippocampal neurons in both CA3 and CA1 fire to combinations of time and object or place (Eichenbaum, 2017; Salz et al., 2016; Howard and Eichenbaum, 2015; Eichenbaum, 2014).

A theory about how time cells are generated by a competitive network in the hippocampus based on inputs from lateral entorhinal cortex time ramping cells has been described in Section 9.3.4 (Rolls and Mills, 2019). The relevant competitive network could be in any of the dentate gyrus, the CA3 (which although it is an attractor network could still operate to help categorise inputs using competitive mechanisms), and CA1.

Evidence described in Section 9.4.3 and by Kesner and Rolls (2015) indicates that the CA1, but not CA3, subregion is involved in the memory for sequences of objects and odors and spatial locations. For example Hunsaker et al. (2008) trained rats to remember unique sequences of spatial locations along a runway box. Rats with lesions to CA1 had especial difficulty with this spatial sequence memory task. Further, the memory for the temporal order of odors (Kesner et al., 2002, 2011) and visual objects is impaired especially by CA1 lesions (Hoge and Kesner, 2007). In humans, the hippocampus becomes activated when the temporal order of events is being processed (Lehn et al., 2009).

The association of time cell firing with object, or spatial, information could most naturally take place in the CA3 autoassociation network, with different neurons responding to time or object or place becoming associated together, so that when the timing input is represented later, the correct objects or places are recalled in the correct temporal sequence. However, time cell firing with object or place information might also become associated together in CA1.

9.3.7.5 Subcortical, vs neocortical backprojection, outputs from CA1

The CA1 network is on anatomical grounds thought to be important for the hippocampus to access the neocortex, and the route by which retrieval to the neocortex would occur (see Fig. 9.2). However, as also shown in Fig. 9.2, there are direct subcortical outputs of the hippocampus. One route is that outputs that originate from CA3 project via the fimbria directly to the medial septum (Gaykema et al., 1991) or indirectly via the lateral septum to the medial septum (Swanson and Cowan, 1977; Saper et al., 1979). The medial septum in turn provides cholinergic and GABAergic inputs back to the hippocampus, especially the CA3 subregion.

In addition to projecting back to the hippocampus, the medial septum also projects to subiculum, entorhinal cortex and mammillary bodies. In turn, the mammillary bodies project to the anterior thalamus which projects to the cingulate cortex, and also to the entorhinal cortex via the pre- and parasubiculum. The outputs from CA3 in the fimbria can thus potentially send information to the entorhinal cortex via direct projections from the medial septum, and via the anterior thalamus. A second subcortical output route is provided by the subiculum and CA1 projections via the fimbria/fornix to the lateral septum, and from the subiculum to the mammillary bodies and anterior thalamic nuclei, which in turn project to the cingulate cortex as well as to the prelimbic cortex (rat), which could provide a potential output to behavior (Vann and Aggleton, 2004; Bubbs, Kinnavane and Aggleton, 2017), and to the entorhinal cortex. A third subcortical output route is that the subiculum and CA1 also project to the nucleus accumbens (Swanson and Cowan, 1977). How might the CA1 to entorhinal cortico-cortical backprojection system, and the different subcortical output routes from the hippocampus, implement different functions?

First, we should note that the CA1 to entorhinal cortico-cortical backprojection system is numerically, in terms of the number of connections involved, large, and this as developed below is likely to be crucial in allowing large numbers of memories to be retrieved from the hippocampus back to the neocortex. This recall operation to the neocortex is described below, but I note here that once a memory has been retrieved to the neocortex, the neocortex then provides a way for hippocampal function to influence behavior. For example, in a place-object recall task, a place cue used to initiate recall of the whole place-object memory in the CA3 would then lead via the backprojections to the object being retrieved (via entorhinal cortex layer 5 and perirhinal cortex) back to the inferior temporal visual cortex (see Fig. 9.2 left), and this object representation could then guide behavior via the other outputs of the inferior temporal visual cortex (Rolls and Deco, 2002; Rolls, 2016b). As objects are represented in the neocortex, it is a strong prediction of the theory that place-object recall will involve this CA1 backprojection pathway back to the neocortex. Backprojections from CA1 via entorhinal cortex to parahippocampal gyrus and thus to parietal cortex or other parts of the neocortex with spatial representations could allow spatial representations to be retrieved in for example an object-place recall task, and this provides a possible route to spatial action (though an alternative subcortical route for spatial action is described below). In addition, there are more direct CA1, subicular, and entorhinal connections to the prefrontal cortex (Jay and Witter, 1991), which could allow the hippocampus to provide inputs to prefrontal cortex networks involved in short-term memory and in planning actions (Deco and Rolls, 2003, 2005a).

Second, I note that the part of the second subcortical pathway that projects from CA1 via the subiculum to the mammillary bodies and anterior thalamus is also numerically large, with in the order of 10^6 axons in the fornix and mamillo-thalamic tract. Although subcortical connections of the hippocampus are well known, their computational functions are not clear (O'Mara and Aggleton, 2019). One hypothesis is that this could provide an information-rich output pathway to regions such as the cingulate cortex (Rolls, 2019c) via which some types of (e.g. spatial) behavioral response could be specified by the hippocampus. This cingulate cortex route may provide an output for more action-directed use of information stored in the hippocampus (Rolls, 2019c). In addition, head direction signals based on vestibular system processing may be introduced into hippocampal circuitry via the mammillary bodies (Dillingham et al., 2015). In contrast, the CA3 projections via the fimbria to the medial septum described as part of the first subcortical route are much less numerous, with indeed for example only approximately 2000 cholinergic neurons in the rat medial septum (Moore et al., 1998). Given further that this first subcortical route returns mainly to the hippocampus and connected structures, this route may be more involved in regulating hippocampal function

(via cholinergic and GABAergic influences damage to which impairs hippocampal function), than in directly specifying behavior (cf. Hasselmo et al. (1995)).

9.3.8 Backprojections to the neocortex, episodic memory recall, and consolidation

The need for information to be retrieved from the hippocampus to influence neocortical areas and recall memories from the hippocampus was noted in Section 9.1. David Marr (1971) realised the importance of a theory for this, promised one in his 1971 paper, but never produced a theory. Rolls did produce a theory of how the recall of information to the neocortex could be implemented via cortico-cortical backprojections from the hippocampus to the neocortex (Rolls, 1990b, 1989f, 1990b), and the theory became quantitative (Treves and Rolls, 1994; Rolls and Treves, 1994), and has been tested by simulation (Rolls, 1995b, 2023c,e). The theory and developments of it are described next.

It is suggested that the modifiable connections from the CA3 neurons to the CA1 neurons allow the whole episode in CA3 to be produced in CA1. This may be assisted as described above by the direct perforant path input to CA1. This might allow details of the input key for the recall process, as well as the possibly less information-rich memory of the whole episode recalled from the CA3 network, to contribute to the firing of CA1 neurons. The CA1 neurons would then activate, via their termination in the deep layers of the entorhinal cortex, at least the pyramidal cells in the deep layers of the entorhinal cortex (see Fig. 9.2). These entorhinal cortex layer 5 neurons would then, by virtue of their backprojections (Lavenex and Amaral, 2000; Witter et al., 2000a) to the parts of cerebral cortex that originally provided the inputs to the hippocampus, terminate in the superficial layers of those neocortical areas, where synapses would be made onto the distal parts of the dendrites of the cortical pyramidal cells (Rolls, 1989a, 1990b, 1989f; Markov et al., 2014b; Pandya et al., 2015). The areas of cerebral neocortex in which this recall would be produced could include multimodal cortical areas (e.g. the cortex in the superior temporal sulcus which receives inputs from temporal, parietal and occipital cortical areas, and from which it is thought that cortical areas such as 39 and 40 related to language developed); and the orbitofrontal and anterior cingulate cortex to retrieve the reward / affective aspects of an episodic memory (Rolls, 2014a, 2019e,c); and also areas of unimodal association cortex (e.g. inferior temporal visual cortex).

Thus when an episodic memory is recalled, it is predicted that activity will be reinstated using backprojections in cortical areas that represent the different semantic features of the episodic memory. For example, if a friend on a ski slope was recalled, activity would be recalled in medial temporal scene and related areas that represent spatial scenes (in primates including humans (Rolls, 2023c), in temporal lobe areas that represent faces, and in the orbitofrontal cortex where reward value and emotion are represented. The episodic memory would be represented in CA3. Each of these other cortical areas would have neurons that represent the semantic features of each attribute or component of the episodic memory. The same prediction is made about the effects of words, which similarly from cortical areas where words are represented (Chapters 8 and 14) would by backprojections activate many different cortical areas in which the different semantic features are represented. This prediction has been confirmed using fMRI (Huth, de Heer, Griffiths, Theunissen and Gallant, 2016). The concept is that the episodic memory would be represented in the hippocampus, the word in language areas (in both using sparse distributed representations), and that each of the components that are active when the episodic memory was formed, or word is normally accessed, using forward inputs from the world, would become activated to represent the relevant semantic parts during the memory recall, or during the presentation of the word.

The backprojections, by recalling previous episodic events, could provide information

useful to the neocortex in the building of new representations in the multimodal and unimodal association cortical areas, which by building new long-term representations can be considered as a form of memory consolidation (Rolls, 1989a, 1990b, 1989f, 1990a,b, 2022b) (Section 9.2.8.5).

The hypothesis of the architecture with which this would be achieved is shown in Fig. 9.2. The feedforward connections from association areas of the cerebral neocortex (solid lines in Fig. 9.2) show major convergence as information is passed to CA3, with the CA3 autoassociation network having the smallest number of neurons at any stage of the processing. The backprojections allow for divergence back to neocortical areas. The way in which I suggest that the backprojection synapses are set up to have the appropriate strengths for recall is as follows (Rolls, 1989a, 1990b, 1989f, 2016b; Kesner and Rolls, 2015; Rolls, 2015a, 2018b). During the setting up of a new episodic memory, there would be strong feedforward activity progressing towards the hippocampus. During the episode, the CA3 synapses would be modified, and via the CA1 neurons and the subiculum, a pattern of activity would be produced on the backprojecting synapses to the entorhinal cortex. Here the backprojecting synapses from active backprojection axons onto pyramidal cells being activated by the forward inputs to entorhinal cortex would be associatively modified. A similar process would be implemented at (at least some) preceding stages of neocortex, that is in the parahippocampal gyrus/perirhinal cortex stage, and in association cortical areas, as shown in Fig. 9.2.

The concept is that during the learning of an episodic memory, cortical pyramidal cells in at least one of the stages would be driven by forward inputs, but would simultaneously be receiving backprojected activity (indirectly) from the hippocampus which would by pattern association from the backprojecting synapses to the cortical pyramidal cells become associated with whichever cortical cells were being made to fire by the forward inputs. Then later on, during recall, a recall cue from perhaps another part of cortex might reach CA3, where the firing during the original episode would be completed. The resulting backprojecting activity would then, as a result of the pattern association learned previously, bring back the firing in any cortical area that was present during the original episode. Thus retrieval involves reinstating the activity that was present in different cortical areas that was present during the learning of an episode. (The pattern association is also called heteroassociation, to contrast it with autoassociation. The pattern association operates at multiple stages in the backprojection pathway, as made evident in Fig. 9.2.) If the recall cue was an object, this might result in recall of the neocortical firing that represented the place in which that object had been seen previously. As noted elsewhere in this Chapter and by McClelland et al. (1995), that recall might be useful to the neocortex to help it build new semantic memories, which might inherently be a slow process and is not part of the theory of recall. It is an interesting possibility that recall might involve several cycles through the recall process. After the information fed back from the first pass with a recall cue from perhaps only one cortical area, information might gradually be retrieved to other cortical areas involved in the original memory, and this would then act as a better retrieval cue for the next pass.

The timing of the backprojecting activity would be sufficiently rapid for this, in that for example inferior temporal cortex (IT) neurons become activated by visual stimuli with latencies of 90–110 ms and may continue firing for several hundred milliseconds (Rolls, 1992a; Rolls and Deco, 2002; Rolls, 2003); and hippocampal pyramidal cells are activated in visual object-and-place and conditional spatial response tasks with latencies of 120–180 ms (Miyashita, Rolls, Cahusac, Niki and Feigenbaum, 1989; Rolls, Miyashita, Cahusac, Kesner, Niki, Feigenbaum and Bach, 1989c). Thus, backprojected activity from the hippocampus might be expected to reach association cortical areas such as the inferior temporal visual cortex within 60 – 100 ms of the onset of their firing, and there would be a several hundred

millisecond period in which there would be conjunctive feedforward activation present with simultaneous backprojected signals in the association cortex.

During recall, the backprojection connections onto the distal synapses of cortical pyramidal cells would be helped in their efficiency in activating the pyramidal cells by virtue of two factors. The first is that with no forward input to the neocortical pyramidal cells, there would be little shunting of the effects received at the distal dendrites by the more proximal effects on the dendrite normally produced by the forward synapses. Further, without strong forward activation of the pyramidal cells, there would not be very strong feedback and feed-forward inhibition via GABA cells, so that there would not be a further major loss of signal due to (shunting) inhibition on the cell body and (subtractive) inhibition on the dendrite. (The converse of this is that when forward inputs are present, as during normal processing of the environment rather than during recall, the forward inputs would, appropriately, dominate the activity of the pyramidal cells, which would be only influenced, not determined, by the backprojecting inputs (Rolls, 1990b, 1989e; Deco and Rolls, 2005b).)

The synapses receiving the backprojections would have to be Hebb-modifiable, as suggested by Rolls (1990b) and Rolls (1989e). This would solve the de-addressing problem, which is the problem of how the hippocampus is able to bring into activity during recall just those cortical pyramidal cells that were active when the memory was originally being stored. The solution hypothesized (Rolls, 1990b, 1989e) arises because modification occurs during learning of the synapses from active backprojecting neurons from the hippocampal system onto the dendrites of only those neocortical pyramidal cells active at the time of learning. Without this modifiability of cortical backprojections during learning at some cortical stages at least, it is difficult to see how exactly the correct cortical pyramidal cells active during the original learning experience would be activated during recall. Consistent with this hypothesis (Rolls, 1990b, 1989e), there are NMDA receptors present especially in superficial layers of the cerebral cortex (Monaghan and Cotman, 1985), implying Hebb-like learning just where the backprojecting axons make synapses with the apical dendrites of cortical pyramidal cells.

The quantitative argument that the backprojecting synapses in at least one stage have to be associatively modifiable is that the information retrieved would otherwise be very low, and parallels that applied to the pattern retrieval performed at the entorhinal to CA3 synapses (Treves and Rolls, 1992) and at the CA3 to CA1 synapses (Schultz and Rolls, 1999). The performance of pattern association networks is considered in detail by Rolls and Treves (1990), Rolls and Treves (1998), other authors (Hertz et al., 1991), and in Appendix B. An interesting development is that dilution in the connectivity of pattern association networks by reducing the probability of two synapses onto a neuron from the same backprojecting input helps to maintain high capacity in the backprojecting system (Rolls, 2015a). If there are some instances of two or more synapses onto a neuron from the same input axon in a pattern association network, the capacity of the system degrades because of distortion and interferences between the stored patterns (Rolls, 2015a). It is also noted that the somewhat greater anatomical spread of the backprojections than the forward connections between two different stages in the hierarchy shown in Fig. 9.2 would not be a problem, for it would provide every chance for the backprojecting axons to find co-active neurons in an earlier cortical stage that are part of the representation that is relevant to the current memory being formed.

Rolls' theory of recall of information back to the neocortex from the hippocampus (Rolls, 1990b; Rolls and Treves, 1994; Treves and Rolls, 1994; Rolls, 2016b, 2018b) has been shown to be compatible with new learning in the cortex when forward inputs are present, and with the operation of the neocortex as a system with local attractors implemented by the local recurrent collaterals (Rolls, 2021c). The new model to show this is based on the neocortical canonical circuit shown in Fig. 1.17, is described in Section 19.7, and utilises the architecture shown in Fig. 9.31. It is shown that a population of pyramidal cells can implement new

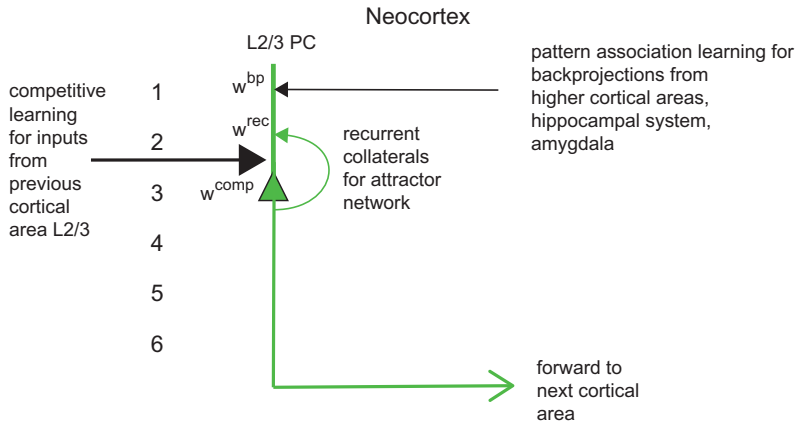

Fig. 9.31 The neocortical model that combines competitive learning using the forward inputs from the preceding cortical region, with associatively modifiable recurrent collateral synapses to form an autoassociation attractor network to maintain neuronal firing for short periods, and with pattern association learning to implement recall or top-down attention using cortico-cortical backprojections. L2/3 PC is a layer 2/3 pyramidal cell. The thick line above the pyramidal cell body is the dendrite, receiving inputs from the previous cortical area that operates by competitive learning using the synapses w^{comp} ; from the recurrent collaterals that operate as an attractor network using synapses w^{rec} ; and back-projections from higher cortical areas for memory recall and top-down attention that operate by pattern association learning using the synapses w^{bp} . 1-6 : the layers of the neocortex. (Reprinted from Rolls (2021) The connections of neocortical pyramidal cells can implement the learning of new categories, attractor memory, and top-down recall and attention. Brain Structure and Function 226: 2523-2536. © Springer.)

learning based on forward inputs when they are present using competitive learning, and at the same time can train the recurrent collaterals to implement an attractor network for later short-term memory, and can simultaneously train the backprojections as a pattern associator to implement later top-down recall (from e.g. the hippocampus) and top-down attention. Later, when a forward input is not present, recall can be initiated by the backprojections, and the activity can be maintained in short-term memory by the autoassociation recurrent collaterals. The architecture is quite simple, as is shown here in Fig. 9.31 to illustrate that point, with details in Section 19.7 and in Rolls (2021c).

If the backprojection synapses are associatively modifiable, we may consider the duration of the period for which their synaptic modification should persist. What follows from the operation of the system described above is that there would be no point, indeed it would be disadvantageous, if the synaptic modifications lasted for longer than the memory remained in the hippocampal buffer store. What would be optimal would be to arrange for the associative modification of the backprojecting synapses to remain for as long as the memory persists in the hippocampus. This suggests that a similar mechanism for the associative modification within the hippocampus and for that of at least one stage of the backprojecting synapses would be appropriate. It is suggested that the presence of high concentrations of NMDA synapses in the distal parts of the dendrites of neocortical pyramidal cells and within the hippocampus may reflect the similarity of the synaptic modification processes in these two regions (Kirkwood et al., 1993). It is noted that it would be appropriate to have this similarity of time course (i.e. rapid learning within 1–2 s, and slow decay over perhaps weeks) for at least one stage in the series of backprojecting stages from the CA3 region to the neocortex. Such stages might include the CA1 region, subiculum, entorhinal cortex, and perhaps the parahippocampal gyrus / perirhinal cortex. However from multimodal cortex (e.g. the parahippocampal gyrus) back to earlier cortical stages, it might be desirable for the backprojecting synapses to persist for a long period, so that some types of recall and top-down processing (Rolls, 1990b, 1989e, 2016b) mediated by the operation of neocortico-neocortical backpro-

jecting synapses could be stable, and might not require modification during the learning of a new episodic memory.

An alternative hypothesis to that above is that rapid modifiability of backprojection synapses would be required only at the beginning of the backprojecting stream. Relatively fixed associations from higher to earlier neocortical stages would serve to activate the correct neurons at earlier cortical stages during recall. For example, there might be rapid modifiability from CA3 to CA1 neurons, but relatively fixed connections from there back (McClelland, McNaughton and O'Reilly, 1995). For such a scheme to work, one would need to produce a theory not only of the formation of semantic memories in the neocortex, but also of how the operations performed according to that theory would lead to recall by setting up appropriately the backprojecting synapses. It is suggested that they could be learned by the same associative processes between the backprojections and the neuronal firing in the preceding cortical area as just described. Also, as noted above, there is evidence that the CA3 inputs to CA1 are much stronger than the entorhinal cortex inputs to CA1 (Zhao, Hsu and Spruston, 2022; Zhao, Wang, Spruston and Magee, 2020) (and N. Spruston, personal communication, 2022), so the theory of McClelland, McNaughton and O'Reilly (1995) about CA1 does not receive support.

We have noted elsewhere that backprojections, which included cortico-cortical backprojections, and backprojections originating from structures such as the hippocampus and amygdala, may have a number of different but compatible functions (Rolls and Deco, 2002; Rolls, 2005a, 1990a,b, 1989e, 1990b, 1989a, 1992a, 2016b) including implementing top-down attention by biased competition (see Chapter 13). The particular function with which we have been concerned here is how memories stored in the hippocampus might be recalled in regions of the cerebral neocortex.

Rolls' theory of how the recall of information to the neocortex could be implemented via cortico-cortical backprojections from the hippocampus to the neocortex (Rolls, 1990b, 1989f, 1990b) was a key conceptual discovery and theory, because it showed how the deaddressing problem could be solved of how the hippocampus could retrieve information to the correct neurons in the neocortex. In a sense, the theory shows how the hippocampus 'points to' the correct neurons in the neocortex for the hippocampal recall. The concept of how the hippocampus could point to the correct neurons in the neocortex had been raised by Teyler and DiScenna (1986), and they used the word 'pointer', but had no theory of how a hippocampal pointer might be implemented or how information might be recalled from the hippocampus back to the correct neurons in the neocortex. That was the theory that Rolls developed (Rolls, 1990b, 1989f, 1990b), and the theory became quantitative (Rolls and Treves, 1994; Treves and Rolls, 1994), and has been tested by simulation (Rolls, 1995b, 2023c,e). The high capacity of memory recall with sparse representations in associative networks (Rolls and Treves, 1990; Treves and Rolls, 1991; Rolls and Treves, 1994; Treves and Rolls, 1994) has been confirmed (Schonsberg, Roudi and Treves, 2021).

9.3.9 Backprojections to the neocortex – quantitative aspects

How many backprojecting fibres does one need to synapse on any given neocortical pyramidal cell, in order to implement the mechanism outlined above? Clearly, if neural network theory were to produce a definite constraint of that sort, quantitative anatomical data could be used for verification or falsification.

Attempts to come up with an estimate of the number of synapses required have sometimes followed the simple line of reasoning presented next, which is shown to be unsatisfactory. [The type of argument to be described has been applied to analyze the capacity of pattern association and autoassociation memories (see for example Marr (1971) and Willshaw and

Buckingham (1990)), and to show that there are limitations in that type of approach, that approach is considered in this paragraph.] Consider first the assumption that hippocampo-cortical connections are monosynaptic and not modifiable, and that all existing synapses have the same efficacy. Consider further the assumption that a hippocampal representation across N cells of an event consists of $a_h N$ cells firing at the same elevated rate (where a_h is the sparseness of the hippocampal representation), while the remaining $(1 - a_h)N$ cells are silent. If each pyramidal cell in the association areas of neocortex receives synapses from an average C^{HBP} hippocampal axons, there will be an average probability $y = C^{\text{HBP}}/N$ of finding a synapse from any given hippocampal cell to any given neocortical one. Across neocortical cells, the number A of synapses of hippocampal origin activated by the retrieval of a particular episodic memory will follow a Poisson distribution of average $ya_h N = a_h C^{\text{HBP}}$

$$P(A) = (a_h C^{\text{HBP}})^A \exp(-a_h C^{\text{HBP}})/A! \quad (9.9)$$

The neocortical cells activated as a result will be those, in the tail of the distribution, receiving at least T active input lines, where T is a given threshold for activation. Requiring that $P(A > T)$ be at least equal to a_{nc} , the fraction of neocortical cells involved in the neocortical representation of the episode, results in a constraint on C^{HBP} . This simple type of calculation can be extended to the case in which hippocampo-cortical projections are taken to be polysynaptic, and mediated by modifiable synapses. In any case, the procedure does not appear to produce a very meaningful constraint for at least three reasons. First, the resulting minimum value of C^{HBP} , being extracted by looking at the tail of an exponential distribution, varies dramatically with any variation in the assumed values of the parameters a_h , a_{nc} , and T . Second, those parameters are ill-defined in principle: a_h and a_{nc} are used having in mind the unrealistic assumption of binary distributions of activity in both the hippocampus and neocortex (although the sparseness of a representation can be defined in general, as shown above, it is the particular definition pertaining to the binary case that is invoked here); while the definition of T is based on unrealistic assumptions about neuronal dynamics (how coincident does one require the various inputs to be in time, in order to generate a single spike, or a train of spikes of given frequency, in the postsynaptic cell?). Third, the calculation assumes that neocortical cells receive no other inputs, excitatory or inhibitory. Relaxing this assumption, to include for example non-specific activation by subcortical afferents, makes the calculation extremely fragile. This argument applies in general to approaches to neurocomputation which base their calculations on what would happen in the tail of an exponential, Poisson, or binomial distribution. Such calculations must be interpreted with great care for the above reasons (Rolls and Treves, 1998).

An alternative way to estimate a constraint on C^{HBP} , still based on very simple assumptions, but which is more robust with respect to relaxing those assumptions, is the following.

Consider a polysynaptic sequence of backprojecting stages, from hippocampus to neocortex, as a string of simple (hetero-)associative memories in which, at each stage, the input lines are those coming from the previous stage (closer to the hippocampus) (Treves and Rolls, 1994) (Fig. 9.2). Implicit in this framework is the assumption that the synapses at each stage are modifiable and have been indeed modified at the time of first experiencing each episode, according to some Hebbian associative plasticity rule. A plausible requirement for a successful hippocampo-directed recall operation is that the signal generated from the hippocampally retrieved pattern of activity, and carried backwards towards neocortex, remains undegraded when compared to the noise due, at each stage, to the interference effects caused by the concurrent storage of other patterns of activity on the same backprojecting synaptic systems. That requirement is equivalent to that used in deriving the storage capacity of such a series of heteroassociative memories, and it was shown in Treves and Rolls (1991) that the maximum

number of independently generated activity patterns that can be retrieved is given, essentially, by the same formula as Equation 9.3 above

$$p \approx \frac{C}{a \ln(\frac{1}{a})} k' \quad (9.10)$$

where, however, a is now the sparseness of the representation at any given backprojection stage, and C is the average number of (back-)projections each cell of that stage receives from cells of the previous one¹⁴. (k' is a similar slowly varying factor to that introduced above.) If p is equal to the number of memories held in the hippocampal memory, it is limited by the retrieval capacity of the CA3 network, p_{\max} . Putting together the formula for the latter with that shown here, one concludes that, roughly, the requirement implies that the number of afferents of (indirect) hippocampal origin to a given neocortical stage (C^{HBP}) must be $C^{\text{HBP}} = C^{\text{RC}} a_{\text{nc}} / a_{\text{CA3}}$, where C^{RC} is the number of recurrent collaterals to any given cell in CA3, the average sparseness of a neocortical representation is a_{nc} , and a_{CA3} is the sparseness of memory representations in CA3.

The above requirement is very strong: even if representations were to remain as sparse as they are in CA3, which is unlikely, to avoid degrading the signal, C^{HBP} should be as large as C^{RC} , i.e. 12,000 in the rat. Moreover, other sources of noise not considered in the present calculation would add to the severity of the constraint, and partially compensate for the relaxation in the constraint that would result from requiring that only a fraction of the p episodes would involve any given cortical area. If then C^{HBP} has to be of the same order as C^{RC} , one is led to a very definite conclusion: a mechanism of the type envisaged here could not possibly rely on a set of monosynaptic CA3-to-neocortex backprojections. This would imply that, to make a sufficient number of synapses on each of the vast number of neocortical cells, each cell in CA3 has to generate a disproportionate number of synapses (i.e. C^{HBP} times the ratio between the number of neocortical and that of CA3 cells). The required divergence can be kept within reasonable limits only by assuming that the backprojecting system is polysynaptic, provided that the number of cells involved grows gradually at each stage, from CA3 back to neocortical association areas (Treves and Rolls, 1994) (cf. Fig. 9.2).

Although backprojections between any two adjacent areas in the cerebral cortex are approximately as numerous as forward projections, and much of the distal parts of the dendrites of cortical pyramidal cells are devoted to backprojections, the actual number of such connections onto each pyramidal cell may be on average only in the order of thousands. Further, not all might reflect backprojection signals originating from the hippocampus, for there are backprojections which might be considered to originate in the amygdala (Amaral et al., 1992) or in multimodal cortical areas (allowing for example for recall of a visual image by an auditory stimulus with which it has been regularly associated). In this situation, one may consider whether the backprojections from any one of these systems would be sufficiently numerous to produce recall. One factor which may help here is that when recall is being produced by the backprojections, it may be assisted by the local recurrent collaterals between nearby (≈ 1 mm) pyramidal cells which are a feature of neocortical connectivity. These would tend to complete a partial neocortical representation being recalled by the backprojections into a complete recalled pattern. (Note that this completion would be only over the local information present within a cortical area about e.g. visual input or spatial input; it provides a local ‘clean-up’

¹⁴The interesting and important insight here is that multiple iterations through a recurrent autoassociative network can be treated as being formally similar to a whole series of feedforward associative networks, with each new feedforward network equivalent to another iteration in the recurrent network (Treves and Rolls, 1991). This formal similarity enables the quantitative analysis developed in general for autoassociation nets (see Treves and Rolls (1991)) to be applied directly to the series of backprojection networks (Treves and Rolls, 1994).

mechanism, and could not replace the global autoassociation performed effectively over the activity of very many cortical areas which the CA3 could perform by virtue of its widespread recurrent collateral connectivity.) There are two alternative possibilities about how this would operate. First, if the recurrent collaterals showed slow and long-lasting synaptic modification, then they would be useful in completing the whole of long-term (e.g. semantic) memories. Second, if the neocortical recurrent collaterals showed rapid changes in synaptic modifiability with the same time course as that of hippocampal synaptic modification, then they would be useful in filling in parts of the information forming episodic memories which could be made available locally within an area of the cerebral neocortex.

This theory of recall by the backprojections thus provides a quantitative account of why the cerebral cortex has as many backprojection as forward projection connections (Treves and Rolls, 1994; Rolls and Treves, 1994; Rolls, 2016b). I know of no alternative quantitative account for this key feature of neocortical design (Rolls, 2016b).

A development of the theory has been in understanding the diluted connectivity in the back-projection pathways. The backprojection pathways have diluted connectivity in that each neocortical neuron may receive up to in the order of 10,000 backprojection synapses, yet the total number of neurons at each neocortical stage in the backprojection hierarchy shown in Fig. 9.2 has very many more neurons than this, at least 10 times as many neurons as there are synapses per neuron. This diluted connectivity in the backprojection pathways is likely to reduce the probability of more than one connection onto a receiving neuron in the backprojecting pathways. It has now been shown that if there were more than one connection onto each neuron in a pattern associator, this would reduce the capacity of the system, which in this case is the number of memories that can be recalled from the hippocampus to the neocortex (Rolls, 2015a). However, given that there is dilution in the connectivity of the backprojection pathways in the neocortex, it may be useful to have the representations not very sparse in the backprojection pathways, for otherwise the pattern association computation that implements the recall may be downgraded (Rolls, 2023e).

These concepts show how the backprojection system to neocortex can be conceptualized in terms of pattern completion, as follows. The information that is present when a memory is formed may be present in different areas of the cerebral cortex, for example of a face in a temporal cortex face area (Rolls, 2012d), of a spatial location in a neocortical scene location area, and of a reward received in the orbitofrontal cortex (Rolls, 2014a, 2023c; Rolls et al., 2023e,c). To achieve detailed retrieval of the memory, reinstatement of the activity during recall of the neuronal activity during the original memory formation may be needed. This is what the backprojection system described could achieve, and is a form of completion of the information that was represented in the different cortical areas when the memory was formed. In particular, the concept of completion here is that if a recall cue from a visual object area is provided and the hippocampus recalls the other components of the episodic memory, then the emotional parts of the episodic memory can be recalled in the orbitofrontal cortex, and the spatial parts in medial temporal lobe cortical areas, with the result that a complete memory is retrieved, with activity recalled into several higher-order cortical areas. Because such a wide set of different neocortical areas must be content-addressed, a multistage feedback system from the hippocampus is required, to keep the number of synapses per neuron in the back-projection pathways down to reasonable numbers (Treves and Rolls, 1994; Rolls and Treves, 1994). (Having CA1 directly address neocortical areas would require each CA1 neuron to have tens of millions of synapses with cortical neurons. That is part of the computational problem solved by the multistage backprojection system shown in Fig. 9.2.) Thus, the back-projection system with its series of pattern associators can each be thought of as retrieving the complete pattern of cortical activity in many different higher-order cortical areas that was present during the original formation of the episodic memory.

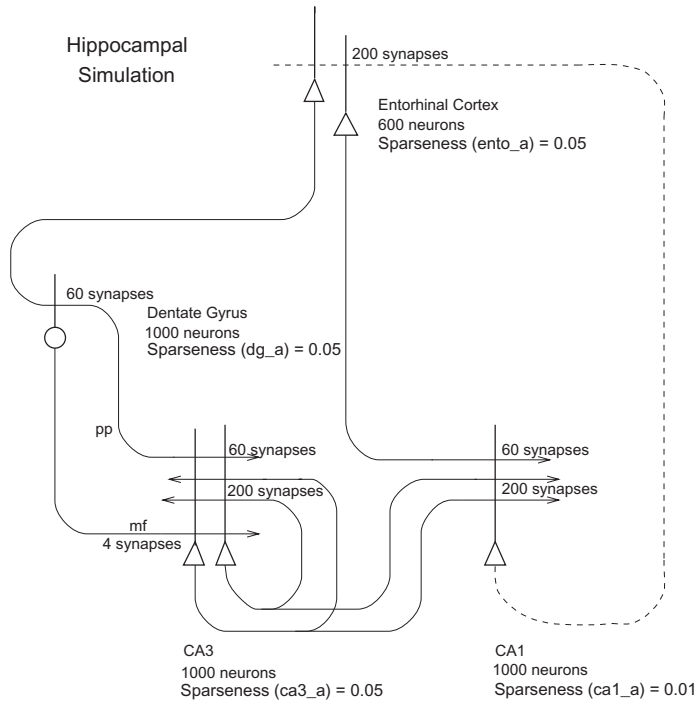

Fig. 9.32 Simulation of a scaled down model of the hippocampus and recall to the neocortex. The numbers of synapses and the sparseness values used are shown. (After Rolls, E. T. (1995) A model of the operation of the hippocampus and entorhinal cortex in memory. *International Journal of Neural Systems* 6, Supplement: 51–70. © World Scientific Publishing Company.)

9.3.10 Simulations of hippocampal operation

In order to test the operation of the whole system for individual parts of which an analytic theory is available (Rolls and Treves, 1998; Treves and Rolls, 1994, 1992; Schultz and Rolls, 1999), Rolls (1995b) simulated a scaled down version of the part of the architecture shown in Fig. 9.2 from the entorhinal cortex to the hippocampus and back to the entorhinal cortex. The network included competitive learning in the dentate gyrus to form a sparse representation, using this to drive the CA3 cells by diluted non-associative mossy fibre connectivity during learning, competitive learning in CA1, and pattern association in the retrieval back to entorhinal cortex (Fig. 9.32). The analytic approaches to the storage capacity of the CA3 network, the role of the mossy fibres and of the perforant path, the functions of CA1, and the operation of the backprojections in recall, were all shown to be computationally plausible in the computer simulations. In the simulation, during recall, partial keys are presented to the entorhinal cortex, completion is produced by the CA3 autoassociation network, and recall is produced in the entorhinal cortex of the original learned vector. The network, which has 1,000 neurons at each stage, can recall large numbers of different sparse random vectors, which approach the calculated storage capacity.

One of the points highlighted by the simulation is that the network operated much better if the CA3 cells operated in binary mode (either firing or not), rather than having continuously graded firing rates (Rolls, 1995b). The reason for this is that given that the total amount of information that can be stored in a recurrent network such as the CA3 network is approximately constant independently of how graded the firing rates are in each pattern (Treves, 1990), then if much information is used to store the graded firing rates in the firing of CA3 cells, fewer patterns can be stored. The implication of this is that in order to store many memories in the hippocampus, and to be able to recall them at later stages of the system in for

example the entorhinal cortex and beyond, it may be advantageous to utilize relatively binary firing rates in the CA3 part at least of the hippocampus.

This finding has been confirmed and clarified by simulation of the CA3 autoassociative system alone, and it has been suggested that the advantage of operation with binary firing rates may be related to the low firing rates characteristic of hippocampal neurons (Rolls, Treves, Foster and Perez-Vicente, 1997c).

Another aspect of the theory emphasized by the results of the simulation was the importance of having effectively a single network provided in the hippocampus by the CA3 recurrent collateral network, for only if this operated as a single network (given the constraint of some topography present at earlier stages), could the whole of a memory be completed from any of its parts (Rolls, 1995b).

Another aspect of the theory illustrated by these simulations was the information retrieval that can occur at the CA3–CA1 (Schaeffer collateral) synapses if they are associatively modifiable (Schultz and Rolls, 1999).

The approach to modelling the whole of the hippocampal system has been extended to allow recall as far back as the neocortex to be modelled, with the architecture shown in Fig. 9.33 (Rolls, 2023c,e). The model has separate regions in the neocortex and entorhinal cortex for the prototypical ‘where’ and ‘what’ inputs to the hippocampus. When trained with ‘where’ and ‘what’ pairs of inputs to the neocortex, the hippocampal system modelled can recall the correct ‘where’ pattern back to the neocortex if the recall cue is a ‘what’ neocortical input, and vice versa. This type of symmetric recall of a whole memory from any part is made possible because of the autoassociation network in CA3. This type of symmetric recall could of course not be achieved by a pattern association network (Appendix B). An interesting aspect emphasised by the operation of the model is that the backprojection patterns to the neocortex that implement recall by pattern association should not be very sparse, for otherwise given the diluted connectivity in the neocortical backprojection pathways the recall to the neocortex can be degraded (Rolls, 2023e). In the hierarchical organisation of the neocortex the sparseness of the activity patterns can be more sparse in the forward direction, because the forward connectivity up through the network operates by competitive learning, which in fact benefits from diluted connectivity and sparse patterns (Rolls, 2016f,b) (Section B.4.3.3).

9.3.11 The learning of spatial view and place cell representations from visual inputs

In the ways just described, the dentate granule cells could be particularly important in helping to build and prepare spatial representations for the CA3 network. The actual representation of space in the primate hippocampus includes a representation of spatial view, whereas in the rat hippocampus it is of the place where the rat is. The representation in the rat may be related to the fact that with a much less developed visual system than the primate, the rat’s representation of space may be defined more by the olfactory and tactile as well as distant visual cues present, and may thus tend to reflect the place where the rat is. However, the spatial representations in the rat and primate could arise from essentially the same computational process as follows (Rolls, 1999c; Critchley and Rolls, 1996a).

The starting assumption is that in both the rat and the primate, the dentate granule cells (and the CA3 and CA1 pyramidal cells) respond to combinations of the inputs received. In the case of the primate, a combination of visual features in the environment will, because of the fovea providing high spatial resolution over a typical viewing angle of perhaps 10–20 degrees, result in the formation of a spatial view cell, the effective trigger for which will thus be a combination of visual features within a relatively small part of space. In contrast,

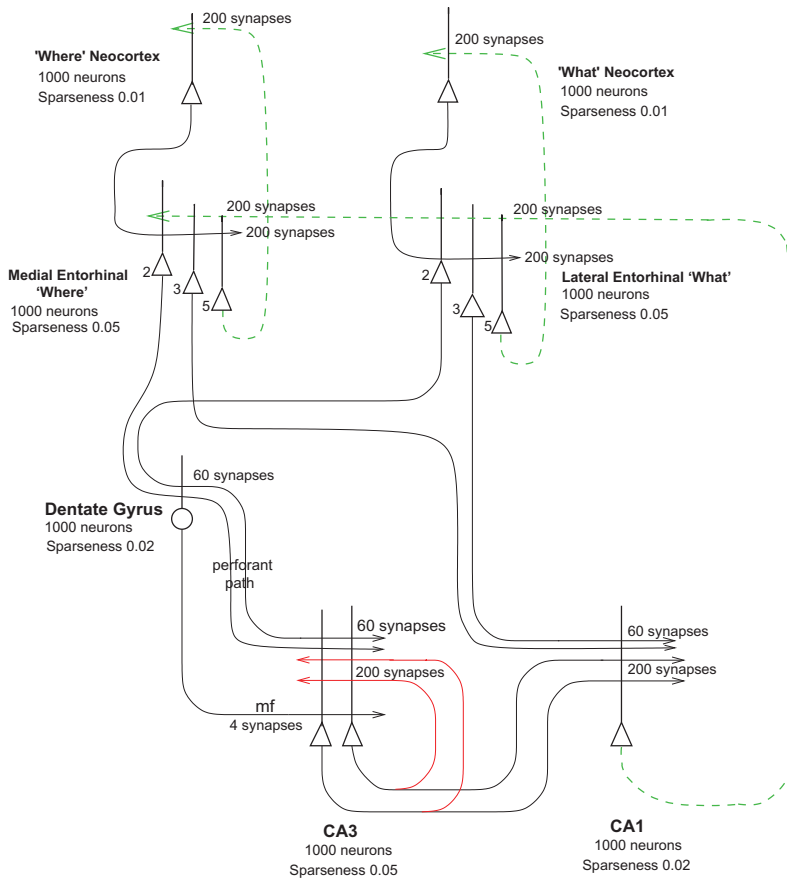

Fig. 9.33 Simulation of neocortical 'what' and 'where' inputs to the hippocampus for the storage of episodic memory, and for the recall of 'what' (object) and 'where' (spatial view) information back to the 'what' and 'where' neocortex. The pyramidal cells bodies are shown as triangles, the dendrites as the thick lines above the cell bodies, and the axons as thin lines terminated with an arrow. The backprojection pathways for memory recall are shown in dashed green lines, and in red the CA3 recurrent collaterals via which 'what' and 'where' representations present at the same time can be associated during episodic memory storage, and via which completion of a whole memory from a part can occur during recall. All synapses are associatively modifiable except for the dentate Gyrus (DG) mossy fibre (mf) synapses on the CA3 pyramidal cells. The dentate granule cells, the CA1 cells, and the entorhinal cortex inputs from the neocortex operate as competitive networks. The CA3 cells operate as an autoassociation attractor network to implement completion. The backprojection connections shown in green operate as pattern association networks. (After Rolls, E. T. (2023) Hippocampal spatial view cells for memory and navigation, and their underlying connectivity in humans. Hippocampus doi: 10.1002/hipo.23467.)

in the rat, given the very extensive visual field subtended by the rodent retina, which may extend over 180–270 degrees, a combination of visual features formed over such a wide visual angle would effectively define a position in space that is a place (see Fig. 9.34). The actual processes by which the hippocampal formation cells would come to respond to feature combinations could be similar in rats and monkeys, involving for example competitive learning in the dentate granule cells, as utilized in the simulations of Critchley and Rolls (1996a) which produced neurons with place-like and spatial view-like tuning. This competitive learning has the required properties, of associating together co-occurrent features, and of ensuring by the competition that each feature combination (representing a place or spatial view) is very different from that of other places or spatial views (pattern separation, and orthogonalizing effect), and is also a sparse representation. Consistent with this, dentate place fields in rats are small (Jung and McNaughton, 1993). Although this computation could be performed to some extent also by autoassociation learning in CA3 pyramidal cells, and competitive learning in

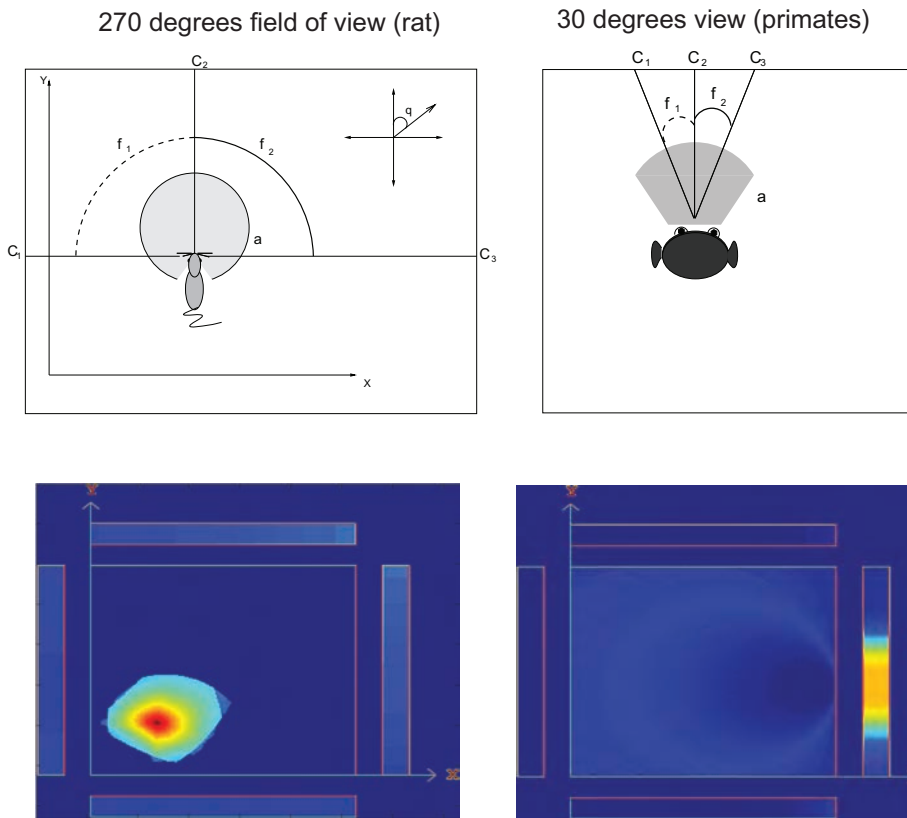

Fig. 9.34 Place cells can be formed in animals such as rodents with a wide field of view, and spatial view neurons can be formed with a small high resolution field of view as provided in primates including humans by the fovea. Simulation of rodent place cells (left) vs primate spatial view cells (right). The agent moved through a grid of all 200×200 places x, y . At each place the head direction θ was rotated in 5 degree increments. Hippocampal cells are activated by a set of 3 or more landmark visual cues within the field of view of the agent α . The firing rates of the hippocampal neurons depended on the angles ϕ subtended by the landmarks. The top left shows that for a rodent with a 270° field of view a combination of such cues defines a place. The top right shows that for a primate with a 30° view the combination of cues in the scene defines a spatial view. The sizes of the fields of view are shown by shading. The bottom left shows that in the simulations place fields arise with a 270° field of view, and the bottom right that spatial view fields arise on one of the walls indicated by the rectangles when the view is 30° . High firing rates are indicated by yellow-red. (Modified from Araujo, I.E.T., Rolls, E. T. and Stringer, S.M. (2001) A view model which accounts for the spatial fields of hippocampal primate spatial view cells and rat place cells. *Hippocampus* 11: 699–706. © Wiley-Liss Inc.)

CA1 pyramidal cells (Rolls and Treves, 1998; Treves and Rolls, 1994), the combined effect of the dentate competitive learning and the mossy fibre low probability but strong synapses to CA3 cells would enable this part of the hippocampal circuitry to be especially important in separating spatial representations, which as noted above are inherently continuous. The prediction thus is that during the learning of spatial tasks in which the spatial discrimination is difficult (for example because the places are close together), then the dentate system should be especially important. Tests of this prediction are described in Section 9.4.

9.3.12 Linking the inferior temporal visual cortex to spatial view and place cell representations

It is now possible to propose a unifying computational hypothesis of the relation between the ventral visual system, and hippocampal spatial representations (Rolls, Tromans and Stringer, 2008f). Let us consider a computational architecture in which a fifth layer is added to the

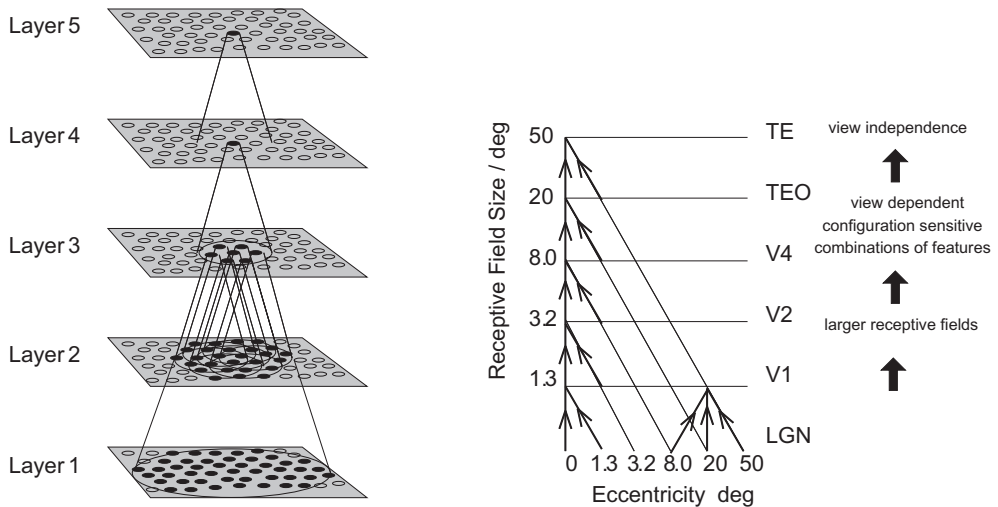

Fig. 9.35 Adding a fifth layer, corresponding to the parahippocampal gyrus / hippocampal system, after the inferior temporal visual cortex (corresponding to layer 4) may lead to the self-organization of spatial view / place cells in layer 5 when whole scenes are presented (see text). Convergence in the visual system is shown in the earlier layers (see Chapter 2). Right – as it occurs in the brain. V1, visual cortex area V1; TE0, posterior inferior temporal cortex; TE, inferior temporal cortex (IT). Left – as implemented in VisNet (layers 1–4). Convergence through the network is designed to provide fourth layer neurons with information from across the entire input retina. (From Rolls, E. T., Tromans, J. and Stringer, S.M. (2008) Spatial scene representations formed by self-organizing learning in a hippocampal extension of the ventral visual system. *European Journal of Neuroscience* 28: 2116–2127. © Federation of European Neuroscience Societies and Blackwell Publishing Ltd.)

VisNet architecture described in Chapter 2, as illustrated in Fig. 9.35. In the anterior inferior temporal visual cortex, which corresponds to the fourth layer of VisNet, neurons respond to objects, but several objects close to the fovea (within approximately 10°) can be represented because many object-tuned neurons have asymmetric receptive fields with respect to the fovea (Aggelopoulos and Rolls, 2005) (see Section 2.8.10). If the fifth layer of VisNet performs the same operation as previous layers, it will form neurons that respond to combinations of objects in the scene with the positions of the objects relative spatially to each other incorporated into the representation (as described in Section 2.8.5). It was found that training now with whole scenes that consist of a set of objects in a given fixed spatial relation to each other results in neurons in the added, fifth, layer that respond to one of the trained whole scenes, but do not respond if the objects in the scene are rearranged to make a new scene from the same objects (Rolls, Tromans and Stringer, 2008f). The formation of these scene-specific representations in the added layer is related to the fact that in the inferior temporal cortex, and, we showed, in the VisNet model, the receptive fields of inferior temporal cortex neurons shrink and become asymmetric when multiple objects are present simultaneously in a natural scene. This also provides a solution to the issue of the representation of multiple objects, and their relative spatial positions, in complex natural scenes (Rolls, Tromans and Stringer, 2008f). The implication of the findings is that in a unifying computational approach, competitive network processes operating in areas such as the parahippocampal cortex, the entorhinal cortex, and/or the dentate granule cells could form unique views of scenes by forming a sparse representation of these object or feature tuned inferior temporal cortex ventral visual stream representations which have some spatial asymmetry into spatial view cells in the hippocampus (Rolls, Tromans and Stringer, 2008f) (see further Section 2.8.14).

It is proposed that this type of learning could be complemented by recurrent collateral connections between the Layer 5 neurons, which would form a continuous attractor network which would encode the relations between parts of the scene, in that nearby parts of the

scene would be associated together because of coactivity. These types of processes are those proposed to be involved in building spatial scene representations on the ventromedial visual stream to the medial parahippocampal gyrus in primates including humans, as described in Section 9.2.8.1 (Rolls, 2023c; Rolls et al., 2023e).

It is an interesting part of the hypothesis just described that because spatial views and places are defined by the relative spatial positions of fixed landmarks (such as buildings), slow learning of such representations over a number of trials might be useful, so that the neurons come to represent spatial views or places, and do not learn to represent a random collection of moveable objects seen once in conjunction. In this context, an alternative brain region to the dentate gyrus for this next layer of VisNet-like processing might be the parahippocampal areas that receive from the inferior temporal visual cortex. Spatial view cells are present in the parahippocampal areas (Georges-François, Rolls and Robertson, 1999; Robertson, Rolls and Georges-François, 1998; Rolls, Robertson and Georges-François, 1997a; Rolls, Treves, Robertson, Georges-François and Panzeri, 1998b; Rolls, Xiang and Franco, 2005c). These spatial view representations could be formed in these regions as, effectively, an added layer to VisNet. Moreover, these cortical regions have recurrent collateral connections that could implement a continuous attractor representation. Alternatively, it is possible that these parahippocampal spatial representations reflect the effects of backprojections from the hippocampus to the entorhinal cortex and thus to parahippocampal areas. In either case, it is an interesting and unifying hypothesis that an effect of adding an additional layer to VisNet-like ventral stream visual processing might with training in a natural environment lead to the self-organization, using the same principles as in the ventral visual stream, of spatial view or place representations in parahippocampal or hippocampal areas (Rolls, Tromans and Stringer, 2008f).

The ventral visual stream inputs that could be used to help build hippocampal spatial view representations of scenes include ventral stream temporal cortex representations of scenes (Kornblith et al., 2013; Nasr et al., 2011; Kamps et al., 2016; Epstein and Julian, 2013; Troiani et al., 2014; Epstein and Baker, 2019). My current hypothesis is that these ventral visual stream inputs are what is used to build hippocampal spatial scene representations. Consistent with this, microstimulation of the occipito-temporal scene area of macaques activated the macaque parahippocampal gyrus (Kornblith et al., 2013) in a parahippocampal region in which we recorded spatial view cells (Georges-François et al., 1999; Robertson et al., 1998; Rolls et al., 1997a, 1998b, 2005c; Rolls, 2023c).

In this situation, the route via the dorsal visual stream and parietal cortex areas to the hippocampal system via the retrosplenial cortex and posterior cingulate cortex (Rolls, 2019c) (Section 3.5) is then used for the idiothetic update of where in the allocentric spatial scene we may be looking, for example in the dark or remembering based on idiothetic information (Rolls, 2021f, 2023c; Rolls et al., 2023e).

9.3.13 A scientific theory of the art of memory: *scientia artis memoriae*

Simonides of Ceos lived to tell the story of how when a banquet hall collapsed in an earthquake, he could identify all the victims by recalling from each place at the table who had been sitting there (Cicero, 55 BC). This way of remembering items was developed into what has become known as *ars memoriae* by Roman senators, who presented the steps of a complex legal argument in a speech that might last a whole day by associating each step in the argument with a location in a spatial scene through which their memory could progress from one end to the other during the speech to recall each item in the correct order (Yates, 1992).

Why is *ars memoriae* so successful in helping to remember complex series of points or arguments or people or objects?

The theory is proposed that *ars memoriae* is implemented in the CA3 region of the hippocampus where there are spatial view cells in primates that allow a particular view to be associated with a particular object in an event or episodic memory. Given that the CA3 cells with their extensive recurrent collateral system connecting different CA3 cells, and associative synaptic modifiability, form an autoassociation or attractor network, the spatial view cells with their approximately Gaussian view fields become linked in a continuous attractor. In this continuous attractor network, the strength of the connections thus reflects the proximity of two spatial views. As the view space is traversed (for example by self-motion), the views are therefore successively recalled in the correct order, with no view missing. Given that each view has been associated with a different discrete item, the items are recalled in the correct order, with none missing (Rolls, Stringer and Trappenberg, 2002). There is some forgetting in the system, so the same view can be used on a later occasion to associate each view in the scene with a new set of items. This is the theory proposed for *ars memoriae* (Rolls, 2017d).

9.3.14 How navigation is performed

9.3.14.1 Navigation using a hippocampal allocentric Euclidean cognitive map

One approach is to use place cells to provide an allocentric representation of space, and to postulate that the space is Euclidean (O'Keefe and Nadel, 1978; O'Keefe, 1990). Head direction cells, which are allocentric, and anchored to the landmarks, for example the room cues, can then potentially help the animal to move in the correct direction to reach a place in allocentric space. If turns need to be made en route, the situation may become more complicated if sufficient allocentric room / landmark cues are not visible for example in a cluttered environment, for then the distance travelled needs to be estimated, and that typically involves self-motion, that is idiothetic, update, based for example on how many steps have been taken, or on integrating over velocity cues computed in the vestibular system.

An approach to how this might work in rodents has been described (Edvardsen, Bicanski and Burgess, 2020). In this model, the CA3 cells respond to places, and the recurrent collaterals in CA3 enable neighbourhood relationships between locations in the explored environment to be retrieved using the recurrent collaterals. Such a system could implement a topological navigation strategy whereby the agent navigates to its goal location by calculating the shortest path in this internal representation of the environment and then following the resultant sequence of place cells' firing fields as its itinerary. The operation of this type of system, which is a continuous attractor network (described in Section B.5), and how it can be moved from place to place has been described previously (Stringer, Rolls, Trappenberg and De Araujo, 2002a). However, such a system must have explored the environment well, so that the shortest path to the goal can be found, for this system relies on the overlapping of the place fields for previously traversed routes. Also, this system is susceptible to difficulties if an unexpected obstacle is found, for that breaks the route in the continuous attractor network. A further problem is that any CA3 spatial continuous attractor could be too bumpy (with valleys in the energy landscape) because of associations with objects etc to implement a continuous spatial chart, and may accordingly be more suitable for episodic memory (Cerasti and Treves, 2013) (see above).

9.3.14.2 Navigation using an entorhinal cortex goal vector system

Partly because of these difficulties, Edvardsen, Bicanski and Burgess (2020) complemented the hippocampal CA3 place cell system with an entorhinal cortex grid cell system to support goal vector representations (Poulter et al., 2018). Given grid cell activity for the present lo-

cation and a trace of the grid cell activity for the goal location, the appropriate straight-line vector across two-dimensional space can be determined with the grid cell system. The agent can then find the correct bearing toward the goal location even across large stretches of unexplored space due to the metric properties of grid cells. This could support navigation in the correct direction across unexplored territory, but would fail if there was an obstacle in the direct path that required a detour. In a combined model, ‘replay’ from a hippocampal CA3 model (described in Section 9.3.4.4) using place cells is used to dynamically adjust the target for the vector navigation process. The whole system uses rodent border cells which respond when a border is encountered (Solstad, Boccara, Kropff, Moser and Moser, 2008), and rodent boundary vector cells (which signal the bearing and distance to a border (Lever et al., 2009)) to help with obstacle avoidance. The system is then programmed with a graph data structure that uses a graph search algorithm for the place cell system, and the agent’s high-level control logic is represented by explicit rules, so it is not clear how the system would operate biologically. Further, in the model, each visited place field is associated with and can recall when useful the unique entorhinal grid cell activity pattern associated with that place cell firing, in order in the model for any location to become the start or end point for vector navigation. Also, the applicability of the system to primates including humans is not clear, as some of the cell types utilized in the model are not known to be present in primates, and some of the types of spatial representation found in the primate hippocampal system (Rolls and Wirth, 2018; Rolls, 2023c) are not part of the approach.

9.3.14.3 Transforms between allocentric and egocentric representations

Because the parietal cortex utilizes in part egocentric coordinates (e.g. direction relative to the head), and the hippocampal system uses allocentric coordinates (e.g. allocentric place cells and allocentric head direction cells), it is important to be able to transform between these representations. For example, if we are in one place in allocentric space, what will the egocentric view look like? Conversely, if we see a set of landmarks in head-based (i.e. egocentric) coordinates, can we work out where we are in allocentric space? Transforms of this type are likely to be important in navigation as well as in spatial memory and in imagery which is typically egocentric. Three approaches to this are described.

One approach utilizes types of neuron found in the rat, and argues that the transform takes place in the retrosplenial cortex (Bicanski and Burgess, 2018) (Fig. 9.36). The model uses boundary vector cells, known in the rat and which respond to the allocentric bearing and distance to a boundary such as a wall, to specify the allocentric place. The egocentric parietal representation used is in head-based coordinates, and the model specifies neurons that respond to extended boundaries (‘PWb neurons’), and neurons that respond to discrete objects (‘PWo neurons’). The receptive fields of both these populations lie in peri-personal space, that is are tuned to distances and egocentric directions ahead, left or right of the agent. Then gain modulation by head direction can be used to convert the egocentric view representation into an allocentric representation, using principles described in Section 3.4.2. It is suggested that the reverse transform could also be performed in the retrosplenial cortex, but the mechanism would be very different. This model does not deal with how eye movements affect spatial vision which is a major part of what is implemented in the primate dorsal visual system in areas such as LIP, VIP, and area 7a together with mechanisms for reaching into space. (Eye movements and reaching into space are poorly developed and understood in rodents, and no set of highly developed dorsal visual stream cortical areas is found in rodents). The proposal (Bicanski and Burgess, 2018) also relies on boundary-vector cells found in rodents. The model does not account for the types of neuron found in the primate dorsal visual system through the parietal hierarchy which even before the retrosplenial cortex show evidence of encoding in allocentric coordinates, as described in Chapter 3.

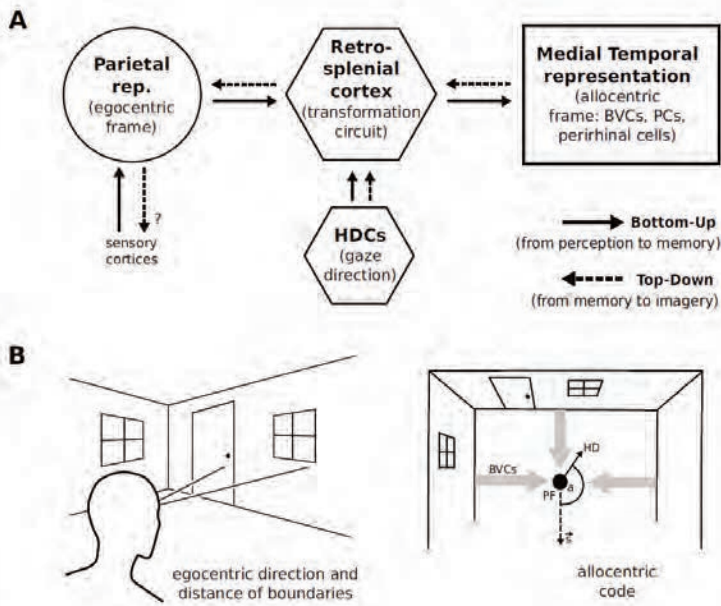

Fig. 9.36 Schematic of the Bicanski and Burgess approach to egocentric to allocentric coordinate transforms. (A) Processed sensory inputs reach parietal areas and support an egocentric representation of the local environment (in a head-centered frame of reference). Retrosplenial cortex uses current head or gaze direction to perform the transformation from egocentric to allocentric coding. At a given location, environmental layout is represented as an allocentric code by activity in a set of Boundary Vector Cells (BVCs), the place cells (PCs) corresponding to the location, and perirhinal neurons representing boundary identities. (In a familiar environment, all these representations are associated via Hebbian learning to form an attractor network.) Black arrows indicate the flow of information during perception and memory encoding (bottom-up). Dotted arrows indicate the reverse flow of information, reconstructing the parietal representation from view-point invariant memory (imagery, top-down). (B) Illustration of the egocentric (left panel) and allocentric frame of reference (right panel), where the vector s indicates South (an arbitrary reference direction) and the angle α is coded for by head direction cells (HDCs), which modulate the transformation circuit. This allows Boundary Vector Cells and Place Cells to code for location within a given environmental layout irrespective of the agent's head direction (HD). The place field (PF, black circle) of an example Place Cell is shown together with possible Boundary Vector Cell inputs driving the Place Cell (broad grey arrows). (Reproduced from Bicanski, A. and Burgess, N. (2018) A neural-level model of spatial memory and imagery. *Elife* 7: e33752.)

A second approach makes an interesting point about the mathematics of the relation between egocentric and allocentric space, as shown in Fig. 9.37 (Ekstrom et al., 2017; Ekstrom and Ranganath, 2018). This approach is much more closely related to the ability of humans to visualize what they see when in different allocentric locations. It discusses evidence that allocentric and egocentric representations are found in quite a large set of brain areas, and argues that navigation is performed by this very distributed system. However, this approach is not developed into a formal computational model that specifies how the computations are performed, that is, what the types of neuron are that are involved, and what computation enables the transforms between different neuron types. Also, as shown below, it is helpful to consider separate navigational strategies that are implemented when the navigation is idiothetic, that is, based on self-motion in the dark or when landmarks cannot be seen, compared to navigation when landmarks can be seen.

The third approach to coordinate transforms builds on the types of neuron actually found at different stages of the hierarchically organised primate dorsal visual system (Rolls, 2020b), is described in Chapter 3, and summarized next in the context of navigation. The parietal cortex hierarchy transforms from egocentric retinal representations to allocentric bearing to a landmark and spatial view representations. The system starts with representations in retinal coordinates, and transforms these into head-based egocentric representations in LIP and VIP

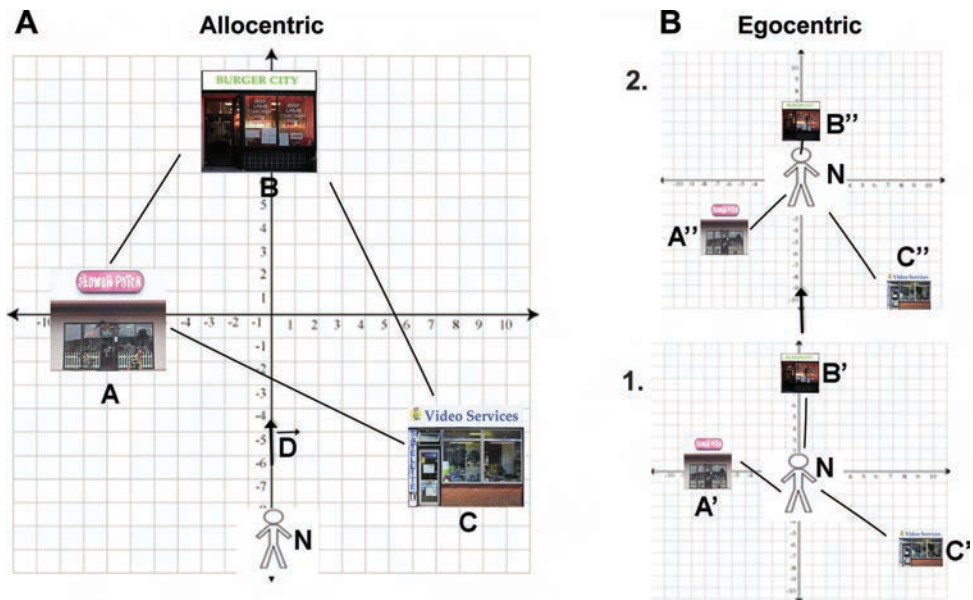

Fig. 9.37 Similarities between allocentric and egocentric coordinate systems. A: within an allocentric coordinate system, A, B, and C are landmark coordinates, N is the position of the navigator, and D is the displacement vector (movement of the navigator). AB, AC, and BC are therefore vectors that indicate both the direction and distance of landmarks to each other. The positions of landmarks stay stable with displacements of the navigator. B: in an egocentric coordinate system, in contrast, the positions of landmarks change continuously with movements of the navigator (i.e., movement from frame 1 to frame 2). The position of the navigator, however, is always centered at the origin. A', B', and C' are positions of landmarks in egocentric frame 1, A'', B'', and C'' are positions of landmarks in egocentric frame 2. These correspond to vectors A'N, B'N, C'N, etc. Within this framework, egocentric to allocentric conversion can be accomplished many different ways. For example, AB, BC, AC in allocentric coordinates can be approximated with vector subtraction (A'N - B'N or A'N - B'N); see McNaughton et al. (1991) for more details. This conversion can also be solved using estimation of the Pythagorean theorem [e.g., $AB = \sqrt{(A'N^2 + B'N^2)}$ or $AB = \sqrt{(A''N^2 + B''N^2)}$]. This is because vectors $AB = A'B' = A''B''$ and the displacement vector (D) are the same in allocentric (A) and egocentric (B) space. This also means the two subspaces have the same basis set. (Reproduced from Ekstrom, A.D., Huffman, D.J. and Starrett, M. (2017) Interacting networks of brain regions underlie human spatial navigation: a review and novel synthesis of the literature. *Journal of Neurophysiology* 118: 3328–3344. © American Physiological Society.)

using gain modulation by eye position. Then the head-centred representation is transformed into an 'allocentric bearing to a landmark' from the primate using gain modulation by head direction (Rolls, 2020b). This type of representation is potentially of great use in navigation, as described below.

Then the 'allocentric bearing to a landmark' representation is transformed into an allocentric *spatial view* representation by gain modulation using translation of the animal to different places (Rolls, 2020b) (see Chapter 3). This builds a representation in the same spatial coordinates used in the primate hippocampus, namely allocentric spatial view that represents a location in allocentric space 'out there', independently of the bearing of the landmark and of the exact place where the individual is located, as well as its head direction and eye position. This type of representation is ideal for the episodic memory functions of the primate hippocampus, for it enables memories to be formed of where in allocentric space an object or person was seen. Because the memory is independent of the exact place where the animal is located, if the same location is seen from a different place, the hippocampal memory system will correctly recall the object or person that was at that location. Similarly, if the object or person is the recall cue, the location in allocentric space where they were seen can be recalled from the CA3 network in the hippocampus, and that memory is suitable for navigation to that location, because it does not depend on the place where the animal is, which would be very restrictive indeed in a memory system (Rolls, 2020b) (see Chapter 3).

This system is likely to apply just as much to humans as to macaques, given the considerable similarity of their visual systems, and the use of a retina with a high resolution fovea that enables particular locations in viewed scenes ‘out there’ and possibly at a considerable distance to be encoded.

How would such a system operate if an egocentric view was being recalled from an allocentric representation? One possibility would be to use the hippocampal spatial view cells, which as a continuous attractor network are effectively a set of viewed items linked in the correct order (Rolls, Stringer and Trappenberg, 2002; Rolls, 2017d). The information is already there in the way that spatial view cells are implemented in the primate hippocampus. This is part of the utility of the primate allocentric spatial view cell system: that it provides a natural route to imagery. This great utility would not apply if only allocentric bearing to a landmark cells were computed in primates. This also may be a useful concept to bear in mind by those who believe that episodic memory is viewpoint dependent. Spatial view cells would make a scene maintain its parts in the correct spatial relationship when viewed from many places, all on the same side of the scene.

It might be more difficult to utilise this type of hippocampal representation to imagine the scene seen from the other side if we have never seen it from the other side before. But for that case, the order would still be present in the hippocampal spatial view continuous attractor, and that could be used to reconstruct in a type of ‘perspective-taking’ what the scene would look like from the other side. This is an interesting way to link human spatial imagery to the representations of scenes ‘out there’ provided in the primate hippocampus by spatial view cells (Rolls, 2018b; Rolls and Wirth, 2018; Rolls, 2023d).

9.3.15 Navigational computations using neuron types found in primates including humans

The analysis of coordinate transforms in the primate dorsal visual system described here (see Chapter 3 and Rolls (2020b)) and referred to above deals with particular types of neuron known to be present in primates, and these neuron types provide very interesting possibilities for different navigational strategies in primates, some of which are described next, based on the types of neuron found in primates, which are relevant to better understanding navigation in humans (Rolls, 2021f). Indeed, exactly the computations described here could be involved in different types of human navigation (Rolls, 2021f). As a reminder, neurotoxic lesions that selectively damage the primate hippocampus impair spatial scene memory (Murray et al., 1998), and spatial location memory (Waters, Basile and Murray, 2023), when for example environmental visual cues are used in foraging and navigation (Hampton, Hampstead and Murray, 2004; Lavenex, Amaral and Lavenex, 2006). Some of the mechanisms involved that are likely to use hippocampal spatial view cells are considered next.

9.3.15.1 Navigation using spatial view cells

In this strategy, navigation is implemented by proceeding via a series of landmarks, to which spatial view cells respond. This is allocentric navigation, as spatial view cells are allocentric. It is illustrated in Fig. 9.38. The individual learns the sequence of landmarks, either by previous trial and error learning, or by following another individual, or in humans by being told the list of landmarks and holding them in working memory. The individual looks for the next landmark in the list (e.g. L2 if at L1), and locomotes to approach it, and then looks for the next landmark, and locomotes towards it (Rolls, 2021f).

If this is the first time the route has been followed in humans, the list of sequential landmarks could be implemented in the hippocampal episodic memory system. The sequence could be stored by using the time-cells described in Chapter 9, and associating each land-

Fig. 9.38 An example of navigation using spatial view cells. The task is to start at Landmark 1 (L1), and to reach Landmark 4 (L4). There is a barrier so that Landmark 4, and for that matter Landmark 3, cannot be seen from Landmark 1. The course followed is shown by red arrows. Each landmark can be thought of as having a waypoint (e.g. W2), or intermediate step in the whole route, associated with it. (After Rolls, E. T. (2020) *Neurons and navigation in primates including humans.*)

mark with a different time in the time-cell system. Another possibility is that the sequence of landmarks is stored in short-term / working memory in the prefrontal cortex (Chapter 13).

Each step in the sequence could have additional information associated with it. One example at W2 could be ‘turn right’, which is egocentric information, and is available in whole body motion cells in the primate hippocampus (O’Mara, Rolls, Berthoz and Kesner, 1994) (known as speed cells in rodents (Kropff et al., 2015)); or ‘turn South’, which is allocentric information, and is available in head direction cells in the primate presubiculum (Robertson, Rolls, Georges-François and Panzeri, 1999). This is exactly the type of information that could be associated together in the primate hippocampus, utilizing especially CA3 cells (see Chapter 9). Another type of information that could also be associated with each step of the sequence is the distance to be travelled between the landmarks, which could be implemented by idiothetic update. The idiothetic update mechanisms are described in Section 9.3.15.4, and could utilize the whole body motion cells (O’Mara et al., 1994).

If the route becomes well learned, it could be implemented by a continuous attractor network in the hippocampus, which would implement the spatial views as being adjacent in the sequence because of overlap of the spatial view fields (Chapter 9). Each step of the continuous attractor could have additional information associated with it, in the way just described. Continuous attractor networks are described in Section B.5, and their use for hippocampal spatial view cell navigation networks has been described (Stringer, Rolls and Trappenberg, 2005; Rolls and Stringer, 2005; Rolls, Tromans and Stringer, 2008f).

Part of the utility of spatial view cells for this computational role in navigation is that they are largely place invariant, as well as invariant with respect to head direction and eye position, and of the bearing of the landmark (Georges-François, Rolls and Robertson, 1999), so are able to guide the animal irrespective of the exact place, head direction, etc from which the next landmark is viewed. Moreover, if the landmark is temporarily obscured, by a barrier, darkness etc, then spatial view cells can still be used to guide the agent to the next landmark, because they can be updated for a few minutes by self-motion (Robertson, Rolls and Georges-François, 1998). A major advantage of navigation using spatial view cells is that this does not require path integration of for example head direction to maintain a sense of direction, and so very long routes with many legs can be followed (Rolls, 2021f).

This type of navigation is illustrated in program NavSVC.m described in Appendix D, and by Rolls (2021f). It is proposed that this is the most common type of navigational strategy used in humans and other primates (Rolls, 2021f).

Humans normally navigate to a viewed object or reward in a scene such as a building,

and non-human primates might locomote to particular locations in the viewed environment with local cues where there are sources of food, water, shelter and a place to sleep etc. In these cases, identifiable environmental features identify each location, and spatial view cells encode the features in these locations, and their spatial overlap with features of nearby locations (Rolls, 2023d). Hippocampal spatial view cells are ideal for this type of navigation. In this context the type of navigation to an unmarked place without local visual cues and relying on relatively distant environmental cues (as in the Morris rodent water maze (Morris, Garrud, Rawlins and O’Keefe, 1982)) is unusual in humans and other primates (Rolls, 2023d). It is like looking for a needle in a haystack using distant hills as navigational cues. What is often studied in rodents as a model of navigation without any local cues as in the Morris water maze may not be at all commonly how humans and other primates navigate. Spatial view cells provide the mechanism often used for navigation in humans and other primates which is typically towards visible landmarks such as a building, the top of a hill, etc (Rolls, 2021f, 2023d). Navigation may thus be performed in primates including humans (Rolls, 2021f, 2023a,d) in very different ways to those utilised in rodents, in which local place-associated cues sensed with the vibrissae or olfactory system define places, and idiothetic navigation between such places often in the dark may be important (McNaughton, Barnes, Gerrard, Gothard, Jung, Knierim, Kudrimoti, Qin, Skaggs, Suster and Weaver, 1996; Moser, Rowland and Moser, 2015; Moser, Moser and McNaughton, 2017). Moreover, because of the limited visual acuity of rodents illustrated in Fig. 9.12 in Section 9.2.5, navigation in rodents is unlikely to be towards small objects or rewards located at distant locations in visual scenes, whereas this is typical of navigation in primates including humans implemented using spatial view cells (Rolls, 2023d).

The type of navigation based on spatial view cells can be considered as a true navigational strategy, because the strategy would include a sequential list of landmarks, with each landmark in the list potentially being associated with for example a body turn or a change of allocentric heading (using head direction cells) to head for example South, to help find the next landmark. Moreover, the navigation can be to a hidden landmark goal, as illustrated in Fig. 9.38 (Rolls, 2021f).

9.3.15.2 Navigation using allocentric bearing to a landmark cells

Neurons that appear to respond to an allocentric bearing to a stimulus in space (an example of which might be a landmark) have been described in the macaque parietal cortex area 7a (Snyder, Grieve, Brotchie and Andersen, 1998) and in the posterior cingulate cortex (Dean and Platt, 2006) (which receives inputs from the parietal cortex including area 7a) (see Section 3.4.2). Neurons that may respond in the same way are found in the primate hippocampus, in that some neurons respond when the macaque looks at a spatial view, but from only some places in a virtual environment (Wirth et al., 2017). Moreover, allocentric bearing to a landmark neurons are generated naturally in a theory and model of spatial coordinate transforms in the dorsal visual system (Rolls, 2020b) (see Chapter 3 and Fig. 3.6).

Navigation that could be implemented by allocentric bearing to a landmark (ABL) neurons is illustrated in Fig. 9.39. The route to be followed is from Waypoint 1 (W1) to Waypoint 4, as shown by the red arrows, and as before a barrier prevents the goal from being seen at the start of the navigation. The individual starts at W1, with the information that it must start with a head direction of East, and locomote until the bearing to landmark L2 becomes 45 degrees. For this, information from only head direction cells and allocentric bearing to a landmark cells is needed. At Waypoint 2 in the sequence, information is associated that a right turn should be made (using whole body motion cells), or that a turn should be made to head in direction South (using head direction cells). The individual then locomotes South until the bearing to landmark L3 becomes 135 degrees. (Of course, the bearings to the other

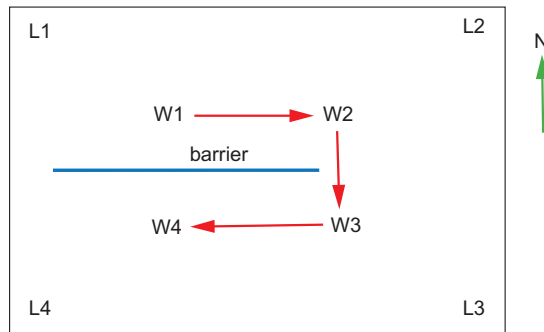

Fig. 9.39 An example of navigation using allocentric bearing to a landmark cells. The task is to start at Waypoint 1 (W1), and to reach Waypoint 4 (W4). There is a barrier so that Waypoint 4, and for that matter Waypoint 3, cannot be seen from Waypoint 1. The course followed is shown by red arrows. The landmarks used are L1–L4. North is indicated by N. (After Rolls, E. T. (2020) *Neurons and navigation in primates including humans.*)

visible landmarks, L2 and L4, could also be used.) At Waypoint 3 in the sequence, information is associated that a right turn should be made (using whole body motion cells), or that a turn should be made to head direction West (using head direction cells), and that locomotion should continue in that direction. The final instruction is that the goal has been reached at W4 when the bearing to landmark L4 is 225 degrees.

The sequence of steps, and the information associated with all steps, could be implemented in the same ways as described for spatial view cells in Section 9.3.15.1.

The interest of this illustration is that it involves navigation to places that are not at landmarks, and uses just two types of neuron found in primates, allocentric bearing to a landmark cells, and head direction or whole body motion cells.

This type of navigation (Rolls, 2021f) is illustrated in program NavABL.m described in Appendix D.

It is noted that if the distance to a landmark is part of what is encoded by allocentric bearing to a landmark cells, then this is helpful, though not essential. In rodents, cells that reflect the bearing and distance to an object have been described (Hoydal et al., 2019), and the primate equivalent that would be useful in navigation is allocentric bearing to a landmark vector cells that encode distance to a landmark as well as allocentric bearing to a landmark.

If more than one ‘allocentric bearing to a landmark’ cell is used at any one time in this type of navigation, then the navigation can be thought of as navigation from place to place, where each place is defined by a combination of active ‘allocentric bearing to a landmark’ cells. Navigation with such a system is considered next.

9.3.15.3 Navigation using combinations of allocentric bearing to a landmark cells, and triangulation

As just noted, if combinations of active allocentric bearing to a landmark cells are formed, these would represent places. Navigation using this type of triangulation is harder to implement in the brain, but is practiced by mariners, and is described for comparison with the methods previously described (Rolls, 2021f).

One way to implement this can be described using the route illustrated in Fig. 9.39. The environment could be defined as a Euclidean allocentric topological space as envisaged for rodent place cells (O’Keefe and Nadel, 1978), with X and Y coordinates to define each place. To locomote from W1 to W2, the agent would calculate its place at every small step of the locomotion, using triangulation based on combinations of the active ‘allocentric bearing to a landmark’ cells. It would then calculate with trigonometry the (allocentric) compass bearing to W2 using its current X,Y position, and its knowledge of the X,Y position of W2, and set off in that direction using head direction cells. This type of navigation works if a topological map

is stored in the head, and if trigonometric calculations can be performed, but may not be biologically plausible without the ability to calculate directions in topological maps. (This type of navigation is illustrated in program NavTRI.m described in Appendix D (Rolls, 2021f).) This type of navigation by triangulation is thus very different from that performed using spatial view cells, which does not require trigonometry in a Euclidean topological space.

Instead of using geometrical computation in a Euclidean space of the type implemented using triangulation as implemented in NavTRI.m, it is suggested that in primates including humans, simultaneously active spatial view cells for different landmarks in a scene can be associated together to form a spatial representation of a scene, seen from a particular place. As a primate traverses through different places and the scene defined by the landmarks gradually changes, storage of a few such scenes (using for example the hippocampus to store such episodic memories) could enable later recall of the place, given the set of spatial view cells that are active by comparison with the stored representations. It is proposed that such a neural mechanism might enable spatial view cells to contribute to the lookup in an association memory of a place where the individual is located. This is proposed as another biologically plausible way for spatial view cells to be involved in navigation, by using the viewed scene to recall a place. Such a mechanism might operate to provide useful accuracy even without the need to store too many scenes. Although allocentric bearing to a landmark cells (which might also encode distance) might be used in addition to or as an alternative to spatial view cells, there is the considerable disadvantage that very many allocentric bearing to a landmark cells could be required, as a number of bearings need to be specifiable for each landmark.

For these reasons, navigation in primates using spatial view cells or ‘allocentric bearing to a landmark’ cells as described in Sections 9.3.15.1 and 9.3.15.2, *or combinations of these approaches*, is more likely to be the type of computation that is typically used in humans, and other primates. Navigation using approach to landmarks has been described as navigation using beacons (Ekstrom and Isham, 2017), though no neural mechanism was proposed. I propose (Rolls, 2021f) that spatial view cells provide an important and natural component of the neural mechanism, and this has been illustrated in Fig. 9.38, with a computational model of this (illustrated in program NavSVC.m). The approach using ‘bearing to a landmark’ cells just described goes beyond navigation to beacons, because it involves the computationally more specific navigation involving taking bearings to beacons, and using that information to make a turn in an allocentric or egocentric direction that is held in memory (Rolls, 2021f).

As soon as one has combinations of primate cells encoding allocentric bearings to landmarks in an environment, as proposed here, then this can provide a key part, it is proposed, of a topological allocentric navigational system. Another important aspect of the approach to navigation in humans and primates described here is that it does not have to be ‘egocentric’ or ‘allocentric’ (Ekstrom and Isham, 2017), but can use egocentric whole body motion and/or allocentric head direction cells, in combination with (allocentric) spatial view cells and/or ‘allocentric bearing to a landmark’ cells (Rolls, 2021f).

9.3.15.4 Idiothetic navigation in primates

A very different strategy for navigation to the use of visual cues about locations in scenes is idiothetic navigation, that is, navigation based on self-motion. This is an important strategy in the dark or when visual landmarks cannot be seen. Idiothetic information may also be combined with information based on visual (or for that matter auditory) inputs as part of a navigational strategy.

Three principal types of neuron in primates provide idiothetic information useful for navigation. The first type is head direction cells found in the primate presubiculum (Robertson, Rolls, Georges-François and Panzeri, 1999) (and probably elsewhere) (Section 9.2.6). These

neurons continue to encode head direction even when the monkey is moved from a familiar room to a relatively unfamiliar corridor (Fig. 9.13), and maintain their directionality for a few minutes in the dark, after which they drift. This is important, for these cells can only maintain head directionality for a relatively short period without visual cues to lock them back into the correct directionality. Their inputs are derived from velocity signals produced in the vestibular nuclei in the brainstem, and reach the parietal vestibular cortical areas (Grusser et al., 1990; Ventre-Dominey, 2014). The direction signal thus reflects a great deal of integration over time, and this is imprecise and noisy resulting in drift. This means that only short-term idiothetic navigation is possible. Similar head direction cells are well known in rodents (Taube et al., 1990a; Cullen and Taube, 2017). Vestibular signals influence neurons in a number of parietal cortex areas including VIP, with neurons that respond to head position (i.e. head direction) or head acceleration, in addition to the many neurons with head velocity tuning (Klam and Graf, 2003). Neurons that respond to vestibular inputs produced by head rotation or translation are also found in area 7a (Avila, Lakshminarasimhan, DeAngelis and Angelaki, 2019).

The second type of neuron that provides idiothetic information useful for navigation in primates are hippocampal whole body motion cells (O'Mara, Rolls, Berthoz and Kesner, 1994) (Section 9.2.4.2). Some of these neurons respond to angular head rotation, and others to linear translation. Some of these neurons respond to vestibular cues, some to the corresponding visual optic flow cues, and some to both. The vestibular inputs are evident when the movements are in the dark. In the light, rotation of the environment to produce optic flow was able to activate some of these neurons. Some of this testing was performed while the monkey was moved on a robot (O'Mara et al., 1994). There may be similar neurons in rodents in the medial entorhinal cortex termed 'speed cells' which respond to translation (i.e. linear motion) (Kropff, Carmichael, Moser and Moser, 2015), and neurons that respond to angular velocity (i.e. head rotation) have also been described in the rat parietal cortex (Wilber et al., 2017, 2014), but the roles of visual vs vestibular inputs for these rodent neurons are not yet clear. It is neurons that respond to vestibular inputs that are important for idiothetic update in the dark. Of course the visual cues produced by the corresponding motion may be used for idiothetic navigation in the light.

Neurons of these two types could be used as follows for navigation in the dark, or without visible landmarks (Rolls, 2021f). We can consider the route illustrated in Fig. 9.39. If the individual starts off with an Easterly head direction at Waypoint 1, then navigation would use head direction cells to keep the direction constant, and integration over linear whole body motion cells (which encode velocity) to locomote for the distance to Waypoint 2. At Waypoint 2, the sequence generator would have associated with it an egocentric 'turn right' signal calibrated by head rotation whole body motion cells; or an allocentric head direction signal to turn to face South. The distance to W3 would then be traversed using integration over the linear whole body motion cells. After the correct distance, the sequence generator would specify an egocentric 'turn right' signal calibrated by head rotation whole body motion cells; or an allocentric head direction signal to turn to face East; etc.

This navigation could thus be performed using only primate head direction and whole body motion cells. The sequence of steps, and the information associated with each step, could be implemented in the same ways as described for spatial view cells in Section 9.3.15.1.

This idiothetic navigation would be suitable for only a few minutes, for after that time the integration required to compute head direction, and distance travelled based on whole body motion / vestibular inputs, becomes inaccurate.

Importantly, this idiothetic type of navigation could be used as a supplement with the strategies described previously using spatial view cells (Section 9.3.15.1) or allocentric bearing to a landmark cells (Section 9.3.15.2) (Rolls, 2021f). For example, when navigation using

bearing to a landmark cells described in Section 9.3.15.2 is being used, it could be helpful to use the known distance between W1 and W2 to help provide information about when W2 had been reached (see Fig. 9.39). The implementation could use the self-motion cues to update the position in a spatial continuous attractor in the ways described by Stringer, Rolls, Trappenberg and De Araujo (2002a) and Stringer, Rolls and Trappenberg (2005).

A third type of neuron, spatial view cells, could also be useful in idiothetic navigation in primates including humans. As described in Section 9.2.4.1, spatial view cells can be updated in the dark and without visual landmarks by the idiothetic signals head direction and eye position, and probably by whole body motion (Robertson, Rolls and Georges-François, 1998). Mechanisms for this idiothetic update are described in Chapter 3 (Rolls, 2020b). Accordingly, navigation could be towards a remembered spatial view location even when the view is not visible. As with other types of idiothetic navigation, it would probably be useful for only a few minutes, due to the inaccuracy of the path integration over the idiothetic signals.

In more detail, the dorsal visual system plays an important role in the idiothetic update of spatial representations, as described in Section 3.4, and indeed this route is likely to be involved in the idiothetic update of hippocampal and parahippocampal spatial view cells (Rolls, 2020b). The idiothetic updates are for eye position, head direction, and place, and allow representations to be formed that are in allocentric spatial view coordinates. This is useful for navigation when visual inputs are not available, for it provides a recall cue to the hippocampal system via the parahippocampal cortex (see Fig. 9.1) that enables the object at a spatial view location to be recalled even when the spatial view is not visible (Rolls, 2021f). That is an important way for identifying the goals for navigation even when vision is not possible. The implication of this is that much of the idiothetic update for spatial representations and navigation is performed in the primate dorsal visual system. This idiothetic update can then communicate with the hippocampal memory system via brain areas such as the retrosplenial cortex and posterior cingulate cortex, as illustrated in Fig. 9.1 (Rolls, 2021f).

9.3.15.5 Conclusions on navigation in primates including humans

The new proposal has been made that key principles of navigation in primates use spatial view cells (Rolls, 2021f). The great development of the primate visual system with its foveate representations that are capitalised on to enable neurons on the hippocampus, parahippocampal gyrus and probably connected brain regions to respond to viewed locations ‘out there’ in space enables navigational strategies to be used very frequently based on spatial view cells. The fact that spatial view cells are allocentric (see Section 9.2.4.1) has important implications for navigation, for it means that independently of the place where the human is located, or of the egocentric coordinates relative to the human observer of a landmark being viewed, or the allocentric bearing of a landmark, navigation can be based on movement towards (or away from) a landmark or sequence of landmarks (Rolls, 2021f).

This type of navigation based on spatial view cells can be considered as a true navigational strategy, because the strategy would include a sequential list of landmarks, with each landmark in the list potentially being associated with for example a body turn or a change of allocentric heading (using head direction cells) to head for example South, to help find the next landmark (Rolls, 2021f). Such a computation could be implemented in a continuous attractor network forming a chart (Battaglia and Treves, 1998b) of linked spatial view cells with associated primate egocentric body turn (‘whole body motion’ cells (O’Mara et al., 1994) or allocentric head direction cells (Robertson et al., 1999) in ways that have been investigated computationally (Rolls and Stringer, 2005; Stringer, Rolls and Trappenberg, 2005; Rolls, Tromans and Stringer, 2008f). Moreover, if the landmarks were temporarily obscured, idiothetic update of them based on self motion could occur (Robertson et al., 1998) using

the gain modulation mechanisms in the dorsal visual system described in Section 3.4 (Rolls, 2020b). An alternative to a continuous attractor network for spatial view cell based navigation could be a short-term or working memory system implemented in the prefrontal cortex (see Chapter 13) to remember the sequence of landmarks, and this could be particularly advantageous for new routes for which a continuous attractor representation has not already been set up by learning.

Geometrical computation using triangulation for navigation in primates including humans could it is proposed be based on the allocentric bearing to a landmark cells as exemplified in Sections 9.3.15.2 and 9.3.15.3 and as described further by Rolls (2021f).

It is proposed that this type of visually guided navigation based on spatial view cells and perhaps allocentric bearing to a landmark cells is the prototypical method used for navigation in humans and other primates (Rolls, 2021f). Humans given instruction about how to find a location are typically given a series of instructions about what to look for as they navigate, often supplemented with body turn information such as ‘turn left when you see Notre Dame’ or heading information such as ‘turn South when you see Notre Dame’. This is not the method of navigation that is typically described based on the place and other neuron types found in rodents (O’Keefe and Nadel, 1978; McNaughton et al., 1996; Bicanski and Burgess, 2018). Those systems in rodents can work almost as well in the dark, yet humans find navigation in the dark without views of spatial scenes very difficult for more than a very few minutes.

The spatial view cell approach to navigation proposed here has considerable advantages over navigation using ‘allocentric bearing to a landmark’ cells, which require a sense of allocentric direction to be maintained while the bearings are being made, which becomes difficult because of inaccuracies in the idiothetic update of the sense of direction for more than a few minutes, with reset being required based for example on a dominant landmark, or on the set of currently viewable landmarks. As a list of waypoints defined by spatial view cells does not suffer from this problem of maintaining a sense of direction, and because of its simplicity as described here, it is proposed that this is the most common type of navigational strategy used in humans and other primates (Rolls, 2021f).

The force of this proposal (Rolls, 2021f) about the use of spatial view cells for navigation in humans and other primates is made evident when we consider navigation by humans without vision, for example in complete darkness, when humans have to fall back on the path integration mechanisms for place using direction and distance traversed of the type that are typically described as being important in rodents (Stringer et al., 2002a; Bicanski and Burgess, 2018). This approach is used for example by mariners as ‘dead-reckoning navigation’ when out of the sight of land. Mariners rely for this type of navigation on a compass, for humans without landmarks can perform idiothetic navigation for only short periods, because head direction cells then quickly lose their sense of direction.

The new proposal for navigation using spatial view cells in primates including humans (Rolls, 2021f) is very different from the much more complex systems for navigation using place cells in rodents that requires a idiothetic update using a topological map of space (O’Keefe and Nadel, 1978; O’Keefe, 1990; Poulter, Hartley and Lever, 2018; Bicanski and Burgess, 2018; Edvardsen, Bicanski and Burgess, 2020). Rodents have poor vision, and rely on local sensing of the place where they are located using touch sensing by vibrissae, olfactory cues, etc, and often navigation underground or in the dark. The rodent place cell system (O’Keefe and Nadel, 1978; Morris et al., 1982; O’Keefe et al., 1998; Hartley et al., 2014) may be specialized for that. But primates including humans have highly developed visual systems that enable completely different types of navigation, using spatial view neurons and mechanisms of the type described here, and only fall back on the very different idiothetic mechanisms when they have to navigate for example in the dark, which most humans know

is a very different type of navigation, which often does rely on somatosensory input to guide the navigation.

These points underline the importance of the spatial view cell navigational strategies described here for humans, rather than the navigational strategies based on place cell idiothetic update proposed for rodents.

The exact brain regions in which navigation using spatial view cells is implemented is a topic for future research. As noted above, the hippocampal system may be involved in relatively new environments when new memories must be formed. Spatial view cells in the medial parahippocampal gyrus (Rolls, 2023c; Rolls et al., 2023e) are likely to be important. For well established navigational routes, brain areas such as the parietal cortex are likely to be involved in processing motion and avoiding obstacles, and semantic parts of the anterior temporal lobe and inferior parietal cortex, may be involved (Chapters 8 and 10). For very well learned routes, for which the strategy may be somewhat different, the habit system (Chapter 16) may be involved.

9.3.15.6 Synthesis: different functions of the parahippocampal scene area and hippocampus in navigation in primates including humans

The Parahippocampal Scene Area (PSA, also known as the Parahippocampal Place Area (PPA)) may in primates including humans build scene representations in the ventromedial visual stream (Fig. 9.18, Rolls et al. (2023e) and Rolls (2023c)). These scene representations could be in the form of continuous attractor networks, in which the features in a scene are associated together based on overlap between the features (or of features held in a local short term memory if the landmark features are too distant). The operation of continuous attractor networks is described in Section B.5, and their implementation of spatial scenes using spatial view cells is described by Rolls and Stringer (2005) and Stringer, Rolls and Trappenberg (2005). Very different scenes, for example scenes in different countries, need not be stored in the same attractor network in the parahippocampal scene area, which is sufficiently large to include many cortical local attractor networks each 1–2 mm in diameter.

These Parahippocampal Scene Area networks would be appropriate for scene representations, but need not implement navigation from one place to another, which in any case might best be kept separate, for many different navigational routes might need to be computed, and it would be advantageous to keep the actual representations of scenes considerably independent of and not distorted by all the particular navigational routes an individual might learn.

The actual navigation from place to place using scene landmark cues encoded by spatial view cells (Rolls, 2023c) could then be implemented in a different network, for example the single attractor network in hippocampal CA3. The advantage of using CA3 for the navigation is that having a single continuous attractor network for a whole route would ensure continuity of the route from location to location. Interestingly, the navigational route might not be in metric Euclidean space, as what is stored for the landmarks in the parahippocampal scene area and connected to the hippocampus might well not be equally spaced landmark cues, but instead just prominent landmark cues, which might not be equally spaced. Accordingly I do not accept the claim made by O’Keefe and Nadel (1978) and O’Keefe (1990) that the navigational space as implemented in the brain is Euclidean and would permit mathematical geometric calculations. Instead, I have suggested above that the navigation is implemented by a trajectory through a continuous attractor network that contains scene information but also other information such as body turn and head direction information (Rolls, 2021f).

It would be appropriate to have the navigational system in the hippocampus separate from the spatial scene system in the parahippocampal scene area, for the navigational system would benefit greatly from information about body turns made at particular points in the route (Rolls, 2021f), which is exactly what is represented in the hippocampus as shown by

whole body motion cells (O'Mara et al., 1994). Similarly head direction information present in the primate presubiculum (Robertson et al., 1999; Rolls, 2023c) would be important for the hippocampal navigational system implemented in the hippocampus.

In humans, long-term semantic representations, perhaps language based, in the neocortex could also be useful in navigation for well known environments and routes, and need to be taken into account when considering effects of hippocampal damage on navigation.

9.4 Tests of the theory of hippocampal cortex operation

Empirical evidence that tests the theory comes from a wide range of investigation methods, including the effects of selective lesions to different subregions of the hippocampal system mainly in rodents, the activity of single neurons in different subregions of the hippocampal system, pharmacological and genetic manipulations of different parts of the system, the detailed neuroanatomy of the system, and functional neuroimaging studies and clinical neuropsychological studies in humans (Kesner and Rolls, 2015).

Because the theory makes predictions about the functions of different parts of the hippocampal system (e.g. dentate, CA3, and CA1), evidence from subregion analysis is very relevant to testing the theory, and such evidence is included in the following assessment, which starts from the dentate gyrus, and works through to CA1. The evidence comes from the effects of selective lesions to different subregions of the hippocampal system, the activity of single neurons in different subregions, together with pharmacological and genetic manipulations of different parts of the system (Kesner and Rolls, 2015).

9.4.1 Dentate gyrus (DG) subregion of the hippocampus

Based on the anatomy of the DG, its input and output pathways, and the development of a computational model, it has been suggested (see Section 9.3, Rolls (1990b), and Rolls (1996d)) that the DG can act as a competitive learning network with Hebb-like modifiability to remove redundancy from the inputs producing a more orthogonal, sparse, and categorized set of outputs. One example of this in the theory is that to the extent that some entorhinal cortex neurons represent space as a grid (Moser et al., 2015), the correlations in this type of encoding are removed by competitive learning to produce a representation of place, with each place encoded differently from other places (Rolls, Stringer and Elliot, 2006c)¹⁵. To the extent then that DG acts to produce separate representations of different places, it is predicted that the DG will be especially important when memories must be formed about similar places. To form spatial representations, learned conjunctions of sensory inputs including vestibular, olfactory, visual, auditory, and somatosensory may be involved. DG may help to form orthogonal representations based on all these inputs, and could thus help to form orthogonal non-spatial as well as orthogonal spatial representations for use in CA3. In any case, the model predicts that for spatial information, the DG should play an important role in hippocampal memory functions when the spatial information is very similar, for example, when the places are close together. As we will see, there is evidence that the DG is involved in several types of pattern separation, including social pattern separation (Kesner and Rolls, 2015; Kesner, 2018).

¹⁵Indeed, it was a prediction of the theory that the mapping from entorhinal cortex grid cells to dentate / CA place cells could be achieved by competitive learning, and this prediction was verified by simulation (Rolls, Stringer and Elliot, 2006c).

Fig. 9.40 Spatial pattern separation impairment produced by dentate gyrus lesions. Mean percent correct performance as a function of spatial separation of control group, CA1 lesion group, and dentate gyrus lesion group on postoperative trials. A graded impairment was found as a function of the distance between the places only following dentate gyrus lesions. (After Gilbert, P.E., Kesner, R.P. and Lee, I. (2001) Dissociating hippocampal subregions: double dissociation between dentate gyrus and CA1. *Hippocampus* 11: 626–636. © Wiley-Liss Inc.)

9.4.1.1 Spatial pattern separation

To examine the contribution of the DG to spatial pattern separation, Gilbert, Kesner and Lee (2001) tested rats with DG lesions using a paradigm that measured one-trial short term memory for spatial location information as a function of spatial similarity between two spatial locations (Gilbert, Kesner and DeCoteau, 1998). Rats were trained to displace an object that was randomly positioned to cover a baited food well in 1 of 15 locations along a row of food wells. Following a short delay, the rats were required to choose between two objects identical to the sample phase object. One object was in the same location as the sample phase object and the second object was in a different location along the row of food wells. A rat was rewarded for displacing the object in the same position as the sample phase object (correct choice) but received no reward for displacing the foil object (incorrect choice). Five spatial separations, from 15 cm to 105 cm, were used to separate the correct object from the foil object on the choice phase. The results showed that rats with DG lesions were significantly impaired at short spatial separations; however, the performance of the DG lesioned rats increased as a function of increased spatial separation between the correct object and the foil on the choice phases. The performance of rats with DG lesions matched controls at the largest spatial separation. The graded nature of the impairment and the significant linear increase in performance as a function of increased separation illustrate the deficit in pattern separation produced by DG lesions (see Fig. 9.40). Based on these results, it can be concluded that lesions of the DG decrease efficiency in spatial pattern separation, which resulted in impairments on trials with increased spatial proximity and hence increased spatial similarity among working memory representations (Gilbert, Kesner and Lee, 2001). In the same study it was found that CA1 lesions do not produce a deficit in this task.

Additional evidence comes from a study (Goodrich-Hunsaker, Hunsaker and Kesner, 2008) using a modified version of an exploratory paradigm developed by Poucet (1989), in which rats with DG lesions and controls were tested on tasks involving a metric spatial manipulation. In this task, a rat was allowed to explore two different visual objects that were separated by a specific distance on a cheese-board maze. On the initial presentation of the ob-

jects, the rat explored each object. However, across subsequent presentations of the objects in their respective locations, the rat habituated and eventually spent less time exploring the objects. Once the rat had habituated to the objects and their locations, the metric spatial distance between the two objects was manipulated so the two objects were either closer together or further apart. The time the rat spent exploring each object was recorded. The results showed that DG lesions impaired detection of the metric distance change in that rats with DG lesions spent significantly less time exploring the two objects that were displaced.

The results of both experiments provide empirical validation of the role of DG in spatial pattern separation, and support the prediction from the computational model presented in this chapter.

There are neurophysiological results that are also consistent, in that McNaughton et al. (1989) found that following colchicine-induced lesions of the DG, there is a significant decrease in the reliability of CA3 place-related firing. Therefore, if CA3 cells display less reliability following DG lesions, the cells may not form accurate representations of space due to decreased efficiency in pattern separation. Also consistent are the findings that the place fields of DG cells and specifically dentate granular cells (Jung and McNaughton, 1993; Leutgeb et al., 2007) are small and highly reliable, and this may reflect the role of DG in pattern separation.

These studies thus indicate that the DG plays an important role in spatial pattern separation in spatial memory tasks. Building and utilizing separate representations for other classes of stimuli engage other brain areas, including for objects the inferior temporal visual cortex (Rolls, 2000a, 2012d), for reward value the orbitofrontal cortex (Rolls, 2014a) and amygdala (Gilbert and Kesner, 2002), and for motor responses the caudate nucleus (Kesner and Gilbert, 2006).

9.4.1.2 Pattern separation and neurogenesis

Based on the observation that neurogenesis occurs in the DG and that new DG granule cells can be formed across time, it has been proposed that the dDG mediates a spatial pattern separation mechanism as well as generates patterns of episodic memories within remote memory (Aimone and Gage, 2011). Thus far, it has been shown in mice that disruption of neurogenesis using low-dose x-irradiation was sufficient to produce a loss of newly born dDG cells. Further testing indicated impairments in spatial learning in a delayed non-matching-to-place task in the radial-arm maze. Specifically, impairment occurred for arms that were presented with little separation, but no deficit was observed when the arms were presented farther apart (Clelland et al., 2009), suggesting a spatial pattern separation deficit. These results are similar to those described for rats in the study by Morris et al. (2012). Another study in mice provided evidence that the disruption of neurogenesis using lentivirus expression of a dominant Wnt protein produced a loss of newly born dDG cells; and these mice were tested in an associative object-in-place task with different spatial separations and observed to be impaired as a function of the degree of separation, again suggesting a spatial pattern separation deficit (Clelland et al., 2009). In another study (Kesner et al., 2014) it was shown that DNA methyltransferase 1-c knockout mice are impaired relative to controls in the spatial pattern separation task (Goodrich-Hunsaker, Hunsaker and Kesner, 2008). These data suggest that neurogenesis in the dDG may contribute to the operation of spatial pattern separation. Thus, spatial pattern separation may play an important role in the acquisition of new spatial information, and there is a good possibility that the dDG may have been the subregion responsible for the impairments in the various tasks described above.

Impaired DG neurogenesis may be involved in some neurological diseases such as Alzheimer's disease and in the relation between aging and memory in humans (Toda, Parylak, Linker and Gage, 2019).

9.4.1.3 Encoding versus retrieval

The theory postulates that the dentate / mossy fibre system is necessary for setting up the appropriate conditions for optimal storage of new information in the CA3 system (which could be called encoding); and that (especially when an incomplete cue is provided) the retrieval of information from CA3 is optimally cued by the direct entorhinal to CA3 connections.

In strong support of the role of the DG in encoding, a study conducted in mice showed that the mossy fibre projections to CA3 are essential for the encoding of spatial information in a water maze reference memory task, but are not necessary for retrieval (Lassalle, Bataille and Halley, 2000).

Another type of evidence comes from a study in which rats had 10 learning trials per day in a Hebb–Williams maze. Lee and Kesner (2004b) found that based on a within-day analysis DG lesions (but not lesions of the perforant path input to CA3) impaired the acquisition of this task, consistent with an encoding or learning impairment. However, when tested using a between-days analysis, retrieval of what had been learned previously was not impaired by DG lesions, but was impaired by lesions of the perforant path input to CA3. This double dissociation is consistent with the hypothesis that the DG is important for optimal encoding, and the entorhinal to CA3 connections for optimal retrieval.

Further evidence for a DG mediation of spatial encoding comes from the observation that rats with DG lesions are impaired in learning the Morris water maze task when the start location varied on each trial (Nanry et al., 1989; Sutherland et al., 1983; Xavier et al., 1999). Under these conditions, spatial pattern separation may be at a premium, for different, partially overlapping, subsets of spatial cues are likely to be visible from the different starting locations.

Further evidence consistent with the hypothesis that the DG is important in spatial learning (acquisition) is that rats with DG lesions are impaired on acquisition of spatial contextual fear conditioning (Lee and Kesner, 2004a).

However, I note that in the studies described in this section (encoding vs retrieval), during acquisition of these tasks over a number of trials both the storage and the retrieval processes are likely to influence the rate of behavioral learning. Thus, even though in behavioral tasks the deficit can be described as an encoding deficit because it is apparent during initial learning, it is not easy to separate the actual underlying processes by which the DG may be important for setting up the representations for new learning in the CA3 system, and the perforant path to CA3 connections for initiating retrieval especially with a partial cue from CA3.

9.4.2 CA3 subregion of the hippocampus

In Rolls' theory of the hippocampus the CA3 system acts as an autoassociation system. This enables arbitrary (especially spatial in animals and probably language for humans as well) associations to be formed between whatever is represented in the hippocampus, in that for example any place could be associated with any object, and in that the object could be recalled with a spatial recall cue, or the place with an object recall cue. The same system must be capable of fast (one-trial) learning if it is to contribute to forming new episodic memories, though it could also play an important role in the encoding of new information requiring multiple trials. The same system is also predicted to be important in retrieval of hippocampus-dependent information when there is an incomplete retrieval cue. The same system has the property that it can maintain firing activity because of the associative recurrent collateral connections, and for this reason is likely to be important in hippocampus-dependent delay / short-term memory tasks. The CA3 recurrent collateral system could also make a contribution to the learning of sequences if it has some temporal asymmetry in its associative synapses, as

described in Section 9.3.5.4. The CA3 system might also contribute to spatial path integration, though this could be performed outside the hippocampus. Tests of these proposed functions are described next.

9.4.2.1 Rapid encoding of new information

The theory proposes that associative learning in the CA3 recurrent collateral connections can occur rapidly, in as little as one trial, so that it can contribute to episodic memory. Evidence for one-trial learning between places and objects or odors, in the hippocampal CA3 is provided in Section 9.4.2.5.

The situation is a little different in a task in which there is one-trial learning of just a spatial location. In one such task, delayed non-matching-to-place (DNMP) for a single spatial location in an 8-arm maze, Lee and Kesner (2002) and Lee and Kesner (2003a) showed that blockade of CA3 NMDA receptors with AP5 or CA3 (neurotoxic) lesions did not impair one-trial learning in a familiar environment, but did impair it in an initial period in a novel environment. The implication is that a place can be remembered over a 10 s delay even without the CA3, but that learning of new spatial environments does require the CA3 subregion. Consistent with this observation is the finding that hippocampal CA3 (dorsal plus ventral) lesions disrupt learning of the standard 8-arm maze where the rats have to learn not to go back to arms previously visited (Handelmann and Olton, 1981). Rats tend to use different sequences on every trial, thus requiring new learning on every trial. When learning a new spatial environment, associations may be made between the different visual cues and their spatial locations, and this type of learning is computationally similar to that involved in object–place or odor–place association learning, providing a consistent interpretation of CA3 function.

Nakazawa, Sun, Quirk, Rondi-Reig, Wilson and Tonegawa (2003) also reported similar findings with mice in which the function of CA3 NMDA receptors was disrupted. These mice were impaired in learning a novel platform location in a working memory water maze task, whereas they were normal in finding familiar platform locations.

Evidence that rapid learning is reflected in the responses of CA3 neurons comes from a study in which it was found that CA3 neurons alter their responses rapidly when rats encounter novel configurations of familiar cues for the first time (Lee et al., 2004). Specifically, rats were trained to run clockwise on a ring track whose surface was composed of four different texture cues (local cues). The ring track was positioned in the centre of a curtained area in which various visual landmarks were also available along the curtained walls. To produce a novel cue configuration in the environment, distal landmarks and local cues on the track were rotated in opposite directions (distal landmarks were rotated clockwise and local cues were rotated counterclockwise by equal amounts).

In sum, these results and those in Section 9.4.2.5 strongly suggest that rapid plastic changes in the CA3 network are essential in encoding novel information involving associations between objects and places, odors and places, or between landmark visual cues and spatial locations, and NMDA receptor-mediated plasticity mechanisms appear to play a significant role in the process.

9.4.2.2 The types of information associated in CA3

A prediction is that the CA3 recurrent collateral associative connections enable arbitrary associations to be formed between whatever is represented in the hippocampus, in that, for example, any place could be associated with any object. Arbitrary in this context refers to the possibility of what is provided for by non-localized connectivity within the CA3–CA3 system, in that any one representation in CA3 can potentially become associated with any other representation in CA3. The prediction is neutral with respect to what is actually represented in the CA3 system, which I note from the effects of lesions almost always includes

space, at least in animals, but could include language in humans. The object representations might originate in the temporal cortical visual areas, and the spatial representations might utilize some information from the parietal cortex such as vestibular inputs related to self-motion (see Section 9.3). Two important issues need to be clarified. First, is the hippocampus the only neural system that supports all types of stimulus-stimulus associations (Eichenbaum and Cohen, 2001)? Based on the observations that the primate orbitofrontal cortex is involved in some types of stimulus-stimulus association, including visual-to-taste and olfactory-to-taste association learning and more generally in rapid and reversible stimulus-reinforcer association learning (Rolls, 2014a; Grabenhorst and Rolls, 2011; Rolls, 2019e,f), there appear to be other neural systems that can learn stimulus-stimulus associations. Second, what is the nature of the information that can be associated in this arbitrary way in the CA3 recurrent collateral system? The studies described next indicate that at least the non-human hippocampus is involved in associations when one of the components is spatial.

In order to directly test the involvement of the CA3 subregion of the hippocampus in spatial paired-associate learning, rats were trained on a successive discrimination Go/No-Go task to examine object-place and odor-place paired associate learning. Normal rats learn these tasks in approximately 240 trials. CA3 lesions impaired the learning of these object-place and odor-place paired associations (Gilbert and Kesner, 2003). Furthermore, lesions of DG or CA1 did not produce a deficit, and the reasons for this are considered later.

In contrast, object-odor paired associate learning was not impaired by CA3 lesions (even with a delay between the object and the odor) (Kesner et al., 2005). Thus, not all types of paired associate learning require the rat hippocampus. This conclusion is supported by the fact that (large or total) hippocampal lesions do not impair the following types of association including odor-odor (Bunsey and Eichenbaum, 1996; Li et al., 1999), odor-reward (Wood et al., 2004), auditory-visual (Jarrard and Davidson, 1990), and object-object associations (Cho and Kesner, 1995; Murray et al., 1993). Thus, in rats paired associate learning appears to be impaired by CA3 lesions only when one of the associates is place. This is consistent with the theory of episodic memory in which the hippocampus is important because the associates of a particular episodic memory and that have therefore to be represented in the hippocampus include place and/or the time at which the event occurred (Rolls, 2018b).

9.4.2.3 Acquisition/encoding associated with multiple trials

The CA3 subregion also appears to be necessary in some tasks that require multiple trials to acquire the task, and a common feature of these tasks is that a new environment must be learned. For example, lesions of the CA3 (but not the CA1) subregion impair the acquisition of object-place and odor-place paired associate learning, a task that requires multiple trials to learn (Gilbert and Kesner, 2003). Another multiple trial task in which a learning set is needed that is affected by CA3, but not by CA1, lesions is acquisition of a non-match to sample one-trial spatial location task on an 8-arm maze with 10 s delays (delayed non-match to place, DNMP). In this case the output from CA3 is via the fimbria, in that fimbria lesions that interrupt the CA3 hippocampal output without affecting the input also impair acquisition of this task. Finally, CA3 lesioned rats are impaired in the standard water maze task which requires multiple trials (Brun et al., 2002; Florian and Rouillet, 2004) (although mice that lacked NMDA receptors in CA3 do not appear to be impaired in learning the water maze (Nakazawa et al., 2002)). These findings are consistent with the hypothesis that when a new environment is learned this may involve multiple associations between different environmental cues, both with each other and with idiothetic (self-motion cues), and that this type of learning depends on new associations formed in the CA3-CA3 connections (see Section 9.3.5.2).

Fig. 9.41 Pattern completion impairment produced by CA3 lesions. The mean (and sem) degree of error in finding the correct place in the cheese-board task when rats were tested with 1, 2, 3 or 4 of the cues available. A graded impairment in the CA3 lesion group as a function of the number of cues available was found. The task was learned in the study phase with the 4 cues present. The performance of the control group is also shown. (After Gold, A.E. and Kesner, R.P. 2005. The role of the CA3 subregion of the dorsal hippocampus in spatial pattern completion in the rat. *Hippocampus* 15: 808–814. See further Kesner, R.P. and Rolls, E. T. 2015. A computational theory of hippocampal function, and tests of the theory: new developments. *Neuroscience and Biobehavioral Reviews* 48: 92–147.)

9.4.2.4 Pattern completion in CA3

The CA3 system is predicted to be important in the retrieval of hippocampus-dependent information when there is an incomplete retrieval cue. Support for the pattern completion process in CA3 can be found in lesion studies. In one study (Gold and Kesner, 2005), rats were tested on a cheese board with a black curtain with four extramaze cues surrounding the apparatus. (The cheese board is like a dry land water maze with 177 holes on a 119 cm diameter board.) Rats were trained to move a sample phase object covering a food well that could appear in one of five possible spatial locations. During the test phase of the task, following a 30 s delay, the animal needs to find the same food well in order to receive reinforcement with the object now removed. After reaching stable performance in terms of accuracy to find the correct location, rats received lesions in CA3. During post-surgery testing, four extramaze cues were always available during the sample phase. However, during the test phase zero, one, two, or three cues were removed in different combinations. The results indicate that controls performed well on the task regardless of the availability of one, two, three, or all cues, suggesting intact spatial pattern completion. Following the CA3 lesion, however, there was an impairment in accuracy compared to the controls especially when only one or two cues were available, suggesting impairment in spatial pattern completion in CA3 lesioned rats (Gold and Kesner, 2005) (see Fig. 9.41). A useful aspect of this task is that the ability to remember a spatial location learned in one presentation can be tested with varying number of available cues, and many times in which the locations vary, to allow for accurate measurement of pattern completion ability when the information stored on the single presentation must be recalled. Based on the observation that the lateral perforant path input into the dentate gyrus mediates visual object information via activation of opioid receptors, it was shown that naloxone (a μ opioid receptor antagonist) injected into the CA3 produced the same pattern completion problem (Kesner and Warthen, 2010).

In another study Nakazawa, Quirk, Chitwood, Watanabe, Yeckel, Sun, Kato, Carr, Johnston, Wilson and Tonegawa (2002) trained CA3 NMDA receptor-knockout mice in an analogous task, using the water maze. When the animals were required to perform the task in an environment where some of the familiar cues were removed, they were impaired in performing the task. The result suggests that the NMDA receptor-dependent synaptic plasticity mechanisms in CA3 are critical to perform the pattern completion process in the hippocampus.

9.4.2.5 Recall and arbitrary associations in CA3

A prediction of the theory is that the CA3 recurrent collateral associative connections enable arbitrary associations to be formed between whatever is represented in the hippocampus, in that for example any place could be associated with any object, and in that the object could be recalled with a spatial recall cue, or the place with an object recall cue.

In one test of this, Day, Langston and Morris (2003) trained rats in a study phase to learn in one trial an association between two flavors of food and two spatial locations. During a recall test phase they were presented with a flavor which served as a cue for the selection of the correct location. They found that injections of an NMDA blocker (AP5) or AMPA blocker (CNQX) to the dorsal hippocampus prior to the study phase impaired encoding, but injections of AP5 prior to the test phase did not impair the place recall, whereas injections of CNQX did impair the place recall. The interpretation is that somewhere in the hippocampus NMDA receptors are necessary for forming one-trial odor–place associations, and that recall can be performed without further involvement of NMDA receptors.

In a development related to the Day, Langston and Morris (2003) experiment, Kesner et al. (2008) designed a task in which a visual object could be recalled from a spatial location, and in an important extension, a spatial location could be recalled from an object. In this task, after training to displace objects, rats in the study phase are placed in the start box and when the door in front of the start box is opened the rats are allowed to displace one object in one location, and then after returning to the start box, the door is opened again and the rats are allowed to displace a second object in another location. There are 50 possible objects and 48 locations. In the test phase, the rat is shown one object (first or second randomized) in the start box as a cue, and then, after a 10-s delay, the door is opened and the rats must go to the correct location (choosing and displacing one of two identical neutral objects). The rats receive a reward for selecting the correct location that was associated with the object cue. A spatial location-recall for a visual object task was also used. For the spatial recall for a visual object task, the study phase is the same, but in this case in the test phase when the door is opened the rat is allowed to displace a neutral object in one location (first or second randomized) on the maze as a location cue, return to the start box, and then, after a 10 s delay, the door is opened and the rats must select the correct object (choosing and displacing one of two visual objects). The rats received a reward for selecting the correct visual object that was associated with the location cue. It was found that CA3a,b lesions produce chance performance on both the one-trial object-place recall task, and on the one-trial place-object recall task (Kesner et al., 2008). The potential implications of such results are that indeed the CA3a,b supports arbitrary associations as well as episodic memory based on one-trial learning. A control fixed visual conditional to place task with the same delay was not impaired, showing that it is recall after one-trial (or rapid) learning that is impaired.

Additional support comes from the finding that in a similar one-trial object–place learning followed by recall of the spatial position in which to respond when shown the object, Rolls and Xiang (2005) showed that some primate hippocampal (including CA3) neurons respond to an object cue with the spatial position in which the object had been shown earlier in the trial. Thus, some hippocampal neurons appear to reflect spatial recall given an object recall cue.

Evidence that the CA3 is not necessarily required during recall in a reference memory spatial task, such as the water maze spatial navigation for a single spatial location task, is that CA3 lesioned rats are not impaired during recall of a previously learned water maze task (Brun et al., 2002; Florian and Roussel, 2004). However, if completion from an incomplete cue is needed, then CA3 NMDA receptors are necessary (presumably to ensure satisfactory CA3–CA3 learning) even in a reference memory task (Nakazawa, Quirk, Chitwood, Watanabe, Yeckel, Sun, Kato, Carr, Johnston, Wilson and Tonegawa, 2002). Thus, the CA3 system appears to be especially needed in rapid, one-trial object–place recall, and when completion from an incomplete cue is needed.

9.4.2.6 Functional analysis of mossy fibre vs direct perforant path input into CA3

The computational model suggests that the dentate granule cell / mossy fibre pathway to CA3 may be important during the learning of new associations in the CA3 network, and that part of the way in which it is important is that it helps by pattern separation to produce relatively sparse and orthogonal representations in CA3 (see Section 9.3.5.8). In contrast, the theory predicts that the direct perforant path input to CA3 is important in initiating retrieval from the CA3 autoassociation network, especially with an incomplete retrieval cue (see Section 9.3.5.9).

Support for this hypothesis comes from the findings of Lee and Kesner (2004b) and Jerman et al. (2006) that lesions of the DG or CA3 (or a crossed lesion) disrupt within-day learning on the Hebb–Williams maze, but that retrieval of information at the start of the following day is not impaired. In contrast, lesions of the perforant path input to CA3 from entorhinal cortex disrupt retrieval (i.e. initial performance on the following day), but not learning within a day (Lee and Kesner, 2004b). These findings support the hypothesis that the CA3 processes both inputs from the DG to support pattern separation; and inputs from the entorhinal cortex via the perforant path to support pattern completion.

The perforant path can be divided into a medial and lateral component. It has been suggested that the medial component processes spatial information and that the lateral component processes non-spatial (e.g. objects, odors) information (Hargreaves et al., 2005; Witter et al., 1989a). In one study, Ferbinteanu et al. (1999) showed that lesions of the medial perforant path (MPP) disrupted water maze learning, whereas lateral perforant path (LPP) lesions had no effect. As predicted by the theory, there is associative LTP between the medial or lateral perforant path and the intrinsic commissural/associational–CA3 synapses (Martinez et al., 2002). Either place or object recall cues could thus be introduced by the associative MPP and LPP connections to CA3 cells.

In addition, Martinez et al. (2002) demonstrated associative (cooperative) LTP between the medial and lateral perforant path inputs to the CA3 neurons. This could provide a mechanism for object (LPP) – place (MPP) associative learning, with either the object or the place during recall activating a CA3 neuron. However, this LPP to MPP cooperative LTP onto a CA3 neuron would be a low capacity memory system, in that there are only 3,300 PP inputs to a CA3 cell, compared to 12,000 recurrent collaterals in the CA3–CA3 connections, and these numbers are the leading term in the memory capacity of pattern association and autoassociation memory systems (see Appendix B).

I note that disruption of DG and mossy fibre input into CA3 does not produce a disruption in the acquisition of the object–place paired associate task unless the stimuli are close together, implying that the DG contribution is important particularly when pattern separation is needed (Gilbert and Kesner, 2003). The implication is that sufficient input for object–place learning can be introduced into the CA3 system (which is required for this object–place learning) by the perforant path inputs provided that spatial pattern separation is not at a premium

(or perhaps the storage of large numbers of different object–place associations is not at a premium, as this is the other condition for which the computational theory indicates that the DG is needed to help produce sparse and orthogonal representations in the CA3 system).

9.4.2.7 Orthogonal representations in CA3

The CA3 subregion may have more distinct representations of different environments than CA1. This may be consistent with the computational point that if CA3 is an autoassociator, the pattern representations in it should be as orthogonal as possible to maximize memory capacity and minimize interference. The actual pattern separation may be performed, the theory holds, as a result of the operation of the dentate granule cells as a competitive net, and the nature of the mossy fibre connections to CA3 cells. Some of the empirical evidence is as follows.

Tanila (1999) showed that CA3 place cells were able to maintain distinct representations of two visually identical environments, and selectively reactivate either one of the representation patterns depending on the experience of the rat. Also, Leutgeb et al. (2004) showed that when rats experienced a completely different environment, CA3 place cells developed orthogonal representations of those different environments by changing their firing rates between the two environments, whereas CA1 place cells maintained similar responses. Evidence on the sparseness of the CA3 cell representation in rats includes evidence that CA3 cell ensembles may support the fast acquisition of detailed memories by providing a locally continuous, but globally orthogonal spatial representation, onto which new sensory inputs can rapidly be associated (Leutgeb and Leutgeb, 2007). Further, CA3 cells are very sensitive to the place where the rat is, and so potentially help to provide a basis for object–place memory in which the place is precisely specified (Leutgeb and Leutgeb, 2007).

In the computational account, each environment would be a separate chart, and the number of charts that could be stored in CA3 would be high if the representations in each chart are relatively orthogonal to those in other charts (see Section B.5.4 and Battaglia and Treves (1998b)), and further, the charts could operate independently (Stringer, Rolls and Trappenberg, 2004). Any one chart of one spatial environment can be understood as a continuous attractor network, with place cells with Gaussian shaped place fields, which overlap continuously with each other. In different charts (different spatial environments) the neurons may represent very different parts of space, and neurons representing close places in one environment may represent distant places in another environment (chart).

9.4.2.8 Short-term memory, path integration, and CA3

The CA3 recurrent collateral associative connections suggest that the CA3 system can operate as an attractor network which can be useful in some types of working memory. Support for this idea comes from a variety of studies analyzed by Kesner and Rolls (2001), including a study where in the short-term (30 s delay) memory for spatial location task to measure spatial pattern separation, it was shown that CA3 lesioned rats were impaired for all pattern separations, consistent with the hypothesis that the rats could not remember the correct spatial location (Gilbert and Kesner, 2006). Furthermore, in the short-term memory-based delayed non-matching to sample place task mentioned above (Lee and Kesner, 2003b), lesions of CA3 impaired the acquisition of this task with 10 s delays. Also single neuron activity has been recorded in CA3 during the delay period in rats in a spatial position short-term memory task (Hampson et al., 2000) and in monkeys in an object–place and a location–scene association short-term memory task (Cahusac et al., 1989). The finding that neuronal representations in the hippocampus switch abruptly from representing a square vs a circular environment on which rats have been trained when the environment changes incrementally between the two (‘remapping’) has also been suggested as evidence that the hippocampus implements

attractor dynamics (Wills et al., 2005). The flickering (alternation) between place-cell maps in the hippocampus in an ambiguous environment also provides evidence for an attractor system in the hippocampus, which can be reset by theta (Jezek et al., 2011).

In a task in which rats were required to remember multiple places, CA3 and CA1 lesions produced a deficit. In the task, during the study phase rats were presented with four different places within sections that were sequentially visited on a newly devised maze (i.e. Tulum maze). Each place was cued by a unique object that was specifically associated with each location within the section during the study phase. Following a 15-s delay and during the test phase in the absence of the cued object, rats were required to recall and revisit the place within one section of the maze that had been previously visited. Both CA1 and CA3 lesions disrupted accurate relocation of a previously visited place (Lee et al., 2005). Thus, short-term memory for multiple places in a one-trial multiple place task depends on both CA3 and CA1. As an attractor network can in general hold only one item active in a delay period by maintained firing, this type of multiple item short-term memory is computationally predicted to require synaptic modification to store each item, and both CA3 and CA1 appear to contribute to this.

The other mechanism in the hippocampus that is likely to be involved in short-term memory is the time cell system described in Sections 9.3.4 and 9.3.7.4.

9.4.2.9 Cholinergic modulation of CA3 towards storage vs recall including pattern completion

Acetylcholine may act to facilitate memory storage by increasing LTP in the CA3–CA3 recurrent collaterals, and reducing the recurrent collateral synaptic recall of previous interfering memories (Hasselmo et al., 1995; Giocomo and Hasselmo, 2007). Consistent with this, scopolamine (which blocks muscarinic cholinergic receptors), but not physostigmine, infusions, into CA3 disrupt encoding. In contrast, physostigmine (which inhibits acetylcholinesterase and thereby increases acetylcholine), but not scopolamine infusions, into CA3 disrupt recall. This was observed during a spatial exploration paradigm (Hunsaker et al., 2007), during Hebb-Williams maze learning (Rogers and Kesner, 2003), and during delay fear-conditioning (Rogers and Kesner, 2004).

These findings are consistent with the hypothesis that acetylcholine in CA3 when low supports recall which involves pattern completion implemented by the recurrent collaterals; and that acetylcholine when high facilitates new learning. Acetylcholine influences the hippocampus via the septum, and the neocortex (including the parietal cortex) via the basal forebrain cholinergic neurons. There are influences of both these cholinergic systems on memory, spatial function, and navigation (Solari and Hangya, 2018). Neurons in the basal forebrain may play a role in increasing memory consolidation, for they are activated in primates by novel and rewarding and punishing stimuli (Wilson and Rolls, 1990c,b,a), which facilitate consolidation. Consistent with this, cholinergic basal forebrain lesions produce severe learning impairments in learning visual scenes and in object-reward associations (Easton, Ridley, Baker and Gaffan, 2002), and damage to the cholinergic basal forebrain neurons is implicated in Alzheimer's disease (Zaborszky et al., 2018).

9.4.3 CA1 subregion of the hippocampus

The CA1 subregion of the hippocampus receives inputs from two major sources: the Schaffer collateral inputs from CA3, and the perforant path inputs from the entorhinal cortex (see Fig. 9.2). CA1 outputs are directed towards the subiculum, entorhinal cortex, prefrontal cortex and many other neural regions including the lateral septum, anterior thalamus, and the mammillary bodies (Amaral and Witter, 1995). The anatomical and physiological characteristics suggest that the CA1 can operate as a competitive network and have triggered the develop-

ment of computational models of CA1 in which for example the CA1 system is involved in the recall process by which backprojections to the cerebral neocortex allow neuronal activity during recall to reflect that present during the original learning (see Section 9.3.8). In this terminology, cortico-cortical backprojections originate from deep (layer 5) pyramidal cells, and terminate on the apical dendrites of pyramidal cells in layer 1 of the preceding cortical area (see Fig. 9.2). In contrast, cortico-cortical forward projections originate from superficial (layers 2 and 3) pyramidal cells, and terminate in the deep layers of the hierarchically next cortical area (see Fig. 9.2). Within this context, the projections from the entorhinal cortex to DG, CA3 and CA1 can be thought of as forward projections; and from CA1 to entorhinal cortex, subiculum etc. as the start of the backprojection system (see Fig. 9.2).

The evidence reviewed next of the effects of selective damage to CA1 indicates that it makes a special contribution to temporal aspects of memory including associations over a delay period, and sequence memory. There is also evidence relating it to intermediate memory as well as consolidation (see for more detail Rolls and Kesner (2006b)). The effects of damage to the CA1 may not be identical to the effects of damage to CA3, because CA1 has some inputs that bypass CA3 (e.g. the direct entorhinal / perforant path input); and CA3 has some outputs that bypass CA1. In particular, the CA3 output through the fimbria projects directly to the lateral septum and then to the medial septum or directly to the medial septum (Amaral and Witter, 1995; Risold and Swanson, 1997). The medial septum, in turn, provides cholinergic and GABAergic inputs to the hippocampus (Amaral and Witter, 1995).

9.4.3.1 Sequence memory and CA1

In Sections 9.3.5.4 and 9.3.7.4 I describe how a sequence memory could be implemented by pairing places with time cells to implement spatial sequence learning.

To test this, Hunsaker et al. (2008) trained rats to remember unique sequences of spatial locations along a runway box. Rats with lesions to either CA3 or CA1 had difficulty with this spatial sequence memory task, although CA1 lesioned animals had a much greater deficit. However, when animals were trained on a non-episodic version of the same task, hippocampal lesions had no effect. The results suggest that the CA3 and CA1 contribute to episodic based spatial sequence memory and pattern completion (Hunsaker et al., 2008). Further results are described by Kesner and Rolls (2015).

9.4.3.2 Associations across time, and CA1

There is evidence implicating the hippocampus in mediating associations across time (Rawlins, 1985; Kesner, 1998), and hypotheses on the mechanisms including time cells are described in Sections 9.3.5.4 and 9.3.7.4.

The CA1 subregion of the hippocampus may play a role in influencing the formation of associations whenever a time component (requiring a memory trace) is introduced between any two stimuli that need to be associated. Support for this idea comes from studies based on a classical conditioning paradigm. Lesions of the hippocampus in rabbits or rats disrupt the acquisition of eye-blink trace conditioning. In trace conditioning a short delay intervenes between the conditioned stimulus (CS) and the unconditioned stimulus (UCS). When, however, a UCS and CS overlap in time (delay conditioning), rabbits with hippocampal damage typically perform as well as normals (Moyer et al., 1990; Weiss et al., 1999). Based on a subregional analysis, it has been shown that ventral, but not dorsal, CA1 lesions impair at least the retention (tested after 48 h) of trace fear conditioning (Rogers et al., 2006). Similar learning deficits in trace fear conditioning (but not in conditioning without a delay between the CS and UCS), were observed for mice that lacked NMDA receptors in both dorsal and ventral CA1 subregions of the hippocampus (Huerta et al., 2000).

Based on a previous finding that the acquisition of an object-odor association is not dependent on the hippocampus, would adding a temporal component to an object-odor association task recruit the hippocampus and more specifically the CA1 region? To test this idea rats were given dorsal CA1, CA3, or control lesions prior to learning an object-delay-odor task. Rats that had dorsal CA1 lesions were unable to make the association and never performed above chance, however CA3 lesioned rats displayed no deficit (Kesner, Hunsaker and Gilbert, 2005). The observation of time cells during the trace in the object-trace-odor task supports the idea that the CA1 supports temporal processing of object and odor information. These results support the idea that the CA1 region is at least on the route for forming arbitrary associations across time even when there is no spatial component.

9.4.3.3 Temporal order memory, and CA1

There are also data on temporal order memory, which does not necessarily imply that a particular sequence has been learned, and could be recalled. Estes (1986) summarized data demonstrating that in human memory there are fewer errors for distinguishing items (by specifying the order in which they occurred) that are far apart in a sequence than those that are temporally adjacent. Other studies have also shown that order judgements improve as the number of items in a sequence between the test items increases (Banks, 1978; Chiba et al., 1994; Madsen and Kesner, 1995). This phenomenon is referred to as a temporal distance effect (sometimes referred to as a temporal pattern separation effect). It is assumed to occur because there is more interference for temporally proximal events than temporally distant events. Hypotheses on the mechanisms involved including time cells are described in Sections 9.3.5.4 and 9.3.7.4.

Based on these findings, Gilbert, Kesner and Lee (2001) tested memory for the temporal order of items in a one-trial sequence learning paradigm. In the task, each rat was given one daily trial consisting of a sample phase followed by a choice phase. During the sample phase, the animal visited each arm of an 8-arm radial maze once in a randomly predetermined order and was given a reward at the end of each arm. The choice phase began immediately following the presentation of the final arm in the sequence. In the choice phase, two arms were opened simultaneously and the animal was allowed to choose between the two arms. To obtain a food reward, the animal had to enter the arm that occurred earliest in the sequence that it had just followed. Temporal separations of 0, 2, 4, and 6 were randomly selected for each choice phase. These values represented the number of arms in the sample phase that intervened between the two arms that were to be used in the test phase. After reaching criterion rats received CA1 lesions. Following surgery, control rats matched their preoperative performance across all temporal separations. In contrast, rats with CA1 lesions performed at chance across 0, 2, or 4 temporal separations and a little better than chance in the case of a 6 separation. The results suggest that the CA1 subregion is involved in memory for spatial location as a function of temporal separation of spatial locations and that lesions of the CA1 decrease efficiency in temporal pattern separation. CA1 lesioned rats cannot separate events across time, perhaps due to an inability to inhibit interference that may be associated with sequentially occurring events. The increase in temporal interference impairs the rat's ability to remember the order of specific events.

The hippocampus is known to process spatial and temporal information independently (O'Keefe and Nadel, 1978; Kesner, 1998). In the previous experiments sequence learning and temporal pattern separation were assessed using spatial cues. Therefore, one possibility is that the CA1 and CA3 deficits were due to the processing of spatial rather than non-spatial temporal information. To determine if the hippocampus is critical for processing all domains of temporal information, it is necessary to use a task that does not depend on spatial information. Since the hippocampus does not mediate short-term (delayed match to sample) memory

for odors (Dudchenko et al., 2000; Otto and Eichenbaum, 1992), it is possible to test whether the hippocampus plays a role in memory for the temporal sequence of odors (i.e. temporal separation effect). Memory for the temporal order for a sequence of odors was assessed in rats based on a varied sequence of five odors, using a similar paradigm described for sequences of spatial locations. Rats with hippocampal lesions were impaired relative to control animals for memory for all temporal distances for the odors, yet the rats were able to discriminate between the odors (Kesner et al., 2002). In a further subregional analysis, rats with dorsal CA1 lesions show a mild impairment, but rats with ventral CA1 lesions show a severe impairment in memory for the temporal distance for odors (Kesner et al., 2011). Thus, the CA1 appears to be involved in separating events in time for spatial and non-spatial information, so that one event can be remembered distinct from another event, but the dorsal CA1 might play a more important role than the ventral CA1 for spatial information, and conversely ventral CA1 might play a more important role than the dorsal CA1 for odor information (Kesner and Rolls, 2015).

In a more recent experiment using a paradigm described by Hannesson et al. (2004), it was shown that temporal order information for visual objects is impaired only by CA1, but not CA3 lesions (Hoge and Kesner, 2007). Thus, with respect to sequence learning or memory for order information one hypothesis that would be consistent with the data is that the CA1 is the critical substrate for sequence learning and temporal order or temporal pattern separation. This would be consistent with CA1 deficits in sequence completion of a spatial task and CA1 deficits in temporal order for spatial locations, odor, and visual objects. Dorsal CA3 contributes to this temporal order or sequence process whenever spatial location is also important. When visual objects are used the CA3 region does not play a role.

These findings support the hypothesis that time cells in these regions are involved in order memory (see Sections 9.3.5.4 and 9.3.7.4).

Many more tests of the theory of hippocampal operation, and a summary of the interactions and dissociations between CA3 and CA1, are provided by Kesner and Rolls (2015), with an update on the dentate gyrus by Kesner (2018). In addition, there is a Special Issue of *Neurobiology of Learning and Memory* devoted to pattern separation and pattern completion in the hippocampal system (Rolls and Kesner, 2016).

9.5 Comparison of spatial processing and computations in primates including humans vs rodents

9.5.1 Similarities and differences between the spatial representations in primates and rodents

Despite the major differences in the spatial representations in the primate and rodent hippocampus, there are important similarities between the operation of the rodent and primate hippocampus, which indicate that the computational operation of these neural systems is comparable in rodents and primates, even though what is represented is different. Some of the similarities of the hippocampal system in primates and rodents were set out as follows (Rolls and Wirth, 2018; Rolls, 2023c,d).

First, the spatial representations are in both cases by most spatial view and place cells primarily allocentric. In monkeys, hippocampal spatial view cells during active locomotion in an open environment respond allocentrically to the view of a position in a spatial scene, relatively independently of the place where the monkey is in the open environment, of head direction, of eye position, and of where the spatial view field is relative to the monkey (Georges-François et al., 1999; Rolls and O'Mara, 1995).

Second, the spatial representations can be updated idiothetically, by one's body or eye motion in primates, as in the rat.

Third, in both cases the firing rates are low: in primates with a typical mean rate of 0.5 spikes/s, and a typical peak response rate of 17-20 spikes/s (Rolls et al., 1997a; Wirth et al., 2017). This matches numerous accounts of firing properties in the rat hippocampus.

Fourth, spatial view cells may fire just before the eyes reach the centre of the spatial view field, and may have their maximal response soon after the eyes reach the spatial view field, and decrease somewhat after that, i.e. show some adaptation (Wirth et al., 2017). Analogous findings have been described for rodent hippocampal cells which generate spike sequences lasting about 2 seconds as rats traverse a place field. The firing rate in the place field shows an asymmetry which changes with experience: as rats become familiar with an environment; cells show an increase in rate before animals reach the place field, followed by a gradual decrease as rats leave the field (Mehta et al., 2000).

Fifth, in macaques, there is evidence for independent representation about spatial view by hippocampal neurons, in that the information rises linearly with the number of neurons (Rolls et al., 1998b). This independence arises when the response profiles of the neurons are uncorrelated (Rolls and Treves, 2011; Rolls, 2021b). This is a powerful encoding, because the number of stimuli (e.g. spatial views) rises exponentially with the number of neurons. (Of course this independence applies only in a high-dimensional environment, and saturates to the limit in lower dimensional environments (Rolls and Treves, 2011; Rolls, 2016b, 2021b).) Ensemble encoding by populations of neurons is found in rodents (Wilson and McNaughton, 1993), and it would be interesting to know whether the coding by different neurons is also independent in rodents.

Sixth, rodent place cells may respond differently on the trajectory to approach a goal depending on the state of the animal (Fyhn et al., 2002; Wood et al., 2000; Ferbinteanu et al., 2011), as in primates (Wirth et al., 2017). This implies that place cells support cognition in both species.

Seventh, in macaques, object-spatial view neurons are found (Rolls et al., 2005c), and one-trial object-place learning and recall can occur (Rolls and Xiang, 2006). In rodents object-place or odor-place neurons have been described (Kim et al., 2011; Komorowski et al., 2009). The presence of a barrier or boundary, which might be thought of as an object, in a place, may also be encoded by rodent hippocampal (Rivard et al., 2004; Wang et al., 2020b,a) and retrosplenial (Alexander et al., 2020) neurons.

Eighth, in macaques, reward-spatial view neurons are found (Rolls and Xiang, 2005), and cells are found to encode reward outcomes (Wirth et al., 2009; Brincat and Miller, 2015). In rodents reward-place neurons have been described (Tabuchi, Mulder and Wiener, 2003), and it was found that place cells are more active after the receipt of a reward (Singer and Frank, 2009).

Ninth, in rodents, distal room cues can influence place cells (Shapiro et al., 1997; Acharya et al., 2016; Aronov and Tank, 2014; Knierim and Rao, 2003). However, this is different to the encoding of a location in a scene that is provided by primate spatial view cells, in that in rodents the distal room cues are used to encode the place where the rodent is located.

Tenth, in both primates and rodents, restricting the view of the environment may have analogous effects. In primates navigating through spatial trajectories in a star maze, many neurons had their responses influenced by place, the direction in which the macaque was facing, and by the part of the trajectory being performed (Wirth et al., 2017). In rats tested in an open foraging environment in which all places and head directions occur, rat place cells tend to have only small directional selectivity. However, in rats tested in linear runways in which a task may be performed and in which only some combinations of head direction and place are common, place cells may be quite directional (Acharya et al., 2016). A possibility

is that in the foraging situation used by Rolls and colleagues (Georges-François et al., 1999; Rolls et al., 1998b; Robertson et al., 1998; Rolls et al., 1997a), all places, views, and head directions occurred, and the cells were dominated by where the animal looked, and not by place or head direction. In contrast, if the macaque in a VR environment was constrained by the star maze to visit only certain places with particular spatial views and head directions that were frequently viewed from each of those places, and was performing a task that required a trajectory to a goal, then the neurons might reflect not only where the macaque was looking in the environment, but also the place from which the looking occurred etc. (Wirth et al., 2017). That is, if certain combinations of spatial view and place are common in an environment, then hippocampal neurons would be likely to encode primarily the combinations of spatial views and the places from which they are primarily seen.

Eleventh, whole body motion cells which respond to either linear velocity or angular velocity are present in the macaque hippocampus (O'Mara, Rolls, Berthoz and Kesner, 1994), and have more recently been described as speed cells in the rodent entorhinal cortex (Kropff et al., 2015; Spalla et al., 2022).

Twelfth, macaques (Rolls, 2005b; Robertson et al., 1999), as well as rodents (Taube et al., 1996, 1990a), have head direction cells in the presubiculum / subiculum.

These considerable similarities between the responses of neurons found in the rodent and primate hippocampal system provide evidence that the systems operate in similar ways in primates and rodents, but with different spatial representations (Rolls and Wirth, 2018). The different representations can be related to the evolution of the primate fovea, and its effects on object representations in the ventral cortical visual stream, and on systems in the primate dorsal visual stream for eye movements to produce foveation and for an interface to produce visually guided actions in the connected parietal cortical areas (Rolls et al., 2023e,d). Moreover, foveation of an object in primates is an efficient way to transmit the coordinates from a visually fixated object to the dorsal visuomotor system (Rolls et al., 2003a; Rolls and Deco, 2002) in the parietal cortex (Rolls et al., 2023d; Gamberini et al., 2020; Galletti and Fattori, 2018; Andersen and Cui, 2009). Further, the saccadic system of primates (including humans) enables a primate in one place to look towards one part of a scene and recall the object there, and then to saccade to another point in the scene and recall the object there. There is no evidence for anything similar in rodents, and this highlights an important difference between primate and rodent hippocampal spatial representation and memory systems that arises because of the primate fovea (Rolls, 2023d).

9.5.2 Hippocampal computational similarities and differences between primates and rodents

Although the spatial representations in the primate and rodent hippocampus are different, it is proposed that the underlying computations performed are similar (Rolls and Wirth, 2018; Rolls, 2023c).

A quantitative and detailed theory and model of how the hippocampus operates as a memory system, and of the way in which information stored in the hippocampus could be recalled back to the neocortex, has been developed (Rolls, 1989b; Treves and Rolls, 1994; Kesner and Rolls, 2015; Rolls, 2016b; Treves and Rolls, 1992; Rolls, 2018b, 2021b), with the architecture illustrated in Fig. 9.2. In the theory, the CA3 network forms an autoassociative or attractor memory, given the associatively modifiable recurrent connectivity between CA3 neurons. According to this theory, this system operates similarly in rodents and primates, to allow arbitrary associations between places in rodents, or spatial views in primates, and objects or rewards, to be rapidly formed, and later the whole memory to be recalled from a part. For

example, the location of an object might be recalled in CA3 when an object recall cue was presented.

Temporal sequences for episodic memory may be remembered by replacing the location cells with the timing cells described by Eichenbaum and colleagues (Howard and Eichenbaum, 2015; Howard et al., 2014; Eichenbaum, 2014; Macdonald et al., 2011; Kraus et al., 2015, 2013), and this applies to primates (Naya et al., 2017) including humans (Umbach et al., 2020) too. A theory of the generation of hippocampal time cells (Rolls and Mills, 2019) from entorhinal cortex cells with time courses of their firing changing over tens or hundreds of seconds (Tsao et al., 2018) could apply equally to primates as rodents. Indeed, consistent with this, neurons in the monkey entorhinal cortex have a spectrum of time constants of their firing (Bright et al., 2020). The theory of the operation of time cells shows a mechanism by which forward and reverse replay of memories could be produced (Rolls and Mills, 2019), and rather than these phenomena being involved in memory consolidation, it is proposed that at least in humans the reward value of episodic memories helps to influence their recall and whether therefore they are retrieved in the neocortex and reorganized for semantic storage and consolidation in the neocortex (Rolls, 2022b). The temporal order of events in an episodic memory might also be implemented using a temporal asymmetry of the synaptic modification in for example the CA3 recurrent collaterals, but such models are expensive in terms of memory capacity and can probably only be used for short sequences in the order of 2 s (Sompolinsky and Kanter, 1986; Hasselmo, Giocomo, Brandon and Yoshida, 2010; Akrami, Russo and Treves, 2012; Spalla, Cornacchia and Treves, 2021).

The leading factor in the number of memories that can be stored and successfully recalled in this system is the number of synapses onto any one CA3 neuron by the associatively modifiable synapses from the recurrent collaterals of other CA3 neurons. With sparse representations, the number of memories that can be stored is in the order of the number of synapses onto each CA3 neuron (Treves and Rolls, 1991). It is interesting that an important difference in evolution arises in humans, in which the CA3 neurons are not well connected across the midline by the hippocampal commissure, given what is found in macaques (Amaral et al., 1984). In rodents, the CA3-CA3 in the two hippocampi are as much connected as within the hippocampus on one side in the brain, and this enables the rodent CA3 hippocampal network to operate as a single hippocampus (Rolls, 2016b, 2021b). In humans, there appear to be effectively separate left and right CA3 hippocampal networks given the poor commissural connectivity. Consistent with this point, there is evidence that the right human hippocampus specialises in spatial including object-place and reward-place memories, and the left hippocampus specialises in more language/word-related memory processes (Crane and Milner, 2005; Burgess et al., 2002; Barkas et al., 2010; Sidhu et al., 2013; Bonelli et al., 2010). The adaptation here is that humans have twice the memory capacity of a hippocampal system connected across the midline as in rodents; and that associations are not typically made between words and their position in space, for the latter are not part of what is implemented for human language. The implication for spatial view neurons in humans is that they may be found more in the right hippocampus and possibly more in the right parahippocampal scene area.

Key points made here are that the primate parietal cortex may implement idiothetic update of hippocampal and parahippocampal spatial view neurons; and that recall of spatial view information from the hippocampus to neocortical areas such as the parietal cortex may be involved in navigation and in visuo-motor processing to reach for and grasp objects or rewards at recalled locations in the world. A possible implication is that the primate including human hippocampus may be especially involved in episodic memory, but that the actual computations for navigation and movements in the environment for navigation and visuo-motor function may be implemented outside the hippocampus, in neocortical areas such

as the parietal cortex. Consistent with this hypothesis, lesions of the human neocortex can produce topographical agnosia and inability to navigate (Kolb and Whishaw, 2021; Barton, 2011), and the retrosplenial cortex is implicated in navigation (Vedder et al., 2017; Alexander and Nitz, 2015; Byrne et al., 2007; Epstein, 2008; Vann et al., 2009). In more detail, lesions restricted to the hippocampus in humans result only in slight navigation impairments in familiar environments, but rather strongly impair learning or imagining new trajectories (Bohbot and Corkin, 2007; Teng and Squire, 1999; Spiers and Maguire, 2006; Maguire et al., 2016; Clark and Maguire, 2016). In contrast, lesions in regions such as the parietal cortex or the retrosplenial cortex produce strong topographical disorientation in both familiar and new environments (Aguirre and D'Esposito, 1999; Habib and Sirigu, 1987; Takahashi et al., 1997; Maguire, 2001; Kim et al., 2015b). This suggests that the core navigation processes (which may include transformations from allocentric representations to egocentric motor commands) is performed independently by neocortical areas outside the hippocampus, which may utilize hippocampal information related to recent memories (Ekstrom et al., 2014; Miller et al., 2013).

Further, and consistent with the spatial view cells found in non-human primates, regions of the human hippocampal formation can become activated when people look at spatial views (Epstein and Kanwisher, 1998; O'Keefe et al., 1998; Epstein and Baker, 2019). Moreover, the right human hippocampus is activated during mental navigation in recently learned but not in highly familiar environments (Hirshhorn et al., 2012). Mental navigation in familiar environments produces activation of cortical areas such as the lateral temporal cortex, posterior parahippocampal cortex, lingual gyrus, and precuneus (Hirshhorn et al., 2012). Further, as noted above, patients with anterograde amnesia may not be impaired in navigation in familiar environments, as contrasted with new environments (Clark and Maguire, 2016; Maguire et al., 2016). The implication is that, at least in primates, the hippocampus may be involved in episodic memory, and that neocortical regions implement navigation (helped when it is useful by recent memories recalled from the hippocampus).

In contrast, the view has often been held that the rodent hippocampus implements navigation. Indeed, in rodents, the existence of place cells has led to hypotheses that the rodent hippocampus provides a spatial cognitive map, and can implement spatial computations to perform navigation (O'Keefe and Nadel, 1978). These navigational hypotheses could not account for what is found in the primate hippocampus. An alternative that is suggested is that, in both rodents and primates, hippocampal neurons provide a representation of space (which for rodents is the place where the rat is located, and for primates includes positions "out there" in space), which are used as part of an episodic memory system. In primates this would enable formation of a memory of where an object was seen (Rolls, 1987, 1989b; Rolls and Kesner, 2006a; Rolls, 2016b, 2018b, 2021b). In rodents, this would enable the formation of memories of where particular objects (defined by olfactory, tactile, and taste inputs for instance) were found (Kesner and Rolls, 2015). Consistent with this theory of hippocampal function, one-trial object-place memory in rodents requires the hippocampus (Takeuchi et al., 2014; Day et al., 2003; Kesner and Rolls, 2015); texture sensed by whiskers and the places of rewards are reflected in neuronal firing (Itskov et al., 2011); some hippocampal neurons respond to behavioral, perceptual, or cognitive events, independently of the place where these events occurred, and may thus be useful for memory functions (Wood et al., 1999; Komorowski et al., 2009; Wood et al., 2000); hippocampal neurons may be activated following relocation of a target object to a new place (Fyhn et al., 2002); some hippocampal neurons alter their response when a different recording chamber is placed in the same location in the room (Leutgeb et al., 2005a); and another continuous dimension than place, namely auditory frequency, can be mapped by rodent hippocampal neurons (Aronov et al., 2017). Thus in primates, and probably also in rodents, the hippocampal representation of space may be appropriate for the

formation of memories of episodic events (for which there is typically a spatial component). These memories would be of use in spatial navigation.

9.6 Synthesis: the hippocampus: memory, navigation, or both?

Much of the evidence described above indicates that the hippocampus is involved in memory, and especially in episodic memory. But some, starting with rodent place cells, propose that the hippocampus is a cognitive map for navigation (O'Keefe and Nadel, 1978; Hartley et al., 2014; Bicanski and Burgess, 2018). I now provide a synthesis, with much of the evidence described above in this Chapter.

1. The evidence is that the hippocampus provides a memory network, with the CA3 recurrent collateral network operating as an autoassociation network with attractor dynamics providing for recall of a whole memory from any part (Rolls, 1989b; Kesner and Rolls, 2015; Rolls, 2018b). Because CA3 is a single network, any input to the hippocampus can be associated with any other input. That is a special property of CA3 not found elsewhere in the brain.
2. Because the CA3 operates with Hebbian associative learning, it associates events that occur within a short time window of 1 to a few seconds. That makes it specialize in single event memory, typical of episodic memory, where the components of the episodic memory are simultaneously present. The hippocampal system uses pattern separation to help somewhat similar episodes to be stored as separate episodic memories (Rolls, 2016f).
3. Because of time cells in the hippocampus, the hippocampus can also be involved in the temporal order of events in an episodic memory, by associating objects, people, or spatial information with the firing of particular time cells (Eichenbaum, 2017; Rolls and Mills, 2019).
4. One of the key inputs to the hippocampus is from spatial view cells in the primate including human medial parahippocampal gyrus PHA1-3 (Rolls et al., 2023e; Rolls, 2023c). Thus spatial information about locations in for example scenes is a prototypical part of human episodic memory.
5. Other key inputs are about objects and people, from the inferior temporal visual cortex via the lateral parahippocampal cortex TF and the perirhinal cortex; and are about reward, value, and emotion from the orbitofrontal cortex (Rolls et al., 2023e; Rolls, 2023c; Rolls et al., 2023c). This enables the human hippocampus to include in a prototypical episodic memory where the events happened, who or what was present and where they were located, and value.
6. The spatial scene input in primates including humans in the hippocampus is built from ventral visual stream features and combinations of features in a scene (Rolls et al., 2023e; Rolls, 2023c). The mechanism for this is associations of features in each foveated part of a scene which form spatial view cells that respond to only a small part of a scene. That was clearly set out and modelled by De Araujo, Rolls and Stringer (2001). As clearly explained in that paper, the spatial view cells formed are relatively independent of the place where the individual is located, because the scene looks similar from different places on the same side of the scene. For example a hill will always be on the left side of a lake as long as the individual is on one side of the scene. That is the sense in which spatial view cells are allocentric with respect to place, as well as of head direction and eye position (Rolls, 2023c). This is because it is the features in the spatial scene that have been associated together in a particular spatial order (e.g. hill then lake then house), and

when those features are seen in that spatial arrangement, the spatial view cell will fire (De Araujo, Rolls and Stringer, 2001). Of course if the individual crosses over and goes behind the viewed scene, then the egocentric view will change (the hill may change from being on the left of the scene to being on the right of the scene. Does that mean that the locations in the scene do not form a cognitive allocentric map of the type envisaged in many models of navigation (O'Keefe and Nadel, 1978; Hartley et al., 2014; Bicanski and Burgess, 2018)? To think about this, let us consider the situation in rodents.

7. The situation is different in rodents, in that they have place cells (O'Keefe, 1979). The computational argument, clearly specified and modelled by De Araujo, Rolls and Stringer (2001), is that place cells are formed because the rodent has such a wide field of view, perhaps 270 degrees, that a combination of features 'out there' (for example the room cues) will define a place where the individual is located. The place field should then be mainly but not completely invariant with respect to head direction, because a rat cannot see the whole 360 degrees of the environment at one time, and as the head rotates, somewhat different features in the environment may become more prominent. In the sense that environmental (e.g. room) cues determine where a place cell fires, rodent place cells are responsive to spatial cues 'out there', which is a feature of what spatial view cells in primates respond to (Rolls and Wirth, 2018; Rolls, 2023c,d).
8. Let us consider further how the parts of a scene are stitched together in primates. When a primate including human with spatial view cells is on one side of a scene, then the nearby parts of the scene become associated together by co-firing of neurons that produce synaptic modification based on how much co-firing there is, and therefore the distance between the spatial view fields. (I assume some sort of Gaussian shaped receptive field spatial sensitivity, as shown for primate hippocampal spatial view cells (Rolls, 2023c).) That forms a continuous attractor network for spatial view in primates (Stringer, Rolls and Trappenberg, 2005; Rolls and Stringer, 2005; Rolls, Tromans and Stringer, 2008f). Exactly the same computational mechanism in rodents potentially builds a continuous attractor network for place fields (Samsonovich and McNaughton, 1997; Stringer, Rolls, Trappenberg and De Araujo, 2002a). Now a continuous attractor network (described in Section B.5) can be regarded as a type of map, for nearby locations in the map are represented by co-firing neurons, and one can imagine moving through a series of nearby items in a trajectory, which may be thought of as a type of navigation (Stringer, Rolls and Trappenberg, 2005; Rolls and Stringer, 2005; Stringer, Rolls, Trappenberg and De Araujo, 2002a). Indeed, if one continued the navigation to get behind the scene, the order in which the landmarks in the scene are linked would be the same (e.g. house then lake then hill), so the representation of the scene would be allocentric, world-based, in that the parts of the map would be linked together in the correct order independently of which side of the scene it was viewed from. The viewpoint-dependent relations, e.g. which landmark was on the left, would change, but not the allocentric world-based representation in which the landmarks are linked in the same order regardless of the exact viewpoint. Thus spatial view cells could be linked in a continuous attractor network to provide an allocentric representation of the structure of the scene (Rolls, 2023d). That allocentric representation could be useful for navigation from landmark to landmark (Rolls, 2021f).

For this analysis, it is important to be clear about different coordinate frameworks (Rolls, 2023d). If the locations of the stimuli are in coordinates relative to the head (craniotopic) or body, these representations are in an **egocentric spatial coordinate framework**. If the representations of the locations of things such as parts of a scene are fixed relative to other parts of a scene, and are encoded provided that location in the world is viewed, inde-

pendently of the location relative to the head, body, or retinal position, then this is in an **allocentric spatial coordinate framework**. These are coordinate frameworks for spatial relationships. Completely different are **viewpoint-dependent spatial frameworks** for relationships, for which left-right is reversed when a scene is viewed from different sides, but that is independent of whether what is viewed is represented in an egocentric spatial framework relative to the head in craniotopic coordinates, or in an allocentric framework that is independent of position relative to the craniotopic egocentric head-based framework (Rolls, 2023c,d).

The following are some implications for understanding the representation of space ‘out there’ in the hippocampus and parahippocampal scene area by spatial view neurons (Rolls, 2023c,d). First, spatial view neurons are allocentric in that they do not depend on the exact place from where a scene is viewed (Georges-François, Rolls and Robertson, 1999; Rolls, 2023c). Second, spatial view cells do not depend on head direction (provided of course that the scene can be viewed), so spatial view cells are not egocentric (Georges-François et al., 1999; Rolls, 2023c). Third, spatial view neurons are spatial in the sense that they can be idiothetically updated in the dark to fire when the individual looks towards the spatial view field (Robertson, Rolls and Georges-François, 1998; Rolls, 2023c). That is not a property of inferior temporal cortex neurons that respond to objects and faces. Fourth, spatial view neurons are allocentric in that they represent features in a scene stitched together in the correct spatial organisation with respect to each other: this more formally is implemented by the continuous attractor network formed because of the co-firing of nearby spatial view neurons with spatially overlapping receptive fields (Rolls and Stringer, 2005; Stringer, Rolls and Trappenberg, 2005). Some of the clear evidence for this is that spatial view neurons start to respond in virtual reality to a part of the scene towards which a movement is being performed even before the view of the scene has even appeared on the VR screen (Wirth et al., 2017). That is evidence that there is a hippocampal representation that has information about the spatial relations of parts of a scene. The same point is made by the idiothetic update of hippocampal spatial view neurons in the dark, in that they fire even in the dark and when the scene is hidden by curtains but the eyes look towards the spatial view field of the spatial view neuron (Robertson, Rolls and Georges-François, 1998). All of this is consistent with the theory that spatial view neurons are in a sense viewing-point dependent, in that they are formed by looking at scenes that are being viewed when the individual is on one side of the scene (Rolls, 2023d). In such a representation part 1 of the scene may be to the left of part 2 of a scene, part 2 may be to the left of part 3, etc, and that relationship will remain as long as the individual is on that side of a scene. In that sense, hippocampal spatial view neurons may have an allocentric world based representation, based in the evidence above, which may nevertheless be stored with the scene viewed from one side, in a viewer-based framework. However, if one moves to the other side of the scene, a continuous attractor network representation already built could still reflect the closeness of the landmarks in a scene, in that part 1 would be close to part 2 but not part 3, etc., and that could still potentially be used in terms of the closeness of parts of a scene, even though when viewed from the other side the left/right relations will be reversed consistent with a viewer-based framework. The closeness of the parts of a scene will still be useful for truly allocentric navigation independently of which side the scene is viewed from (Rolls, 2023d).

Thus it is proposed that spatial view cells form allocentric representations of scenes, even though the left-right viewpoint-dependent relationships are different on different sides of the scene when the viewpoint changes. The spatial representation provided by spatial

view cells is allocentric in that it is not craniotopic, even when it may look “egocentrically” different from a “first person perspective” to a viewer who is on different sides of a scene (Wirth, 2023), in what should most clearly be described as a view-dependent allocentric representation (Rolls, 2023d). Moreover that allocentric representation even though it may have viewpoint dependence may however also have important viewpoint-independent topological properties, for example about the closeness of the different parts of the scene, which is important for navigation (Rolls, 2023d). Thus viewpoint dependence of scenes is important (Rolls, 2023d), but is completely different from egocentric vs allocentric encoding (Rolls, 2023d), and it is important to be clear about this (Wirth, 2023).

9. However, as noted above, a continuous attractor network of this type might not operate very well for navigation, because the association of items and rewards with spatial locations might make the energy landscape too bumpy and the attractor might be likely to become stuck (Soldatkina, Schonsberg and Treves, 2022; Ryom, Stendardi, Ciaramelli and Treves, 2023).
10. Given the evidence described above that navigation may not be impaired in familiar environments in humans with hippocampal damage, and is only impaired in new environments since the hippocampal damage, there may be brain regions outside the hippocampus (for example the retrosplenial cortex) that play key roles in navigation, with the hippocampus specialising primarily in event memory, in line with the evidence just summarized.
11. In summary, the evidence is that the hippocampal system in primates including humans is primarily for episodic memory, with the ability to retrieve a whole memory in CA3 from any part, and then to retrieve the components back to the relevant regions of neocortex, where they can be used to help form semantic memories in memory consolidation, where an important modulating factor is likely to be the value of the episodic memory (Rolls, 2022b). The hippocampal system contributes to navigation in novel environments because it can learn about the organisation of the features/landmarks in a novel environment. The hippocampus is likely to be involved in human navigation that proceeds from landmark to landmark, because landmarks are encoded by parahippocampal and hippocampal spatial view cells (Rolls, 2021f). Whether the hippocampus implements geometrical computations on place cell maps to organize novel trajectories involving novel short cuts through a place cell topology remains to be shown.

What is shown in this section is that spatial view cells are allocentric in the sense that they respond to features in scenes relatively independently of the place where the individual is located, because what is viewed in a distant scene is not very dependent on exactly where the individual is located, or on head direction.

Further, it is shown that a continuous attractor network of spatial view cells could be allocentric, world-based, in that the neighbourhood relations between parts of a scene would be useful on either side of the scene to implement a trajectory from landmark to landmark. The viewpoint-dependent representation would be reversed on different sides of a scene, with what is to the left of what reversed, but the allocentric map useful for trajectories would still be useful as an allocentric map useful for navigation from landmark to landmark (Rolls, 2023d, 2021f).

9.7 Comparison with other theories of hippocampal function

The theory described here is quantitative, and supported by both formal analyses and quantitative simulations. Many of the points made, such as on the number of memories that can be stored in autoassociative networks, the utility of sparse representations, and the dynamics of the operation of networks with recurrent connections, are quite general, and will apply to networks in a number of different brain areas. With respect to the hippocampus, the theory specifies the maximum number of memories that could be stored in it, and this has implications for how it could be used biologically. It indicates that if this number is approached, it will be useful to have a mechanism for recalling information from the hippocampus for incorporation into memories elsewhere. With respect to recall, the theory provides a quantitative account for why there are as many backprojections as forward projections in the cerebral cortex. Overall, the theory provides an explanation for how this part of the brain could work, and even if this theory needs to be revised, it is suggested that a fully quantitative computational theory along the lines proposed which is based on the evidence available from a wide range of techniques will be essential before we can say that we understand how a part of the cortex operates. This theory is almost unique in being a *quantitative* theory of hippocampal function.

Hypotheses have been described in this chapter about how a number of different parts of hippocampal and related circuitry might operate. Although these hypotheses are consistent with a theory of how the hippocampus operates, some of these hypotheses could be incorporated into other views or theories. In order to highlight the differences between alternative theories, and in order to lead to constructive analyses that can test them, the theory described above is compared with other theories of hippocampal function in this section. Although the differences between the theories are highlighted in this section, the overall view described here is close in different respects to the views of a number of other investigators (Marr, 1971; Brown and Zador, 1990; Eichenbaum, Otto and Cohen, 1992; McNaughton and Nadel, 1990; Squire, 1992; McClelland, McNaughton and O'Reilly, 1995; Moscovitch, Rosenbaum, Gilboa, Addis, Westmacott, Grady, McAndrews, Levine, Black, Winocur and Nadel, 2005; Wang and Morris, 2010; Preston and Eichenbaum, 2013; Winocur and Moscovitch, 2011) and of course priority is not claimed on all the propositions put forward here.

Some theories postulate that the hippocampus performs spatial computation. The theory of O'Keefe and Nadel (1978) that the hippocampus implements a cognitive map, placed great emphasis on spatial function. It supposed that the hippocampus at least holds information about allocentric space in a form which enables rats to find their way in an environment even when novel trajectories are necessary, that is it permits an animal to "go from one place to another independent of particular inputs (cues) or outputs (responses), and to link together conceptually parts of the environment which have never been experienced at the same time". O'Keefe (1990) extended this analysis and produced a computational theory of the hippocampus as a cognitive map, in which the hippocampus performs geometric spatial computations. Key aspects of the theory are that the hippocampus stores the centroid and slope of the distribution of landmarks in an environment, and stores the relationships between the centroid and the individual landmarks. The hippocampus then receives as inputs information about where the rat currently is, and where the rat's target location is, and computes geometrically the body turns and movements necessary to reach the target location. In this sense, the hippocampus is taken to be a spatial computer, which produces an output which is very different from its inputs. This is in contrast to the present theory, in which the hippocampus is a memory device, which is able to recall what was stored in it, using as input a partial cue. The theory of O'Keefe postulates that the hippocampus actually performs a spa-

tial computation. The well-deserved award of a Nobel prize to John O'Keefe and colleagues explicitly recognized the spatial aspects of his approach, referring to an "inner GPS" in the brain. Updates to the theory (Burgess, Recce and O'Keefe, 1994; Burgess, Jackson, Hartley and O'Keefe, 2000; Edvardsen, Bicanski and Burgess, 2020) also make the same postulate, but now the firing of place cells is determined by the distance and approximate bearing to landmarks, and the navigation is performed by increasing the strength of connections from place cells to "goal cells", and then performing gradient-ascent style search for the goal using the network. Rolls' discoveries and theory are thus somewhat different from those of O'Keefe and colleagues, in that Rolls has shown that spatial view cells may be especially relevant to the operation of the hippocampus in primates including humans; and in that the roles of the hippocampal system in memory are emphasized. Further, Rolls has developed theories about how the spatial view and other cells found in the primate hippocampal and related parietal cortex systems could be involved in navigation (Section 9.3.15).

McNaughton et al. (1991) have also proposed that the hippocampus is involved in spatial computation. They propose a "compass" solution to the problem of spatial navigation along novel trajectories in known environments, postulating that distances and bearings (i.e. vector quantities) from landmarks are stored, and that computation of a new trajectory involves vector subtraction by the hippocampus. They postulate that a linear associative mapping is performed, using as inputs a "cross-feature" (combination) representation of (head) angular velocity and (its time integral) head direction, to produce as output the future value of the integral (head direction) after some specified time interval. The system can be reset by learned associations between local views of the environment and head direction, so that when later a local view is seen, it can lead to an output from the network which is a (corrected) head direction. They suggest that some of the key signals in the computational system can be identified with the firing of hippocampal cells (e.g. local view cells) and subicular cells (head direction cells). It should be noted that this theory requires a (linear) associative mapping with an output (head direction) different in form from the inputs (head angular velocity over a time period, or local view). This is pattern association (with the conditioned stimulus local view, and the unconditioned stimulus head direction), not autoassociation, and it has been postulated that this pattern association can be performed by the hippocampus (cf. McNaughton and Morris (1987)). This theory is again in contrast to the present theory, in which the hippocampus operates as a memory to store events that occur at the same time, and can recall the whole memory from any part of what was stored. (A pattern associator uses a conditioned stimulus to map an input to a pattern of firing in an output set of neurons which is like that produced in the output neurons by the unconditioned stimulus. A description of pattern associators and autoassociators in a neurobiological context is provided in Appendix B. The present theory is fully consistent with the presence of 'spatial view' cells and whole body motion cells in the primate hippocampus (Rolls and Xiang, 2006; Rolls, 1999c; Rolls and O'Mara, 1993) (or place or local view cells in the rat hippocampus, and head direction cells in the presubiculum), for it is often important to store and later recall where one has been (views of the environment, body turns made, etc), and indeed such (episodic) memories are required for navigation by "dead reckoning" in small environments.

The present theory thus holds that the hippocampus is used for the formation of episodic memories using autoassociation. This function is often necessary for successful spatial computation, but is not itself spatial computation. Instead, we believe that spatial computation is more likely to be performed in the neocortex (utilising information if necessary recalled from the hippocampus). Consistent with this view, hippocampal damage impairs the ability to learn new environments but not to perform spatial computations such as finding one's way to a place in a familiar environment, whereas damage to the parietal cortex and parahippocampal cortex can lead to problems such as topographical and other spatial agnosias,

in humans (Grusser and Landis, 1991; Kolb and Whishaw, 2021; Maguire et al., 2016; Rolls and Wirth, 2018) (see Section 10.6). This is consistent with spatial computations normally being performed in the neocortex. (In monkeys, there is evidence for a role of the parietal cortex in allocentric spatial computation. For example, monkeys with parietal cortex lesions are impaired at performing a landmark task, in which the object to be chosen is signified by the proximity to it of a “landmark” (another object) (Ungerleider and Mishkin, 1982).)

A theory closely related to the present theory of how the hippocampus operates has been developed by McClelland, McNaughton and O’Reilly (1995). It is very similar to the theory we have developed (Rolls, 1987, 1989a, 1990b, 1989f; Treves and Rolls, 1992, 1994; Rolls, 1996d; Rolls and Treves, 1998; Rolls and Kesner, 2006b; Rolls, 2008e, 2010b; Kesner and Rolls, 2015) at the systems level, except that it takes a stronger position on the gradient of retrograde amnesia, emphasises that recall from the hippocampus of episodic information is used to help build semantic representations in the neocortex, and holds that the last set of synapses that are modified rapidly during the learning of each episode are those between the CA3 and the CA1 pyramidal cells (see Fig. 9.2). It also emphasizes the important point that the hippocampal and neocortical memory systems may be quite different, with the hippocampus specialized for the rapid learning of single events or episodes, and the neocortex for the slower learning of semantic representations which may necessarily benefit from the many exemplars needed to shape the semantic representation. In the formulation by McClelland, McNaughton and O’Reilly (1995), the entorhinal cortex connections via the perforant path onto the CA1 cells are non-modifiable (in the short term), and allow a representation of neocortical long-term memories to activate the CA1 cells. The new information learned in an episode by the CA3 system is then linked to existing long-term memories by the CA3 to CA1 rapidly modifiable synapses. All the connections from the CA1 back via the subiculum, entorhinal cortex, parahippocampal cortex etc. to the association neocortex are held to be unmodifiable in the short term, during the formation of an episodic memory. The formal argument that leads us to suggest that the backprojecting synapses are associatively modifiable during the learning of an episodic memory is similar to that which we have used to show that for efficient recall, the synapses which initiate recall in the CA3 system (identified above with the perforant path projection to CA3) must be associatively modifiable if recall is to operate efficiently (Treves and Rolls, 1992). The present theory holds that it is possible that for several stages back into neocortical processing, the backprojecting synapses should be associatively modifiable, with a similar time course to the time it takes to learn a new episodic memory. It may well be that at earlier stages of cortical processing, for example from inferior temporal visual cortex to V4, and from V4 to V2, the backprojections are relatively more fixed, being formed (still associatively) during early developmental plasticity or during the formation of new long-term semantic memory structures. Having such relatively fixed synaptic strengths in these earlier cortical backprojection systems could ensure that whatever is recalled in higher cortical areas, such as objects, will in turn recall relatively fixed and stable representations of parts of objects or features. Given that the functions of backprojections may include many top-down processing operations, including attention (Deco and Rolls, 2005a) and priming, it may be useful to ensure that there is consistency in how higher cortical areas affect activity in earlier “front-end” or preprocessing cortical areas. Indeed, the current theory shows that at least one backprojection stage, the hippocampo-cortical connections must be associatively modifiable during the learning of an episodic memory, but does not require the associative backprojection learning to occur at all backprojection stages during the learning of the episodic memory. Crucial stages might include CA1 to subiculum or to entorhinal cortex (see Fig. 9.2), or entorhinal cortex to parahippocampal gyrus and perirhinal cortex. It would be interesting to test this using local inactivation of NMDA receptors at different stages of the backprojection

system to determine where this impairs the learning of for example place–object recall, i.e. a task that is likely to utilize the hippocampo-cortical backprojection pathways.

If a model of the hippocampal / neocortical memory system could store only a small number of patterns, it would not be a good model of the real hippocampal / neocortical memory system in the brain. Indeed, this appears to be a major limitation of another model presented by Alvarez and Squire (1994). The model specifies that the hippocampus helps the operation of a neocortical multimodal memory system in which all memories are stored by associative recurrent collaterals between the neocortical neurons. Although the idea worked in the model with twenty neurons and two patterns to be learned (Alvarez and Squire, 1994), the whole idea is computationally not feasible, because the number of memories that can be stored in a single autoassociative network of the type described is limited by the number of inputs per neuron from other neurons, not by the number of neurons in the network (Treves and Rolls, 1991, 1994). This would render the capacity of the whole neocortical multimodal (or amodal) memory store very low (in the order of the number of inputs per neuron from the other neurons, that is in the order of 5,000–10,000) (O’Kane and Treves, 1992). This example makes it clear that it is important to take into account analytic and quantitative approaches when investigating memory systems. The current work is an attempt to do this.

The discovery of hippocampal time cells (Macdonald et al., 2011; Eichenbaum, 2017; Salz et al., 2016; Howard and Eichenbaum, 2015; Eichenbaum, 2014) has transformed our understanding of how the order of items in a memory could be implemented. A mechanism for the generation of time cells has been described (Rolls and Mills, 2019) (Section 9.3.4). A side effect of the way in which time cells are generated in the model is the generation of reverse replay, as well as forward replay. There have been many discoveries about these forward and reverse replay phenomena, in the context that they may be involved in the transfer of memories from the hippocampal system to the neocortex (Wilson and McNaughton, 1994; Foster and Wilson, 2006; Foster, 2017). The concept advocated there is for a type of undirected burst of replay in the hippocampus, which would transfer the information, presumably in its raw episodic form, to the neocortex. Sharp wave ripples are associated with these ‘replay’ events and are generated for example in CA1 during slow wave sleep and quiescent wakefulness (Buzsaki, 2015), and occur in humans when memories are being stored or recalled (Norman, Yeagle, Khuvis, Harel, Mehta and Malach, 2019). However, my view is that recall of episodic information to the neocortex could best be initiated by a recall cue from the neocortex, which would lead to completion of the whole episodic memory from the hippocampus, which would then recall the whole memory to the neocortex in the quantitative way described in Section 9.3.8. This recall would reinstate activity in the cortical neurons that had been present during learning of the original episodic memory. It would then be up to the cortex to use that information, in conjunction with much semantic information it already has, to add to that semantic (including autobiographical) memory in a way that could usefully extend the semantic memory. The example I provided was of recalling a train journey, and using the particular information from that, to help build a semantic geographical map. In humans, this would best be performed when thinking about the semantic information, recalling the episode from the hippocampus, and then actively adjusting the semantic map in the light of the episodic information. Memory consolidation guided by value is described in Section 9.2.8.5 (Rolls, 2022b).

A different type of sequence memory uses synaptic adaptation to effectively encode the order of the items in a sequence (Deco and Rolls, 2005c). This could be implemented in recurrent networks such as the prefrontal cortex.

The proposal that acetylcholine could be important during encoding by facilitating CA3–CA3 LTP, and should be lower during retrieval (Hasselmo, Schnell and Barkai, 1995; Hasselmo and Sarter, 2011; Zaborszky, Gombkoto, Varsanyi, Gielow, Poe, Role, Ananth, Ra-

jebhosale, Talmage, Hasselmo, Dannenberg, Mincses and Chiba, 2018), is a useful concept. This has been extended by the concept that memory consolidation in humans is influenced by the posterior orbitofrontal cortex that influences the basal forebrain cholinergic system that projects to the neocortex; and by the vmPFC and anterior cingulate cortex that influences the cholinergic septal system that projects to the hippocampus (Rolls, 2022b; Rolls et al., 2023c)(Section 9.2.8.5).

An approach linked to neuropsychology and neuroimaging is that the hippocampus is involved in the construction of spatial scenes, and that patients with hippocampal damage are devoid of visual representations of scenes (Maguire et al., 2016; McCormick et al., 2018; Zeidman et al., 2015; Clark et al., 2019). That is of course very close to the view developed in this chapter, that the primate including human hippocampal system is especially involved in the construction of visual scenes using spatial view cells, with the ‘construction’ being implemented by continuous attractor networks, which provide a way in which the brain builds cognitive maps where there is continuity of the representations, as is the case for spatial representations. Moreover, the present approach links to the evidence that other types of continuous space are natural candidates for implementation as continuous attractors in the entorhinal cortex / hippocampal attractor networks (Constantinescu et al., 2016; Bellmund et al., 2018; Nau et al., 2018b).

Teyler and DiScenna (1986) proposed that the hippocampus stores pointers to neocortical areas, and uses those pointers to recall memories in the cortex. The present theory is different, for it emphasizes that spatial and temporal order representations are present in the hippocampus, and can be combined with object information to store episodic memories in the hippocampus by forming associations between these components. However, the theory also shows how recall of these episodic memories within the hippocampus can then using back-projections to neocortical areas allow neocortical representations present at the time of the encoding to be retrieved, and then potentially stored in the neocortex in a schema or semantic memory. The actual retrieval process to neocortex is implemented by using associatively modified synapses in at least one stage of the backprojection system, and this provides a dead-addressing method for the hippocampus to retrieve a content-addressable neocortical memory. This deaddressing process for recall to the neocortex that is part of the current theory can be likened to the use of a pointer, but rather than being a metaphor as in Teyler and DiScenna (1986), the current theory specifies a mechanism by which the correct set of neurons in the neocortex can be brought into activity during recall, and provides the only solution I know to how information is correctly retrieved from the hippocampus to the correct set of neurons in the neocortex. The present theory (Rolls, 1990b, 1996d, 2010b; Rolls and Kesner, 2006b; Kesner and Rolls, 2015; Rolls, 2016b, 2018b, 2023c, 2022b) is I believe unique in that it enables both the hippocampal storage process, and the recall to the neocortex, to be understood quantitatively.

The aim of this comparison of the present theory with other theories has been to highlight differences between the theories, to assist in the future assessment of the utility and the further development of each of the theories.

Overall, the approach taken in this chapter shows how it is now possible to understand quantitatively how the circuitry in a major brain system could actually operate to store and later recall memories.

10 The parietal cortex, spatial functions, and navigation

10.1 Introduction and overview

10.1.1 Overview of what is computed in the parietal cortex

1. The dorsal visual stream projects up into the parietal cortex to intraparietal sulcus regions such as LIP, VIP, and MIP, and then to area 7 regions, as shown in Fig. 3.1 and Fig. 10.2 (see Chapter 3 and Sections 10.3 and 10.4). This system includes neurons that link visual responsiveness with action such as grasping an object (Galletti and Fattori, 2018; Bisley and Goldberg, 2010) (see also Chapter 15).
2. One of the visual coordinate frames that is represented in some parietal cortex areas is head-based. That facilitates coordination between spatial representations in the visual and auditory systems using bimodal visual-auditory neurons that respond to the same position in head-centred space, because auditory space is necessarily in head-based coordinates in primates including humans. This facilitates for example saccades towards positions in space where a sound was heard.
3. Visual regions in the greatly developed inferior parietal cortex PG regions (PGi, PGs, PGp and also PFm) receive visual motion-related inputs from some of the more superior intraparietal sulcus and area 7 regions, and have connectivity also with inferior temporal visual ‘what’ cortex to produce motion-related representations of objects, faces and the body, which communicate with superior temporal sulcus regions with similar activity.
4. The primary somatosensory cortex areas 1, 2 and 3 are in the parietal cortex, and project via a ‘ventral somatosensory stream’ (Section 6.1.8.1) through frontal opercular (FOP) regions and the insula to parietal PF regions that reach finally region PF itself where somatosensory representations about felt objects and the body image can be combined with visual inputs to provide multimodal representations.
5. The primary somatosensory cortex areas 1, 2 and 3, also project into parietal areas 5 and 7, in a ‘dorsal somatosensory stream’ (Section 6.1.8.2) in which somatosensory information is brought together with visual information for functions such as reaching for and grasping objects. Neurons with movement-related activity in the parietal cortex as well as in premotor cortex area F5 respond to the sight of grasping an object, as well as to actually grasping an object, in the mirror neuron system (Rizzolatti and Craighero, 2004; Rizzolatti and Sinigaglia, 2016; Rizzolatti and Rozzi, 2018) (Section 15.3).
6. Somatosensory including proprioceptive inputs are represented in parietal cortex areas BA 1, 2 and 3a, which then project to area 5, and thus to 7 in the ‘dorsal somatosensory stream’. The representations in early stages may be of single joint positions, but become more complex up through the hierarchy because neurons come to represent combinations of joint positions, which can then represent for example the position of the arm in egocentric space, for example relative to the trunk.
7. The human inferior parietal cortex multimodal regions including PGi and PF provide inputs to and are part of the semantic language-related regions that extend through the

temporo-parieto-occipital junction (TPOJ) regions and the superior temporal sulcus (STS) regions that extend to the temporal pole that are further described in Chapter 14.

10.1.2 Overview of how the computations are performed in the parietal cortex

1. A feature hierarchy for proprioceptive information through the parietal cortex from the primary somatosensory cortex through area 5 to macaque area 7b is proposed to lead to representations of the egocentric position in space relative to the body of for example an arm. This would be appropriate for movements made to positions in egocentric space. The feature hierarchy it is proposed performs this computation by forming combinations of the positions of single joints that are represented at early stages of the hierarchy.
2. Similarly a feature hierarchy for touch information is proposed to lead to combinations of local touch information in for example several parts of the hand to enable tactile object recognition. Whether a trace synaptic learning rule is used in making such object representations show position invariance (even across the right and left hands) is an interesting but untested possibility. A different mechanism might be use of invariant visual object recognition to help set up by association the correct invariant touch object representations in a multimodal region, which might be more in a ventral stream area such as the anterior temporal lobe.
3. Visual and proprioceptive information, both in egocentric coordinates, could combine by pattern association learning, or by competitive learning with a mixture of visual and somatosensory inputs, to form neurons that could respond in egocentric coordinates, to help guide arm movements to a viewed target. In this way, the parietal cortex is involved in actions in space (Goodale, 2014).
4. Visual information and auditory information about spatial location in head-based coordinates could be combined by pattern association learning, or by competitive learning with a mixture of visual and auditory inputs.
5. The coordinate transforms present in the parietal lobe could be performed by gain field modulation, made more efficient it is suggested by the memory trace synaptic modification rule described in Chapter 3.
6. These coordinate transforms are used to help control eye movements, and it is proposed to provide update of parahippocampal gyrus spatial view representations as described in Section 9.2.8.2.

10.2 Inferior parietal cortex somatosensory stream, PF regions

The somatosensory cortex in the superior anterior parts of the parietal cortex (regions 3b, 3a, 1, and 2) connect via frontal opercular (FOP) and opercular (OP) regions to the insula, which then has connectivity to anterior inferior parietal cortex regions such as PFop and PF, as described in Section 6.1.8 and illustrated in Fig. 6.7. The stream that involves anterior inferior parietal cortex regions PFcm, PFop, PFt, and PF is described in this section (Rolls et al., 2023d). The connectivity of the last stage of this somatosensory hierarchy, region PF, where information from other modalities is also received, is shown in Fig. 10.1. A key concept is that the top of this parietal somatosensory stream, PF, integrates somatosensory and proprioceptive information with visual object information from inferior temporal visual cortex region PHT. This is highly appropriate for tool use. As shown in Yokoyama, Autio, Ikeda,

Fig. 10.1 Effective connectivity of region PF in the human brain. The widths of the red lines and the size of the arrowheads indicate the magnitude and direction of the effective connectivity with PF. The black outline encloses the postero-ventral memory-related regions of the posterior cingulate cortex. PF receives somatosensory inputs from many cortical regions including PFop which in turn receives from somatosensory 5 and fronto-opercular regions such as OP4 which in turn receive from somatosensory cortex such as 3a. (The green arrows help to illustrate the somatosensory hierarchy from for example 3a etc via OP4 to PFop to PF.) PF also receives some visual inputs from AIP, LIPd, IP2 and 7Pm. PF has outputs to premotor cortical areas (6) including the mid-cingulate cortex. The abbreviations are listed in Section 1.12. (From Rolls,E.T., Deco,G., Huang,C-C. and Feng,J. (2023) The human posterior parietal cortex: effective connectome, and its relation to functions. *Cerebral Cortex* 33: 3142-3170. doi: 10.1093/cercor/bhac266. Copyright © Oxford University Press.)

Sallet, Mars, Van Essen, Glasser, Sadato and Hayashi (2021), these PF regions in humans correspond approximately to area 7b in macaques.

Topologically (Caspers et al., 2008; Caspers and Zilles, 2018), PF areas are more anterior in the inferior parietal cortex, and the PG areas are more posterior (Fig. 10.1). In terms of alternative terminology in common use for the inferior parietal cortex, the supramarginal gyrus BA40 is mainly represented in the HCP-MMP (Glasser et al., 2016a) by PF, PFT, and

the PeriSylvian language area PSL, and is related in the left hemisphere to phonology, and is also part of the mirror neuron system which may be used to interpret the gestures and actions of other people (Caspers et al., 2008; Rizzolatti and Roszi, 2018). The angular gyrus BA 39 is posterior and may include HCP-MMP regions IP1, IP0, PGI, PGs, and PFm and is implicated in memory and semantic processing, with damage on the left related to dyslexia and agraphia and on the right to body image (Davis et al., 2018). The HCP-MMP, based as it is on cortical thickness and myelination, functional connectivity, and task-related activations (Glasser et al., 2016a) (Section 1.12), thus provides a more detailed parcellation than BA 40 the supramarginal gyrus, and BA 39 the angular gyrus.

The PF areas (which are anterior in the inferior parietal cortex, and excluding PFm), as shown in Fig. 10.1 receive effective connectivity from somatosensory cortical areas (including 2, 5L and 5mv), and have effective connectivities directed towards somatomotor premotor areas including 6ma, 6mp, 6a, 6d, 6r and 6v and midcingulate premotor regions 23c, 24dd and 24dv (Rolls et al., 2023d). The effective connectivities indicate that PF is at the top of a somatosensory hierarchy, with somatosensory inputs from especially PFop, frontal opercular 4 and 5 (FOP4 and FOP5), and the mid insula (MI) (Fig. 10.1). PFop receives input from PFt and somatosensory Frontal Opercular FOP2-4, posterior Opercular OP4, 5l and 5mv and the insula (green in Fig. 10.1). OP4 receives effective connectivity from somatosensory 1, 2, 3a and 3b at the bottom of the somatosensory hierarchy (Fig. 10.1). Thus part of the function of these PF areas may be related to somatosensory / body image and the sense of body ownership and of self that this bestows (Ronchi et al., 2018). The connectivity with the somatosensory insula and adjoining frontal operculum (FOP regions) (in which somatosensory responses are also found (Verhagen et al., 2004; Rolls et al., 2015b)), further provides a foundation for understanding a function of the PF regions as involving body image, and indeed consistent with this, it has been argued that the insula is involved in the human awareness of feelings from the body (Craig, 2011). Further than this, it has been shown that although somatosensory cortical areas 1-3 respond as much to the sight of touch as to the touch itself, the insula responds to the real touch only, and not to the sight of touch, which led to the proposal that the insula is involved in awareness that it is one's own body that is being touched, and not someone else's body (Rolls, 2010a; McCabe et al., 2008). This then fits with the concept that the PF Posterior Parietal Cortex regions (which receive inputs from the insula) are involved in representing one's own body, and that anosognosia and other disorders of awareness of the body can be produced by PF damage in humans (Ronchi et al., 2018).

There is a clear transition of functionality from anterior to posterior within the PF regions. PFcm and PFop have mainly somatosensory inputs, and premotor outputs. PFcm has inputs from OP1-4, and is further implicated in responsiveness to vestibular inputs (Huber et al., 2022). Indeed, OP1-4 correspond approximately to the parieto-insular vestibular cortex (Huber et al., 2022; Grusser et al., 1990), and may make a contribution to heading direction useful for navigation (Chen et al., 2016a). PFt (which is more dorsal, and closer to parietal visual areas) also receives effective connectivity from superior parietal (7Al, 7Am, 7PC and 7PL) and intraparietal (AIP, LIPv, MIP and VIP) regions, and so is implicated in visuo-motor as well as somatosensory functions. Indeed, the combination of visual and somatosensory inputs is likely to be important for reaching with the correct shape of the hand to grasp an object, and when the object is felt that provides further information relevant to the action being performed. These regions (PFcm, and PFop) also receive inputs from the supracallosal anterior cingulate cortex, which is a region with somatosensory inputs that responds to many aversive stimuli (Rolls et al., 2023c; Grabenhorst and Rolls, 2011).

More posteriorly, and in a sense higher up the inferior parietal somatosensory hierarchy, PF (Fig. 10.1) (which receives from PFop) also has somatosensory and premotor and visuo-spatial inputs relating to 7Am and intraparietal AIP, but adds to these, beyond what is found

for earlier stages, strong effective connectivity from the posterior inferior temporal visual cortex (PHT, which is likely to introduce visual information about the shape of objects useful for performing actions on objects), from the reward-related medial orbitofrontal cortex 111 (which will provide reward-related information useful in building a semantic representation of felt objects and in influencing whether actions should be performed to obtain them), and, consistent with this concept, PF has effective connectivity directed towards language-related regions - the PeriSylvian language area (PSL), TPOJ2, STSvp (Rolls et al., 2022b), and to prefrontal cortex areas involved in short-term memory related functions IFsa and 46 (Rolls et al., 2023d). The diffusion tractography (Rolls et al., 2023d) further emphasizes connections with language-related areas 44, 45 and PSL. PF also adds extensive connectivity to dorsolateral prefrontal 46 regions, implicated in short-term memory (Goldman-Rakic, 1996; Passingham, 2021; Miller et al., 2018) (Chapter 13), and appropriate for maintaining a memory of a tactile object active during delays.

PF may on this connectivity evidence (Fig. 10.1) be the top of a somatosensory hierarchy which adds visual and reward inputs to form semantic representations of felt objects, which can then gain access to language systems, as well as having outputs to superior parietal and intraparietal areas involved in performing actions such as reaching and grasping for felt or seen objects. PF may thus build a multimodal, semantic, representation of felt objects. The PeriSylvian Language region (PSL) is very interesting, because it receives somatosensory inputs from PF, and has connections to STS semantic areas, so PSL may be a route for tactile inputs to become part of object representations (Rolls et al., 2022b). All of the somatosensory-related inferior parietal areas are conspicuous in not having effective connectivity with the posterior cingulate cortex and in having little connectivity with the hippocampal memory system.

Consistent with this connectivity, damage to the human inferior parietal cortex can result in tactile agnosia (also termed stereognosis), which is the inability to recognize objects through palpation in the absence of elementary sensory deficits (Klingner and Witte, 2018). Recognition through the visual modality is preserved, and this aspect of semantics is suggested to rely on object/semantic representations in the temporal lobe (Rolls et al., 2022b). The inferior parietal deficit can be interpreted as a failure of the associative-semantic system to match the tactile features identifying an object with its meaning (Berti et al., 2015; Berti and Neppi-Modona, 2012).

The input to PF regions (mainly to PF itself) from anterior cingulate regions including a24pr, d32, p24pr; and orbitofrontal OFC, 111 which are involved in punishment and reward (Grabenhorst and Rolls, 2011; Rolls et al., 2023c; Rolls, 2019c,e,f) deserves further consideration. It is found that the pleasantness and painfulness of touch is related to activations of the orbitofrontal cortex, whereas activations of somatosensory cortex are related to physical aspects of the stimuli such as their intensity (Rolls, O'Doherty, Kringelbach, Francis, Bowtell and McGlone, 2003d). Further evidence that the reward value of touch and related visual stimuli are not represented in parietal cortex is that 'visual fixation neurons' (Mountcastle, Lynch, Georgopoulos, Sakata and Acuna, 1975) do not reflect the reward value of visual stimuli measured by a devaluation experiment in which macaques were fed to satiety, and the neurons did not reverse the visual stimulus to which they responded when the reward value of the two stimuli was reversed in a visual discrimination task (Rolls, Perrett, Thorpe, Puerto, Roper-Hall and Maddison, 1979a). (This was tested following a visit to Vernon Mountcastle's lab in which he confirmed his view that reward value was represented by the parietal "command" neurons (Mountcastle et al., 1975).) Evidence that parietal neurons are related to decision-making (Platt and Glimcher, 1999) does not contradict the hypothesis presented above, for the decision-making need not be about reward value but could be about the physical properties of the stimuli. Evidence about the fact that a stimulus is harmful could of course be

Fig. 10.2 Effective connectivity of the human Dorsal Visual Cortical Stream which reaches (partly via V3, V3A and LO3) the MT+ complex regions (FST, LO1, LO2, LO3, MST, MT, PH, V3CD and V4t), and then the intraparietal regions (AIP, LIPd, LIPv, MIP, VIP, IP0, IP1 and IP2) and then the area 7 regions: schematic overview. Connectivity to the inferior parietal cortex region PGp, which in turn has effective connectivity to the parahippocampal scene area in PHA1-3 (Rolls et al., 2023d) is shown. Inputs to this stream from ventral stream regions such as FFC and TE2p are shown with dashed lines. (From Rolls, E.T., Deco, G., Huang, C.-C. and Feng, J. (2023) Multiple cortical visual streams in humans. *Cerebral Cortex* 33: 3319-3349. doi: 10.1093/cercor/bhac276. Copyright © Oxford University Press.)

useful in the parietal cortex to facilitate withdrawal, and about reward and punishment could be useful to provide evidence that an action has been successfully completed (or not), which could occur in the absence of a primary representation of the reward and painful affective value of touch, which appears to be in the human orbitofrontal and anterior cingulate cortex (Rolls, O’Doherty, Kringelbach, Francis, Bowtell and McGlone, 2003d; McCabe, Rolls, Bilderbeck and McGlone, 2008).

10.3 Intraparietal sulcus posterior parietal cortex, regions AIP, LIPd, LIPv, MIP, VIP, IP0, IP1, and IP2

Fig. 10.2 shows the effective connectivity of some of the human parietal cortex regions in the cortex in the intraparietal sulcus, and in area 7 (Rolls et al., 2023d,e). This figure shows the

same effective connectivity as in Fig. 3.12, but here it is emphasised that this is relevant to understanding the connectivity and functions of these posterior parietal cortex visual motion and visuo-motor regions.

As shown in Fig. 10.2, these regions in the intraparietal sulcus that respond to visual motion have strong effective connectivity from dorsal visual stream cortical regions (Chapter 3) including from several MT+ complex visual regions in which neurons respond to global optic flow (Kolster et al., 2010; Galletti and Fattori, 2018) (MST, FST, PH and V3CD), intraparietal sulcus area 1 (IPS1), V3B, V6A (which is a visuo-motor region involved in grasping seen objects (Gamberini et al., 2020)), V7, and superior parietal area 7 regions involved in visuo-motor actions. These intraparietal regions also receive in humans from ventral stream visual cortical regions including the fusiform face cortex (FFC), and inferior temporal cortex regions PIT, PHT, TE1p and TE2p (Fig. 10.2). These ventral stream regions are likely to bring shape / visual form information (Rolls, 2021d; Rolls et al., 2023e; Rolls, 2021b) to the intraparietal cortex regions important in shaping the hand to grasp and manipulate objects and tools. These intraparietal sulcus regions also have connectivity with the inferior frontal gyrus and with the dorsolateral prefrontal cortex (especially 46, 8C, a9-46, i6-8 and p9-46v), which are likely to be important when there is a delay between the visual input and when the action can be performed (Funahashi, Bruce and Goldman-Rakic, 1989). These connectivities are stronger to these prefrontal areas (Rolls et al., 2023d), as is appropriate for the operation of short-term memory systems so that the memory does not dominate sensory inputs (Rolls, 2016b, 2021b). There is also connectivity directed towards the parahippocampal TH cortex (PHA3) which may be useful in providing information about visuo-motor actions to the hippocampal memory system (Rolls et al., 2022a; Rolls, 2018b). There is also connectivity with the frontal pole p10p, which is likely to be important when sequencing and planning is involved in actions (Shallice and Cipolotti, 2018; Shallice and Burgess, 1996; Gilbert and Burgess, 2008). The connectivity from the intraparietal areas is strongly towards premotor cortical areas including especially 6a, and to the frontal eye field FEF and prefrontal eye field PEF (from especially AIP, LIPd, LIPv and VIP) (Rolls et al., 2023d) (Fig. 10.2), which provides action-related outputs from these visuo-motor intraparietal regions. There is also connectivity especially for IP1 and IP2 from the orbitofrontal cortex (medial regions, 11l and OFC) which may provide reward/no-reward feedback (Rolls, 2019e,f) of potential utility in learning whether actions made are correct, and with the frontal pole. There is also some connectivity with inferior parietal regions including PGp and PGs. Interestingly, this intraparietal part of the parietal cortex has relatively little effective connectivity with the posterior or anterior (or mid) cingulate cortex (Rolls et al., 2023d), though in the right hemisphere IP1 has effective connectivity with 31a, d23ab and POS2.

The functional connectivity is largely consistent (Rolls et al., 2023d), but indicates more interactions with early visual cortical areas; with somatosensory/premotor areas; with the hippocampal system; with TE1p and TE2p, with posterior cingulate including DVT; and with supracallosal anterior cingulate 33pr and p24pr (Rolls et al., 2023c). The diffusion tractography is also consistent, but suggests in addition connections with auditory cortex that may be useful in orienting gaze towards sounds (Rolls et al., 2023d,h).

Neurons in macaques in area VIP represent the direction and speed of visual motion (Colby, Duhamel and Goldberg, 1993), and may be useful in for example tracking moving visual stimuli, and encoding optic flow which can be useful in assessing self-motion and thereby in navigation. These neurons do not respond in relation to saccades. Neurons in macaques in LIP are active in visual, attentional and saccadic processing (Gnadt and Andersen, 1988; Colby et al., 1996; Munuera and Duhamel, 2020). The ventral part of LIP (LIPv) has strong connections with two oculomotor centres, the frontal eye field and the deep layers of the superior colliculus, and may be especially involved in the generation of saccades (Chen

et al., 2016b). The dorsal part (LIPd) may be more involved in visual processing, responding for example to visual targets for saccades (Chen et al., 2016b). Neurons in MIP (which may be the parietal reach region, PRR) are related to arm movement preparation and execution (Passarelli et al., 2021). They are implicated in the sensory-to-motor transformation required for reaching toward visually defined targets (Gamberini et al., 2020; Andersen, 1995b; Huang and Sereno, 2018; Urgen and Orban, 2021; Orban et al., 2021b).

The intraparietal cortical regions in humans thus are likely in terms of their connectivity (Rolls et al., 2023d,e) to perform visuomotor functions (without somatosensory processing unlike area 7 regions), and the extensive research on these regions in macaques provides a guide to their functions in humans, including the control of eye movements to acquire and track visual stimuli given the outputs to the Frontal Eye Fields (FEF) and Premotor Eye Fields (PEF). There are also outputs to regions 6a and 6r that might produce head and body movements to help stabilize images for the visual system. The output to the posterior inferior temporal visual cortex PHT is of interest, and might be involved in the stabilization of images for processing in later parts of the ventral visual system.

10.4 Posterior superior parietal cortex, regions 7AL, 7Am, 7PC, 7PL, and 7Pm

The connectivity of some of the area 7 regions, involved in visuo-motor functions, are shown in Fig. 10.2, and are considered here. Region 7Pm is in the medial parietal cortex and is part of the precuneus (together with the Precuneus Visual region PCV), and as it is included in the Posterior Cingulate Division of the HCP-MMP atlas (Section 1.12), it is considered in Chapter 12.

The more posterior parts of this group (7PC, 7PL) receive inputs strongly from VIP, and from LIP and MIP (Rolls et al., 2023d). 7PC and 7PL also have some inputs from early visual cortical areas including intraparietal sulcus area 1 (IPS1), V6A, MT, MST and LO3 and FST; somatosensory/premotor areas (regions 1, 2, 5 and 6); some inputs from inferior parietal PF and PG; some inputs from the posterior cingulate cortex (including DVT, the Dorsal Visual Transitional region) (Rolls et al., 2023i); from the supracallosal anterior cingulate cortex (p24pr) which has much somatosensory/motor connectivity and is involved in aversive events (Rolls et al., 2023c; Grabenhorst and Rolls, 2011); and the dorsolateral prefrontal cortex (46 and 9-46d). Interestingly, there are also inputs from ventral visual stream regions including the posterior inferior temporal cortex PHT. Thus some information about the shape of objects reaches these regions, and that may be important for the control of grasping. In turn, there is effective connectivity from the posterior regions of the superior parietal cortex to premotor cortical and somatosensory cortical areas (6, 5) and the midcingulate cortex, which in most cases is stronger from the posterior parietal cortex than to it (see Fig. 10.2) (Rolls et al., 2023d).

These area 7 regions therefore have connectivity that seems appropriate for making visually guided arm reach and grasp responses that are shaped properly because of shape inputs from the ventral visual system to seen objects. The more anterior parts of area 7 (7AL and 7Am) have more connectivity with somatosensory cortical areas (which are immediately anterior to them), and less with early visual cortical areas (Fig. 2), so may be involved more in proprioceptive and somatosensory integration than visuo-motor functions. 7Pm (which is medial) has connectivity with the nearby posterior cingulate regions DVT, POS1 and RSC, which are implicated in spatial including scene processing (Rolls et al., 2023i). This may be an interesting and telling difference in the connectivity of lateral vs medial posterior parietal area 7 regions, with the lateral regions more involved in somatomotor functions, and

the medial area 7 regions more involved in visuo-spatial functions, which would be in line with minimising connection length as a principle that influences the topology of the cerebral cortex (Rolls, 2016b). These area 7 regions also have effective connectivity directed to the hippocampal system, especially to parahippocampal gyrus TH (PHA2-3), and to the temporoparietal-occipital junction area (TPOJ2-3) (Rolls et al., 2023d).

The functional connectivity and diffusion tractography also provide evidence for some connectivity with auditory cortical areas, and this may be related to auditory cues being signals for orientation in space. They also provide further evidence (Rolls et al., 2023d) for connectivity with the posterior cingulate cortex especially the antero-dorsal part involved in visuo-spatial functions (Rolls et al., 2023i) (Chapter 12).

The area 7 parietal regions thus combine visuomotor with somatosensory functions, and the extensive research on these regions in macaques (Snyder et al., 1998; Orban et al., 2021b; Passarelli et al., 2021; Gamberini et al., 2020) provides a guide to their functions in humans, including reaching for, grasping, and manipulating objects in space and tool use. These area 7 regions are also implicated in coordinate transforms from egocentric eye-based frames to allocentric world-based frames suitable for idiothetic update of hippocampal spatial representations (Snyder et al., 1998; Rolls, 2020b, 2021f; Dean and Platt, 2006; Vedder et al., 2017; Andersen, 1995b) (see further Section 3.4). Consistent with this, vestibular as well as optic flow signals influence neurons in macaque 7a (Avila, Lakshminarasimhan, DeAngelis and Angelaki, 2019). How these coordinate transforms are performed is considered in Section 3.5.

10.5 Inferior parietal cortex, visual regions PFm, PGi, PGs and PGp

These regions are implicated in humans in a number of functions, including visual object and face motion analysis for social functions, theory of mind, and memory, and their connectivity and functions (Rolls et al., 2023d) are described in this section. The effective connectivities of two key regions, PGi and PGp, are illustrated in Figs. 10.3 and 10.4.

The PG areas and PFm, located posteriorly (Figs. 10.3 and 10.4), and compared to PF areas, have more effective connectivity with visual cortical areas and have less connectivity than the PF regions with somatosensory and premotor cortical areas. This fits with the location in the brain of the PG areas, and the importance of minimizing connection length in the brain, so that brain regions with many interconnections are found close together in the brain, where possible (Rolls, 2016b). However, the connectivity of PGi, PGs, PFm, and PGp are all quite different, suggesting different functions for each of these regions, so they are considered separately.

In this context, a key concept is that visual motion information in the intraparietal and area 7 regions can connect in part via IP1 and IP2 to regions such as PFm and PGs (green arrows in Fig. 10.3) which in turn have connectivity to PGi and thus to the visual motion regions in the cortex in the superior temporal sulcus (STS) (Rolls et al., 2023d). Support for this concept comes also from the functional connectivity and from the connections shown with diffusion tractography (Rolls et al., 2023d). The IP1 and IP2 regions may be new in humans, and in providing this connectivity may be connecting the well-developed intraparietal and area 7 systems also present in other primates to the PGs, PFm and then PGi regions of the inferior parietal cortex that are so highly developed in humans.

Fig. 10.3 Effective connectivity of region PGI (red arrows). The widths of the lines and the size of the arrowheads indicate the magnitude and direction of the effective connectivity. 7Pm and IP1 connect to PGs which in turn connects to PGI, providing a route for PGI to receive visual motion information, and to connect that to areas such as STSda, STSva, STSdp and STSvp. The green arrows show some of the ways in which visual motion information in the intraparietal and area 7 regions can connect in part by IP1 and IP2 to regions such as PFM and PGs which in turn have connectivity to PGI and thus to the STS visual motion regions. The black outline encloses the postero-ventral memory-related regions of the posterior cingulate cortex, which connect to the hippocampal system (Rolls et al., 2023i). (Modified from Rolls, E.T., Deco, G., Huang, C.-C. and Feng, J. (2023) The human posterior parietal cortex: effective connectome, and its relation to functions. *Cerebral Cortex* 33: 3142-3170. doi: 10.1093/cercor/bhac266. Copyright © Oxford University Press.)

10.5.1 Region PGi

This most inferior part of the inferior parietal lobule is closest to ventral stream areas, and has connectivity (Rolls et al., 2023d) very interestingly with object / ‘what’ brain regions including for vision the anterior inferior temporal TE1a, TE1m, TE1p, and TE2a regions; from all the superior temporal sulcus (STS) auditory - visual association / semantic areas (Section 8.4); and from the anterior temporal lobe TG semantic regions (Price et al., 2015; Bonner and Price, 2013) (Fig. 10.3). It also has connectivity with the temporo-parieto-occipital junction region TPOJ3 implicated in semantic processing, theory of mind, and social behavior (DiNicola et al., 2020; Buckner and DiNicola, 2019; Schurz et al., 2017; Quesque and Brass, 2019). TPOJ regions and PGi are activated by faces (including face expression and other socially relevant visual representations (Patel et al., 2019)) vs other visual stimuli, as are the TE1a and superior temporal sulcus (STS) regions that have effective connectivity with PGi (Yokoyama, Autio, Ikeda, Sallet, Mars, Van Essen, Glasser, Sadato and Hayashi, 2021). It is important to recognise that regions in the STS include not only auditory responsiveness dorsally, but in much of the STS visual responsiveness, so STS regions should not be considered as only ‘auditory association cortex’. Indeed, it was discovered that single neurons in the macaque STS respond to face expression and also to face and head movement to encode the social relevance of stimuli (Hasselmo, Rolls, Baylis and Nalwa, 1989b; Hasselmo, Rolls and Baylis, 1989a; Robin, Hirshhorn, Rosenbaum, Winocur, Moscovitch and Grady, 2015). For example, a neuron might respond to closing of the eyes, or to turning of the head away from facing the viewer, both of which break social contact (Hasselmo et al., 1989b,a). Some neurons respond to the direction of gaze (Perrett et al., 1987). It was assumed that some of the movement-related information required to account for the neuronal responses in the cortex in the STS came from the dorsal visual stream and could be combined in the STS with ventral stream information about the identity of the faces. It was found that many of the neurons in the STS respond only or much better to moving faces or objects (Hasselmo, Rolls and Baylis, 1989a), whereas in the anterior inferior temporal cortex neurons were discovered that responded well to static visual stimuli, and were tuned for face identity (Perrett, Rolls and Caan, 1982; Rolls, 1984, 2000a; Rolls and Treves, 2011; Rolls, Treves, Tovee and Panzeri, 1997d; Rolls, Treves and Tovee, 1997b; Hasselmo, Rolls and Baylis, 1989a).

It is now proposed that PGi, with its inputs from PGs which has connectivity with superior parietal and intraparietal regions that encode visual motion, is part of this processing stream for socially relevant face-related information. Consistent with this, PGi, and some temporo-parieto-occipital regions, are activated by faces (Yokoyama et al., 2021). Also consistent with this proposal, the effective connectivity is strong from PGi to STS regions, though there is some effective connectivity also from PGs and PFm to STS regions (Fig. 10.3). In humans, representations of this type could provide part of the basis for the development of systems to interpret the social and emotional significance of such stimuli, including theory of mind. Consistent with this, PGi and PGs receive inputs from PCV (the precuneus visual area) and 7m which are regions of medial parietal cortex related to the precuneus (Rolls et al., 2023i), which is implicated in visual and self-referential processing (Cavanna and Trimble, 2006; Freton, Lemogne, Bergouignan, Delaveau, Lehericy and Fossati, 2014). Connectivity with the pregenual reward-related anterior cingulate cortex introduces reward value into this region, potentially useful in forming semantic including social representations of objects and faces. Very interestingly, there is also connectivity with the postero-ventral parts of the posterior cingulate cortex (31pd, 31pv, 7m, d23ab, v23ab) that are implicated in episodic memory (Rolls et al., 2023i), and with the hippocampal system (parahippocampal TF) and PGi is thus likely to be involved in the memory-related functions of the inferior parietal cortex (Davis et al., 2018). Consistent with this, the functional connectivity reveals some interactions with the

hippocampal system (hippocampus, entorhinal cortex, parahippocampal TF and TH (PHA1-3)) (Rolls et al., 2023d). The tractography provides some evidence for connections with the Peri-Sylvian Language area (PSL), and with Broca's area region 44 (Rolls et al., 2023d). PGI also has very extensive connectivity with dorsolateral prefrontal cortex regions (8BL, 8Ad, 8Av, 9a, 9b, s6-8) implicated in short-term memory (Fig. 10.3).

10.5.2 Region PGs

PGs is posterior to PGI (and therefore closer to visual cortical areas), and is superior to PGI (Fig. 10.3). In contrast to PGI, PGs has connectivity with visuo-motor areas that are intraparietal (IP1) and in area 7 (e.g. 7Pm), but it does also (as PGI) have connectivity with object areas such as the visual inferior temporal cortex (TE1a, TE1m, TE1p) (Fig. 10.3). PGs also has connectivity with the Frontal pole (10d, p10p), regions implicated in planning and sequencing (Shallice and Cipolotti, 2018; Shallice and Burgess, 1996; Gilbert and Burgess, 2008) and prospective as well as retrospective memory especially about the self (Underwood et al., 2015). It also has connectivity with the postero-ventral (7m, 31pd, 31pv, d23ab, d23ab) part of the posterior cingulate cortex, which has effective connectivity to the hippocampal episodic memory system (Rolls et al., 2023i), and connectivity directly to the hippocampal memory system (hippocampus, entorhinal cortex, presubiculum, and parahippocampal PHA2), to PF and PGI, and with the dorsolateral prefrontal cortex. The functional connectivity provides an indication in addition of some interactions with STS regions, and the tractography is consistent with this and with some connections with TPOJ regions (Rolls et al., 2023d). The effective connectivity from PGs to PGI may provide PGI with visual motion information, where it can be combined with object and face information. PGI in turn has connectivity to STS regions (Fig. 10.3), and may provide a route for dorsal visual stream information to reach the STS areas where neurons often respond primarily to moving faces, heads, or objects (Hasselmo, Rolls, Baylis and Nalwa, 1989b; Hasselmo, Rolls and Baylis, 1989a). Consistent with this, PGI does have strong effective connectivity to STSda, STSdp, STSva and STSvp (Rolls et al., 2023d).

10.5.3 Region PFM

PFM is not a somatosensory area (unlike other PF areas). PFM receives from high order visual (TE1m, TE1p, TE2a) and visual / auditory (STSvp) areas that represent objects and faces and (for the STS) their motion and face expression (Hasselmo, Rolls and Baylis, 1989a). It has some intraparietal visuo-motor inputs (IP1 and IP2), and has connectivity with the visuo-motor (dorsal / anterior) parts of the posterior cingulate cortex (23d, 31a) and not the memory related parts; it also receives from the frontal pole (a10p, p10p and 10pp); and it has effective connectivity with the reward related regions (orbitofrontal cortex region OFC and pregenual anterior cingulate d32) and punishment-related orbitofrontal cortex a47r (Grabenhorst and Rolls, 2011; Rolls et al., 2023c). PFM thus appears to be a part of the parietal cortex that communicates with the visuo-spatial part of the posterior cingulate cortex (Rolls et al., 2023i), and could thereby reach the hippocampus for visuo-spatial functions. In particular, the retrosplenial complex in the posterior cingulate cortex visuo-spatial part is especially important with respect to the location of landmarks (Persichetti and Dilks, 2019) (Chapter 12); and posterior cingulate area 31 is implicated by neuroimaging in representing heading direction (Baumann and Mattingley, 2021). A small region in the parieto-occipital sulcus (POS) that has been considered in connection with the posterior cingulate cortex (Rolls et al., 2023i) has also been described as in the medial parietal cortex directly anterior to the visually scene-selective medial place area (Silson et al., 2016), and has strong functional connectivity with

anterior portions of the scene-selective parahippocampal place area (Epstein, 2008) (aPPA), located in the medial temporal cortex. This connectivity-defined region overlaps with regions of the medial parietal cortex engaged during memory recall, and there may be distinct regions for people and places (Silson et al., 2019). PFm has extensive connectivity with the dorso-lateral and inferolateral prefrontal cortex regions, and is likely to be involved in short-term memory, which plays a key role in top-down attention by providing the continuing top-down bias for biased competition in the cortical regions linked to these prefrontal cortical areas enabling attentional interactions between the spatial and object streams (Rolls, 2016b, 2021b; Deco and Rolls, 2005b,a).

PFm thus appears to combine visual motion with temporal lobe object / face information, and has connectivity with posterior cingulate areas involved in scene (/place) processing. It also has connectivity with language-related areas (Broca's area 44).

10.5.4 Region PGp

PGp is a far posterior part of PG (Fig. 10.4), and it has effective connectivity (Rolls et al., 2023d) with some early visual cortical areas related to scene processing (e.g. VMV2 and LO3) (Sulpizio et al., 2020; Rolls et al., 2022a; Kamps et al., 2016); and with intraparietal (e.g. MIP, VIP, IP0) and superior parietal 7 (e.g. 7Pm, 7PL) visuo-motor regions, both of which distinguish PGp from PGI and PGs and PFm (Fig. 10.4). However, PGp also has connectivity to parahippocampal TH areas PHA1-3 and with posterior cingulate DVT and ProS, all of which with VMV areas are implicated in visual scene processing (Rolls et al., 2023i, 2022a; Sulpizio et al., 2020) (Fig. 9.18). Functional connectivity between PGp in the human angular gyrus and the parahippocampal scene area, hippocampus, and retrosplenial complex (Boccia et al., 2017) is consistent with and supports what is described here and elsewhere (Rolls et al., 2023i). PGp also has connectivity with TPOJ3 and TE2p, and has no connectivity with the orbitofrontal cortex, or with prefrontal areas involved in short-term memory. The functional connectivity provides evidence for, in addition, interactions with early visual cortical regions including other VMV regions, and with more intraparietal and area 7 regions, and the diffusion tractography provides additional indications of this (Rolls et al., 2023d).

The connectivity of PGp, because it has connectivities with scene and egomotion regions, and with the parahippocampal cortex in which spatial view cells are found (Rolls and Wirth, 2018; Georges-François et al., 1999; Rolls et al., 1998b; Robertson et al., 1998; Rolls et al., 1997a; Tsitsiklis et al., 2020; Wirth et al., 2017; Rolls, 2023c), implicates PGp in navigation (Rolls, 2020b, 2021f, 2023c). PGp may be involved together with its connected intraparietal regions in the coordinate transforms necessary to map from retinal inputs to scenes which require representations of these types (Rolls, 2020b, 2021f) (see further Sections 3.4 and 3.5).

It is thus proposed that PGp provides a route for visuo-spatial parietal cortex regions involved in spatial coordinate transforms (Snyder et al., 1998; Rolls, 2020b) (see further Sections 3.4 and 3.5) to provide the hippocampal system with information useful in the idiothetic (self-motion) update of hippocampal spatial view representations of allocentric space (Robertson et al., 1998; Rolls, 2021f; Rolls and Wirth, 2018; Wirth et al., 2017; Rolls, 2023c, 2022b). Consistent with this, PGp also receives from visual scene-related areas (Sulpizio et al., 2020) DVT and ventromedial visual cortex (VMV2) (Fig. 10.4).

Supporting evidence is that the caudal inferior parietal lobule (cIPL, which includes PGp) has functional connectivity with the anterior part of the parahippocampal place (or scene) area (Baldassano et al., 2016), and although not strongly responsive to standard scene localizers showing sequences of unfamiliar and unrelated scene images (Baldassano et al., 2016; Sulpizio et al., 2020), cIPL is activated by familiar places. For example, cIPL is involved in

Fig. 10.4 Effective connectivity of region PGp. The widths of the lines and the size of the arrowheads indicate the magnitude and direction of the effective connectivity. PGp has effective connectivity from area 7 and intraparietal regions, and has effective connectivity directed to parahippocampal TH (PHA1-3). It is proposed that this provides a route for visuo-spatial parietal cortex regions involved in spatial coordinate transforms to provide the hippocampal system with information useful in the idiothetic (self-motion) update of hippocampal spatial representations of allocentric space. Consistent with this, PGp also receives from visual scene-related areas DVT (part of the retrosplenial scene area (Sulpizio et al., 2020)) and ventromedial visual cortex (VMV2). (From Rolls, E.T., Deco, G., Huang, C.-C. and Feng, J. (2023) The human posterior parietal cortex: effective connectome, and its relation to functions. *Cerebral Cortex* 33: 3142-3170. doi: 10.1093/cercor/bhac266. Copyright © Oxford University Press.)

memory for visual scenes (Montaldi et al., 2006; Takashima et al., 2006; Elman et al., 2013; van Assche et al., 2016), object-place associations in a virtual reality environment (Burgess et al., 2001), and imagining past events or future events in familiar places (Hassabis et al., 2007; Szpunar et al., 2009).

10.6 Navigation: What computations are performed in the parietal and related cortex

The hippocampus plays an important role in episodic memory, as described in Chapter 9. Key components of the episodic memories implemented by the hippocampus include spatial locations, and/or time. Given that spatial processing is an important component of what computations are performed by the hippocampus, it has been implicated in the important spatial function of navigation, especially by research in rodents (O'Keefe, 1991; Burgess and O'Keefe, 1996; Buzsaki and Moser, 2013; Aronov and Tank, 2014) (see Chapter 9).

The situation is not as clear in humans, in which some of the evidence indicates that the hippocampus is involved in navigation when recent memories are required for the navigation, but is less involved when navigation is being performed when the spatial information is well known, and does not need to be memorized (Maguire et al., 2016; Rolls and Wirth, 2018). An implication is that some of the key computations involved in navigation may take place in the neocortex, in areas that include and are connected to parietal cortex areas, and not in the hippocampus. The role of the hippocampus in navigation in humans may be to store new information, which of course may be needed if the navigation is in a novel environment. Evidence on this is considered next.

Lesions to the human neocortex can produce topographical agnosia and inability to navigate (Kolb and Whishaw, 2021; Barton, 2011), and the retrosplenial cortex is implicated in navigation (Vedder et al., 2017; Alexander and Nitz, 2015; Byrne et al., 2007; Epstein, 2008; Vann et al., 2009). In more detail, lesions restricted to the hippocampus in humans result only in slight navigation impairments in familiar environments, but rather strongly impair learning or imagining new trajectories (Bohbot and Corkin, 2007; Teng and Squire, 1999; Spiers and Maguire, 2006; Maguire et al., 2016; Clark and Maguire, 2016). In contrast, lesions in regions such as the parietal cortex or the retrosplenial cortex produce strong topographical disorientation in both familiar and new environments (Aguirre and D'Esposito, 1999; Habib and Sirigu, 1987; Takahashi, Kawamura, Shiota, Kasahata and Hirayama, 1997; Maguire, 2001; Kim, Aminoff, Kastner and Behrmann, 2015b). This suggests that some of the core navigation processes (which may include transformations from allocentric representations to egocentric motor commands) are performed independently by neocortical areas outside the hippocampus, which may utilize hippocampal information related to recent memories (Ekstrom et al., 2014; Miller et al., 2013).

It was suggested in Chapter 3 that the dorsal visual system with its coordinate transforms to what may be allocentric bearing and spatial view coordinates provides a useful input to the hippocampal system via the parahippocampal gyrus (see Fig. 9.1) for idiothetic (self-motion) update of hippocampal spatial representations related to where one is currently looking in allocentric space, in for example the dark. Given the role of the entorhinal cortex grid cell system in idiothetic update of place, at least in rodents (see Chapter 9), it may be that the hippocampus receives its idiothetic update for place from the entorhinal cortex system. However, in primates including humans the idiothetic updates required to perform the coordinate transforms from retinal to head-centred coordinates, from head-centred to allocentric bearings to landmarks, and to allocentric representations of spatial view, are performed in the dorsal visual system and its extensions into the parietal cortex, as described in Sections 3.4

and 3.5, in Chapter 3, and using in part pathways in the posterior cingulate cortex, retrosplenial regions, and medial parietal cortex (Chapter 12) (Fig. 9.1).

10.7 How the computations are performed in the parietal cortex

Key computations performed in the parietal cortex include coordinate transforms. Some of these involve the coordinate transforms just described from retinal representations to allocentric spatial view representations (Section 3.4). Other coordinate transforms are needed for controlling arm movements to reach for and grasp objects in peripersonal space. The principles of how transforms of these types may be performed are described in Section 3.5.

Hierarchical organisation is another key computational process evident in the parietal lobe as well as elsewhere. One example of the somatosensory hierarchy to reach region PF, which appears to be at the top of the somatosensory ‘what’ hierarchy for representing what object is being touched, and to represent the body image.

Another example is the hierarchy from MT+ regions to intraparietal regions involved in visual motion analysis, and in the control of eye movements such as saccades and visual tracking. That hierarchy continues to the area 7 regions where somatosensory information is combined with visual information to perform the computations required to reach for and grasp objects and to manipulate them.

Another parietal hierarchy is that involving visual regions such as PFm, PGs and PGI, in which visual representation of motion are combined with ventral visual stream information about what object is present to produce representations that appear to involve combinations of object ‘what’ and motion information. Indeed, it is quite remarkable how these inferior parietal cortex regions, which develop so greatly in humans, are connected to inferior temporal cortex including TE regions involved in representing objects, and to regions in the cortex in the superior temporal sulcus (STS) that represent movements of objects, faces, and bodies that are likely to be produced in these parietal cortex visual regions.

Another aspect of the parietal hierarchy is that regions such as PGI provide information about moving objects, faces and bodies, and PF provides information from the somatosensory system about felt objects and about body image, to the semantic systems involved in language which include the whole suite of regions from PGI and probably PF through the temporo-parieto-occipital junction TPOJ regions to the superior temporal sulcus STS regions and the temporal pole, as described in Chapter 14.

Another principle of cortical computation evident in the parietal cortex as well as elsewhere is that after a hierarchy of mainly unimodal processing, information is then combined from different modalities to form multimodal representations.

One example is that in the parietal somatosensory ‘what’ hierarchy, it is especially in PF at the top of the hierarchy that ‘what’ visual information from the inferior temporal cortical regions is introduced to form multimodal representations.

Another example is that in the inferior parietal visual areas PFm, PGs and PGI, it is especially in PGI at the top of this hierarchy which receives visual motion information from intraparietal and area 7 regions that this information is combined with visual object ‘what’ information from the visual inferior temporal cortex.

Another example is that it is especially the information in these multimodal areas that has connectivity into the semantic systems for language that have just been referred to and are described in Chapters 8 and 14.

11 The orbitofrontal cortex, amygdala, reward value, emotion, and decision-making

11.1 Introduction and overview

11.1.1 Introduction

The orbitofrontal cortex receives from the ends of all sensory processing systems, and converts these representations of what the stimuli are into representations of their reward value (Fig. 11.1 and 4.2). The orbitofrontal cortex is therefore a key brain region in emotions, which can be defined as states elicited by rewards and punishers (Rolls, 2000e, 2014a, 2023b). Indeed, orbitofrontal cortex activations are linearly related to the subjectively reported pleasantness (or unpleasantness) of stimuli.

The orbitofrontal cortex then projects this reward value information to other structures, which implement behavioral output. One output region is the anterior cingulate cortex, which learns actions to obtain the reward outcomes signalled by the orbitofrontal cortex (see Chapter 12).

Another output region is the basal ganglia, which learn stimulus-response associations where a stimulus is linked directly to a response to produce a habit. This type of reinforcement learning may benefit from projections of reward and non-reward information from the orbitofrontal cortex to the dopamine neurons in the midbrain, which help with such stimulus-response habit learning by relaying a reward prediction error signal to the basal ganglia and some other brain regions.

The Orbitofrontal Cortex (Rolls, 2019e) provides a description of the functions of the orbitofrontal cortex, and as that is available, this Chapter focuses particularly on computational aspects, especially what is computed in the orbitofrontal cortex, and how it is computed.

11.1.2 Overview of what is computed in the orbitofrontal cortex

1. The orbitofrontal cortex is the first stage of processing to represent reward value. A representation of value is shown by rapid (one-trial) reversal of visual responses to stimuli when the reward value is reversed, and by a decrease to zero of the responses of orbitofrontal cortex neurons when the stimulus is devalued. The reward value is that of each particular stimulus, as shown by the discovery that sensory-specific satiety is computed in the orbitofrontal cortex. This systems-level organisation of reward value is not the case in rodents, which have a much less developed orbitofrontal cortex than in primates including humans, and in which value appears to be represented much earlier in processing hierarchies. Indeed, most of the evidence described in this Chapter, and in this book, is about the operation of brain systems in primates including humans, because the systems-level functional organisation of most brain systems is so different in rodents, as set out in Section 19.10.

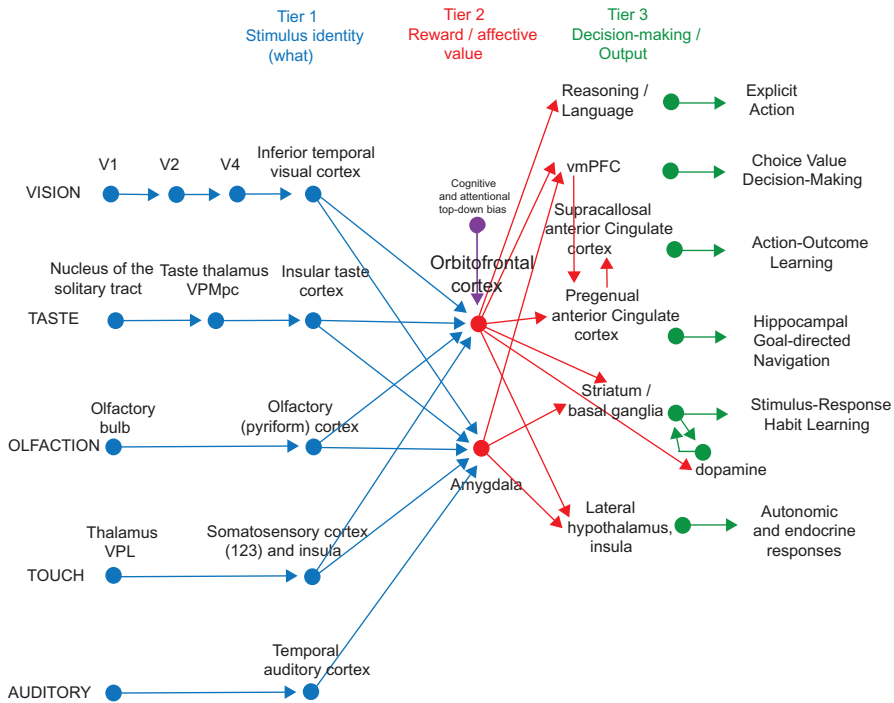

Fig. 11.1 The systems level organization of the brain for emotion in primates including humans. In Tier 1, representations are built of visual, taste, olfactory and tactile stimuli that are independent of reward value and therefore of emotion. In Tier 2, reward value and emotion are represented. A pathway for top-down attentional and cognitive modulation of emotion is shown in purple. In Tier 3 actions are learned in the supracallosal (or dorsal) anterior cingulate cortex to obtain the reward values signaled by the orbitofrontal cortex and amygdala that are relayed in part via the pregenual anterior cingulate cortex and vmPFC. Decisions between stimuli of different reward value can be taken in the ventromedial prefrontal cortex, vmPFC. In Tier 3, orbitofrontal cortex inputs to the reasoning / language systems enable affective value to be incorporated and reported. In Tier 3, stimulus-response habits can also be produced using reinforcement learning. In Tier 3 autonomic responses can also be produced to emotion-provoking stimuli. Auditory inputs also reach the amygdala. V1: primary visual (striate) cortex; V2 and V4: further cortical visual areas. PFC: prefrontal cortex. The Medial PFC area 10 is part of the ventromedial prefrontal cortex (vmPFC). VPL: ventro-postero-lateral nucleus of the thalamus, which conveys somatosensory information to the primary somatosensory cortex (areas 1, 2 and 3). VPMpc: ventro-postero-medial nucleus pars parvocellularis of the thalamus, which conveys taste information to the primary taste cortex.

2. The orbitofrontal cortex represents the expected value, outcome value, and negative reward prediction error for particular stimuli.
3. The orbitofrontal cortex represents neuroeconomic value: the representations reflect for example the quantity available, the probability, and the reward value of each good.
4. The orbitofrontal cortex is involved in reward value and emotional experience, in that activations in the orbitofrontal cortex are often linearly related to the conscious subjective pleasantness (or unpleasantness) of stimuli. Connectivity from the orbitofrontal cortex to language regions is likely to be involved in declarative reports about subjective emotional state (Rolls et al., 2023b).
5. The orbitofrontal cortex is involved in social and emotional behavior, in that face expression and face identity are both represented in the orbitofrontal cortex, and in that social and emotional behavior are severely impaired by damage to the human orbitofrontal cortex.
6. A key computational capacity of the orbitofrontal cortex is one-trial object-reward associations, which are rule-based. This enables very rapid changes in behavior when the current reinforcement contingencies change, and this is very likely to be important in primate

- social behavior, in which rapid sensitivity to social / rewarding feedback can be very important. This type of one-trial rule-based reversal learning appears not to occur in rodents.
7. Negative reward prediction error (nRPE) is represented by primate orbitofrontal cortex neurons that increase their firing rates when an expected reward is not obtained. The nRPE neurons may be important in changing reward behavior when expected rewards are no longer obtained, in for example one-trial reward reversal.
 8. The orbitofrontal cortex provides a common scale for the reward value for different rewards, but does not convert to a common currency. A common scale is important for the inputs to decision-making networks. Conversion to a common currency would not be adaptive, because the decision-making system needs to keep the particular reward that has won in the competition active, while goal-directed action is performed to obtain the reward. A common currency would not specify the winning reward and goal for action. The dopamine system in contrast may use a common currency for its reinforcement learning of stimulus-response habits.
 9. Relative and absolute value are both represented in the orbitofrontal cortex. Absolute value is important for consistent long-term choice and transitive preferences. Relative value is useful for short-term choice, for example on a particular trial or a block of trials.
 10. Top-down cognition and attention, even from the level of language, exert effects on the orbitofrontal cortex, and bias its representations of value.
 11. Decision-making about value is represented in the ventromedial prefrontal cortex, VMPFC. Whereas much of the orbitofrontal cortex represents value on a continuous scale, in a more anterior part which may be part of medial prefrontal cortex area 10 and which may be described as the ventromedial prefrontal cortex, decisions are made between stimuli of different reward value.
 12. The orbitofrontal cortex plays a key role in emotion, which can be defined as states elicited by rewards and punishers, which are what is represented in the orbitofrontal cortex.
 13. The orbitofrontal cortex does not represent actions or behavioral responses: the orbitofrontal cortex contains representations of sensory stimuli in terms of their reward value. It sends this information to the anterior cingulate cortex which learns actions to obtain rewarding outcomes signalled by the orbitofrontal cortex; and to the striatum which interfaces stimuli to responses, using reinforcement information provided in part by the dopamine neurons which receive inputs from the orbitofrontal cortex.
 14. Reward value information is also sent from the orbitofrontal cortex to the hippocampus, where reward and emotional value can become part of an episodic memory. In addition, the reward value component of an episodic memory may influence how often it is retrieved and processes that are then involved in memory consolidation.
 15. The pOFC region of the human medial orbitofrontal cortex has effective connectivity to the basal forebrain cholinergic nucleus of Meynert, which in turn provides the cholinergic input to the neocortex. This is likely to provide a key route that enables value representations decoded in the orbitofrontal cortex to influence memory consolidation.
 16. Region OFC of the human medial orbitofrontal cortex has effective connectivity directed towards the substantia nigra pars compacta (SNpc) and ventral tegmental area (VTA), which contain dopaminergic neurons, and this is a key way in which, in part via the ventral striatum and habenula, reward information can reach dopamine neurons to enable their representation of reward prediction error.
 17. The amygdala in humans has effective connectivity from anterior temporal lobe regions, has little backprojection to the cortex, and overall has much less cortical connectivity than the orbitofrontal cortex. Damage to the amygdala in humans has much smaller effects than damage to the orbitofrontal cortex on reported emotion, and may be involved in

Fig. 11.2 The orbitofrontal cortex forms the ventral (lower) part of the frontal lobes of the primate (illustrated) including human brain. This diagram shows some of the gustatory, olfactory, visual, and auditory pathways to the orbitofrontal cortex, and some of the outputs of the orbitofrontal cortex. The secondary taste cortex and the secondary olfactory cortex are within the orbitofrontal cortex. The medial orbitofrontal cortex (areas 13 and 11) is shaded green, and the lateral orbitofrontal cortex (area 12) is shaded red. V1, primary visual cortex. V4, visual cortical area V4. Abbreviations: as, arcuate sulcus; cc, corpus callosum; cf, calcarine fissure; cgs, cingulate sulcus; cs, central sulcus; ls, lunate sulcus; ios, inferior occipital sulcus; mos, medial orbital sulcus; os, orbital sulcus; ots, occipito-temporal sulcus; ps, principal sulcus; rhs, rhinal sulcus; sts, superior temporal sulcus; the Sylvian (or lateral) fissure has been opened to reveal the insula; TA (22), superior temporal auditory association cortex; TF and TH, parahippocampal cortex; TG, temporal pole cortex; 3,1,2, somatosensory cortex; 4, motor cortex; 6, premotor cortex; 14, gyrus rectus; 28, entorhinal cortex; 51, olfactory (prepyriform and periamygdaloid) cortex. (From Rolls, E. T. (2019) *The Orbitofrontal Cortex*. Oxford University Press: Oxford.)

humans as in rodents more in autonomic and related behavioral responses such as freezing implemented via brainstem outputs.

11.1.3 Overview of how the computations are performed by the orbitofrontal cortex

1. Some stimuli, such as food and water, have their reward value modulated in the orbitofrontal cortex by internal homeostatic signals, such as gastric distension, and the effects of absorbed nutrients and water. One route for these satiety signals to reach the orbitofrontal cortex is via the visceral insula. This is part of the mechanism that influences the reward value of a number of stimuli in the orbitofrontal cortex.
2. Sensory-specific satiety, a key process by which the reward value of a particular reward that is being received diminishes over time, is implemented in the orbitofrontal cortex using it is suggested temporal adaptation of the synapses transmitting information to

orbitofrontal cortex neurons. This is a key process with a time course of minutes or more that ensures that animals switch occasionally to different rewards, which is evolutionarily adaptive. Sensory-specific decreases in activity are not a property of orbitofrontal cortex neurons that respond to aversive stimuli, which again is evolutionarily adaptive.

3. The learning of associations between visual and other stimuli and primary reinforcers (such as taste or pleasant touch or pain) can be implemented by pattern association learning.
4. An attractor network mechanism for the computation involved in generating non-reward (negative reward prediction error, nRPE) neurons in the orbitofrontal cortex is described.
5. The one-trial rule-based reversal of orbitofrontal cortex neurons is non-associative, and requires a short-term memory network to hold online which stimuli are currently associated with rewards. Neural network models of this computation are described, and utilise a non-reward (negative reward prediction error) signal to initiate the reversal of the rule attractor network.
6. Part of how the computations work in this system must be that the systems such as the anterior cingulate cortex that receive inputs from the orbitofrontal cortex must be organized to learn actions that will promote behavior to work for the stimuli when the reward neurons are firing, and to work to escape from or avoid the stimuli if neurons that respond to aversive stimuli are active.
7. Evidence that decisions between different rewards are taken in the anterior orbitofrontal cortex / VMPFC by attractor networks in which the decision variables compete to win is described. Decision-making attractor networks, which are probably implemented in a number of different cortical areas for different types of decision, are described, with an integrate-and-fire model analyzed. These attractor decision-making networks are probabilistic, because they are influenced by the almost Poisson (random) spiking times for a given mean firing rate of the neurons in the network. The confidence in the decision can be read out from these networks by the final firing rate, which reflects the difference between the decision variables. The attractor network can maintain its decision to act as a goal for behavior because of the positive feedback within the network.

11.2 The topology and connections of the orbitofrontal cortex

The orbitofrontal cortex is on the lower (ventral) surface of the frontal lobes. The topology and many connections of the orbitofrontal cortex are shown in Fig. 11.2. The term **medial orbitofrontal cortex** refers to areas 13 and 11 shown in Figs. 11.2 and 11.3, and **lateral orbitofrontal cortex** refers to area 12 (12/47 in humans) (Rolls, 2019e; Rolls, Cheng and Feng, 2020a). The medial orbitofrontal cortex in humans tends to represent rewards, and the lateral orbitofrontal cortex punishers (Rolls, 2019e; Rolls et al., 2020a). Also shown in Fig. 11.3 on the medial view (above) is the anterior cingulate cortex areas 24 and 32. On the medial view of the human brain (left), areas 14r (the gyrus rectus) and 10m and 10r can be described as the ventromedial prefrontal cortex. Fig. 11.3 also shows that the macaque orbitofrontal cortex has relatively similar areas to humans, but the rodent appears to have no granular orbitofrontal cortex (Wise, 2008; Passingham and Wise, 2012; Rolls, 2019e; Passingham, 2021) (see Section 19.10). (Granular cortex, light gray or colored in Fig. 11.3, has small cells in layer 4 that give it a granular appearance, and cytoarchitectural differences such as this, as well as differences of the connections, are what make the primate including human orbitofrontal cortex appear different to what is present in rodents.)

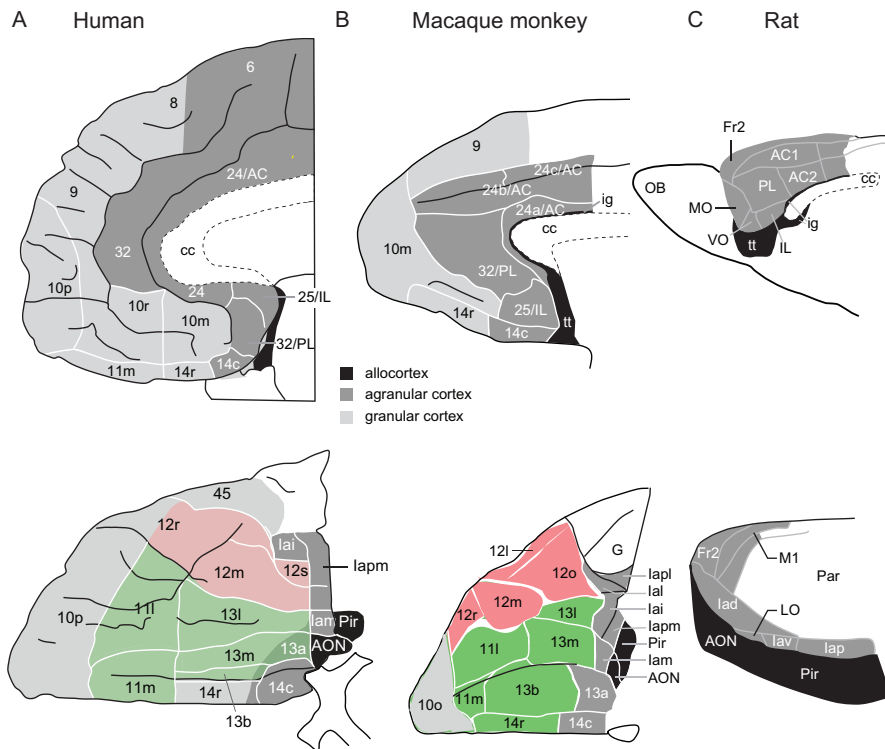

Fig. 11.3 Comparison of the orbitofrontal (below) and medial prefrontal (above) cortical areas in humans, macaque monkeys, and rats. (A) Medial (top) and orbital (bottom) areas of the human frontal cortex (Ongur et al. 2003). The medial orbitofrontal cortex is shown in green (areas 13 and 11), and the lateral orbitofrontal cortex in red (area 12). Almost all of the human orbitofrontal cortex except area 13a is granular. Agranular cortex is shown in dark grey. The part of area 45 shown is the orbital part of the inferior frontal gyrus pars triangularis. (B) Medial (top) and orbital (bottom) areas of the macaque frontal cortex (Carmichael and Price 1994). (C) Medial (top) and lateral (bottom) areas of rat frontal cortex (Palomero-Gallagher and Zilles 2004). Rostral is to the left in all drawings. Top row: dorsal is up in all drawings. Bottom row: in (A) and (B), lateral is up; in (C), dorsal is up. Not to scale. Abbreviations: AC, anterior cingulate cortex; AON, anterior olfactory 'nucleus'; cc, corpus callosum; Fr2 second frontal area; la, agranular insular cortex; ig, induseum griseum; IL, infralimbic cortex; LO, lateral orbital cortex; MO, medial orbital cortex; OB, olfactory bulb; Pir, piriform (olfactory) cortex; PL, prelimbic cortex; tt, tenia tecta; VO, ventral orbital cortex; Subdivisions of areas are labelled caudal (c); inferior (i), lateral (l), medial (m); orbital (o), posterior or polar (p), rostral(r), or by arbitrary designation (a, b). 11.2.1 Inputs to the orbitofrontal cortex

Some of the connections of the orbitofrontal cortex (Price, 2006; Ongur and Price, 2000) are shown in Figs. 11.1, 11.2, and 11.4. A brief summary will be provided here, with citations of many of the original papers available (Rolls, 2019f,e). Although much of the literature is based on tract tracing in macaques, consistent data are now becoming available from humans in studies using functional connectivity (in which correlations between the signal in different brain regions are used to infer connectivity, even if some of it may be trans-synaptic (Du, Rolls, Cheng, Li, Gong, Qiu and Feng, 2020; Rolls, Deco, Huang and Feng, 2023c), from diffusion tensor neuroimaging which can show direct connections (Hsu, Rolls, Huang, Chong, Lo, Feng and Lin, 2020; Rolls, Deco, Huang and Feng, 2023c), and from effective connectivity which can show the strength in both directions of the connectivity, and which can

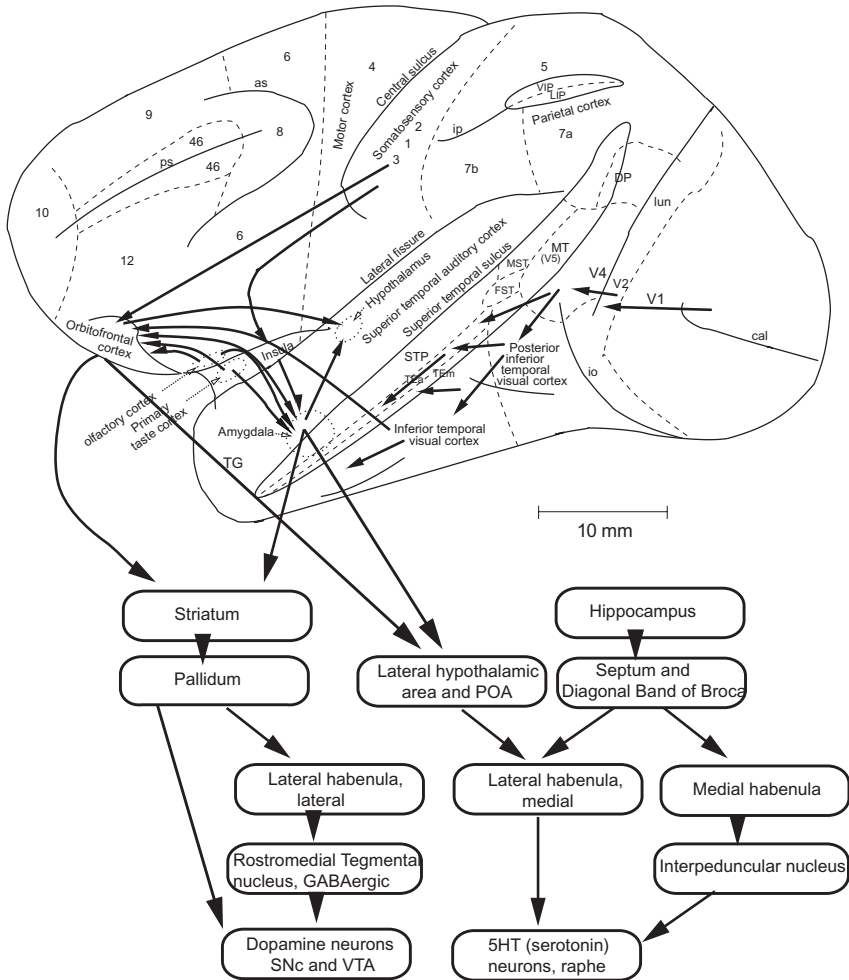

Fig. 11.4 Possible routes for reward and non-reward related information from the primate orbitofrontal cortex and amygdala to reach the brainstem dopamine and serotonin (5-HT) neurons (see text). One route is via the ventral striatum and ventral pallidum. A second route is via the ventral striatum, ventral pallidum, lateral habenula, and rostromedial tegmental nucleus. as, arcuate sulcus; cal, calcarine sulcus; cs, central sulcus; lf, lateral (or Sylvian) fissure; lun, lunate sulcus; ps, principal sulcus; io, inferior occipital sulcus; ip, intraparietal sulcus (which has been opened to reveal some of the areas it contains); sts, superior temporal sulcus (which has been opened to reveal some of the areas it contains). AIT, anterior inferior temporal cortex; FST, visual motion processing area; LIP, lateral intraparietal area; MST, visual motion processing area; MT, visual motion processing area (also called V5); PIT, posterior inferior temporal cortex; POA, preoptic area; SNc, substantia nigra pars compacta; STP, superior temporal plane; TA, architectonic area including auditory association cortex; TE, architectonic area including high order visual association cortex, and some of its subareas TEa and TEm; TG, architectonic area in the temporal pole; V1–V4, visual areas V1–V4; VIP, ventral intraparietal area; TEO, architectonic area including posterior visual association cortex; VTA, ventral tegmental area. The numerals refer to architectonic areas, and have the following approximate functional equivalence: 1,2,3, somatosensory cortex (posterior to the central sulcus); 4, motor cortex; 5, superior parietal lobule; 7a, inferior parietal lobule, visual part; 7b, inferior parietal lobule, somatosensory part; 6, lateral premotor cortex; 8, frontal eye field; 12, part of orbitofrontal cortex; 46, dorsolateral prefrontal cortex. (Modified from Rolls, E. T. (2017) The roles of the orbitofrontal cortex via the habenula in non-reward and depression, and in the responses of serotonin and dopamine neurons. *Neuroscience and Biobehavioral Reviews* 75: 331–334. © Elsevier Ltd.)

be described as causal, partly in the sense that it provides a generative model for functional connectivity (Rolls et al., 2023c). Evidence on the connectivity of the orbitofrontal cortex in humans (Rolls et al., 2023c) is described in Section 11.3.10.

Taste inputs reach the orbitofrontal cortex from the insular primary taste cortex (Baylis, Rolls and Baylis, 1995).

Olfactory inputs reach the orbitofrontal cortex from the pyriform, primary olfactory, cortex (Carmichael et al., 1994).

Somatosensory inputs reach the orbitofrontal cortex from somatosensory cortical areas 1, 2 and SII in the frontal and pericentral operculum, and from the somatosensory insula (Barbas, 1988; Preuss and Goldman-Rakic, 1989; Morecraft et al., 1992; Carmichael and Price, 1995b; Saleem et al., 2008).

Visceral inputs may reach the posteromedial and lateral areas of the orbitofrontal cortex from the ventral part of the parvocellular division of the ventroposteromedial nucleus of the thalamus (VPMpc) (Carmichael and Price, 1995b). Visceral inputs may also reach the orbitofrontal cortex from the antero-ventral insula (just below the primary taste cortex) (Baylis, Rolls and Baylis, 1995), from which neurons project to the orbitofrontal cortex, and which is probably an area of visceral cortex (Rolls, 2016c; Critchley and Harrison, 2013; Hassanpour et al., 2018). (In humans, there is also a mid-insular region that has activity related to visceral effects (Hassanpour et al., 2018).)

Visual inputs reach the orbitofrontal cortex directly from the inferior temporal visual cortex, the cortex in the superior temporal sulcus, and the temporal pole, especially from areas TEav and the fundus and ventral bank of the superior temporal sulcus, and the temporal pole (Jones and Powell, 1970; Barbas, 1988, 1993, 1995; Petrides and Pandya, 1988; Barbas and Pandya, 1989; Seltzer and Pandya, 1978, 1989; Morecraft et al., 1992; Carmichael and Price, 1995b; Kondo et al., 2003; Saleem et al., 2008, 2014).

There are corresponding auditory inputs, which reach the lateral orbitofrontal cortex area 12 and the adjacent inferior temporal gyrus areas BA45 and BA44 from temporal cortical auditory areas (Barbas, 1988, 1993; Plakke and Romanski, 2014).

The inputs to the human orbitofrontal cortex (Rolls et al., 2023c) are described in Section 11.3.10.

11.2.2 Outputs of the orbitofrontal cortex

The orbitofrontal cortex has major outputs to the anterior cingulate cortex (Carmichael and Price, 1995a; Morecraft and Tanji, 2009; Vogt, 2009; Garcia-Cabezas and Barbas, 2017; Rolls, 2019c; Du, Rolls, Cheng, Li, Gong, Qiu and Feng, 2020; Hsu, Rolls, Huang, Chong, Lo, Feng and Lin, 2020) and to the ventral striatum (Choi et al., 2017), as well as projections back to many of the areas that send afferents to it.

The caudal orbitofrontal cortex (area 13) has strong reciprocal connections with the amygdala (Price et al., 1991; Carmichael and Price, 1995a; Barbas, 2007; Garcia-Cabezas and Barbas, 2017).

Some of the output pathways of the orbitofrontal cortex (and amygdala) reward processing systems to the subcortical systems that utilize dopamine and serotonin (5-hydroxytryptamine) as neurotransmitters are considered next. The operation of the dopamine systems is considered further in Section 16.4.3.

A somewhat unaddressed issue is how the dopamine neurons in the midbrain, implicated in positive reward prediction error signalling to brain regions such as the striatum (Schultz, 2013, 2016b) (Section 16.4.3), and in addiction (Koob and Volkow, 2016), receive their information about rewards. In this context, it has now been suggested that reward and non-reward areas of the brain such as the orbitofrontal cortex and amygdala do provide a source of relevant inputs to the dopamine neurons (Rolls, 2017c). Pathways that provide a route for reward and emotion-related information to reach the dopamine neurons in the midbrain are shown in Fig. 11.4. One pathway is via a basal ganglia route (striatum, ventral pallidum, and globus pallidus / bed nucleus of the stria terminalis) to influence the Lateral Habenula, lateral part, which in turn via the GABAergic Rostromedial Tegmental nucleus can influence

dopamine neurons in the Substantia Nigra pars compacta and ventral Tegmental Area (SNc and VTA). This provides a route for reward, non-reward, and reward prediction error signals of largely cortical origin to influence the dopamine neurons. Details of some of these anatomical connections are provided elsewhere (Haber, 2014; Proulx et al., 2014; Loonen and Ivanova, 2016), and the operation of this dopamine system and the source of its inputs is considered in Chapter 16.

Serotonin neurons, whose cell bodies are in the raphe nucleus in the brainstem, also have widespread projections throughout the brain, and serotonin is implicated in the effects of some antidepressants (Rolls, 2018a). The origin of the relevant inputs to the serotonin neurons is also a somewhat unaddressed question: how do the serotonin neurons in the raphe nucleus in the midbrain receive inputs that might influence depression in the first place? In this context, it has now been suggested that reward and non-reward areas of the brain such as the orbitofrontal cortex and amygdala do provide a source of relevant inputs to the 5-HT neurons, via brain regions such as the habenula and ventral striatum (Proulx et al., 2014; Loonen and Ivanova, 2016; Rolls, 2017c) (Fig. 11.4). Many antidepressant drugs may influence this cortical to brainstem pathway by influencing the effects of the 5-HT neurons, which terminate in many brain areas.

The outputs of the human orbitofrontal cortex (Rolls et al., 2023c) are described in Section 11.3.10.

11.3 What is computed in the orbitofrontal cortex

11.3.1 The orbitofrontal cortex represents reward value

An overall framework for helping to understand the functions of the orbitofrontal cortex is shown in Fig. 11.1 on page 476, which shows three tiers of processing, with the orbitofrontal cortex in Tier 2.

In Tier 1 (Fig. 11.1) in primates, information is processed to a level at which the neurons represent ‘what’ the stimulus is, independently of the reward or punishment and hence emotional value of the stimulus. In Tier 2 in the orbitofrontal cortex in particular, reward value is represented, as shown for example by the effects of devaluation by feeding a food to satiety, reversal of neuronal responses when the reward value of stimuli is reversed, and correlations of activations with subjectively reported pleasantness. Some of the evidence (Rolls, 2019e) is summarized next.

11.3.1.1 Orbitofrontal cortex representations of the reward value for taste, olfaction, oral texture, and touch

Neurons in the insular primary taste cortex represent what the taste is, but not its reward value, as shown by the findings that neurons in the primary taste cortex do not decrease their responses to zero when the macaque is fed to satiety, with consistent fMRI evidence in humans. Correspondingly, activations in the insular primary taste cortex are correlated with the subjective intensity but not the subjective pleasantness of the taste (Section 4.2.3). In contrast, the reward value of taste is represented in the orbitofrontal cortex, as shown by devaluation (Section 4.2.4) and sensory-specific satiety effects (Section 4.2.5) (Rolls, 2016g, 2019f).

Similarly, the reward value and pleasantness of oral texture, is represented in the orbitofrontal cortex (Rolls et al., 1999a; Grabenhorst et al., 2010b), and so is temperature (Kadohisa et al., 2004; Rolls et al., 2008a; Grabenhorst et al., 2010a).

In the human primary olfactory (pyriform) cortex, activations are correlated with the subjective intensity but not pleasantness of odors (Rolls, Grabenhorst, Margot, da Silva and

Velazco, 2008b). In the orbitofrontal cortex, activations are correlated with the subjective pleasantness of odors (Rolls, Kringelbach and De Araujo, 2003c; Rolls, Grabenhorst, Margot, da Silva and Velazco, 2008b) (Fig. 5.4 and Section 5.2.6). Further, neurons in the orbitofrontal cortex stop responding to a food odor after devaluation and implement olfactory sensory-specific satiety (Section 5.2.6), and show olfactory-to-taste reversal (Section 5.2.5).

The pleasantness of touch is also represented in the orbitofrontal cortex (Section 6.1.6).

11.3.1.2 The expected value of visual stimuli is represented in the orbitofrontal cortex, and can be reversed in one trial

For visual stimuli, the identity but not the reward value is represented at the end of the ventral visual stream in the inferior temporal cortex, in that neurons here do not reverse during visual-to-taste visual discrimination reversal, and do not reduce their response during devaluation by feeding to satiety (Rolls, Judge and Sanghera, 1977) (Section 2.4.1, Fig. 2.6).

We have been able to show that there is a major visual input to many neurons in the orbitofrontal cortex, and that what is represented by these neurons is in many cases the reinforcer (reward or punisher) association of visual stimuli (Thorpe, Rolls and Maddison, 1983; Rolls, Critchley, Mason and Wakeman, 1996b). Many of these neurons reflect the relative preference or reward value of different visual stimuli, in that their responses decrease to zero to the sight of one food on which the monkey is being fed to satiety, but remain unchanged to the sight of other food stimuli (Critchley and Rolls, 1996a). In this sense the visual reinforcement-related neurons predict the reward value that is available from the primary reinforcer, the taste.

The fact that these neurons represent the reinforcer associations of visual stimuli and hence the expected value has been shown to be the case in formal investigations of the activity of orbitofrontal cortex visual neurons, which in many cases reverse their responses to visual stimuli when the taste with which the visual stimulus is associated is reversed by the experimenter (Thorpe, Rolls and Maddison, 1983; Rolls, Critchley, Mason and Wakeman, 1996b). An example of the responses of an orbitofrontal cortex neuron that reversed the visual stimulus to which it responded during reward reversal is shown in Fig. 11.5.

Visual reversal to compute expected value can be rapid and rule-based in primates including humans

This reversal by orbitofrontal visual neurons can be very fast, in as little as one trial, that is a few seconds (see for example Fig. 11.6). The significance of the visual stimulus, a syringe from which the monkey was fed, was altered during the trials. On trials 1–5, no response of the neuron occurred to the sight of the syringe from which the monkey had been given glucose solution to drink from the syringe on the preceding trials. On trials 6–9, the neuron responded to the sight of the same syringe from which he had been given aversive hypertonic saline drink on the preceding trial. Two more reversals (trials 10–15, and 16–17) were performed. The reversal of the neuron's response when the significance of the visual stimulus was reversed shows that the responses of the neuron only occurred to the stimulus when it was associated with aversive saline and not when it was associated with glucose reward.

It is of great importance for understanding the functions of the primate including human orbitofrontal cortex that this reward reversal learning can be very fast, in one trial. This is shown by the fact that after an expected reward was not obtained due to a reversal contingency being applied, on the very next trial the macaque selected the previously non-rewarded stimulus. This occurred despite the fact that the stimulus now chosen had been previously associated with punishment. This shows that rapid reversal can be performed by a non-associative process, and must be rule-based. The primate must learn the rule that if one stimulus is no longer rewarded, then the other stimulus will be rewarded on the next trial. More generally,

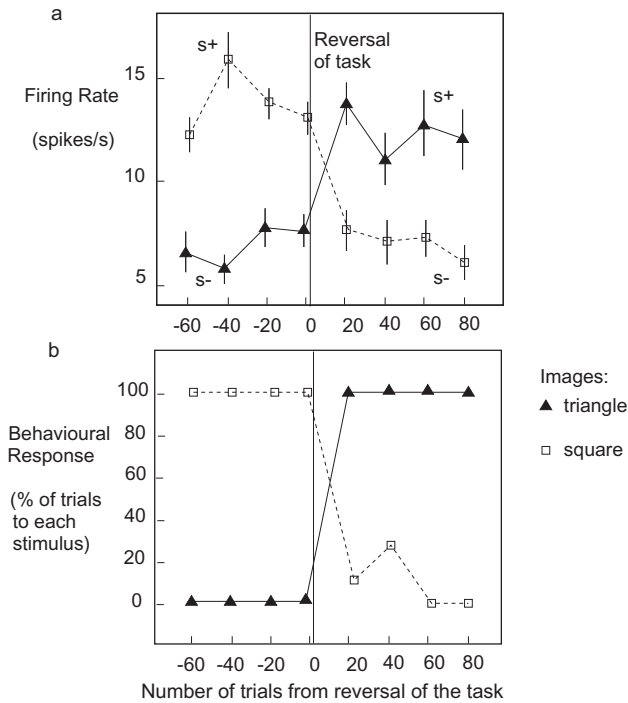

Fig. 11.5 Orbitofrontal cortex: visual discrimination reversal. The activity of an orbitofrontal visual neuron during performance of a visual discrimination task and its reversal. The stimuli were a triangle and a square presented on a video monitor. (a) Each point represents the mean poststimulus activity in a 500 ms period of the neuron based on approximately 10 trials of the different visual stimuli. The standard errors of these responses are shown. After 60 trials of the task the reward associations of the visual stimuli were reversed. s+ indicates that a lick response to that visual stimulus produces fruit juice reward; s- indicates that a lick response to that visual stimulus results in a small drop of aversive tasting saline. This neuron reversed its responses to the visual stimuli following the task reversal. (b) The behavioral response of the monkey to the task. It is shown that the monkey performs well, in that he rapidly learns to lick only to the visual stimulus associated with fruit juice reward. (Reproduced from E. T. Rolls, H.D.Critchley, R.Mason, and E.A.Wakeman (1996) Orbitofrontal cortex neurons: role in olfactory and visual association learning. *Journal of Neurophysiology* 75: 1970–1981. © The American Physiological Society.)

if a stimulus is no longer rewarded, then behavior should change to another stimulus. This is of great adaptive value for many aspects of primate (including human) behavior, including social behavior, in which it may be appropriate to adjust behavior after even a subtle change in reinforcing feedback (outcome) is received. An example of this demonstrated in an fMRI study is shown in Fig. 11.15. This one-trial, rule-based, reversal activates especially the human right lateral orbitofrontal cortex (Rolls, Vatansever, Li, Cheng and Feng, 2020e), which supports the hypotheses that a lateral orbitofrontal cortex non-reward mechanism is involved in depression (Section 18.5). A model for this rule-based reversal is the subject of Section 11.5.3.

This rapid stimulus-reward learning and reversal, so important in primate behavior, has not been demonstrated in rodents as far as I know (and see Hervig et al. (2020)), and may be one of the fundamental advances provided for by the great evolution of the primate including human orbitofrontal cortex, especially in the context of the representations of social reinforcers that are described in Section 11.3.3. For the slower type of reversal found in rodents, the rodent lateral orbitofrontal cortex is involved, as shown by pharmacological inactivation (Hervig et al., 2020).

Consistent with this evidence that the responses of some orbitofrontal cortex neurons reflect the learned predictive reward value of visual stimuli, Thorpe, Rolls and Maddison

Fig. 11.6 Orbitofrontal cortex: one-trial visual discrimination reversal by a neuron. On trials 1–5, no response of the neuron occurred to the sight of a 2 ml syringe from which the monkey had been given orally glucose solution to drink on the previous trial. On trials 6–9, the neuron responded to the sight of the same syringe from which he had been given aversive hypertonic saline to drink on the previous trial. Two more reversals (trials 10–15, and 16–17) were performed. The reversal of the neuron’s response when the significance of the same visual stimulus was reversed shows that the responses of the neuron only occurred to the sight of the visual stimulus when it was associated with a positively reinforcing and not with a negatively reinforcing taste. Moreover, it is shown that the neuronal reversal took only one trial. (Reproduced from S.J.Thorpe, E.T. Rolls, and S.Maddison (1983) *The orbitofrontal cortex: Neuronal activity in the behaving monkey*. *Experimental Brain Research* 49: 93–115. © Springer Nature.)

(1983) and Tremblay and Schultz (2000) found that orbitofrontal cortex neurons learned to respond differently to new stimuli that did or did not predict reward. Different neurons in the orbitofrontal cortex are tuned to different learned or conditioned reinforcers, with for example approximately 5% responding to visual stimuli associated with taste reward, and 3% to visual stimuli associated with taste punishment (Thorpe, Rolls and Maddison, 1983; Rolls, Critchley, Mason and Wakeman, 1996b).

Although using a somewhat different test situation, classical conditioning, Saez, Saez, Paton, Lau and Salzman (2017) found consistent evidence: they found that neuronal responses to reward-predictive cues update more rapidly in the macaque orbitofrontal cortex than amygdala, and activity in the orbitofrontal cortex but not the amygdala was modulated by recent reward history.

Visual stimulus-selective expected value neurons

In the visual discrimination reversal task, a second class of neuron was found that codes for particular stimuli only if they are associated with reward, and not if they are associated with punishment. Such a neuron might respond to a green stimulus associated with reward; after reversal not respond to the green stimulus when it was associated with punishment; and not respond to a blue stimulus irrespective of whether it was associated with reward or punishment (Thorpe, Rolls and Maddison, 1983) (see example in Fig. 11.7). They may be described as *conditional visual stimulus-to-taste reward neurons* or *conditional expected value neurons* (Rolls et al., 1996b), and are analogous to their olfactory counterparts (Rolls et al., 1996b). These neurons are probably important in the mechanisms that implement rapid reversal, as described in Section 11.5.3. More generally, they are part of a mechanism that enables the orbitofrontal cortex to specify individual objects or individuals who may be currently associated with reward, or not.

In addition to selectivity for which stimulus or class of stimulus is currently associated with reward, the fact that many different types of primary reinforcer are present in the orbito-

Fig. 11.7 A conditional reward neuron recorded in the orbitofrontal cortex. The neuron responded only to the Green stimulus when it was associated with reward (G+), and not to the Blue stimulus when it was associated with Reward (B+), or to either stimuli when they were associated with a punisher, the taste of salt (G- and B-). The mean firing rate \pm the s.e.m. is shown. (Reproduced from S.J.Thorpe, E.T. Rolls, and S.Maddison (1983) *The orbitofrontal cortex: Neuronal activity in the behaving monkey*. Experimental Brain Research 49: 93–115. © Springer Nature.)

frontal cortex enables it to represent the expected value of many different types of primary reinforcer.

This reversal learning found in orbitofrontal cortex neurons probably is implemented in the orbitofrontal cortex, for it does not occur one synapse earlier in the visual inferior temporal cortex (Rolls, Judge and Sanghera, 1977), and it is in the orbitofrontal cortex that there is convergence of visual and taste pathways on to the same neurons (Thorpe, Rolls and Maddison, 1983; Rolls, Critchley, Mason and Wakeman, 1996b).

Devaluation shows that orbitofrontal cortex visual neurons represent expected value

Another way in which it has been shown that the visual neurons in the orbitofrontal cortex reflect the expected value predicted by visual stimuli is by reducing the reward value by feeding to satiety in devaluation experiments. With this sensory-specific satiety (or reward devaluation) paradigm, it has been shown that the visual (as well as the olfactory and taste) responses of orbitofrontal cortex neurons in the macaque decrease to zero as the monkey is fed to satiety with one food, but remain unchanged to another food not eaten in the meal (Critchley and Rolls, 1996a) (see example in Fig. 11.8). In that these neurons parallel the changing preference of the monkey for the food being eaten to satiety vs the food not being eaten to satiety, they reflect the relative preference for different visual stimuli, that is the expected value (Thorpe, Rolls and Maddison, 1983; Rolls, Critchley, Mason and Wakeman, 1996b) (as found also by Tremblay and Schultz (1999) and Wallis and Miller (2003)).

All this evidence shows that the great majority of neurons in the orbitofrontal cortex encode stimuli, frequently in terms of the (outcome) value or expected value, and do not reflect the actions or responses or spatial responses being performed by the macaques (Thorpe, Rolls and Maddison, 1983; Rolls, Critchley, Mason and Wakeman, 1996b; Critchley and Rolls, 1996a; Rolls and Baylis, 1994; Rolls, 2014a; Wallis and Miller, 2003; Padoa-Schioppa and Assad, 2006; Grattan and Glimcher, 2014). Indeed, most orbitofrontal cortex neurons that we have recorded do not respond in relation to movements or actions (such as the lick instrumental responses made in a visual discrimination task), and in this sense reflect the value of sensory stimuli, though some do respond to oral or perioral somatosensory stimuli (Thorpe et al., 1983; Rolls et al., 1996b; Critchley and Rolls, 1996a; Rolls and Baylis, 1994; Rolls, 2014a). Consistent with this, orbitofrontal cortex neurons were found to respond to rewards but not to the eye movements being made to obtain the rewards (Grattan and Glimcher, 2014).

Fig. 11.8 Orbitofrontal cortex neuron with visual, olfactory and taste responses, showing the responses before and after feeding to satiety with blackcurrant juice. The solid circles show the responses to blackcurrant juice. The olfactory stimuli included apple (ap), banana (ba), citral (ct), phenylethanol (pe), and caprylic acid (cp). The spontaneous firing rate of the neuron is shown (sp). (Reproduced from H.D.Critchley and E. T. Rolls (1996) Hunger and satiety modify the responses of olfactory and visual neurons in the primate orbitofrontal cortex. *Journal of Neurophysiology* 75: 1673–1886. © The American Physiological Society.)

These findings are consistent with the hypothesis that expected reward value is represented in the orbitofrontal cortex, reflects stimulus–reinforcer (sensory–sensory) association learning, and that this information is projected to other structures such as the cingulate cortex for action–outcome learning (Chapter 12), or to the basal ganglia for stimulus–response habit learning (Chapter 16). Outputs of the orbitofrontal cortex to the dorsolateral prefrontal cortex may be used in tasks requiring planning, for example where rewarding stimuli must be flexibly linked to particular actions, and where delays may be involved, in ways that have been modelled by Deco and Rolls (2003) and Deco and Rolls (2005d).

Given that reward value and not action is implemented in the orbitofrontal cortex, it is an interesting further question about whether the reward value represented in the orbitofrontal cortex is influenced by the costs of actions. Some evidence for this was that in the macaque orbitofrontal cortex, some (but not other) neurons responded less to an expected reward if the cost involved in obtaining it was high (Cai and Padoa-Schioppa, 2019). The neurons that represent value independently of cost are important, for in a sense they represent the absolute value of the good, which is necessary for long-term economic choice. The neurons that have their value representation affected by the cost of the action to obtain the reward correspond more to relative value representations, which may be useful to guide choice in the current session especially when the costs for different rewards are altered. In a lesion study, monkeys with medial orbitofrontal cortex lesions were impaired in estimating the ‘desirability’ of food (in updating their choices based on changes in reward value manipulated by sensory-specific satiety), while monkeys with lateral orbitofrontal cortex lesions (termed ventrolateral prefrontal cortex lesions) were impaired in updating choices in response to changes in reward availability (as manipulated by the probability of obtaining food) (Rudebeck, Saunders, Lundgren and Murray, 2017).

The types of visual–taste reward associations that have been studied in primates have been confirmed as applying in humans in an fMRI study (O’Doherty et al., 2002). However in humans it was very interesting to investigate whether the orbitofrontal cortex is involved in more abstract rewards, such as monetary rewards, or points. In an fMRI study, O’Doherty, Kringelbach, Rolls, Hornak and Andrews (2001a) used a visual discrimination task in which one

The Medial and Lateral Orbitofrontal Cortex (OFC) in the Monetary Incentive Delay Task

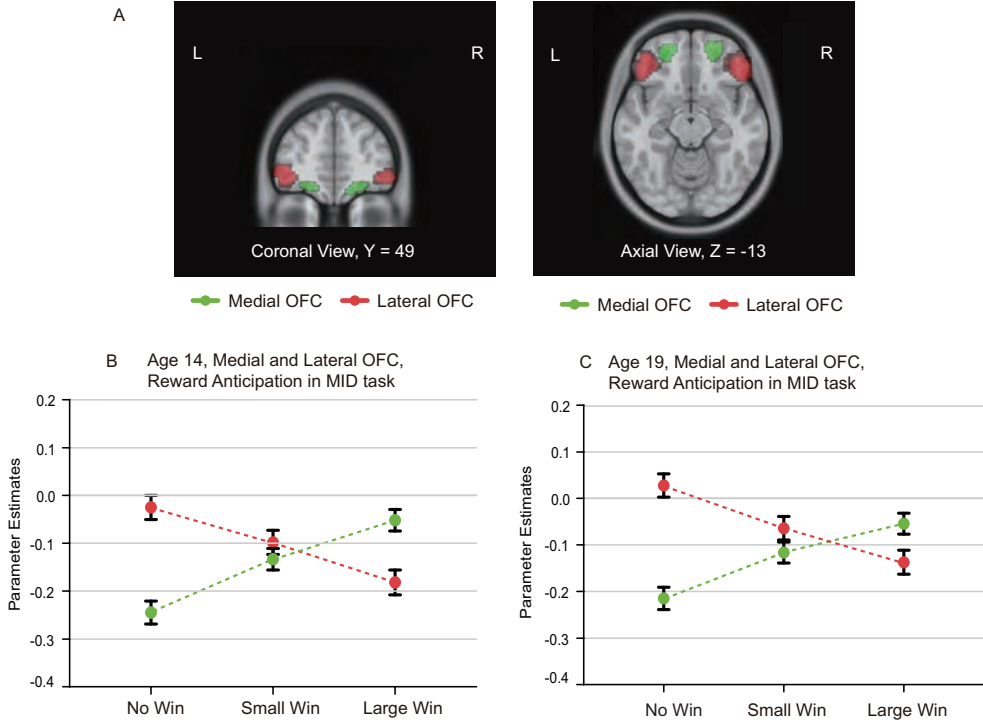

Fig. 11.9 The lateral orbitofrontal cortex is activated by not winning, and the medial orbitofrontal cortex by winning, in the monetary incentive delay task. The lateral orbitofrontal cortex region in which activations increased towards no reward (No Win) in the monetary incentive delay task are shown in red in 1140 participants at age 19 and in 1877 overlapping participants at age 14. The conditions were Large win (10 points) to Small Win (2 points) to No Win (0 points) (at 19; sweets were used at 14). The medial orbitofrontal cortex region in which activations increased with increasing reward from No Win to Small Win to High Win) is shown in green. The parameter estimates are shown from the activations for the participants (mean \pm sem) with the lateral orbitofrontal in red and medial orbitofrontal cortex in green. The interaction term showing the sensitivity of the medial orbitofrontal cortex to reward and the lateral orbitofrontal cortex to non-reward was significant at $p = 10^{-50}$ at age 19 and $p < 10^{-72}$ at age 14. In a subgroup with depressive symptoms as shown by the Adolescent Depression Rating Scale, it was further found that there was a greater activation to the No Win condition in the lateral orbitofrontal cortex; and the medial orbitofrontal cortex was less sensitive to the differences in reward value. (Modified from Xie, C., Jia, T., Rolls, E. T. et al. (2021) Reward vs non-reward sensitivity of the medial vs lateral orbitofrontal cortex relates to the severity of depressive symptoms. *Biological Psychiatry: Cognitive Neuroscience and Neuroimaging* 6: 259-269. doi: 10.1016/j.bpsc.2020.08.017.)

stimulus was associated with monetary reward, and a different visual stimulus with monetary loss (punishment). The actual amounts of money won on reward trials and lost on punishment trials were probabilistic. This part of the design, and the fact that unexpected visual discrimination reversals occurred so that there were trials on which money was lost, enabled us to show that the magnitude of the activation of the medial orbitofrontal cortex was correlated with the amount of money won on each trial, and the magnitude of the activation of the lateral orbitofrontal cortex was correlated with the amount of money lost on each trial (O’Doherty, Kringelbach, Rolls, Hornak and Andrews, 2001a).

These findings have been extended by showing that the medial orbitofrontal cortex has greater activation as reward increases, and that the lateral orbitofrontal cortex has increasing activations as reward decreases to zero, in an investigation in 1,877 participants, as shown in Fig. 11.9 (Xie, Jia, Rolls et al (2021)).

11.3.2 Neuroeconomic value is represented in the orbitofrontal cortex

Further evidence that these orbitofrontal cortex neurons encode expected value is that they represent choices made when the ‘offers’ (the visual stimuli) are different amounts or different qualities of the ‘goods’ (for example the type of fruit juice that is the reward outcome of the choice and different probabilities of obtaining reward) (Padoa-Schioppa and Assad, 2006; Padoa-Schioppa, 2011; Padoa-Schioppa and Conen, 2017).

In the terminology of neuroeconomics, value represents a common unit of measure to make a comparison between the reinforcing stimuli or ‘goods’ (Padoa-Schioppa, 2011; Padoa-Schioppa and Conen, 2017). In that terminology, a ‘commodity’ is a unitary amount of a specified good independently of the circumstances in which it is available (e.g. quantity, cost, delay, etc.). The value of each good is computed at the time of choice on the basis of multiple ‘determinants’, which include the specific commodity, its quantity, the current motivational state, the cost of obtaining it, the behavioral context of choice (i.e. the other choices that are currently available), etc. The collection of these determinants thus defines the value of the ‘good’.

The hypothesis is that while choosing, individuals compute the values of different options independently of one another. It is argued that the ‘net reward value’, i.e. the value of each good minus the cost of obtaining it, must be computed and represented on a common scale of value as the input to the decision-making process, which makes the choice (Grabenhorst and Rolls, 2011). The reason that the net value must be computed is that the decision-making process itself, performed it is suggested by an attractor decision-making network (Section 11.5.1), cannot by itself receive as inputs separate values and costs for each choice, for these variables related to a specific choice could not be related to each other in the decision-making attractor network.

A brain region that does appear to compute the actions needed to obtain a stimulus with the particular value, and which takes into account the costs of actions (which we have termed the extrinsic costs (Grabenhorst and Rolls, 2011)), is the cingulate cortex (Rushworth et al., 2011; Grabenhorst and Rolls, 2011; Rolls, 2019c), which receives value information about the goods in its anterior cingulate part from the orbitofrontal cortex (Rolls, 2005a, 2009a; Grabenhorst and Rolls, 2011). It is argued that the computation of net value in the orbitofrontal cortex does not depend on the sensori-motor contingencies of choice (the spatial configuration of the offers or the specific action that will implement the choice outcome), for the behavioral responses and actions are not represented in the orbitofrontal cortex, which represents the value of stimuli, and does not represent actions and responses (Thorpe, Rolls and Maddison, 1983; Rolls, 2005a; Padoa-Schioppa, 2011; Padoa-Schioppa and Conen, 2017). These action contingencies may, however, affect values in the form of action costs. In particular, the actions necessary to obtain different goods often bear different costs. There is evidence that these ‘extrinsic costs’ (the costs of the actions necessary to obtain a reward (Grabenhorst and Rolls, 2011)) are represented in the orbitofrontal cortex (Cai and Padoa-Schioppa, 2019).

The *extrinsic factors* that influence the value of a good and the value of a choice include:

1. The action costs, including the difficulty of the actions needed to obtain the good;
2. the time delay (with future rewards being discounted as a function of the length of the delay, and differently discounted by different individuals);
3. the ‘risk’, i.e. the probability that the reward will be obtained;
4. the amount of the good obtained if it is chosen;
5. the quality of the good, e.g. one juice may be preferred over another;
6. ambiguity (i.e. poor knowledge about the probability that a reward will be obtained).

The *intrinsic or internal factors* that influence the value of stimuli include (Grabenhorst and Rolls, 2011; Padoa-Schioppa, 2011; Padoa-Schioppa and Conen, 2017):

1. motivational state;
2. patience vs impulsiveness;
3. risk attitude, that is choice when the outcome is probabilistic, for example whether one is likely to gamble;
4. ambiguity attitude;
5. whether the stimulus which may have pleasant components has in addition unpleasant components.

Further factors important in understanding choices in the field of neuroeconomics, many described in more detail below, are:

1. The value of each good must be computed 'online' at the time of choice, for value is influenced by for example motivational state.
2. While choosing, individuals normally compute the values of different goods independently of one another. Such 'menu invariance' implies transitive preferences (Padoa-Schioppa, 2011; Padoa-Schioppa and Conen, 2017).
3. Absolute value is important for long-term choice and transitive preferences. This may be represented in the orbitofrontal cortex.
4. Relative value is useful for short-term choice, for example on a particular trial or a block of trials, and may be separately represented in the orbitofrontal cortex.

In one neuroeconomics study that illustrates how the responses of orbitofrontal cortex neurons encode the value of a stimulus or choice, the value of the choice was manipulated by providing different numbers of drops of juice (quantity) of different quality (e.g. grape juice (A) and peppermint tea (B), which were termed commodities) to monkeys (Padoa-Schioppa and Assad, 2006). The monkey preferred juice A. When offered one drop of juice A versus one drop of juice B (offer 1A:1B), the animals chose juice A. However, the animals were thirsty: they generally preferred larger amounts of juice to smaller amounts of juice. The amounts of the two juices offered against each other varied from trial to trial, which induced a commodity quantity trade-off in the choice pattern. For example in one session (Fig. 11.10), offer types (indicated by the number of small squares on a screen that were available for A and for B) included 0B:1A, 1B:2A, 1B:1A, 2B:1A, 3B:1A, 4B:1A, 6B:1A, 10B:1A and 3B:0A. The monkey generally chose 1A when 1B or 2B were available as the alternative, it was roughly indifferent between the two juices when offered 3B:1A, and it chose B when 4B, 6B or 10B were available (Fig. 11.10). In other words, the monkey assigned to 1A a value roughly equal to the value it assigned to 3B. A neuron recorded in the orbitofrontal cortex responded with a low rate (several spikes/s) when the offer was 2B or less, at an intermediate rate (approximately 10 spikes/s) when the offer was 3B or 4B, and at a high rate (approximately 17 spikes/s) when the offer was 6B or higher relative to 1A (Fig. 11.10). The neuron thus encoded the value of the offer, where the value assigned by the monkey reflected a commodity \times quantity tradeoff.

The offer value neurons respond when the visual stimulus indicating the taste/flavor reward that will be obtained is shown (Padoa-Schioppa and Assad, 2006; Padoa-Schioppa, 2011; Padoa-Schioppa and Conen, 2017). They thus correspond to the orbitofrontal cortex neurons described by Rolls and colleagues that respond to a visual stimulus, for example in a visual discrimination task, that indicates the value of the reward or punisher that will be obtained (Thorpe, Rolls and Maddison, 1983; Rolls, Critchley, Mason and Wakeman, 1996b; Critchley and Rolls, 1996a). These visual neurons reflect expected reward value in that they respond to a particular visual stimulus when the value is high, and gradually respond less

Fig. 11.10 Orbitofrontal cortex neuron encoding the offer value. On individual trials, the monkey was offered different numbers of drops of peppermint tea (juice B) versus 1 drop of grape juice (juice A). Black circles indicate the behavioral choice pattern (relative value in the upper left) and red symbols indicate the neuronal firing rate when the offer of different amounts of juice B was made vs 1 drop of juice A (1A). Red diamonds and circles refer, respectively, to trials in which the animal chose juice A and juice B. There is a sigmoid relationship between the firing rate of the neuron and the quantity of juice B offered to the monkey. (Reproduced from Camillo Padoa-Schioppa (2009) Range-adapting representation of economic value in the orbitofrontal cortex. *Journal of Neuroscience* 29: 14005. © Society for Neuroscience.)

to the visual stimulus as gradually it becomes devalued by feeding to satiety (Critchley and Rolls, 1996a) (Fig. 11.8). These visual neurons also respond to a visual stimulus when it signifies a high value, and do not respond when it is devalued by visual discrimination reversal learning so that it signifies after learning a low reward value (Rolls, Critchley, Mason and Wakeman, 1996b) (Fig. 11.5). In addition, these studies show that other neurons reflect the punisher value of a visual stimulus, responding for example to a visual stimulus when it signifies the punisher of a taste of saline if the visual stimulus is selected (Fig. 11.6) (Thorpe, Rolls and Maddison, 1983; Rolls, Critchley, Mason and Wakeman, 1996b).

Padoa-Schioppa and Assad (2006) also described neurons that in the same task responded when the juice taste reward was delivered. Their taste neurons reflected value, in that they had for example a large response when 4B or greater was delivered, an intermediate response when 3B was delivered, and no response when 2B or less was delivered (Fig. 11.10) (Padoa-Schioppa, 2011). These neurons again correspond to the taste reward neurons of Rolls and colleagues analyzed in the orbitofrontal cortex (Rolls, Yaxley and Sienkiewicz, 1990; Rolls, Critchley, Verhagen and Kadohisa, 2010a), which respond to a taste when it has a high value, and gradually respond less to that taste when it is gradually devalued by feeding to satiety (Rolls, Sienkiewicz and Yaxley (1989d), e.g. Fig. 4.8).

11.3.3 A representation of face and voice expression and other socially relevant stimuli in the orbitofrontal cortex

Socially relevant stimuli, such as the emotional expression on a face, and in the voice, are represented in the orbitofrontal cortex. There is a population of orbitofrontal cortex face-selective neurons (Rolls, Critchley, Browning and Inoue, 2006a) that respond in many ways similarly to those in the temporal cortical visual areas (Rolls, 1984, 1992a, 2000a, 2007e, 2008b, 2011d, 2012d, 2016b). The orbitofrontal face-responsive neurons, first observed by Thorpe, Rolls and Maddison (1983), then by Rolls, Critchley, Browning and Inoue (2006a), tend to respond with longer latencies than temporal lobe neurons (140–200 ms typically, compared with 80–100 ms); they also convey information about which face is being seen, by having different responses to different faces; and are typically rather harder to activate strongly than temporal cortical face-selective neurons, in that many of them respond much

Fig. 11.11 Orbitofrontal cortex face-selective neuron tuned to face identity in the macaque. Firing rate histogram of cell be009 to different face stimuli (306-311 and 381) and different non-face stimuli (125, 264, 312, 313, 314, 372 and 374). Stimuli 305–308 and 381 were macaque faces with different identities, 309-311 were human face stimuli with different identities, and the other stimuli were different non-face stimuli (25=hand, 372=triangle, 374=saline-associated square, 312 - Fourier boundary curvature descriptor, 313 grating, 314 shirt). The means and standard error of the mean (sem) of the responses in spikes/s are shown as changes from the spontaneous rate (Spont.) (Reproduced from Rolls, E. T., Critchley, H. D., Browning, A. S. and Inoue, K. (2006) Face-selective and auditory neurons in the primate orbitofrontal cortex. *Experimental Brain Research* 170: 743–787. © Springer Nature.)

Fig. 11.12 Orbitofrontal cortex face-selective neuron tuned to face expression in the macaque. A firing rate histogram of cell aq045 to different face expressions is shown. The means and standard error of the mean (sem) of the responses in spikes/s are shown as changes from the spontaneous rate (Spont.) (Reproduced from Rolls, E. T., Critchley, H. D., Browning, A. S. and Inoue, K. (2006) Face-selective and auditory neurons in the primate orbitofrontal cortex. *Experimental Brain Research* 170: 743–787. © Springer Nature.)

better to real faces than to two-dimensional images of faces on a video monitor (cf. Rolls and Baylis (1986)). As shown in Fig. 11.11, some orbitofrontal cortex neurons respond to face identity.

Other orbitofrontal cortex face-selective neurons are tuned to the emotional expression of a face, as illustrated in Fig. 11.12.

We hypothesized that both face identity and face expression information is represented in the macaque orbitofrontal cortex because it is important to take into account both the identity

Fig. 11.13 Orbitofrontal cortex face-selective neuron tuned to some movements of a head, but with no response when the head was still. (Reproduced from Rolls, E. T., Critchley, H. D., Browning, A. S. and Inoue, K. (2006) Face-selective and auditory neurons in the primate orbitofrontal cortex. *Experimental Brain Research* 170: 743–787. © Springer Nature.)

of the individual and the expression on a face in order to produce an appropriate emotional and social response to a face (Rolls et al., 2006a).

In addition to categorising face expression, some orbitofrontal cortex neurons categorise faces by their social significance, such as young faces (Barat, Wirth and Duhamel, 2018). In another study, it was reported that some orbitofrontal cortex face-selective neurons are sensitive to the rank of the individual being viewed in the social hierarchy, with neurons also reflecting social hierarchy in the amygdala and anterior cingulate cortex (Munuera et al., 2018).

Some of the orbitofrontal cortex face-selective neurons are responsive to face gesture or movement, as illustrated in Fig. 11.13 (Rolls et al., 2006a). Such neurons are very likely to be involved in social situations, when for example the turn of a head towards or away from the viewer may have great social significance.

The discovery of face-selective neurons in the primate orbitofrontal cortex is consistent with the likelihood that these neurons are activated via the inputs from the temporal cortical visual areas in which face-selective neurons are found (see Fig. 11.1). The significance of the neurons is likely to be related to the fact that faces convey information that is important in social reinforcement, both by conveying face expression (cf. Hasselmo, Rolls and Baylis (1989a)), which can indicate reinforcement, and by encoding information about which individual is present, also important in evaluating and utilizing reinforcing inputs in social situations (Rolls, Critchley, Browning and Inoue, 2006a; Rolls, 2011d).

Consistent with these findings in macaques, and as described above, in humans, activation of the lateral orbitofrontal cortex occurs when a rewarding smile expression is expected, but an angry face expression is obtained, in a visual discrimination reversal task (Kringelbach and Rolls, 2003). This is an example of the operation of a social reinforcer, and, consistent with these results, Farrow et al. (2001) have found that activation of the orbitofrontal cortex is found when humans are making social judgements. In addition, activation of the medial orbitofrontal cortex is correlated with face attractiveness (O’Doherty et al., 2003b).

These orbitofrontal cortex face-selective neurons are frequently found close to the lateral orbitofrontal sulcus (Rolls, Critchley, Browning and Inoue, 2006a), and with fMRI in humans,

activation of this region by faces is found (area PO) (D'Urso et al., 2017). Face selective neurons have also been found in the inferior prefrontal cortex below the principal sulcus (O'Scalaidhe et al., 1997; Romanski and Diehl, 2011; Diehl and Romanski, 2014) (area PL), and in the anterior bank of the arcuate sulcus (O'Scalaidhe et al., 1997) (area PA).

We also discovered that some orbitofrontal cortex neurons are activated by auditory stimuli, such as socially relevant vocalization (Fig. 7.5) (Rolls, Critchley, Browning and Inoue, 2006a). This has been confirmed (Plakke and Romanski, 2014), and indeed in the ventrolateral prefrontal cortex (which includes areas 12, 45, and 44) neurons may be tuned to the type of call or to the identity of the caller (Plakke et al., 2013; Plakke and Romanski, 2014). Neurons in this ventrolateral prefrontal cortex region can also be influenced by the sight or the sound of a vocalization, and by mismatches between these (Diehl and Romanski, 2014). Auditory stimuli may have similar representations in the orbitofrontal cortex related to their affective value. For example, Blood et al. (1999) found a correlation between subjective ratings of dissonance and consonance of musical chords and the activations produced in the orbitofrontal cortex (see also Blood and Zatorre (2001) and Frey et al. (2000)). The transition of harmony towards a pleasant resolution also activates the orbitofrontal cortex (Fujisawa and Cook, 2011).

In one study in a social situation it was found that neurons in the macaque orbitofrontal cortex predominantly encoded rewards that were delivered to the self (Chang et al., 2013). But in a social situation in which rewards were given to the self and to another monkey, some orbitofrontal cortex neurons reflected not only the value of the reward, but also the identity and social status of the other monkey (Azzi et al., 2012).

We were able to confirm the importance of this system for face expression analysis and social behavior in a group of patients with ventral frontal lobe damage who had impairments in the identification of facial and vocal emotional expression, and who had socially inappropriate behavior (Hornak, Rolls and Wade, 1996; Rolls, 1999b).

11.3.4 Negative reward prediction error neurons in the orbitofrontal cortex, and visual stimulus–reinforcer association learning and reversal during decision-making

In addition to the neurons that encode the reward value of visual stimuli, other neurons (3.5%) in the orbitofrontal cortex detect different types of non-reward, i.e. negative reward prediction error, the difference between the expected value and the reward outcome value (Thorpe, Rolls and Maddison, 1983). For example, some neurons responded in extinction, immediately after a lick had been made to a visual stimulus that had previously been associated with fruit juice reward, but no reward was obtained. Other neurons responded in a reversal task, immediately after the monkey had responded to the previously rewarded visual stimulus, but had obtained the punisher of salt taste rather than reward (see example in Fig. 11.14). Other orbitofrontal cortex neurons respond to other types of non-reward, including the removal of a formerly approaching taste reward, and the termination of a taste reward (Thorpe, Rolls and Maddison, 1983). Thus the error neurons can be specific to different tasks, and this could provide a mechanism for reversal in one task to be implemented, while at the same time not reversing behavior in another task. Neurons selective for different types of error have been found in a region to which the orbitofrontal cortex projects, the anterior cingulate cortex (Oemisch et al., 2019).

The existence of neurons in the middle part of the macaque orbitofrontal cortex that respond to non-reward (Thorpe, Rolls and Maddison, 1983) (originally described by Thorpe, Maddison and Rolls (1979) and Rolls (1981b)) is confirmed by recordings that revealed 10 such non-reward neurons (of 140 recorded, or approximately 7%) found in delayed match to

Fig. 11.14 Error neuron: Responses of an orbitofrontal cortex neuron that responded only when the monkey licked to a visual stimulus during reversal, expecting to obtain fruit juice reward, but actually obtaining the taste of aversive saline because it was the first trial of reversal. Each single dot represents an action potential; each vertically arranged double dot represents a lick response. The visual stimulus was shown at time 0 for 1 s. The neuron did not respond on most reward (R) or saline (S) trials, but did respond on the trials marked x, which were the first trials after a reversal of the visual discrimination on which the monkey licked to obtain reward, but actually obtained saline because the task had been reversed. It is notable that after an expected reward was not obtained due to a reversal contingency being applied, on the very next trial the macaque selected the previously non-rewarded stimulus. This shows that rapid reversal can be performed by a non-associative process, and must be rule-based. A model for this is the subject of Section 11.5.3. (Redrawn from S.J.Thorpe, E.T.Rolls, and S.Maddison (1983) The orbitofrontal cortex: Neuronal activity in the behaving monkey. *Experimental Brain Research* 49: 93–115. © Springer Nature.)

sample and delayed response tasks by Joaquin Fuster and colleagues (Rosenkilde, Bauer and Fuster, 1981).

We have also been able to obtain evidence that non-reward used as a signal to reverse behavioral choice is represented in the human orbitofrontal cortex. Kringelbach and Rolls (2003) used the faces of two different people, and if one face was selected then that face smiled, and if the other was selected, the face showed an angry expression. After good performance was acquired, there were repeated reversals of the visual discrimination task (see Fig. 11.15). Kringelbach and Rolls (2003) found that activation of a lateral part of the orbitofrontal cortex in the fMRI study was produced on the error trials, that is when the human chose a face, and did not obtain the expected reward (see Fig. 11.16). Control tasks showed that the response was related to the error, and the mismatch between what was expected and what was obtained, in that just showing an angry face expression did not selectively activate this part of the lateral orbitofrontal cortex. An interesting aspect of this study that makes it relevant to human social behavior is that the conditioned stimuli were faces of particular individuals, and the unconditioned stimuli were face expressions. Moreover, the study reveals that the human orbitofrontal cortex is very sensitive to social feedback when it must be used to change behavior (Kringelbach and Rolls, 2003, 2004).

Further, the right lateral orbitofrontal cortex is strongly activated by non-reward in a one-trial rule-based reward reversal task (Rolls et al., 2020e). In this reversal, after a reward has not been provided when it was expected, on the very next trial that the stimulus formerly associated with punishment is shown, that stimulus is selected (Thorpe, Rolls and Maddison, 1983; Rolls, Vatansever, Li, Cheng and Feng, 2020e). This shows that this is a non-associative, rule-based, process that cannot be accounted for by model-free reinforcement

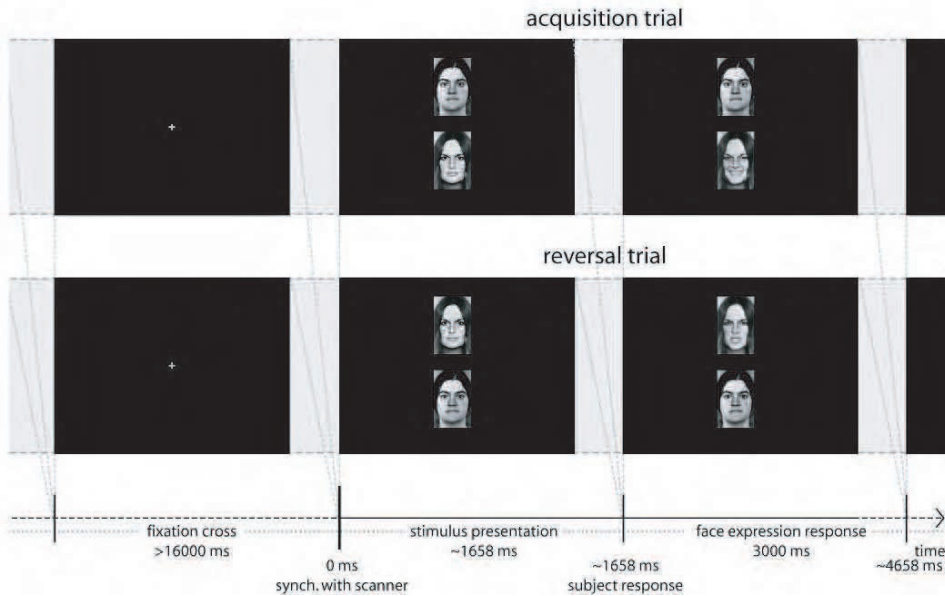

Fig. 11.15 Social reversal task: The trial starts synchronized with the scanner and two people with neutral face expressions are presented to the subject. The subject has to select one of the people by pressing the corresponding button, and the person will then either smile or show an angry face expression for 3000 ms depending on the current mood of the person. The task for the subject is to keep track of the mood of each person and choose the 'happy' person as much as possible (upper row). Over time (after between 4 and 8 correct trials) this will change so that the 'happy' person becomes 'angry' and vice versa, and the subject has to learn to adapt her choices accordingly (bottom row). Randomly intermixed trials with either two men, or two women, were used to control for possible gender and identification effects, and a fixation cross was presented between trials for at least 16000 ms. (Reprinted from Morten L. Kringelbach and Edmund T. Rolls (2003) Neural correlates of rapid reversal learning in a simple model of human social interaction. *NeuroImage* 20: 1371–83. © Elsevier Inc.)

learning (Rolls et al., 2020e). This is a function of the primate including human orbitofrontal cortex in a type of behavior that is not known to occur in rodents (Hervig et al., 2020), whose orbitofrontal cortex is very different (Rolls, 2019e) (Section 19.10).

One behavioral effect of not receiving reward is that it may be important to stop the behavior. One way to investigate this is in the stop-signal task, in which a signal is delivered on some trials indicating that the response being made should be stopped. In the stop-signal task, the lateral orbitofrontal cortex and the adjoining inferior frontal gyrus are both activated (Deng, Rolls et al (2017)). Impairments in the performance of the stop-signal task, which measures a type of motor impulsiveness, are associated with damage to the right inferior frontal gyrus (Aron, Robbins and Poldrack, 2014). It is proposed that one route by which non-reward can stop behavior is via the pathway from the lateral orbitofrontal cortex to the right inferior frontal gyrus (Rolls, Deco, Huang and Feng, 2023c; Rolls, Cheng, Du, Wei, Qiu, Dai, Zhou, Xie and Feng, 2020b; Du, Rolls, Cheng, Li, Gong, Qiu and Feng, 2020).

The hypotheses about the role of the orbitofrontal cortex in the rapid alteration of stimulus–reinforcer associations, and the functions more generally of the orbitofrontal cortex in human behavior, have been investigated in studies in humans with damage to the orbitofrontal cortex. In a visual discrimination reversal task, patients could learn to obtain points by touching one stimulus when it appeared on a video monitor, but had to withhold a response when a different visual stimulus appeared, otherwise a point was lost. After the subjects had acquired the visual discrimination, the reinforcement contingencies unexpectedly reversed. The patients with orbitofrontal lesions made more errors in the reversal (or in a similar extinction) task, and

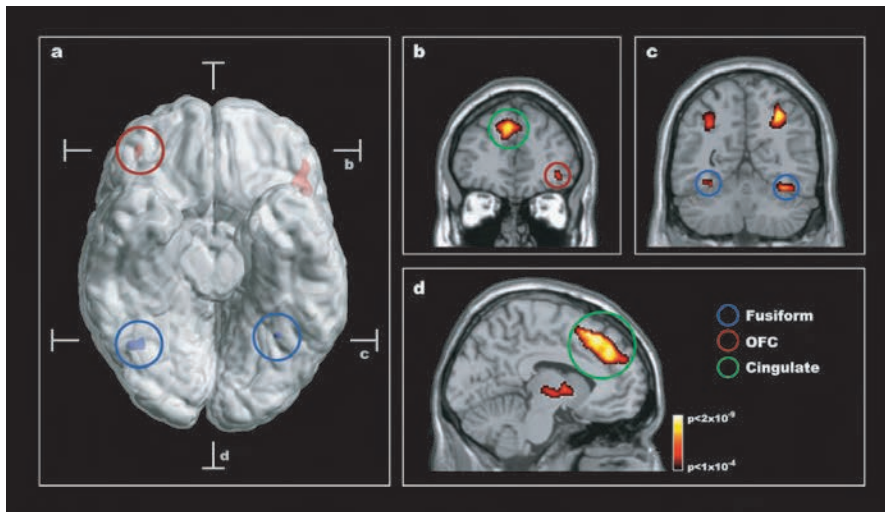

Fig. 11.16 Social reversal: the human lateral orbitofrontal cortex and supracallosal anterior cingulate cortex are activated on reversal trials. Composite figure showing that changing behavior based on face expression is correlated with increased brain activity in the human orbitofrontal cortex. a) The figure is based on two different group statistical contrasts from the neuroimaging data which are superimposed on a ventral view of the human brain with the cerebellum removed, and with indication of the location of the two coronal slices (b,c) and the transverse slice (d). The red activations in the orbitofrontal cortex (denoted OFC, maximal activation: $z=4.94$ [$42\ 42\ -8$]; and $z=5.51$ [$-46\ 30\ -8$]) shown on the rendered brain arise from a comparison of reversal events with stable acquisition events, while the blue activations in the fusiform gyrus (denoted Fusiform, maximal activation: $z > 8$ [$36\ -60\ -20$] and $z=7.80$ [$-30\ -56\ -16$]) arise from the main effects of face expression. b) The coronal slice through the frontal part of the brain shows the cluster in the right orbitofrontal cortex across all nine subjects when comparing reversal events with stable acquisition events. Significant activity was also seen in an extended area of the anterior cingulate/paracingulate cortex (denoted Cingulate, maximal activation: $z=6.88$ [$-8\ 22\ 52$]; green circle). c) The coronal slice through the posterior part of the brain shows the brain response to the main effects of face expression with significant activation in the fusiform gyrus and the cortex in the intraparietal sulcus (maximal activation: $z > 8$ [$32\ -60\ 46$]; and $z > 8$ [$-32\ -60\ 44$]). d) The transverse slice shows the extent of the activation in the anterior cingulate/paracingulate cortex when comparing reversal events with stable acquisition events. Group statistical results are superimposed on a ventral view of the human brain with the cerebellum removed, and on coronal and transverse slices of the same template brain (activations are thresholded at $p=0.0001$ for purposes of illustration to show their extent). (Reprinted from Morten L. Kringsbach and Edmund T. Rolls (2003) Neural correlates of rapid reversal learning in a simple model of human social interaction. *NeuroImage* 20: 1371–83. © Elsevier Inc.)

completed fewer reversals, than control patients with damage elsewhere in the frontal lobes or in other brain regions (Rolls, Hornak, Wade and McGrath, 1994a) (see Fig. 11.17). A reversal deficit in a similar task in patients with ventromedial prefrontal cortex damage was also reported by Fellows and Farah (2003). In macaques orbitofrontal cortex lesions also impair object reversal learning (Murray and Izquierdo, 2007), with further evaluation of the effects of lesions of the orbitofrontal cortex in macaques provided by Rolls (2019e). Neurotoxic lesions of the macaque orbitofrontal cortex produce effects that are difficult to interpret (Murray and Rudebeck, 2018; Sallet et al., 2020), perhaps because these lesions have not always been based on knowledge of where neurons and activations related to reversal learning are found, and the difficulty of disabling all such orbitofrontal cortex neurons (Rolls, 2023b).

An important aspect of the findings of Rolls, Hornak, Wade and McGrath (1994a) was that the reversal learning impairment correlated highly with the socially inappropriate or disinhibited behavior of the patients (Fig. 11.17), and also with their subjective evaluation of the changes in their emotional state since the brain damage. The patients were not impaired at other types of memory task, such as paired associate learning. It is of interest that the patients can often verbalize the correct response, yet commit the incorrect action. This is consistent with the hypothesis that the orbitofrontal cortex is normally involved in executing behavior when the behavior is performed by evaluating the reinforcement associations of environmental stimuli (see below). The orbitofrontal cortex seems to be involved in this in both humans

Fig. 11.17 Impaired visual discrimination reversal performance in humans with damage to the ventral part of the frontal lobe (orbitofrontal cortex). The task was to touch the screen when one image, the S+, was shown in order to obtain a point; and to refrain from touching the screen when a different visual stimulus, the S-, was shown in order to obtain a point. The scattergraph shows that during the reversal the group with ventral damage were more likely to touch the previously rewarded stimulus (Old S+), and that this was related to the score on a Behavior Questionnaire. Each point represents one patient in the ventral frontal group or in a control group. The Behavior Questionnaire rating reflected high ratings on at least some of the following: disinhibited or socially inappropriate behavior; misinterpretation of other people's moods; impulsiveness; unconcern about or underestimation of the seriousness of his condition; and lack of initiative. (Reproduced from E. T. Rolls, J. Hornak, D. Wade and J. McGrath (1994) Emotion-related learning in patients with social and emotional changes associated with frontal lobe damage. *Journal of Neurology, Neurosurgery and Psychiatry* 57: 1518–25. © BMJ Publishing Group Ltd.)

and non-human primates, when the learning must be performed rapidly, in, for example, acquisition, and during reversal.

To seek positive confirmation that effects on stimulus–reinforcer association learning and reversal were related to orbitofrontal cortex damage rather than to any other associated pathology, a different reversal-learning task was used with a group of patients with discrete, surgically produced, lesions of the orbitofrontal cortex. In the new visual discrimination task (the same as that used in our monetary reward functional neuroimaging task, O'Doherty, Kringelbach, Rolls, Hornak and Andrews (2001a)), two stimuli are always present on the video monitor and the patient obtains 'monetary' reward by touching the correct stimulus, and loses 'money' by touching the incorrect stimulus. This design controls for an effect of the lesion in simply increasing the probability that any response will be made (cf. Aron et al. (2003) and Clark et al. (2004)). The task also used probabilistic amounts of reward and punishment on each trial, to make it harder to use a verbal strategy with an explicit rule. It was found that a group of patients with bilateral orbitofrontal cortex lesions were severely impaired at the reversal task, in that they accumulated less money (Hornak, O'Doherty, Bramham, Rolls, Morris, Bullock and Polkey, 2004). These patients often failed to switch their choice of stimulus after a large loss; and often did switch their choice even though they had just received a reward, and this was quantified in a later study (Berlin, Rolls and Kischka, 2004). The impor-

tance of the failure to rapidly learn about the value of stimuli from negative feedback has also been described as a critical difficulty for patients with orbitofrontal cortex lesions (Fellows, 2007; Wheeler and Fellows, 2008; Fellows, 2011), and has been contrasted with the effects of lesions to the anterior cingulate cortex which impair the use of feedback to learn about actions (Fellows, 2011; Camille et al., 2011) (see Chapter 12).

We have seen in this section that orbitofrontal cortex non-reward neurons are important in reward-related decision-making, and that damage to this system is associated with impairments in emotion and social behavior in humans. Further analyses of how the orbitofrontal cortex operates during decision-making are described by Rolls (2019e). For example, evidence is described that different rewards (such as flavor and a thermal stimulus applied to the hand) are scaled to the same range in the orbitofrontal cortex (Grabenhorst, D'Souza, Parris, Rolls and Passingham, 2010a), which helps with the decision-making mechanisms implemented in the orbitofrontal cortex / ventromedial prefrontal cortex described below. In Section 18.5 the concepts described here are extended to depression, which is related to the functions of the lateral orbitofrontal cortex in responding to non-reward, which can be associated with depressive feelings.

11.3.5 The human medial orbitofrontal cortex represents rewards, and the lateral orbitofrontal cortex non-reward and punishers

Activations found in functional neuroimaging studies by many types of reward appear to involve relatively medial parts of the human orbitofrontal cortex, and unpleasant stimuli or non-reward more lateral parts of the human orbitofrontal cortex (Grabenhorst and Rolls, 2011; Rolls, 2014a; Kringelbach and Rolls, 2004; Rolls, 2019f; Rolls et al., 2020a; Xie et al., 2021). For example, we have obtained evidence from an experiment using pleasant, painful and neutral somatosensory stimulation that there is some spatial segregation of the representation of rewards and punishers, where the effects of pleasant somatosensory stimulation are spatially dissociable from the effects of painful stimulation in the human orbitofrontal cortex (Rolls, O'Doherty, Kringelbach, Francis, Bowtell and McGlone, 2003d). Further, pleasant odors activate medial, and unpleasant odors lateral, regions of the human orbitofrontal cortex (Rolls, Kringelbach and De Araujo, 2003c). Another example comes from the finding that the administration of amphetamine to naive human subjects activates the orbitofrontal cortex and two regions to which it projects the pregenual cingulate cortex and ventral striatum (Völlm, De Araujo, Cowen, Rolls, Kringelbach, Smith, Jezzard, Heal and Matthews, 2004) (Fig. 11.22). An indication that a rewarding effect is being produced by the amphetamine in part because of an action in the orbitofrontal cortex is that macaques will self-administer amphetamine to the orbitofrontal cortex (Phillips, Mora and Rolls, 1981). A clear indication of a differentiation in function between medial versus lateral areas of the human orbitofrontal cortex was found in our study investigating visual discrimination reversal learning, which showed a clear dissociation between the medial orbitofrontal areas correlating with monetary gain, and the lateral areas correlating with monetary loss (O'Doherty, Kringelbach, Rolls, Hornak and Andrews, 2001a). This result, and some of the other studies included in a meta-analysis (Kringelbach and Rolls, 2004), can be interpreted as evidence for a difference in humans between medial orbitofrontal cortex areas involved in decoding and monitoring the reward value of reinforcers, and lateral areas involved in evaluating punishers that when detected may lead to a change in current behavior. A good example of a study showing the latter involved a visual discrimination reversal task in which face identity was associated with a face expression (Kringelbach and Rolls, 2003). When the face expression associated with one of the faces reversed and the face expression was being interpreted as a punisher and indicated

Fig. 11.18 Subjective pleasure is correlated with activations (yellow) in the human medial orbitofrontal cortex and pregenual anterior cingulate and ventromedial prefrontal cortex. Subjective unpleasantness is correlated with activations (white) in the human lateral orbitofrontal cortex and supracallosal anterior cingulate cortex. Yellow: sites where activations correlate with subjective pleasantness. White: sites where activations correlate with subjective unpleasantness. The numbers refer to effects found in specific studies. Taste: 1, 2; odor: 3-10; flavor: 11-16; oral texture: 17, 18; chocolate: 19; water: 20; wine: 21; oral temperature: 22, 23; somatosensory temperature: 24, 25; the sight of touch: 26, 27; facial attractiveness: 28, 29; erotic pictures: 30; laser-induced pain: 31. (Modified from Fabian Grabenhorst and Edmund T. Rolls (2011) Value, pleasure and choice in the ventral prefrontal cortex. *Trends in Cognitive Sciences* 15: 56–67. © Elsevier Ltd.)

that behavior should change, then lateral parts of the orbitofrontal cortex became activated (Fig. 11.16).

At sites where positive value, produced by a reward, are represented, there are, when they are measured, correlations between the conscious, subjective, state of pleasure and the brain activations, where both are measured on every trial. Similarly, at sites where negative value, produced by a punisher or non-reward, are represented, there are correlations between the subjective state of unpleasantness and the brain activations. Fig. 11.18 shows the peaks of the correlations found in many different investigations related to these subjective states of pleasantness (yellow) and of unpleasantness (white) for both the orbitofrontal and the cingulate and ventromedial prefrontal cortices (see also Chapter 12) (Grabenhorst and Rolls, 2011).

Although our study on abstract reward found that monetary reward and punishment are correlated with activations in different regions of the orbitofrontal cortex (O’Doherty, Kringelbach, Rolls, Hornak and Andrews, 2001a), even this evidence does not show that rewards and punishers have totally separate representations in the human brain. In particular, the medial regions of the orbitofrontal cortex that had activations correlating with the magnitude of monetary reward (area 11) also reflected monetary punishers in the sense that the activations in these medial regions correlated positively with the magnitude of monetary wins and negatively with losses. Similarly, the more lateral regions (area 10) had activations that correlated negatively with the magnitudes of monetary wins and gains, and positively with monetary loss/punishment. This means that in this experiment the medial and lateral regions were apparently coding for both monetary reward and punishment (albeit in opposite ways). An investigation by Xie, Jia, Rolls et al (2021) with 1,877 participants supports this (Fig. 11.9). Further evidence for the same principle, but now for pleasant vs unpleasant odors, is illustrated in Fig. 5.4 (Rolls et al., 2003c).

What account might we give for why so many different types of reward are represented in the human medial orbitofrontal cortex? [The types of reward include, as described above, food reward as shown in sensory-specific satiety experiments (Kringelbach et al., 2003), pleasant odors (Rolls et al., 2003c; Grabenhorst et al., 2007; Rolls et al., 2008b), pleasant flavors (McCabe and Rolls, 2007; Rolls and McCabe, 2007; Grabenhorst et al., 2008a; Grabenhorst and Rolls, 2008), pleasant touch (Rolls et al., 2003d; McCabe et al., 2008; Rolls et al., 2008a), face attractiveness (O'Doherty et al., 2003b), monetary reward (O'Doherty et al., 2001a; Rolls et al., 2008e), conditioned stimuli associated with drug self-administration in addicts (Childress et al., 1999), and also the administration of amphetamine to drug-naïve human subjects (Völlm et al., 2004).] I suggest that part of the functional utility of this is that there can be comparison of the magnitudes of what may be quite different types of reward, facilitated by the local lateral inhibition mediated via the inhibitory interneurons (Rolls, 2019e).

I suggest that another part of the utility of functional segregation of reward in the human medial orbitofrontal cortex, and punishment / non-reward in the lateral orbitofrontal cortex, is that this enables attractor networks implemented by the local recurrent collaterals between nearby pyramidal cells to find the correct type of neuron within range to build an attractor. For example, if non-reward neurons tend to be in the lateral orbitofrontal cortex, they may be more likely to find neurons nearby that also respond to non-reward, and then to build a non-reward attractor because of their connections and their co-activity during non-reward. As we have seen, there is evidence for non-reward attractors in the orbitofrontal cortex (Fig. 11.14); and they are likely to be useful because keeping the non-reward state active for at least a few seconds if not longer can help with subsequent behavior on the next few trials; with resetting a rule-based attractor (Section 11.5.4); and with maintaining an emotional state, such as frustrative non-reward, active for at least a short time, which is likely to be evolutionarily adaptive.

In this context, it is interesting that the medial orbitofrontal cortex has strong connectivity with the pregenual anterior cingulate cortex, and that the lateral orbitofrontal cortex has strong connectivity with the supracallosal anterior cingulate cortex (Hsu et al., 2020; Rolls et al., 2019; Du et al., 2020). Perhaps this has the same function, of keeping reward and non-reward systems separate in the anterior cingulate cortex to help in the maintenance of attractors; and to facilitate this by connecting non-reward parts of the orbitofrontal cortex and anterior cingulate together to help the reciprocal connections maintain non-reward attractors. This arrangement may help to make emotional states persist for some time.

11.3.6 Decision-making in the orbitofrontal / ventromedial prefrontal cortex

We have shown that patients with damage to the orbitofrontal cortex are impaired in decision-making tasks, and that a key part of the impairment is that they continue to choose a previously rewarded stimulus when it is no longer rewarded in the reversal of a visual discrimination task (Rolls, Hornak, Wade and McGrath, 1994a). This has been confirmed (Fellows and Farah, 2003). In a probabilistic reversal learning task, patients with surgically induced and therefore localized lesions of the orbitofrontal cortex were impaired, and often failed to switch their choice of stimulus after a large loss; and often did switch their choice even though they had just received a reward (Hornak, O'Doherty, Bramham, Rolls, Morris, Bullock and Polkey, 2004), and this has been further quantified (Berlin, Rolls and Kischka, 2004). The deficit has been related to the inability to respond correctly to non-reward, as described in Section 11.3.4. The importance of the failure to rapidly learn about the value of stimuli from negative feedback as a critical difficulty for patients with orbitofrontal cortex lesions has been confirmed (Fellows, 2007; Wheeler and Fellows, 2008; Fellows, 2011).

Bechara and colleagues also have findings that are consistent with those described above in patients with frontal lobe damage when they perform the Iowa gambling task (Bechara et al., 1994, 1996, 1997; Damasio, 1994; Bechara et al., 2005; Glascher et al., 2012). Fellows and Farah (2005) found that patients with ventromedial prefrontal or with dorsolateral frontal lobe damage were impaired on the Iowa gambling task, yet only the orbitofrontal / ventromedial frontal damage group had a reversal deficit. Moreover the deficit on the gambling task of the orbitofrontal / ventromedial prefrontal patients was related to the fact that in the Iowa gambling task the first few choices of a high-risk deck are rewarded, and that later, when a large loss is received from a high-risk deck, an implicit reversal is required. Thus the deficit of patients with orbitofrontal cortex / ventromedial prefrontal cortex damage in the gambling task may be related at least in part to their failure to perform stimulus–reinforcer association reversal learning, rather than for other reasons. Further, reversal learning may more precisely measure the learning difficulty of patients with orbitofrontal cortex damage than the Iowa gambling task.

In fMRI studies, there is evidence that the orbitofrontal cortex itself represents value on a continuous scale, with the BOLD signal linearly related to pleasantness ratings, whereas a more anterior and medial region, which includes part of medial area 10 and is sometimes termed ventromedial prefrontal cortex, is activated when choices must be made between rewards (Grabenhorst et al., 2008b; Rolls et al., 2010d; Rolls and Grabenhorst, 2008). This was shown in tasks in which decisions were about the pleasantness of olfactory (Rolls, Grabenhorst and Parris, 2010d) or thermal (Grabenhorst, Rolls and Parris, 2008b) stimuli, compared to making ratings of pleasantness about the same stimuli.

Following up on these findings, a biologically plausible integrate-and-fire model of decision-making was used to make predictions of the fMRI signature of decision-making. (The decision-making model is described in Sections 11.5.1 and 11.5.2.) One key prediction was that the fMRI BOLD signal would be linearly related to the difference in magnitude between the decision variables (ΔI) in brain regions where choice decisions were being made. If the difference is large, the decision-making is easy, and participants have confidence in their decision even before the outcome is known.

Figure 11.19 shows experimental data with the fMRI BOLD signal measured on easy and difficult trials of the olfactory affective decision task (left) and the thermal affective decision task (right) (Rolls, Grabenhorst and Deco, 2010b). The upper records are for prefrontal cortex medial area 10 in a region identified by the following criterion as being involved in choice decision-making. The criterion was that a brain region for identical stimuli should show more activity when a choice decision was being made than when a rating on a continuous scale of affective value was being made. Figure 11.19 shows for ventromedial prefrontal cortex area 10 that there is a larger BOLD signal on easy than on difficult trials. The top diagram shows the medial prefrontal area activated in this contrast for decisions about which olfactory stimulus was more pleasant (yellow), and for decisions about whether the thermal stimulus would be chosen in future based on whether it was pleasant or unpleasant (red). Moreover, there was an approximately linear relation between the BOLD signal and ΔI for both the olfactory pleasantness and the thermal pleasantness decision-making tasks, as predicted by the model of decision-making. The neuronal network decision-making model could also predict the BOLD signal on error trials (Rolls, Grabenhorst and Deco, 2010c).

Thus there is evidence both from lesions and from fMRI that decisions between different rewards are made in the ventromedial prefrontal cortex (vmPFC) / anterior orbitofrontal cortex. The theory about how the decisions are made by an attractor decision-making network is described in Section 11.5.1. The finding of the signature of this type of decision-making network in a brain region implicated in the decision-making by larger activations when deci-

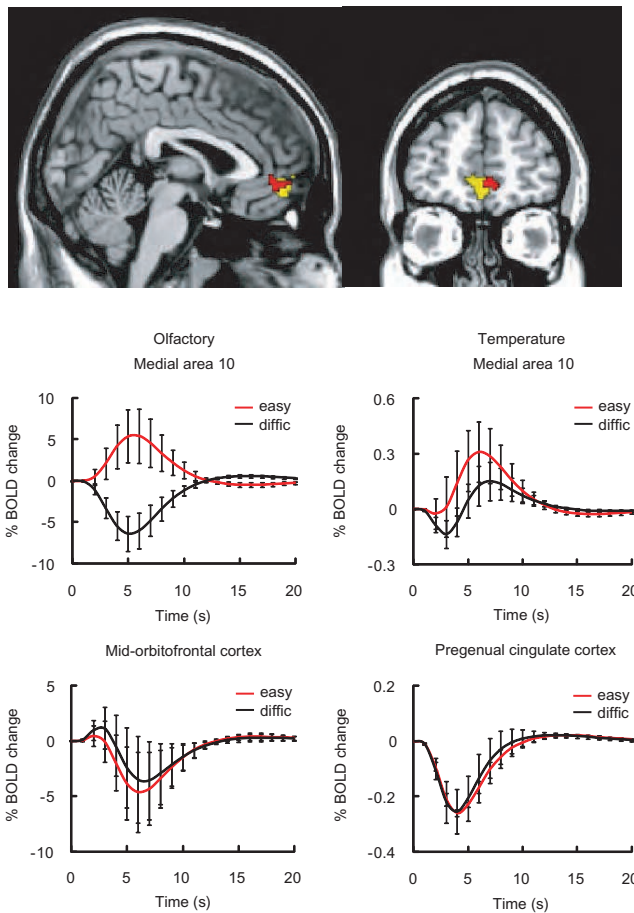

Fig. 11.19 The ventromedial prefrontal cortex area 10 (VMPFC) is implicated in reward-related decision-making. Top: Medial prefrontal cortex area 10 / VMPFC area activated on easy vs difficult trials in the olfactory pleasantness decision task (yellow) and the thermal pleasantness decision task (red). Middle: experimental data showing the BOLD signal in medial area 10 on easy and difficult trials of the olfactory affective decision task (left) and the thermal affective decision task (right). This medial area 10 was a region identified by other criteria (see text) as being involved in choice decision-making. Bottom: The BOLD signal for the same easy and difficult trials, but in parts of the pregenual cingulate and mid-orbitofrontal cortex implicated by other criteria (see text) in representing the subjective reward value of the stimuli on a continuous scale, but not in making choice decisions between the stimuli, or about whether to choose the stimulus in future. (Reprinted from Edmund T. Rolls, Fabian Grabenhorst, and Gustavo Deco (2010) Choice, difficulty, and confidence in the brain. *NeuroImage* 53: 694–706. © Elsevier Inc.)

sions were being made than when ratings of the identical stimuli were being made provides support for this theory and model of decision-making in the brain (Rolls and Deco, 2010).

11.3.7 The ventromedial prefrontal cortex and memory

Damage to the ventromedial prefrontal cortex (vmPFC) has been found to impair the ability to retrieve vivid autobiographical memories and imagine scenes (McCormick, Ciaramelli, De Luca and Maguire, 2018; Bonnici and Maguire, 2018). These patients are unlike patients with hippocampal damage, who do not have the differences in emotion that are characteristic of patients with damage to the ventromedial prefrontal cortex and orbitofrontal cortex. A characterisation of the difference is that patients with vmPFC damage have an inability to initiate internal reflections, including mental visualizations of extended events, while hippocampal patients seem able to initiate mental events but they are devoid of visual representations of

scenes (McCormick et al., 2018). Patients with vmPFC damage show a reduced frequency of mind-wandering and, on the occasions when mind-wandering had occurred, there was a reduced focus on future-oriented thoughts and an increased focus on present-related thought (McCormick et al., 2018).

It has been proposed that part of the reason for difficulties with autobiographical memories in patients with ventromedial prefrontal cortex damage is that the emotional, reward-related, aspects of autobiographical memory will be diminished (Rolls, 2022b). There are connections between the orbitofrontal cortex / vmPFC and the medial temporal lobe and hippocampal system, by both the ventral and dorsal routes, as shown in Figs. 9.1 and 11.28. Given that the emotional context is often part of autobiographical memory, it could be that without this component of autobiographical memory for use in the hippocampal memory system, the hippocampal memory system operates less well in retrieving memories. That would leave as the remaining components scenes, objects and temporal order, as described in Chapter 9. The hippocampal attractor network in CA3 may operate less effectively in recall when one of its major inputs, from the orbitofrontal / ventromedial prefrontal cortex, is absent. Without that input, the hippocampal recall system may receive insufficient input to implement recall properly: the input may be too incomplete to allow for completion by CA3 (Rolls, 2022b).

However, it is also the case that the vmPFC with its inputs from the orbitofrontal cortex may have a special role in memory, because the vmPFC does have strong connections (Morecraft et al., 1992) and connectivity in humans (Rolls et al., 2023c) (see Fig. 11.28) with the posterior cingulate cortex and hippocampal memory system. It has further been proposed (Rolls, 2022b), based on investigations of the connectivity of these regions in humans (Rolls et al., 2023c), that the orbitofrontal cortex and its onward connectivity with the vmPFC and anterior cingulate cortex, play important roles in memory consolidation. These roles include modulation of cholinergic pathways that connect in part via the fornix with the hippocampal system, and with the neocortex; and increasing the depth of processing for episodic memories with some value component, both of which are important in memory consolidation (Rolls, 2022b) (Section 9.2.8.5).

Further, the vmPFC also has connectivity in humans with the posterior cingulate cortex (Rolls et al., 2023c), which is involved in memory (Rolls et al., 2023i) (Chapter 12), and which also receives from the anterior thalamic nuclei, which receive inputs from the mammillo-thalamic tract. The mammillary bodies receive inputs from the hippocampal system via the fornix (and from the vestibular system), and are part of a subcortical system damage to which can impair memory (Bubb, Kinnavane and Aggleton, 2017). That may fit with the observation that neurons in the macaque anterior thalamic nuclei respond to familiar stimuli in a running recognition task (Rolls, Perrett, Caan and Wilson, 1982d). It also fits with the persistent interest in subcortical pathways that include the fornix, mammillary bodies, and anterior thalamic nuclei related to the hippocampal system that somehow relate to the functions of the hippocampal system in memory (Bubb, Kinnavane and Aggleton, 2017; Mathiasen, O'Mara and Aggleton, 2020; Aggleton, Nelson and O'Mara, 2022; Aggleton and O'Mara, 2022). However, the subcortical pathways do not have the network architecture to perform memory-related computations with high memory capacity that cortical regions including the hippocampus do have, as described in Chapter 9 (Rolls, 2018b). For example, thalamic nuclei probably mainly implement a high pass filter because of the local lateral inhibition provided for by the inhibitory interneurons, as in the lateral geniculate nucleus where this is understood (see Chapter 2 and Rolls and Deco (2002)). These subcortical pathways may thus affect how well the memory-related computations are performed in the hippocampal system (Chapter 9), but are most unlikely to perform the memory storage and recall computational operations.

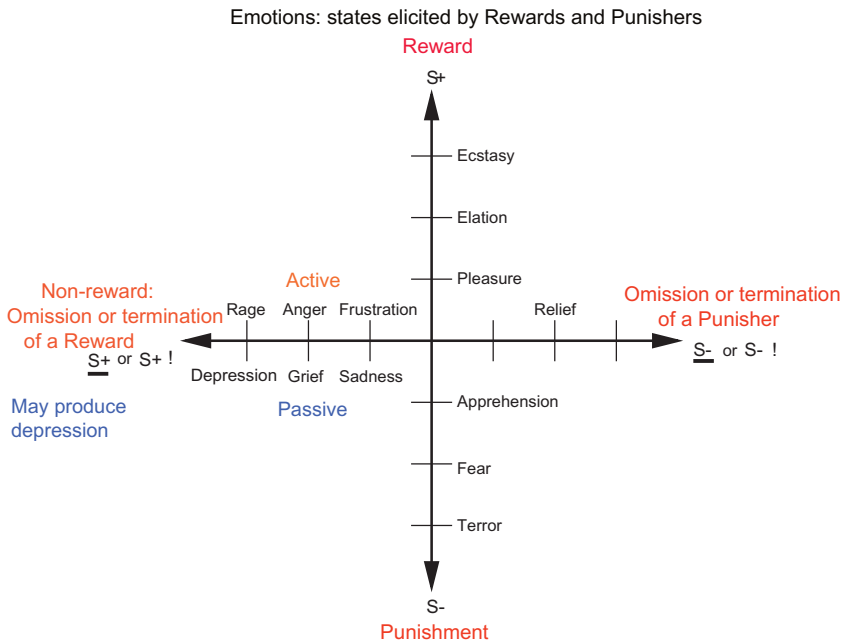

Fig. 11.20 Some of the emotions associated with different reinforcement contingencies are indicated. Intensity increases away from the centre of the diagram, on a continuous scale. The classification scheme created by the different reinforcement contingencies consists with respect to the action of (1) the delivery of a reward (S+), (2) the delivery of a punisher (S-), (3) the omission of a reward (S₊) (extinction) or the termination of a reward (S+!) (time out), and (4) the omission of a punisher (S₋) (avoidance) or the termination of a punisher (S-!) (escape). Note that the vertical axis describes emotions associated with the delivery of a reward (up) or punisher (down). The horizontal axis describes emotions associated with the non-delivery of an expected reward (left) or the non-delivery of an expected punisher (right). For the contingency of non-reward (horizontal axis, left) different emotions can arise depending on whether an active action is possible to respond to the non-reward, or whether no action is possible, which is labelled as the passive condition. In the passive condition, non-reward may produce depression. The diagram summarizes emotions that might result for one reinforcer as a result of different contingencies. Every separate reinforcer has the potential to operate according to contingencies such as these. This diagram does not imply a dimensional theory of emotion, but shows the types of emotional state that might be produced by a specific reinforcer. Each different reinforcer will produce different emotional states, but the contingencies will operate as shown to produce different specific emotional states for each different reinforcer.

11.3.8 The orbitofrontal cortex and emotion

We have seen that the orbitofrontal cortex is a key brain region involved in representing the reward and punishment value of stimuli. This makes it the key brain region involved in emotion, for emotions can be defined as states elicited by rewards and punishers, that is, by instrumental reinforcers (Rolls, 2014a, 2019e, 2018a, 2013d, 2005a, 1999a).

A reward is anything for which an animal will work. A punisher is anything that an animal will work to escape or avoid, or that will suppress actions on which it is contingent. The force of ‘instrumental’ in this definition is that the emotional states are seen as defining the goals for arbitrary behavioral actions, made to obtain the instrumental reinforcer. This is very different from classical conditioning, in which a response, typically autonomic, may be elicited to a stimulus, without any need for an intervening state. An important part of the function of emotion is to provide an intervening state, after for example the delivery of a non-reward, in which behavior can be reorganized, with perhaps a new action substituted for what was performed previously, in order to obtain the goal / reward (Rolls, 2014a).

An outline of a classification scheme for how different reinforcement contingencies (delivery of reward, omission or termination of reward, delivery of punishment, omission or termination of punishment) are related to different emotions is shown in Fig. 11.20 (Rolls, 2014a, 2023b). Movement away from the centre of the diagram represents increasing inten-

sity of emotion, on a continuous scale. The diagram shows that emotions associated with the delivery of a reward (S+) include pleasure, elation and ecstasy. Of course, other emotional labels can be included along the same axis. Emotions associated with the delivery of a punisher (S-) include apprehension, fear, and terror (see Fig. 11.20). Emotions associated with the omission of a reward (S+) or the termination of a reward (S+!) include frustration, anger and rage. Emotions associated with the omission of a punisher (S-) or the termination of a punisher (S-!) include relief.

An important point about Fig. 11.20 is that there are a large number of different primary (unlearned, gene-specified) reinforcers, and that for example the reward label S+ shows states that might be elicited by just one type of reward, such as a pleasant touch. There will be a different reward axis (S+) and non-reward axis (S+ and S+!) for each type of reward (e.g. pleasant touch vs sweet taste); and, correspondingly, a different punisher axis (S-) and non-punisher axis (S- and S-!) for each type of punisher (e.g. pain vs bitter taste). Examples of the reinforcers include food reward, water reward, pleasant touch, pain, a potential mate, kin including children, and altruism, with many examples provided in Table 2.1 of *Emotion and Decision-Making Explained* (Rolls, 2014a) (available on line at <https://www.oxcns.org>) and by Rolls (2023b).

Previously neutral stimuli can become associated by learning with these primary reinforcers, and become secondary reinforcers, which thereby become goals for action. An example is the sight of a new food, which may become a secondary reinforcer by association between its sight and the primary reinforcer of its taste.

It is argued that brains are designed around reward and punishment value systems, because this is the way that genes can build a complex system that will produce appropriate but flexible behavior to increase their fitness (Rolls, 2014a). The way that evolution by natural selection does this is to build us with reward and punishment systems that will direct our behavior towards goals in such a way that survival and in particular reproductive fitness are achieved. By specifying goals, rather than particular responses, genes leave much more open the possible behavioral strategies that might be required to increase their fitness. Specifying particular responses would be inefficient in terms of behavioral flexibility as environments change during evolution, and also would be more genetically costly to specify (in terms of the information to be encoded and the possibility of error). This view of the evolutionary adaptive value for genes to build organisms using reward- and punishment-decoding and action systems in the brain places one squarely in line as a scientist developing ideas from Darwin (1859) onwards (Hamilton, 1964, 1996; Dawkins, 1976), and is a key part of Rolls' theory of emotion and motivation (Rolls, 2014a, 2013d, 2018a, 2019e, 2023b).

The theory helps in understanding much of sensory information processing in the cortex, followed by reward and punishment value encoding, followed by decision-making and action selection to obtain the goals identified by the sensory/reinforcer decoding systems. Value coding systems must be separate from purely sensory or motor systems, and while a goal is being sought, or if a goal is not obtained, the value-related representation must remain to direct further goal-directed behavior, and it is these continuing goal-related states to which emotion is related. The theory is strongly supported by the effects of damage to the orbitofrontal cortex, which impairs emotional feelings and behavior, face and voice expression recognition, and socially appropriate behavior, as well as reward reversal learning (Hornak, Rolls and Wade, 1996; Rolls, 1999b; Rolls, Hornak, Wade and McGrath, 1994a; Hornak, Bramham, Rolls, Morris, O'Doherty, Bullock and Polkey, 2003; Hornak, O'Doherty, Bramham, Rolls, Morris, Bullock and Polkey, 2004; Berlin, Rolls and Kischka, 2004; Berlin, Rolls and Iversen, 2005; Fellows and Farah, 2003; Camille, Tsuchida and Fellows, 2011).

Fig. 11.21 Multiple routes to the initiation of actions and responses to rewarding and punishing stimuli in primates including humans. The lowest (spinal cord and brainstem) levels in the hierarchy are involved in reflexes, including for example reflex withdrawal of a limb to a nociceptive stimulus, and unlearned autonomic responses. The second level in the hierarchy involves associative learning in the amygdala and orbitofrontal cortex between primary reinforcers such as taste, touch and nociceptive stimuli and neutral stimuli such as visual and auditory stimuli from association cortex (e.g. inferior temporal visual cortex) to produce learned autonomic and some other behavioural responses such as approach. The anteroventral visceromotor insula may be one link from the orbitofrontal cortex to autonomic output. A third level in the hierarchy is the route from the orbitofrontal cortex and amygdala via the basal ganglia especially the ventral striatum to produce implicit stimulus-response habits. A fourth level in the hierarchy important in emotion is from the orbitofrontal cortex to the anterior cingulate cortex for actions that depend on the value of the goal in action-outcome learning. For this route, the orbitofrontal cortex implements stimulus-reinforcer association learning, and the anterior cingulate cortex action-outcome learning (where the outcome refers to receiving or not receiving a reward or punisher). A fifth level in the hierarchy is from the orbitofrontal cortex (and much less the amygdala (Rolls et al., 2023b)) via multiple step reasoning systems involving syntax and language. Processing at this fifth level may be related to explicit conscious states. The fifth level may also allow some top-down control of emotion-related states in the orbitofrontal cortex by the explicit processing system. Pallidum / SN - the globus pallidus and substantia nigra. (After Rolls, E. T. 2023b. Emotion, motivation, decision-making, the orbitofrontal cortex, anterior cingulate cortex, and the amygdala. Brain Structure and Function)

A more full description of Rolls' theory of emotion is available in *Emotion and Decision-Making Explained* (Rolls, 2014a), *The Brain, Emotion, and Depression* (Rolls, 2018a), and in Rolls (2023b), all available for free download from <https://www.oxcns.org>.

11.3.9 Emotional orbitofrontal vs rational routes to action

The evidence in Section 11.3 provides a firm conceptual framework for understanding why the orbitofrontal cortex is so important in emotion, as considered also in *Emotion and Decision-Making Explained* (Rolls, 2014a). In this section (11.3.9), I show that at least in humans, there are other routes to action that can be invoked in emotion-related situations in which the orbitofrontal cortex may take a role in emotion and action, but not necessarily the whole or only role. Here rational refers to reasoning.

11.3.9.1 Some of the different routes to action produced by emotion-related stimuli

Fig. 11.21 shows several major routes to behavior related to emotional stimuli in primates including humans. An important point made by Fig. 11.21 is that there are multiple routes to output including to action that can be produced by stimuli that produce emotional states. Here emotional states are the states elicited by reward and punishing / non-reward stimuli, as illustrated in Fig. 11.20. The multiple routes are organized in a set of hierarchies, with

each level in the system added later in evolution, but with all levels left in operation over the course of evolution (Rolls, 2016b, 2023b). The result of this is that a response such as an autonomic response to a stimulus that happens also to be rewarding might be produced by only the lower levels of the system operating, without necessarily the highest e.g. explicit levels being involved.

The lowest levels in the hierarchy illustrated in Fig. 11.21 are involved in reflexes, including for example reflex withdrawal of a limb to a nociceptive stimulus, and autonomic responses. The second level in the hierarchy can produce learned autonomic and some other behavioural responses to for example a previously neutral visual or auditory stimulus after it has been paired with, for example, a nociceptive or sweet taste stimulus. This route involves classical conditioning (Pavlovian learning) in the amygdala and orbitofrontal cortex. A third level in the hierarchy shown in Fig. 11.21 is the route from the orbitofrontal cortex and amygdala via the basal ganglia especially the ventral striatum to produce implicit stimulus-response habits with dopamine used to facilitate the stimulus-response associations (Chapter 16). A fourth level in the hierarchy that is important in emotion is from the orbitofrontal cortex to the anterior cingulate cortex for actions that depend on the value of the goal (Rolls, 2023b). The orbitofrontal cortex is involved in the stimulus-reward or stimulus-punishment (i.e. stimulus-stimulus) association learning, and the anterior cingulate cortex in the action-outcome learning, where the outcome is the reward or punisher that is or is not delivered. The emotional states implemented at this level may not necessarily be conscious. A fifth level in the hierarchy shown in Fig. 11.21 is from the orbitofrontal cortex (and much less the amygdala (Rolls et al., 2023b)) via multiple step reasoning systems involving syntax and language, which may be related to explicit conscious states (especially I argue if a higher order syntactic thought system for correcting lower order thoughts is involved) (Rolls, 2020a, 2008a, 2014a, 2023a) (see Section 19.6.3). Another route (shown in Fig. 11.28) involves providing goals to the hippocampal and related systems for navigation (Rolls et al., 2023c; Rolls, 2023c).

The route involving a **reasoning system** that may use some form of language with syntax (grammar) to plan several steps ahead is a focus in this Section. This route enables actions to be performed for completely different goals than those specified by genes as primary reinforcers that can use the earlier routes just described for output. This reasoning system is very important for understanding human emotion, because its decisions can be made in a completely different way, and do not necessarily lead to decisions that are consistent with those specified by the gene-defined reinforcers that are important in the first ‘emotion-related’ route to behavioral output. I argue in this Section that our reasoning system enables us to go beyond what ‘Selfish Genes’ might encourage (Dawkins, 1976), and that when we use the term ‘free will’, it is to the rational system that we may wish to refer, together with the non-deterministic, probabilistic, nature of brain computation that is described in Sections 11.5.1 and B.7 – B.8.3 (Rolls and Deco, 2010; Rolls, 2012e, 2014a, 2016b, 2020a). The orbitofrontal cortex has effective connectivity to the language areas via for example Broca’s area, and this provides a route for the orbitofrontal cortex, and much less the amygdala, to introduce emotion / reward-related information into the explicit system (Rolls et al., 2023b,f,c).

I will give a simple example to make the point clear. Our genes may predispose us to like foods that are sweet and fatty (with modern supernormal examples ice cream and chocolate), and these may be rewarding to us because of the processes taking place in brain regions such as the orbitofrontal cortex and amygdala. But our reasoning system may know about discoveries in science and medicine that provide evidence that these foods may tend to promote obesity and poor health if eaten in quantity (Rolls, 2016g). So our reasoning system may enable us to override what our gene-based emotional system involving the orbitofrontal cortex urges, and instead to eat the healthy foods, for the potential advantage to the individual person of a healthy and long life.

11.3.9.2 Examples of some complex behaviors that may be performed implicitly

A starting point is that many actions can be performed relatively automatically, without apparent conscious intervention, that is implicitly (Rolls, 2020a).

An example sometimes given is driving a car for a short distance while the person may be thinking about something else.

Another example is the identification of a visual stimulus that can occur without conscious awareness if the stimulus is very short (as in backward masking) or weak (Rolls and Tovee, 1994; Rolls, 2003).

Another example is much of the sensory processing and actions that involve the dorsal stream of visual processing to the parietal cortex, such as a patient posting a letter through a letter box at the correct orientation even when the patient may not be aware of what the object is (Milner and Goodale, 1995; Goodale, 2004; Milner, 2008) because of damage to the ventral visual stream which implements object recognition (Rolls, 2016b).

Another example is blindsight, in which humans with damage to the visual cortex may be able to point to objects even when they are not aware of seeing an object (Weiskrantz, 1997, 1998, 2009).

Similar evidence applies to emotions, some of the processing for which can occur without conscious awareness (De Gelder et al., 1999; Phelps and LeDoux, 2005; LeDoux, 2008; LeDoux and Pine, 2016; LeDoux et al., 2018).

Consistent with the hypothesis of multiple routes to action, only some of which involve conscious awareness, is the evidence that split-brain patients may not be aware of actions being performed by the ‘non-dominant’ (typically right) hemisphere (Gazzaniga and LeDoux, 1978; Gazzaniga, 1988, 1995). An example is of split brain patients who when the ‘non-dominant’ right hemisphere was shown a picture of the left side of a house on fire (which would reach the right hemisphere) chose the non-burning house but said ‘there is no specific reason for my choice’, and ‘the two houses are the same anyway’.

Also consistent with multiple, including non-verbal, routes to action, patients with focal brain damage, for example to the orbitofrontal cortex, may perform actions, yet comment verbally that they should not be performing those actions (Rolls, Hornak, Wade and McGrath, 1994a; Hornak, Bramham, Rolls, Morris, O’Doherty, Bullock and Polkey, 2003). In both these types of patient, confabulation may occur, in that a verbal account of why the action was performed may be given, and this may not be related at all to the environmental event that actually triggered the action (Gazzaniga and LeDoux, 1978; Gazzaniga, 1988, 1995; Rolls, Hornak, Wade and McGrath, 1994a).

11.3.9.3 A reasoning, rational, route to action

A reasoning-based, ‘explicit’, route to action in (at least) humans involves a computation with many ‘if ... then’ statements, to implement a plan to obtain a reward (Rolls, 2014a, 2019d, 2020a). In this case, the reward may actually be deferred as part of the plan, which might involve working first to obtain one reward, and only then to work for a second more highly valued reward, if this was thought to be overall an optimal strategy in terms of resource usage (e.g. time). In this case, syntax is required, because the many symbols (e.g. names of people) that are part of the plan must be correctly linked or bound. Such linking might be of the form: ‘if A does this, then B is likely to do this, and this will cause C to do this ...’. The requirement of syntax for this type of planning implies that involvement of a syntactic system in the brain is required (see Fig. 11.21). **Thus the explicit language system in humans may allow working for deferred rewards by enabling use of a one-off, individual, plan appropriate for each situation.** This explicit system may allow immediate rewards to be deferred, as

part of a long-term plan. This ability to defer immediate rewards and plan syntactically in this way for the long term may be an important way in which the explicit system extends the capabilities of the implicit emotion systems that respond more directly to rewards and punishers, or to rewards and punishers with fixed expectancies such as can be learned by reinforcement learning (Sections 19.5 and B.17).

Consistent with the point being made about evolutionarily old emotion-based decision systems vs a recent rational system present in humans (and perhaps other animals with syntactic processing) is that humans trade off immediate costs/benefits against cost/benefits that are delayed by as much as decades, whereas non-human primates have not been observed to engage in unpreprogrammed delay of gratification involving more than a few minutes (Rachlin, 1989; Kagel, Battalio and Green, 1995; McClure, Laibson, Loewenstein and Cohen, 2004; Rosati, 2017).

Another building block for such planning operations in the brain may be the type of short-term memory in which the prefrontal cortex is involved (Chapter 13). This short-term memory may be, for example in non-human primates, of where in space a response has just been made. A development of this type of short-term memory system in humans to enable multiple short-term memories to be held in place correctly, preferably with the temporal order of the different items in the short-term memory coded correctly, may be another building block for the multiple step ‘if ... then’ type of computation in order to form a multiple step plan. Such short-term memories are implemented in the (dorsolateral and inferior convexity) prefrontal cortex of non-human primates and humans (Goldman-Rakic, 1996; Petrides, 1996; Deco and Rolls, 2003; Rolls, 2016b), and may be part of the reason why prefrontal cortex damage impairs planning and executive function (Gilbert and Burgess, 2008; Shallice and Cipolotti, 2018; Rolls et al., 2023a).

We may examine some of the advantages and behavioral functions that language, present as the most recently added layer to the above system (Fig. 11.21), would confer.

One major advantage would be the ability to plan actions through many potential stages and to evaluate the consequences of those actions without having to perform the actions. For this, the ability to form propositional statements, and to perform syntactic operations on the semantic representations of states in the world, would be important.

Also important in this system would be the ability to have second-order thoughts about the type of thought that I have just described (e.g. I think that she thinks that ..., involving ‘theory of mind’), as this would allow much better modelling and prediction of others’ behavior, and therefore of planning, particularly planning when it involves others. Second-order thoughts are thoughts about thoughts. Higher-order thoughts refer to second-order, third-order, etc., thoughts about thoughts ... This capability for higher-order thoughts would also enable reflection on past events, which would also be useful in planning ¹⁶.

In contrast, non-linguistic behavior would be driven by learned reinforcement associations, learned rules etc., but not by flexible planning for many steps ahead involving a model of the world including others’ behavior.

It is important to state that the language ability referred to here is not necessarily human verbal language (though this would be an example). What is suggested is important to multiple step planning is the syntactic manipulation of symbols, and it is this syntactic

¹⁶A thought may be defined briefly as an intentional mental state, that is a mental state that is about something. Thoughts include beliefs, and are usually described as being propositional (Rosenthal, 2005). An example of a thought is “It is raining”. A more detailed definition is as follows. A thought may be defined as an occurrent mental state (or event) that is intentional – that is a mental state that is about something – and also propositional, so that it is evaluable as true or false. Thoughts include occurrent beliefs or judgements. An example of a thought would be an occurrent belief that the earth moves around the sun / that Maurice’s boat goes faster with two sails / that it never rains in southern California.)

manipulation of symbols that is the sense in which language is defined and used here (Rolls, 2014a, 2004b; Fodor, 1994; Rolls and Deco, 2015a) (see Chapter 14).

Fig. 11.21 shows some direct connections from early cortical visual regions (such as the primary and secondary cortical areas in a hierarchy) to language regions, that bypass association cortical regions (such as the inferior temporal visual cortex). The reason for this suggestion is that explicit, declarative, reports about low-level features of sensory processing that may not be present in association cortical regions (such as the inferior temporal visual cortex where invariant representations with respect to for example position are formed (Rolls, 2021d)), are present in human subjective experience (Rolls, 2004b, 2011b, 2014a, 2020a).

In summary, I understand **reasoning, and rationality**, to involve syntactic manipulations of symbols. Reasoning thus typically may involve multiple steps of ‘if ... then’ conditional statements, all executed as a one-off or one-time process (see below), and is very different from associatively learned conditional rules typically learned over many trials, such as ‘if yellow, a left choice is associated with reward’.

11.3.9.4 The Selfish Gene vs The Selfish Phenotype

I have provided evidence in the earlier part of this section (11.3.9) that there are two main types of route to decision-making and action. The first type of route selects actions by gene-defined goals for action, is closely associated with emotion, and involves brain systems such as the orbitofrontal cortex and cingulate cortex. The second type of route involves multistep planning and reasoning which requires syntactic processing to keep the symbols involved at each step separate from the symbols in different steps. (This second type of route is used by humans and perhaps by closely related animals.) Now the ‘interests’ of the first and second routes to decision-making and action are different. As argued convincingly by Richard Dawkins in *The Selfish Gene* (Dawkins, 1976, 1989), and by others (Hamilton, 1964; Ridley, 1993; Hamilton, 1996), many behaviors occur in the interests of the survival of the genes, not of the individual (nor of the group), and much behavior can be understood in this way.

I have extended this approach by arguing that an important role for some genes in evolution is to define the goals for actions that will lead to better survival of those genes; that emotions are the states associated with these gene-defined goals; and that the defining of goals for actions rather than actions themselves is an efficient way for genes to operate, as it leaves flexibility of choice of action open until the animal is alive (Rolls, 2014a). This provides great simplification of the genotype, as action details do not need to be specified, just rewarding and punishing stimuli; and also provides flexibility of action in the face of changing environments faced by the genes. Thus the interests that are implied when the first route to action (that typically involves the orbitofrontal and cingulate cortices) is chosen are those of the ‘selfish genes’, not those of the individual.

However, the second type of route to action allows, by reasoning, decisions to be taken that might not be in the interests of the genes, might be longer term decisions, and might be in the interests of the individual. An example might be a choice not to have children, but instead to devote oneself to science, medicine, music, or literature. The reasoning, rational, system presumably evolved because taking longer-term decisions involving planning rather than choosing a gene-defined goal might be advantageous at least sometimes for genes. But an unforeseen consequence of the evolution of the rational system might be that the decisions would, sometimes, not be to the advantage of any genes in the organism. After all, evolution by natural selection operates utilizing genetic variation like a Blind Watchmaker (Dawkins, 1986). In this sense, the interests when the second route to decision-making is used are at least sometimes those of the ‘selfish phenotype’. Hence the decision-making referred to in this Section (11.3.9) is between a first system where the goals are gene-defined, and a second rational system in which the decisions may be made in the interests of the genes, or in

the interests of the phenotype and not in the interests of the genes. Thus we may speak of the choice as sometimes being between the ‘Selfish Genes’ and the ‘Selfish Phenotypes’ (Rolls, 2014a).

Now what keeps the decision-making between the ‘Selfish Genes’ and the ‘Selfish Phenotypes’ more or less under control and in balance? If the second, rational, system chose too often for the interests of the ‘Selfish Phenotype’, the genes in that phenotype would not survive over generations. Having these two systems in the same individual will only be stable if their potency is approximately equal, so that sometimes decisions are made with the first route, and sometimes with the second route. If the two types of decision-making, then, compete with approximately equal potency, and sometimes one is chosen, and sometimes the other, then this is exactly the scenario in which stochastic processes in the decision-making mechanism are likely to play an important role in the decision that is taken. The same decision, even with the same evidence, may not be taken each time a decision is made, because of noise in the system.

The system itself may have some properties that help to keep the system operating well. One is that if the second, rational, system tends to dominate the decision-making too much, the first, gene-based emotional (orbitofrontal cortex) system might fight back over generations of selection, and enhance the magnitude of the reward value specified by the genes, so that emotions might actually become stronger as a consequence of them having to compete in the interests of the selfish genes with the rational decision-making process.

Another property of the system may be that sometimes the rational system cannot gain all the evidence that would be needed to make a rational choice. Under these circumstances the rational system might fail to make a clear decision, and under these circumstances, basing a decision on the gene-specified emotions involving the orbitofrontal cortex is an alternative. Indeed, Damasio (1994) argued that under circumstances such as this, emotions might take an important role in decision-making. In this respect, I agree with him, basing my reasons on the arguments above. He called the emotional feelings gut feelings, and, in contrast to me (Rolls, 2014a), hypothesized that actual feedback from the gut was involved. His argument seemed to be that if the decision was too complicated for the rational system, then send outputs to the viscera, and whatever is sensed by what the periphery sends back could be used in the decision-making, and would account for the conscious feelings of the emotional states. My reading of the evidence is that the feedback from the periphery is not necessary for the emotional decision-making, or for the feelings, nor would it be computationally efficient to put the viscera and more generally the periphery in the loop given that the information starts from the brain (Rolls, 2014a).

Another property of operation is that the interests of the second, rational, system, although involving a different form of computation, should not be too far from those of the gene-defined emotional system, for the arrangement to be stable in evolution by natural selection. One way that this could be facilitated would be if the gene-based goals felt pleasant or unpleasant in the rational system, and in this way contributed to the operation of the second, rational, system. This is something that I propose is the case. This provides an account of why rewards feel good (Rolls, 2014a).

11.3.9.5 Decision-making between the implicit and explicit systems

The question then arises of how decisions are made in animals such as humans that have both the implicit, direct reward-based, and the explicit, rational, planning systems (see Fig. 11.21). One particular situation in which the first, implicit, system may be especially important is when rapid reactions to stimuli with reward or punishment value must be made, for then the direct connections from structures such as the orbitofrontal cortex to the basal ganglia may allow rapid actions. Another is that when there may be too many factors to be taken into

account easily by the explicit, rational, planning, system, then the implicit system may be used to guide action.

In contrast, when the implicit system continually makes errors, it would then be beneficial for the individual to switch from automatic, direct, action based on obtaining what the orbitofrontal cortex system decodes as being the most positively reinforcing choice currently available, to the explicit conscious control system that can evaluate with its long-term planning algorithms what action should be performed next. Indeed, it would be adaptive for the explicit system to be regularly assessing performance by the more automatic system, and to switch itself in to control behavior quite frequently, as otherwise the adaptive value of having the explicit system would be less than optimal.

Another factor that may influence the balance between control by the implicit and explicit systems is the presence of pharmacological agents such as alcohol, which may alter the balance towards control by the implicit system, may allow the implicit system to influence more the explanations made by the explicit system, and may within the explicit system alter the relative value it places on caution and restraint vs commitment to a risky action or plan.

There may also be a flow of influence from the explicit, verbal system to the implicit system, in that the explicit system may decide on a plan of action or strategy, and exert an influence on the implicit system that will alter the reinforcement evaluations made by and the signals produced by the implicit system. An example of this might be that if a pregnant woman feels that she would like to escape a cruel mate, but is aware that she may not survive in the jungle, then it would be adaptive if the explicit system could suppress some aspects of her implicit behavior towards her mate, so that she does not give signals that she is displeased with her situation¹⁷. Another example might be that the explicit system might, because of its long-term plans, influence the implicit system to increase its response to for example a positive reinforcer. One way in which the explicit system might influence the implicit system is by setting up the conditions in which, for example, when a given stimulus (e.g. person) is present, positive reinforcers are given, to facilitate stimulus–reinforcement association learning by the implicit system of the person receiving the positive reinforcers. Conversely, the implicit system may influence the explicit system, for example by highlighting certain stimuli in the environment that are currently associated with reward, to guide the attention of the explicit system to such stimuli.

However, it may be expected that there is often a conflict between these systems, in that the first, implicit, system is able to guide behavior particularly to obtain the greatest immediate reinforcement, whereas the explicit system can potentially enable immediate rewards to be deferred, and longer-term, multistep, plans to be formed. This type of conflict will occur in animals with a syntactic planning ability, that is in humans and any other animals that have the ability to process a series of ‘if ... then’ stages of planning. This is a property of the human language system, and the extent to which it is a property of non-human primates is not yet fully clear. In any case, such conflict may be an important aspect of the operation of at least the human mind, because it is so essential for humans to decide correctly, at every moment, whether to invest in a relationship or a group that may offer long-term benefits, or whether to pursue immediate benefits directly (Nesse and Lloyd, 1992).

Decision-making as implemented in neural networks in the brain is now becoming understood, and is described in Sections 11.5.1, B.6.3, B.8.2 and B.8.3. As shown there, two attractor states, each one corresponding to a decision, compete in an attractor single network with the evidence for each of the decisions acting as biases to each of the attractor

¹⁷In the literature on self-deception, it has been suggested that unconscious desires may not be made explicit in consciousness (or actually repressed), so as not to compromise the explicit system in what it produces (Alexander, 1979; Trivers, 1985; Nesse and Lloyd, 1992).

states. The non-linear dynamics, and the way in which noise due to the random spiking of neurons makes the decision-making probabilistic, makes this a biologically plausible model of decision-making consistent with much neurophysiological and fMRI data (Wang, 2002; Rolls and Deco, 2010; Deco, Rolls, Albantakis and Romo, 2013; Rolls, 2016b, 2021b).

I propose (Rolls, 2005a, 2014a) that this model applies to taking decisions between the implicit (unconscious) and explicit (conscious) systems in emotional decision-making, where the two different systems could provide the biasing inputs λ_1 and λ_2 to the model. An implication is that noise will influence with probabilistic outcomes which system takes a decision, depending on the magnitude of the competing inputs from the emotional and rational systems.

An additional way in which this type of decision-making might be influenced is by the reasoning, language-based, system exerting a top-down influence on the emotional system in the orbitofrontal cortex, to perhaps decrease the reward value represented in the orbitofrontal cortex (or perhaps to enhance the emotion-related orbitofrontal cortex representation, when for example listening to opera) (Rolls et al., 2023b,f,c).

When decisions are taken, sometimes confabulation may occur, in that a verbal account of why the action was performed may be given, and this may not be related at all to the environmental event that actually triggered the action (Gazzaniga and LeDoux, 1978; Gazzaniga, 1988, 1995; Rolls, 2014a; LeDoux, 2008; Rolls, 2012e, 2020a). It is accordingly possible that sometimes in normal humans when actions are initiated as a result of processing in a specialized brain region such as the orbitofrontal cortex involved in some types of rewarded behavior, the language system may subsequently elaborate a coherent account of why that action was performed (i.e. confabulate). This would be consistent with a general view of brain evolution in which, as areas of the cortex evolve, they are laid on top of existing circuitry connecting inputs to outputs, and in which each level in this hierarchy of separate input–output pathways may control behavior according to the specialized function it can perform (Rolls, 2016b). This hierarchical overlaying is an important concept for understanding emotion, the different brain systems involved in different aspects of emotion and decision-making, and the relation between the implicit and explicit systems (Rolls, 2014a). When a new layer is added, previous layers may lose some of their importance, as appears to occur in the taste system in which in primates the subcortical processing from the brainstem nucleus of the solitary tract is lost (Section 19.10); when the granular orbitofrontal cortex of primates becomes relatively more important than the amygdala (Rolls et al., 2023b); and when language areas are added on top of existing circuitry (Fig. 11.21) (Rolls, 2016b).

11.3.9.6 The emotional vs rational brain systems, and the strength of emotions in humans

Emotions often seem very intense in humans, indeed sometimes so intense that they produce behavior that does not seem to be adaptive, such as fainting instead of producing an active escape response, or freezing instead of avoiding, or vacillating endlessly about emotional situations and decisions, or falling hopelessly in love even when it can be predicted to be without hope or to bring ruin. The puzzle is not only that the emotion is so intense, but also that even with our rational, reasoning, capacities, humans still find themselves in these situations, and may find it difficult to produce reasonable and effective decisions and behavior for resolving the situation. The reasons for this include, I suggest, the following.

In humans, the reward and punishment brain systems may operate implicitly in comparable ways to those in other animals. But in addition to this, humans have the explicit system, which enables us consciously to look and predict many steps ahead (using language and syntax) the consequences of environmental events, and also to reflect on previous events (Rolls, 2014a, 2018a, 2019d, 2020a). The consequence of this explicit processing is that we can see the full impact of rewarding and punishing events, both looking ahead to see how this will

impact us, and reflecting back to previous situations that we can see may never be repeated. For example, in humans grief occurs with the loss of a loved one, and this may be much more intense than might occur simply because of failure to receive a positively reinforcing stimulus, because we can look ahead to see that the person will never be present again, can process all the possible consequences of that, and can remember all the previous occasions with that person. In another example, someone may faint at the sight of blood, and this is more likely to occur in humans because we appreciate the full consequences of major loss of blood, which we all know is life-threatening.

Thus what happens is that reinforcing events may have a very much greater reinforcing value in humans than in other animals, because we have so much cognitive, especially linguistic, processing that leads us to evaluate and appreciate many reinforcing events far more fully than can other animals. Thus humans may decode reinforcers to have supernormal intensity relative to what is usual in other animals, and the supernormal appreciated intensity of the decoded reinforcers leads to super-strong emotions. The emotional states can then be so strong that they are not necessarily adaptive, and indeed language has brought humans out of the environmental conditions under which our emotional systems evolved. For example, the autonomic responses to the sight of blood may be so strong, given that we know the consequences of loss of blood, that we faint rather than helping. Another example is that panic and anxiety states can be exacerbated by feeling the heart pounding, because we are able to use our explicit processing system to think and worry about all the possible causes. One can think of countless other examples from life, and indeed make up other examples, which of course is part of what novelists do (Rolls, 2012e, 2018a).

A second reason for such strong emotions in humans is that the stimuli that produce emotions may be much stronger than those in which our emotional systems evolved. For example, with man-made artefacts (such as cars and guns that may injure many people simultaneously, or a large bus speeding towards one, both of which produce super-normal stimuli), the sights and related stimuli that can be produced in terms of damage to humans are much more intense than those present when our emotional systems evolved. In this way, the things we see can in some cases produce super-strong emotions.

A third reason for the intensely mobilizing, and sometimes immobilizing, effects of emotions in humans is that we can evaluate linguistically, with reasoning, the possible courses of action open to us in emotional situations. Because we can evaluate the possible effects of reinforcers many steps ahead in our plans, and because language enables us to produce flexible one-off plans for actions, and enables us to work for deferred rewards based on one-off plans (Rolls, 2014a, 2018a, 2019d, 2020a), the ways in which reinforcers are used in decision-making becomes much more complex than in those animals that cannot produce similar one-off plans using syntax. The consequence of this is that decision-making can become very difficult, with so many potential but uncertain reinforcement outcomes, that humans may vacillate. They are trying to compute by this explicit method the most favourable outcome of each plan in terms of the net reinforcements received, rather than using reinforcement implicitly to select the highest currently available reinforcer.

A fourth reason for complexity in the human emotional system is that there are, it is suggested, two routes to action for emotions in humans, an implicit (unconscious) and an explicit route. These systems may not always agree. The implicit system may tend to produce one type of behavior, typically for immediately available rewards. The explicit system may tend to produce another planned course of action to produce better deferred rewards. Conflict between these systems can lead to many difficult situations, will involve conscience (what is right as conceived by the explicit system) and the requirement to abide by laws (which assume a rational explicit system responsible for our actions). It appears that the implicit system does often control our behavior, as shown by the effects of frontal lobe damage in humans, which

may produce deficits in reward-reversal tasks, even when the human can explicitly state the correct behavior in the situation. (The conflicts that arise between these implicit and explicit systems are again some of the very stuff on which novels in literature often capitalize (Rolls, 2018a)).

A fifth reason for complexity in the human emotional system is that we, as social animals, with major investments in our children who benefit from long-term parental co-operation, and with advantages to be gained from social alliances if the partners can be trusted, may be built to try to estimate the goals and reliability of those we know. For example, it may matter to a woman with children whether her partner has been attracted by / is in love with / a different woman, as this could indicate a reduction of help and provision. Humans may thus be very interested in the emotional lives of each other, as this may impact on their own lives. Indeed, humans will, for this sort of reason, be very interested in who is co-operating with whom, and gossip about this may even have acted as a selective pressure for the evolution of language (Dunbar, 2017). In these circumstances, fascination with unravelling the thoughts and emotions of others (using the capacity described as theory of mind (Frith and Frith, 2012)), and empathy which may facilitate this (Kanske, Bockler and Singer, 2017), would have adaptive value, though it is difficult computationally to model the minds and interactions of groups of other people, and to keep track of who knows what about whom, as this requires many levels of nested syntactical reference. Our resulting fascination with this, and perhaps the value of experience of as wide a range of situations as possible, may then be another reason why human emotions, and guessing others' emotions in complex social situations, may also be part of the stuff of novelists, playwrights, and poets. Indeed, it may be important for us to find it attractive to engage in this type of processing because of its potential adaptive value, and this may be part of the reason why we find drama, novels, and poetry so fascinating (Rolls, 2012e, 2018a).

A sixth reason for complexity in the human emotional system is that high level cognitive processing can reach down in to the emotional systems and influence how they respond. This was demonstrated in the experiment by De Araujo, Rolls et al. (2005) in which it was shown that processing at the linguistic level, in the form of a word label, can influence processing as far down in sensory processing as the secondary olfactory cortex in the orbitofrontal cortex, the first stage in cortical processing at which the reward- or punishment-related (hence affective) significance of stimuli is made explicit in the neuronal representations of stimuli (Section 5.2.7). This emphasizes the importance of cognitive influences on reward value and emotion, and shows how, in situations that might range from enjoying food to a romantic evening, the cognitive top-down influences can play an important role in influencing affective representations in the brain. Indeed, these findings lend support to the hypothesis that an interesting role for cognitive systems in emotion is to help set up the optimal conditions in terms of the reinforcers available and contextual surroundings for reinforcers to produce affective states.

11.3.9.7 The emotional systems in animals, and welfare

An implication of the above approach to emotion and motivation is that when considering animal welfare, it is likely to be important to take into account what value each species places on different rewards and the avoidance of possible aversive stimuli. This can in principle be measured by the choices that animals make between different rewards or avoiding different potential punishers. The procedures are well known in neuroeconomics, in which it is possible to measure for example how many drops of fruit juice A are chosen equally often as two drops of fruit juice B (Kuwabara et al., 2020; Cai and Padoa-Schioppa, 2019; Padoa-Schioppa and Conen, 2017; Rolls, 2014a; Cai and Padoa-Schioppa, 2012; Padoa-Schioppa and Cai, 2011; Padoa-Schioppa, 2011; Padoa-Schioppa and Assad, 2008; Padoa-Schioppa,

2007; Padoa-Schioppa and Assad, 2006; Platt et al., 2016; Yamada et al., 2018; Glimcher and Fehr, 2013; Dawkins, 2021). Similar titration procedures could be used to measure what value, measured by choice, a species places on for example food vs bedding vs having other animals nearby vs overcrowding vs being able to take a swim or shower vs being able to sit on a perch vs being able to reach a branch high above the ground vs being able to perform reproductive behavior, etc. When measuring these choices, it is important to ensure that the choice is being made by the goal-directed reward system for instrumental action, and not by any system involved in a reflex or fixed action pattern, or a learned habit (Rolls, 2023b).

Measuring instrumental goal-directed choices made by particular species may be useful to minimize over-anthropomorphic inferences about the value that a species may place on different 'goods' (the term used in neuroeconomics). Further, even the evidence taken from humans may need to be carefully assessed, for humans are able to provide reasons with their declarative system for their choices made with their syntactic learning system, but may confabulate reasons why they chose a good when the choice has been made by the emotional or by the automatic habit system (Gazzaniga and LeDoux, 1978; Rolls, 2020a, 2011b, 2010c, 2020a).

Another implication is that the taste, olfactory and food texture systems present in different species may result in adequate nutrition in their natural environment, but care may be needed to ensure in other environments that the nutrition being made available is appropriate. In this context, it must be remembered that animals do not have flavor mechanisms built to ensure that every possible nutrient needed is being selected by specific appetites for different nutrients. Instead, in the natural environment animals condition to new foods that provide useful nutrients by physiological effects that may occur some time after the food is ingested (Scott, 2011; Berthoud, Morrison, Ackroff and Sclafani, 2021) (Section 4.2.10).

A set of criteria for achieving good welfare in farm animals, known as the Five Freedoms (Farm Animal Welfare Council (2009)) consist of 1. Freedom from hunger and thirst. 2. Freedom from discomfort. 3. Freedom from pain, injury and disease. 4. Freedom to express normal behavior. 5. Freedom from fear and distress. The present approach suggests that when assessing (4), it will be useful to measure the value of the different types of 'normal behavior' to help assess priorities. The present approach suggests that when assessing (5), farm animals may often be protected from the fears, stressors, and predators that are present in the natural world, but that these provide a scale against which other fear and distress might be calibrated.

11.3.9.8 The orbitofrontal cortex and addiction

Most investigations of the neurobiology of addiction have focussed on habit-related stimulus-response effects mediated by dopamine and fronto-striatal circuitry (Everitt, Giuliano and Belin, 2018; Luscher, Robbins and Everitt, 2020; Compton, Wargo and Volkow, 2022), with opiate drugs also operating via the dopamine pathways (Galaj and Xi, 2021).

However, the administration of amphetamine to naive human participants activates the orbitofrontal cortex and two regions to which it projects, the pregenual anterior cingulate cortex and ventral striatum as illustrated in Fig. 11.22 (Völlm, De Araujo, Cowen, Rolls, Kringelbach, Smith, Jezzard, Heal and Matthews, 2004). An indication that a rewarding effect is being produced by the amphetamine in part because of an action in the orbitofrontal cortex is that macaques will self-administer amphetamine to the orbitofrontal cortex (Phillips, Mora and Rolls, 1981). This indicates that at least part of the reward and pleasure produced by the psychomotor stimulants may be being produced by activation of the medial orbitofrontal and pregenual anterior cingulate cortex, both of which receive dopamine inputs, and in both of which there are neurons and activations produced by natural rewards. Consistently, the orbitofrontal cortex as well as the areas to which it projects such as the ventral striatum are activated in cocaine (another psychomotor stimulant) addicts by exposure to drug-related

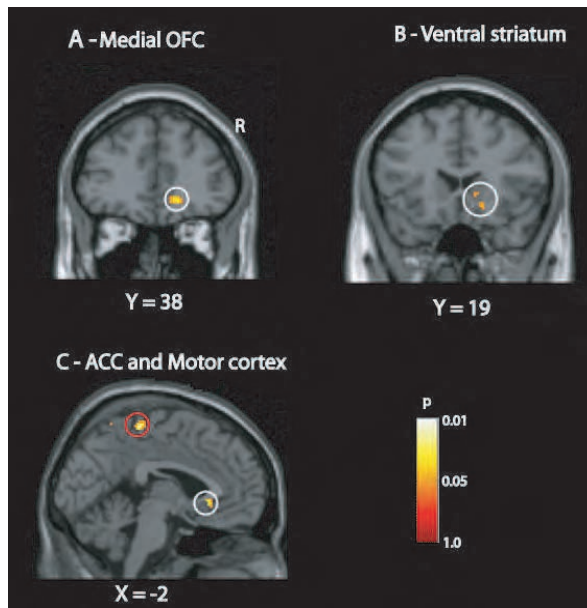

Fig. 11.22 Amphetamine activates the medial orbitofrontal cortex, ventral striatum, and anterior cingulate cortex in drug-naive human participants. The contrast is amphetamine - saline. Activations (shown within the white circles) were found in (a) the medial orbitofrontal cortex (OFC), (b) ventral striatum, and (c) anterior cingulate cortex (ACC), and motor cortex (red circle). The p-values shown are with the small volume correction procedure. (After Völlm, De Araujo, Cowen, Rolls, Kringelbach, Smith, Jezzard, Heal, and Matthews (2004). Methamphetamine activates reward circuitry in drug naive human subjects. *Neuropsychopharmacology* 29: 1715–1722.)

conditioned stimuli associated with the cocaine (Volkow et al., 2013; Koob and Volkow, 2016; Volkow et al., 2017).

Further, the (Pavlovian) conditioned cues that support addiction and may lead to relapse to addiction by Pavlovian-instrumental transfer (see Cardinal et al. (2002)) may operate in part via the orbitofrontal cortex, for Childress et al. (1999) have shown that cocaine-related cues shown visually in a video to addicts activate the orbitofrontal cortex, and also parts of the anterior cingulate and medial prefrontal cortex. Moreover, the orbitofrontal cortex activation in humans to these drug-conditioned cues can be decreased by baclofen, the GABA-B agonist (Childress et al., 1999). In rodents, cues associated by Pavlovian learning with drug administration also influence the prefrontal and cingulate cortices and related areas (Kelley and Berridge, 2002; Kelley, 2004).

These types of evidence suggest that the primate including human orbitofrontal cortex may play a role in addiction to at least some drugs. The computational hypotheses are as follows. (1) Unconditioned drug reinforcers including the psychomotor stimulants such as amphetamine and cocaine activate the medial orbitofrontal cortex, anterior cingulate cortex, and ventral striatum (Völlm et al., 2004). (2) To-be-conditioned stimuli, such as drug-associated visual stimuli, reach the orbitofrontal cortex via the inferior temporal visual cortex. (3) The visual stimuli become associated with the primary drug-related reinforcer in the orbitofrontal cortex by its stimulus-reinforcer association learning. The mechanism is pattern association learning (Section B.2). (4) When the conditioned visual stimulus is encountered in future, incentive motivation is produced, and this increases the likelihood that the drug will be selected despite what the rational (reasoning) system may be indicating. Incentive motivation is also known as the ‘salted nut phenomenon’, and was discussed by Hebb (1949). Incentive motivation refers to the fact that delivery of an incentive, e.g. the smell of bread cooking, increases the motivation to obtain bread. Incentive motivation is widely used in advertising, and has

Fig. 11.23 Summary of the effective connectivity of the human medial orbitofrontal cortex. The medial orbitofrontal cortex has taste, olfactory and inferior temporal visual cortex inputs, and connectivity with the hippocampus, pregenual anterior cingulate cortex, ventromedial prefrontal cortex (vmPFC), posterior cingulate cortex (e.g. 31), parietal cortex, inferior prefrontal cortex, and frontal pole. The main regions with which the medial OFC has connectivity are indicated by names with the words in black font. The width of the arrows and the size of the arrow heads in each direction reflects the strength of the effective connectivity. The abbreviations are listed in Section 1.12. (From Rolls, E. T. 2023. Emotion, motivation, decision-making, the orbitofrontal cortex, and the amygdala. *Brain Structure and Function* doi: 10.1007/s00429-023-02644-9)

been banned at the entrances to supermarkets in the UK because it has such a strong effect on choice. The evolutionary value of incentive motivation is that this introduces hysteresis into the reward selection system, which makes the selected actions more efficient by preventing continually switching between almost equal rewards (Rolls, 2014a). Incentive motivation is probably implemented in the orbitofrontal cortex, and occurs before sensory-specific satiety which is implemented in the orbitofrontal cortex (Section 4.2.5) (Rolls, 2014a). (5) Because drugs act on regions beyond where sensory-specific satiety is computed (which is implemented for example in the afferent synapses to the orbitofrontal cortex, Section 4.2.5), drugs are not subject to sensory-specific satiety, and that contributes to their prolonged reward value, because they are a type of reward to which sensory-specific satiety does not apply (Rolls, 2014a). (6) These orbitofrontal cortex processes may be important in the subjective pleasure that can be produced by addictive drugs via the lateral orbitofrontal cortex connectivity with language cortical regions (Rolls et al., 2023b,c), and via connections to the ventral striatum, anterior cingulate cortex, etc (Rolls, 2017c; Rolls et al., 2023b,c).

11.3.10 The connectivity of the human orbitofrontal cortex, and its relation to function

In this section evidence is described on the connectivity of the human orbitofrontal cortex, and its implications for functions (Rolls et al., 2023c,b). The evidence is based on use of the Human Connectome Project - Multimodal cortical Parcellation (HCP-MMP, Section 1.12), and measuring effective connectivity, complemented by functional connectivity and diffusion tractography (Section 1.13) with data from the Human Connectome Project. An example of an effective connectivity map to indicate the underlying measurements is provided in Fig. 12.8 from Rolls et al. (2023c).

11.3.10.1 Human medial orbitofrontal cortex connectivity

The medial orbitofrontal cortex regions defined in the HCP-MMP atlas are 11l, 13l, OFC, pOFC. A summary of the effective connectivity of the human medial orbitofrontal cortex is shown on Fig. 11.23, and the effective connectivity of examples for these regions are shown schematically for region pOFC in Fig. 11.24 and for region 13l in Fig. 11.25 (Rolls et al., 2023c,b).

Parts of the medial orbitofrontal cortex (11l, 13l, OFC and pOFC, which are interconnected) have effective connectivity with the taste/olfactory/visceral anterior agranular insular complex (AAIC); the piriform (olfactory) cortex; the entorhinal cortex (EC); the inferior temporal visual cortex (TE1p, TE2a, TE2p); superior medial parietal 7Pm; inferior parietal PF which is somatosensory (Rolls et al., 2023d); with parts of the posterior cingulate cortex (31pv, 7m, d23ab) related to memory (Rolls et al., 2023i); with the pregenual anterior cingulate cortex (s32, a24, p24, p32, d32) and much less with the supracallosal anterior cingulate cortex (only 33pr); with ventromedial prefrontal 10r, 10d and 9m; with the frontal pole (10pp, p10p, a10p); with lateral orbitofrontal cortex (47m, 47s, a47r); and dorsolateral prefrontal cortex (46 and a9-46v) (Rolls et al., 2023c) (Figs. 11.24 and 11.25). The connectivities are stronger towards the medial orbitofrontal cortex for the inferior temporal visual cortex and frontal pole regions. Medial orbitofrontal cortex regions also have effective connectivity directed towards the caudate nucleus and nucleus accumbens (Rolls et al., 2023c).

Region OFC is remarkable for effective connectivities directed towards more cortical regions than other parts of the medial orbitofrontal cortex, including somatosensory cortex regions 5L and 5m; the fusiform face area (FFC) and some other relatively early visual cortical areas; and some parietal areas including PGp, PGs, and some superior parietal parts of area 7 and intraparietal areas described elsewhere (Rolls et al., 2023d) (Chapter 10). Region OFC also has effective connectivity directed towards the substantia nigra pars compacta (SNpc) and ventral tegmental area (VTA) (Rolls et al., 2023c), which contain dopaminergic neurons.

Regions 11l and 13l have outputs directed to inferior prefrontal areas (IFS and IFJ regions) and to dorsolateral prefrontal areas 46 and a9-46v (Rolls et al., 2023f) both involved in short-term memory (Chapter 13).

pOFC is the only cortical area with effective connectivity directed to the nucleus basalis of Meynert which includes cholinergic neurons that project to the neocortex (Huang et al., 2022; Zaborszky et al., 2018, 2008).

The functional connectivity is generally consistent, adding some evidence for interactions with frontal opercular FOP4 which is probably taste-related, and the somatosensory insula (MI) (Rolls et al., 2023c,f). The diffusion tractography provides evidence that medial orbitofrontal cortex regions have direct connections with the anterior agranular insular complex (AAIC) which is probably taste/olfactory/visceral-related, and with the piriform cortex (Pir); with the hippocampal system; and with temporal pole TGd involved in semantic representations (Rolls et al., 2022b).

Fig. 11.24 Effective connectivity of the human medial orbitofrontal cortex region pOFC: schematic diagram. The width of the arrows reflects the effective connectivity with the size of the arrowheads reflecting the connectivity in each direction. One arrow in some cases reflects effective connectivity with several related regions: pregenual anterior cingulate a24, p24 and d32; RSC and 23d; frontal pole a10p and p10p. Effective connectivity is shown of pOFC with pyriform (olfactory) cortex Pir, taste cortex AVI and putative visceromotor cortex AAIC, inferior temporal cortex TE2a, pregenual anterior cingulate cortex; and to the hippocampus Hipp. The abbreviations are listed in Section 1.1.2. (From Rolls, E.T., Deco, G., Huang, C.-C. and Feng, J. (2023) Human amygdala compared to orbitofrontal cortex connectivity, and emotion. *Progress in Neurobiology* 220: 102385.)

To synthesize, with further synthesis below, the medial orbitofrontal cortex is found in humans to have connectivity with regions at the ends of sensory processing hierarchies that provide evidence for ‘what’ stimulus is present, including taste, olfactory, visual and somatosensory brain systems. This is consistent with the functions described above of representing unlearned rewards; and learning stimulus-reward associations to implement expected value. The medial orbitofrontal cortex also has connectivity that enables it to provide inputs to memory systems, including the hippocampal memory system; and the pregenual cingulate cortex that has onward connectivity to the hippocampal memory system; and parts of the posterior inferior parietal cortex that are related to memory. The medial orbitofrontal cortex also has some connectivity with the supracallosal anterior cingulate cortex implicated in guiding actions to obtain rewards and avoid punishers in action-outcome learning (Chapter 12); and with the lateral orbitofrontal cortex.

Fig. 11.25 Effective connectivity of the human medial orbitofrontal cortex region 13l: schematic diagram. The width of the arrows reflects the effective connectivity with the size of the arrowheads reflecting the connectivity in each direction. One arrow reflects effective connectivity with several related regions: IFSa, a9-46v, p9-46v, and p47r. Inputs are shown to 13l from inferior temporal cortex TE1p; with other orbitofrontal cortex regions; with many lateral prefrontal cortex regions; and from 13l to the perirhinal cortex. The abbreviations are listed in Section 1.12. (From Rolls, E.T., Deco, G., Huang, C.-C. and Feng, J. (2023) Human amygdala compared to orbitofrontal cortex connectivity, and emotion. *Progress in Neurobiology* 220: 102385.)

11.3.10.2 Human lateral orbitofrontal cortex connectivity

The lateral orbitofrontal cortex regions defined in the HCP-MMP atlas are 47s, 47l, a47r, p47r and 47m. A summary of the effective connectivity of the human lateral orbitofrontal cortex is shown on Fig. 11.26, and the effective connectivity of an example, 47s, is shown in Fig. 11.27 (Rolls et al., 2023c,b).

The lateral orbitofrontal cortex areas a47r, p47r and 47m share generally similar effective connectivities from the visual inferior temporal cortex (TE areas); from parts of the parietal cortex (PFm which receives visual and auditory object-level information and IP2 which is visuomotor (Rolls et al., 2023d)); from the medial orbitofrontal cortex (11l, 13l, pOFC); from the inferior frontal gyrus regions including IFJ, IFS and BA45; from the dorsolateral prefrontal cortex (8Av, 8BL, a9-46v and p9-46v) implicated in short-term memory (Chapter 13); and from the frontal pole (a10p, p10p, 10pp) (Fig. 11.27) (Rolls et al., 2023c,b). 47m (which is relatively medial in this group) also has effective connectivity with the hippocampal system (Hipp, EC, perirhinal, and TF), and with ventromedial prefrontal region 10r; and

Fig. 11.26 Summary of the effective connectivity of the human lateral orbitofrontal cortex. The lateral orbitofrontal cortex has taste, olfactory and inferior temporal visual cortex inputs, and connectivity with the hippocampus, supracallosal (dorsal) anterior cingulate cortex, inferior and dorsolateral prefrontal cortex, and frontal pole. However, the lateral OFC also has connectivity with language regions (the cortex in the superior temporal sulcus and Broca's area). The main regions with which the lateral OFC has connectivity are indicated by names with the words in black font. The width of the arrows and the size of the arrow heads in each direction reflects the strength of the effective connectivity. The abbreviations are listed in Section 1.12. (From Rolls, E. T. 2023. Emotion, motivation, decision-making, the orbitofrontal cortex, anterior cingulate cortex, and the amygdala. *Brain Structure and Function* doi: 10.1007/s00429-023-02644-9)

with the frontal pole (10d, and 9m (Rolls et al., 2023a)). Although in most cases there are effective connectivities from a47r, p47r and 47m to these other cortical regions, the effective connectivities are in most cases stronger towards the lateral orbitofrontal, except that the connectivities are stronger from the lateral orbitofrontal cortex towards the set of inferior prefrontal regions including IFJ, IFS, 45 and 44. The functional connectivity is generally consistent. The diffusion tractography provides in addition evidence for connections of these parts of the lateral orbitofrontal cortex with the anterior ventral insular region (AVI) and the frontal opercular areas FOP4 and FOP5 which include the insular taste cortex (Rolls, 2015d, 2016c; Rolls et al., 2023c,b); with the anterior agranular insular complex (AAIC) which may be visceral (Rolls, 2016c) and also has taste-olfactory convergence (De Araujo et al., 2003a); with the middle insular region (MI) which is somatosensory; and with the piriform (olfactory) cortex.

Regions 47s and 47l (which tend to be more posterior, and are close to Broca's region 45) have effective connectivity (Rolls et al., 2023c,b) with regions involved in language (Rolls et al., 2022b). For example, 47s and 47l have effective connectivity with superior temporal

Fig. 11.27 Effective connectivity of the human lateral orbitofrontal cortex region 47s: schematic diagram. The width of the arrows reflects the effective connectivity with the size of the arrowheads reflecting the connectivity in each direction. Some arrows reflect effective connectivity of several related regions: taste cortex AVI and putative visceral cortex AAC; supracallosal anterior cingulate and medial prefrontal d32 and 9m; dorsal prefrontal 9a, 9p and 8BL; TGv and TGv. The abbreviations are listed in Section 1.12. (From Rolls, E.T., Deco, G., Huang, C.-C. and Feng, J. (2023) Human amygdala compared to orbitofrontal cortex connectivity, and emotion. *Progress in Neurobiology* 220: 102385)

(STS and STG) auditory association / semantic cortical areas; with the temporal pole TG areas implicated in semantic representations; with the PeriSylvian language (PSL), STV and TPOJ regions involved in language (Rolls et al., 2022b); with the superior frontal language area (SFL); and directed to inferior prefrontal regions including IFJ, IFS, 45 and 44 (Broca's area). The connectivity of 47s and 47l with the STS/STG regions is not evident in the diffusion tractography, and may be implemented via the laterally adjacent areas 45 (inferior frontal gyrus pars triangularis) and 44 (inferior frontal gyrus pars opercularis) (both parts of Broca's area), which do have direct connections with these lateral orbitofrontal cortex areas, and towards which 47s and 47l have strong effective connectivity (Rolls et al., 2023c,b). Apart from these language-related connectivities, 47s and 47l have connections with other cortical regions that are similar to those of the other parts of the lateral orbitofrontal cortex (a47r, p47r and 47m) with which they also have connectivity, and it is accordingly proposed that 47s and 47l provide access from the orbitofrontal cortex reward / punishment system to language regions for subjective reports of pleasantness, unpleasantness, and affective value.

The lateral orbitofrontal cortex also has some effective and functional connectivity with

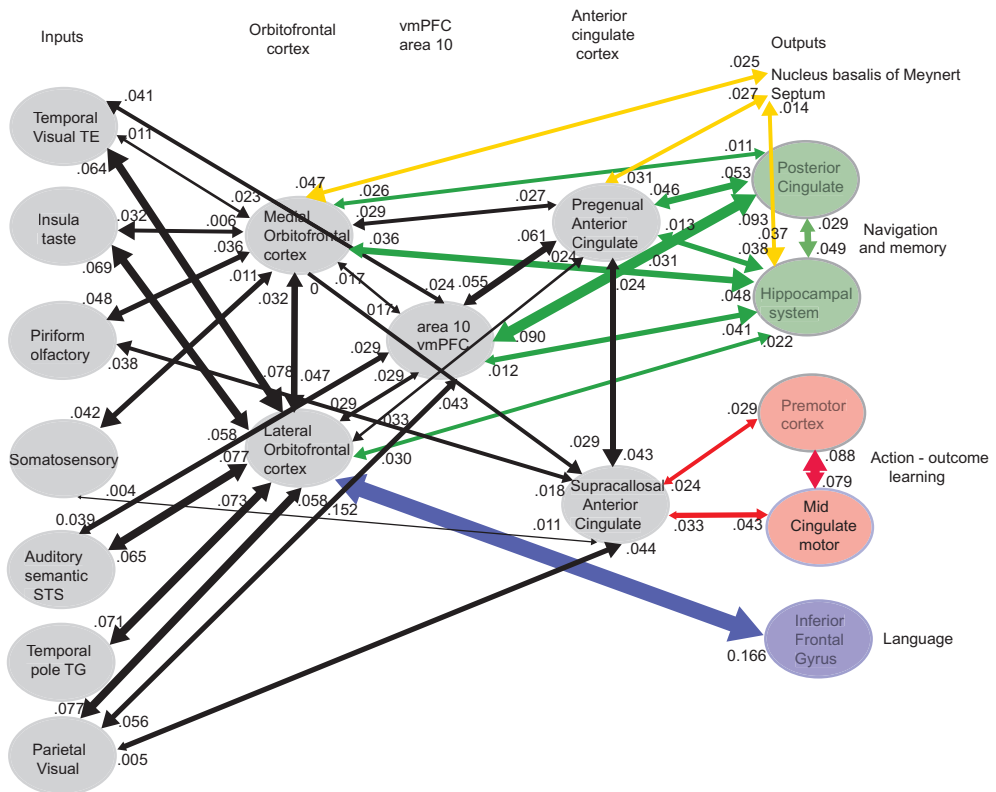

Fig. 11.28 Synthesis of the effective connectivity of the orbitofrontal cortex, vmPFC, and anterior cingulate cortex shown in the middle, with inputs on the left and outputs on the right. The regions included for each of the 5 central ellipses are as defined in the paper cited below. The width of the arrows is proportional to the effective connectivity in the highest direction, and the size of the arrows reflects the strength of the effective connectivity in each direction. The effective connectivities shown are for the strongest link where more than one link between regions applies for a group of brain regions. Effective connectivities with hippocampal memory system regions are shown in green; with premotor / mid-cingulate regions in red; with inferior prefrontal language system in blue; and in yellow to the basal forebrain nuclei of Meynert which contains cholinergic neurons that project to the neocortex and to the septal nuclei which contain cholinergic neurons that project to the hippocampus. The Somatosensory regions include 5 and parietal PF and PFop, which also connect to the pregenual anterior cingulate but are not shown for clarity; the Parietal regions include visual parietal regions 7, PGi and PFm. The connectivity with dorsolateral prefrontal cortex is not included here for clarity. Connectivity is shown for the five groups in the centre of the Figure, and does not include for example connectivity between somatosensory and premotor cortical regions. (From Rolls,E.T., Deco,G., Huang,C-C. and Feng,J. (2023) The human orbitofrontal cortex, vmPFC, and anterior cingulate cortex effective connectome: emotion, memory, and action. *Cerebral Cortex* 33: 350-356. doi: 10.1093/cercor/bhac070. Copyright © Oxford University Press.)

supracallosal medial prefrontal region 8BM (which is of interest as activations produced by aversive / unpleasant / non-reward stimuli extend into this region (Grabenhorst and Rolls, 2011; Rolls, 2019c; Rolls et al., 2020e)).

A major difference of the connectivity of the lateral orbitofrontal cortex from the other orbitofrontal, ventromedial prefrontal, and anterior cingulate regions (Rolls et al., 2023c,b) is its connectivity with Broca’s area (45 and 44) in the inferior frontal gyrus (Rolls et al., 2022b).

A synthesis of the effective connectivity of the human orbitofrontal cortex showing how it has onward connectivity to further regions via the ventromedial prefrontal and anterior cingulate cortex is provided in Fig. 11.28 (Rolls et al., 2023c). Highlights of this human orbitofrontal cortex connectivity, and their implications for function, are considered next.

11.3.10.3 Connectivity of the orbitofrontal cortex to the hippocampal memory system, and memory consolidation

Fig. 11.28 shows how a major output of the human orbitofrontal cortex reaches the hippocampal memory system, both directly, and via the ventromedial prefrontal cortex, and pregenual anterior cingulate cortex and posterior cingulate cortex which are considered further in Chapter 12.

It is proposed in Section 9.2.8.5 that this connectivity enables reward and punishment information that relates to emotion to become a key component of episodic memory, together with ‘where’ or ‘when’ and ‘what’ information. During recall of an episodic memory, the reward / aversive / emotion component can then be recalled back to the orbitofrontal cortex, as described in Chapter 9.

However, even beyond that, it is proposed that the reward / aversive input to the hippocampus provides a ‘value’ component to each episodic memory, with episodic memories with a ‘value’ component more likely to be frequently recalled and thought about in humans, and thereby making an important contribution to what becomes consolidated into long-term, typically semantic, memory. This is described further in Section 9.2.8.5 and by Rolls (2022b). This proposal also helps to provide an account of how damage to the orbitofrontal cortex / ventromedial prefrontal cortex / anterior cingulate cortex impairs episodic memory (Section 9.2.8.5, and Rolls (2022b)).

11.3.10.4 Connectivity of the orbitofrontal cortex to the cholinergic basal forebrain nucleus of Meynert, and memory consolidation

Fig. 11.28 shows (in yellow) how another key output of the human orbitofrontal cortex, in particular region pOFC, reaches the cholinergic basal forebrain nucleus of Meynert. This nucleus provides the cholinergic innervation of the neocortex, where acetylcholine is involved in memory consolidation. Accordingly it is proposed that rewarding or punishing stimuli and events, which produce emotion, are decoded by the orbitofrontal cortex, and activate the basal nucleus cholinergic projection to the neocortex. Thus the orbitofrontal cortex plays an important role in this way too in memory consolidation. The evidence for this is presented in Section 9.2.8.5, and by Rolls (2022b). This proposal also helps to provide an account of how damage to the orbitofrontal cortex / ventromedial prefrontal cortex / anterior cingulate cortex impairs episodic memory (Section 9.2.8.5, and Rolls (2022b)).

11.3.10.5 Connectivity of the orbitofrontal cortex to the supracallosal anterior cingulate cortex for action-outcome learning

Fig. 11.28 shows how the human orbitofrontal cortex also has connectivity to the supracallosal anterior cingulate cortex, which is implicated in action-outcome learning. For this type of learning, it is proposed that the orbitofrontal cortex provides the reward or non-reward or punishment outcome that follows an action. The supracallosal anterior cingulate cortex is the part of the anterior cingulate cortex that is proposed to be involved in action-outcome learning, for it has extensive connectivity with premotor cortex regions including the mid-cingulate motor area that are involved in actions, as shown in Fig. 11.28. The evidence for this is described in Chapter 12 and by Rolls et al. (2023c). This is the key output of the orbitofrontal cortex by which it is involved in goal-directed instrumental learning, which is an important aspect of emotion (Rolls, 2014a, 2023b).

The orbitofrontal cortex outputs to language areas (blue in Fig. 11.28) provide one route via which orbitofrontal reward / punishment decoded inputs and thereby emotional states can become incorporated into declarative (experienced) emotion (Rolls et al., 2023b).

11.3.10.6 Connectivity of the orbitofrontal cortex to the basal ganglia and dopaminergic system

The orbitofrontal cortex outputs to the head of the caudate nucleus and ventral striatum provide a route for reinforcers to guide stimulus-response habit learning, as described in Chapter 16.

Very interestingly, in humans orbitofrontal cortex region OFC has effective connectivity to the substantia nigra pars compacta and ventral tegmental area (Rolls et al., 2023c), where the dopamine neurons are located (Rockland et al., 1994). As described in Sections 11.2.2 and 11.4, this is the most likely source of the reward-related information needed if dopamine neurons are to reflect reward prediction error (Schultz, 2016a, 2017), as described further in Chapter 16.

11.3.11 Mental problems associated with the orbitofrontal cortex

The important roles of the orbitofrontal cortex in depression are considered in Section 18.5.

The role in autism of the orbitofrontal cortex and amygdala, and the cortex in the superior temporal sulcus regions that connect to the orbitofrontal cortex and amygdala, is considered in Sections 2.4.9 and 8.2 (Cheng, Rolls, Gu, Zhang and Feng, 2015; Cheng, Rolls, Zhang, Sheng, Ma, Wan, Luo and Feng, 2016b; Rolls, Zhou, Cheng, Gilson, Deco and Feng, 2020f).

The effects of damage to the orbitofrontal cortex and amygdala on emotion in humans are considered earlier in this Chapter 11 (Rolls, 2021h; Rolls et al., 2023b).

However, reduced volume or area or reduced functional connectivity of the orbitofrontal cortex found in a number of neurodevelopmental disorders are associated with emotional and behavioral problems in children and adults, together with cognitive performance reductions associated with reductions in other brain regions. These disorders are of interest not only in neuroscience, but also to clinicians, and are described here.

In one investigation, childhood traumatic events (such as abuse and neglect, and defined by the ‘Childhood Trauma’ questions in the UK Biobank database) were associated in 9,535 participants aged 45-79 from the UK Biobank with lower functional connectivity involving the medial orbitofrontal cortex and superior temporal sulcus regions that connect to the orbitofrontal cortex conveying social information; the medial temporal cortex memory-related regions; the precuneus (implicated in the sense of self); and the superior, middle and inferior prefrontal cortex (implicated in working memory). These lower functional connectivities significantly mediated the associations between childhood traumatic events and addiction, anxiety, depression and well-being, and cognitive performance (including prospective memory and fluid intelligence) (Wan, Rolls, Cheng and Feng, 2022).

In another investigation, lower parental age, especially in the mother, was associated in the children when 9-11 of 8,709 mothers with lower volume of the anterior cingulate cortex, medial and lateral orbitofrontal cortex and amygdala, parahippocampal gyrus and hippocampus, and temporal lobes. The lower cortical volumes and areas in the children significantly mediated the association between the parental age and the behavioral and cognitive problems in the children. The effects were large, such as the 71% higher depressive problems score, and 28% higher rule-breaking score, in the children of mothers aged 15-19 than the mothers aged 34-35 (Du, Rolls, Gong, Cao, Vatansever, Zhang, Kang, Cheng and Feng, 2022).

In another investigation in 8,756 children aged 9-11 from the Adolescent Brain Cognitive Developmental study, we showed that high family conflict and low parental monitoring scores are associated with the children’s behavioral problems, as well as with smaller cortical areas of the orbitofrontal cortex, anterior cingulate cortex, and middle temporal gyrus (Gong, Rolls, Du, Feng and Cheng, 2021).

In another investigation, severe and prolonged nausea and vomiting in pregnancy (extending after the second trimester), was associated in 10,710 children aged 9-11 years with low cortical area and volume, especially of the cingulate cortex, precuneus, and superior medial prefrontal cortex, and with emotional, behavioral, and cognitive problems. The emotional and behavioral problems scores included measures such as anxious/depressed, withdrawn/depressed, somatic complaints, social problems, thought problems, rule-breaking behavior, and aggressive behavior. The cognitive measures were from the NIH Toolbox. The lower cortical volume and area of some brain regions significantly mediated the association between severe and prolonged nausea and vomiting in pregnancy, and the emotional, behavioral and cognitive problems measured in the children when aged 9-11 years (Wang, Rolls, Du, Du, Yang, Li, Li, Cheng and Feng, 2020c).

In another investigation, lower gestational ages were associated in 11,847 adolescents with graded lower cognition and school achievements and with smaller brain volumes of the orbitofrontal and cingulate cortex, fronto-parieto-temporal, fusiform, insula, postcentral, hippocampal, thalamic, and pallidal regions (Ma, Wang, Rolls, Xiang, Li, Li, Zhou, Cheng and Li, 2022b).

It is striking that in these investigations the set of brain regions with reduced volume or area, or reduced functional connectivity, was somewhat similar, and included typically parts of the orbitofrontal and/or anterior cingulate cortex involved in emotion, temporal lobe regions involved in memory, and prefrontal regions involved in executive function. It may be that these regions are particularly susceptible to environmental factors of the type described. However, although many covariates were removed in these investigations (often including the Townsend social deprivation index), the populations involved are complex, and a number of differences including genetic differences may contribute to the associations that have been found. However, that does not at all diminish the fact that there are associations of this type between the orbitofrontal cortex and some other brain regions, and emotional and behavioral problems. Nor does it diminish the clinical relevance of the findings, for it may be useful when assessing problems such as those described to take into account the associated factors such as gestational age, events during pregnancy, and events in the first few years of life. A striking discovery is that the associations described with brain structure and function, and emotional and cognitive measures, lasted into late childhood, early adolescence, and mature adulthood.

11.4 What is computed in the amygdala for emotion

A brain structure that has somewhat similar connections to the orbitofrontal cortex, the amygdala, but is much older in evolution, is described in this section, to help highlight what is special about the orbitofrontal cortex. It will be argued that with the great development of the orbitofrontal cortex in primates including humans, the orbitofrontal cortex becomes much more important in emotion and related functions in humans than the amygdala.

11.4.1 Overview of the functions of the amygdala in emotion

The amygdala is an evolutionarily old subcortical structure with parts of it present in amphibians and reptiles. This is in contrast with the orbitofrontal cortex, which develops greatly in primates including humans as shown in Fig. 11.3 (Passingham, 2021).

The connections of the amygdala are similar to those of the orbitofrontal cortex, as shown in Figs. 11.1 and 11.29, and the amygdala connections do involve many with the orbitofrontal cortex.

The amygdala does have neurons that respond to primary reinforcers such as the taste, flavor, and smell of food; touch; and aversive stimuli. The amygdala also has neurons that learn associations between visual and auditory stimuli, and primary reinforcers. However, this learning does not support rule-based one-trial reversal learning, so the amygdala is less good at this rapid emotion-related learning than the orbitofrontal cortex (Section 11.3.1.2). The primate amygdala also contains a population of neurons specialized to respond to faces, and damage to the human amygdala can alter the ability to discriminate between different facial expressions, though this may be related to how faces are visually fixated.

Classically conditioned responses such as autonomic, freezing, and startle responses to auditory stimuli can depend on outputs from the amygdala to structures such as the hypothalamus and ventral striatum. Bilateral damage to the amygdala can produce a deficit in learning to associate visual and other stimuli with a primary (i.e. unlearned) reward or punisher. For example, monkeys with damage to the amygdala when shown foods and non-foods pick up both and place them in their mouths. When such visual or auditory discrimination learning is tested more formally, it is found that primates including humans with amygdala damage have difficulty in associating the sight or sound of a stimulus with whether it produces a reward, or is noxious and should be avoided. Sensory-specific satiety (the reduced choice of a food devalued by feeding to satiety) is impaired by damage to the amygdala (as is also the case for the orbitofrontal cortex).

In humans and other primates the amygdala does not appear to play such an important role in emotional and social behavior as the orbitofrontal cortex, with the changes to emotion much more subtle after amygdala damage. Further, the deficits described after amygdala damage involve fear conditioning (with classical conditioning of for example autonomic responses and effects on startle especially studied), and somewhat subtle aspects of face expression processing. In evolution, the balance may have moved to the orbitofrontal cortex, which has evolved much more recently, and may allow more powerful computations, such as those involved in rapid reversal learning and rapid correction of behavior, to be implemented.

Indeed, LeDoux, who has performed research on the rodent amygdala, is, with colleagues, now suggesting that the amygdala may have little to do with subjective feelings of emotion (LeDoux et al., 2018); and consistent with this, it has relatively little effective connectivity directed back to neocortical regions (Rolls et al., 2023b). In contrast, the orbitofrontal cortex may be much more closely related to emotional feelings, in that activations in it are linearly related to subjective affective ratings of pleasantness; damage to the orbitofrontal cortex impairs subjective emotional feelings as described earlier in this Chapter and by Rolls (2019e); and the orbitofrontal cortex does have connectivity directed back to many cortical regions, including language areas, providing routes for emotional states to be subjectively reported (Rolls et al., 2023b).

A much fuller analysis of the functions of the amygdala in emotion in primates including humans is provided by Rolls (2014a), with further human studies described in Whalen and Phelps (2009). The rodent literature and how it has focussed on conditioned responses and not on emotional feelings is described more fully elsewhere (Quirk et al., 1996; LeDoux, 2012b; LeDoux and Pine, 2016; LeDoux et al., 2018).

11.4.2 The amygdala and the associative processes involved in emotion-related learning

The amygdala is implicated in some learning processes involved in emotion including some classically conditioned effects, but not in other learning processes involved in emotion. To clarify this, I briefly summarize some of these learning processes, with a much fuller analy-

sis provided elsewhere (Cardinal, Parkinson, Hall and Everitt, 2002; Rolls, 2014a; Balleine, 2019).

When a conditioned stimulus (CS) (such as a tone) is paired with a primary reinforcer or unconditioned stimulus (US) (such as a painful stimulus), then there are opportunities for a number of types of association to be formed.

Some of these involve ‘classical conditioning’ or ‘Pavlovian conditioning’, in which no action is performed that affects the contingency between the conditioned stimulus and the unconditioned stimulus. Typically an unconditioned response (UR), for example an alteration of heart rate, is produced by the US, and will come to be elicited by the CS as a conditioned response (CR). These responses are typically autonomic (such as the heart beating faster), or endocrine (for example the release of adrenaline (epinephrine in American usage) by the adrenal gland).

In addition to classical conditioning, the organism may learn to perform an instrumental response with the skeletal muscles in order to alter the probability that the primary reinforcer will be obtained. In our example, the experimenter might alter the contingencies so that when the tone sounded, if the organism performed an action such as pressing a lever, then the painful stimulus could be avoided. This is confirmed to be instrumental learning if the response learned is arbitrary, for example performing the opposite response, such as raising the lever to avoid the painful stimulus.

In the instrumental learning situation there are still opportunities for many classically conditioned responses including emotional states such as fear to occur. For example, in Pavlovian–instrumental transfer, if a stimulus that predicts the arrival of sucrose as a result of Pavlovian conditioning is provided during an instrumental task such as working to obtain sucrose, the responding (e.g. lever pressing) can be enhanced. Further, approach to a food may be under Pavlovian rather than instrumental control. Finally, we must beware of the facts that after overtraining, habits may be formed in which stimuli may become inflexibly linked to responses, with the reward value of the goal no longer directly influencing behavior, as shown by the fact that the response may continue for at least one trial after the goal has been devalued by for example feeding to satiety. This had led to some confusion in the literature (Berridge and Robinson, 1998; Berridge et al., 2009), for when the goal controls the behavior, wanting is driven by liking, and what happens during habits is not an exception, as habits are stimulus-response associations and have little to do with wanting or liking a goal (Rolls, 2014a, 2013d, 2023b).

11.4.3 Connections of the amygdala

The amygdala is a subcortical region in the anterior part of the temporal lobe. It receives massive projections in the primate from the overlying temporal lobe cortex (Van Hoesen, 1981; Amaral et al., 1992; Ghashghaei and Barbas, 2002; Freese and Amaral, 2009) (see Fig. 11.29). Via these inputs, the amygdala receives inputs about objects and faces that could become secondary reinforcers, as a result of pattern association in the amygdala with primary reinforcers. The amygdala also receives inputs that are potentially about primary reinforcers, e.g. taste inputs (from the insula, and from the secondary taste cortex in the orbitofrontal cortex), and somatosensory inputs, potentially about the rewarding or painful aspects of touch (from the somatosensory cortex via the insula). The amygdala receives strong projections from the posterior orbitofrontal cortex (see Fig. 11.29, areas 12 and 13) where there are value representations, and from the anterior cingulate cortex (Carmichael and Price, 1995a; Ghashghaei and Barbas, 2002; Freese and Amaral, 2009).

Although there are some inputs from early on in some sensory pathways, for example auditory inputs from the medial geniculate nucleus (LeDoux, 1992; Pessoa and Adolphs,

Fig. 11.29 Connections of the amygdala shown on lateral, ventral, and medial inverted views of the monkey brain. Abbreviations: as, arcuate sulcus; cc, corpus callosum; cf, calcarine fissure; cgs, cingulate sulcus; cs, central sulcus; ls, lunate sulcus; ios, inferior occipital sulcus; mos, medial orbital sulcus; os, orbital sulcus; ots, occipito-temporal sulcus; ps, principal sulcus; rhs, rhinal sulcus; sts, superior temporal sulcus; lf, lateral (or Sylvian) fissure (which has been opened to reveal the insula); A, amygdala; ACC, anterior cingulate cortex; INS, insula; T, thalamus; TE (21), inferior temporal visual cortex; TA (22), superior temporal auditory association cortex; TF and TH, parahippocampal cortex; TG, temporal pole cortex; 12, 13, 11, orbitofrontal cortex; 24, 32, parts of the anterior cingulate cortex; 25, subgenual cingulate cortex; 28, entorhinal cortex; 51, olfactory (prepyriform and periamygdaloid) cortex. The cortical connections shown provide afferents to the amygdala, but are reciprocated. (Redrawn and updated from G.W. Van Hoesen (1981) The differential distribution, diversity and sprouting of cortical projections to the amygdala in the rhesus monkey. In Y. Ben-Ari (ed.), *The Amygdaloid Complex*, pp. 77–90. © Elsevier Inc.)

2010), this route is unlikely to be involved in most emotions, for which cortical analysis of the stimulus is likely to be required. Emotions are usually elicited to environmental stimuli analyzed to the object level (including other organisms), and not to retinal arrays of spots or the frequency (tone) of a sound as represented in the cochlea (Rolls, 2014a).

Some of the outputs of the amygdala relevant to different types of response in rodents are shown in Fig. 11.30, and in addition there are backprojections to the neocortical areas that project to the amygdala.

11.4.4 Effects of amygdala lesions

11.4.5 Amygdala lesions in primates

Bilateral removal of the amygdala in monkeys produces striking behavioral changes which include tameness, a lack of emotional responsiveness, excessive examination of objects, often with the mouth, and eating of previously rejected items such as meat (Weiskrantz, 1956). These behavioral changes comprise much of the Kluver–Bucy syndrome which is produced in monkeys by bilateral anterior temporal lobectomy (Kluver and Bucy, 1939). In analyses of the bases of these behavioral changes, it has been observed that there are deficits in some

Fig. 11.30 The pathways for fear-conditioning to pure-tone auditory stimuli associated with footshock in the rat. The lateral amygdala (LA) receives auditory information directly from the medial part of the medial geniculate nucleus (the auditory thalamic nucleus), and from the auditory cortex. Intra-amygdala projections (directly and via the basal and basal accessory nuclei, B) end in the central nucleus (Ce) of the amygdala. Different output pathways from the central nucleus and the basal nucleus mediate different conditioned fear-related effects. d, dorsal; v, ventral; m, medial; l, lateral. The 'high road' via the auditory cortex is likely to be important for more complex auditory stimuli than pure tones. (Modified from G.J.Quirk, J.L.Armony, J.C.Repa, X.F.Li, and J.E.LeDoux (1996) Emotional memory: a search for sites of plasticity. Cold Spring Harbor Symposia on Quantitative Biology 61: 247–257. © Cold Spring Harbor Laboratory Press.)

types of learning. For example, Larry Weiskrantz (1956) found that bilateral ablation of the amygdala in the monkey produced a deficit in learning an active avoidance task. The monkeys failed to learn to make a response when a light signalled that shock would follow unless the response was made. He was perhaps the first to suggest that these monkeys had difficulty with forming associations between stimuli and reinforcers, when he suggested that “the effect of amygdalotomy is to make it difficult for reinforcing stimuli, whether positive or negative, to become established or to be recognized as such” (Weiskrantz, 1956). In this avoidance task, associations between a stimulus and punishers were impaired.

It has been confirmed with the more selective type of neurotoxic amygdala lesion that non-foods as well as foods are picked up and eaten, and also that emotional responses to snakes and human intruders are impaired (Murray and Izquierdo, 2007), but there are relatively minor changes in social behavior (Amaral, 2003; Bliss-Moreau, Moadab, Bauman and Amaral, 2013; Bliss-Moreau, Moadab, Santistevan and Amaral, 2017), and this is consistent with the trend for the orbitofrontal cortex to become relatively more important in emotion and social behavior in primates including humans. The amygdala is implicated by lesion studies in learning associations between visual stimuli and rewards, and devaluation by feeding to satiety is impaired too (Murray and Izquierdo, 2007). Interactions between the orbitofrontal cortex and the amygdala may be involved in devaluation of food reward, and interactions between the anterior cingulate cortex and the amygdala may be involved in social valuations (Murray and Fellows, 2022).

A difference between the effects of selective amygdala lesions and orbitofrontal cortex lesions in monkeys is that selective amygdala lesions have no effect on object reversal learning, whereas orbitofrontal cortex lesions do impair object reversal learning (Murray and Izquierdo, 2007). Further, and consistently, orbitofrontal but not selective amygdala lesions impair instrumental extinction (i.e. they showed a large number of choices of the previously

rewarded object when it was no longer rewarded) (Murray and Izquierdo, 2007). This is consistent with the evidence that the orbitofrontal cortex is important in rapid, one-trial, learning and reversal between visual stimuli and primary reinforcers using both associative and rule-based mechanisms, and its representations of outcome value, expected value, and negative reward prediction error (Thorpe, Rolls and Maddison, 1983; Rolls, 2014a; Rolls and Grabenhorst, 2008). These contributions of the orbitofrontal cortex are facilitated by its neocortical architecture, which can operate using attractors that are important in many functions including short-term memory, attention, rule-based operation with switching, long-term memory, and decision-making. This neocortical computational ability may help the orbitofrontal cortex to compute and utilize non-reward to reset value representations in the orbitofrontal cortex (Rolls, 2014a, 2016b, 2019e).

11.4.6 Amygdala lesions in rats

In rats, there is also evidence that the amygdala is involved in behavior to stimuli learned as being associated with reward as well as with punishers. We may summarize these investigations in the rat as follows. The central nuclei of the amygdala encode or express Pavlovian S–R (stimulus–response, CS–UR) associations (including conditioned suppression, conditioned orienting, conditioned autonomic and endocrine responses, and Pavlovian–instrumental transfer) (Rolls (2014a) Section 4.6.1; (Cardinal et al., 2002; Balleine, 2019; Burton and Balleine, 2022)); and modulate perhaps by arousal the associability of representations stored elsewhere in the brain (Gallagher and Holland, 1994, 1992; Holland and Gallagher, 1999). In contrast, the basolateral amygdala (BLA) encodes or retrieves the affective value of the predicted US, and can use this to influence action–outcome learning via pathways to brain regions such as the nucleus accumbens and prefrontal cortex including the orbitofrontal cortex (Cardinal et al., 2002). We shall see below that the nucleus accumbens is not involved in action–outcome learning itself, but does allow the affective states retrieved by the BLA to conditioned stimuli to influence instrumental behavior by for example Pavlovian–instrumental transfer, and facilitating locomotor approach to food which appears to be in rats a Pavlovian process (Cardinal, Parkinson, Hall and Everitt, 2002; Cardinal and Everitt, 2004; Everitt and Robbins, 2013; Rolls, 2014a). This leaves parts of the prefrontal and cingulate cortices as strong candidates for action–outcome learning.

In a different model of fear-conditioning in the rat, Davis and colleagues (Davis, 2006), have used the fear-potentiated startle test, in which the amplitude of the acoustic startle reflex is increased when elicited in the presence of a stimulus previously paired with shock. Lesions of either the central nucleus or the lateral and basolateral nuclei of the amygdala block the expression of fear-potentiated startle. These latter amygdala nuclei may be the site of plasticity for fear conditioning, because local infusion of the NMDA (N-methyl-d-aspartate) receptor antagonist AP5 (which blocks long-term potentiation, an index of synaptic plasticity) blocks the acquisition but not the maintenance of fear-potentiated startle (Davis, 2006). These investigations have now been extended to primates, in which similar effects are found, with ibotenic acid-induced lesions of the amygdala preventing the acquisition of fear-potentiated startle, though, remarkably, not the expression of fear-potentiated startle when fear conditioning was carried out prior to the lesion (Davis et al., 2008).

Reconsolidation refers to a process in which after a memory has been stored, it may be weakened or lost if recall is performed during the presence of a protein synthesis inhibitor (Haubrich and Nader, 2018; Debiec, LeDoux and Nader, 2002; Debiec, Doyere, Nader and LeDoux, 2006). The implication that has been drawn is that whenever a memory is recalled, some reconsolidation process requiring protein synthesis may be needed. The computational utility of reconsolidation is considered by Rolls (2016b). Here, it is of interest that this applies

to fear association mechanisms in the amygdala (Doyere et al., 2007), and drug-associated memories in the amygdala (Milton et al., 2008). The findings have interesting implications for the treatment of fear-associated memories. For example, in humans old fear memories can be updated with non-fearful information provided during the reconsolidation window. As a consequence, fear responses are no longer expressed, an effect that can last at least a year and is selective only to reactivated memories without affecting other memories (Schiller et al., 2010), although success has so far been limited (Kroes, Schiller, LeDoux and Phelps, 2016; Haubrich and Nader, 2018). Procedures that influence the extinction of fear memory may also be useful in the treatment of fear states (Davis, 2011).

11.4.7 Neuronal activity in the primate amygdala to reinforcing stimuli

There is clear evidence that some neurons in the primate amygdala respond to stimuli that are potentially primary reinforcers. For example, Sanghera, Rolls and Roper-Hall (1979) found some amygdala neurons with taste responses. In an extensive study of 1416 macaque amygdala neurons, Kadohisa, Rolls and Verhagen (2005b) showed that a very rich and detailed representation of the stimulus (such as food) that is in the mouth is provided by neurons that respond to oral stimuli, including taste, viscosity, fat texture, and oral temperature.

Less is known about whether it is the reinforcer value of the stimuli that is represented. It has been shown that satiety produces a rather modest (on average 58%) reduction in the responses of amygdala neurons to taste (Yan and Scott, 1996; Rolls and Scott, 2003), in comparison to the essentially complete reduction of responsiveness found in orbitofrontal cortex taste neurons (Rolls, Sienkiewicz and Yaxley, 1989d). Further, the representation in the amygdala of these oral stimuli does not appear to be on any simple hedonic basis, in that no direction in the multidimensional taste space in Fig. 7 of Kadohisa, Rolls and Verhagen (2005b) reflected the measured preference of the monkeys for the stimuli, nor were the response profiles of the neurons to the set of stimuli closely related to the preferences of the macaques for the stimuli (Kadohisa, Rolls and Verhagen, 2005b). The failure to find very strong effects of satiety on the responsiveness of amygdala taste neurons (Yan and Scott, 1996; Rolls and Scott, 2003) mirrors the earlier finding of Sanghera, Rolls and Roper-Hall (1979) of inconsistent effects of feeding to satiety on the responses of amygdala visual neurons responding to the sight of food.

Recordings from single neurons in the amygdala of the monkey have shown that some neurons do respond to visual stimuli, consistent with the inputs from the temporal lobe visual cortex (Sanghera, Rolls and Roper-Hall, 1979). Other neurons responded to auditory, gustatory, olfactory, or somatosensory stimuli, or in relation to movements. In tests of whether the neurons responded on the basis of the association of stimuli with reinforcers, it was found that approximately 20% of the neurons with visual responses had responses that occurred primarily to stimuli associated with reinforcers, for example to food and to a range of stimuli which the monkey had learned signified food in a visual discrimination task for food reward (Sanghera, Rolls and Roper-Hall, 1979; Rolls, 1981c; Wilson and Rolls, 1993, 2005; Rolls, 2000c). Many of these neurons responded more to the positive discriminative stimulus (S+) than to the negative visual discriminative stimulus (S-) in the Go/NoGo visual discrimination task (Rolls, 2000c; Wilson and Rolls, 2005). However, none of these neurons (in contrast with some neurons in the orbitofrontal cortex) responded exclusively to rewarded stimuli, in that all responded at least partly to one or more neutral, novel, or aversive stimuli.

The degree to which the visual responses of these amygdala neurons are associated with reinforcers has been assessed in learning tasks. When the association between a visual stimulus and an instrumental reinforcer was altered by reversal (so that the visual stimulus formerly associated with juice reward became associated with aversive saline and vice versa), it was

found that 10 of 11 neurons did not reverse their responses (and for the other neuron the evidence was not clear) (Sanghera, Rolls and Roper-Hall, 1979; Rolls, 1992b, 2000c).

Although more investigations would be useful, the evidence now available indicates that primate amygdala neurons do not alter their activity flexibly and rapidly (in one or even a few trials) in visual discrimination reversal learning (Rolls, 1992b, 2000c, 2014a). What has been found in contrast is that neurons in the orbitofrontal cortex do show very rapid, often one-trial, reversal of their responses in visual discrimination reversal, and it therefore seems likely that the orbitofrontal cortex is especially involved when repeated relearning and re-assessment of stimulus–reinforcer associations are required, as described above, rather than initial learning, in which the amygdala may be involved. (It is noted that some other studies do not address the issue convincingly of rapid reversal, for they were not studying one-trial reversal with instrumental learning, but instead slow classical conditioning (Paton, Belova, Morrison and Salzman, 2006; Morrison, Saez, Lau and Salzman, 2011). However, more recent studies in that series are in fact consistent with the discoveries we have made that the orbitofrontal cortex updates reward value representations more rapidly and flexibly than the amygdala, in that neural responses to reward-predictive cues updated more rapidly in the orbitofrontal cortex than amygdala, and activity in the orbitofrontal cortex but not the amygdala was modulated by recent reward history (Saez, Saez, Paton, Lau and Salzman, 2017).

Evidence that primate amygdala neurons encode reward value is that while monkeys chose between saving liquid reward with interest and spending the accumulated reward, some of the neurons reflected the accumulating value (Grabenhorst et al., 2012) and reflect whether a macaque will perform economic saving (Hernadi et al., 2015; Grabenhorst et al., 2016). Macaque amygdala neurons can even reflect the value of an object learned by watching the behavior of another monkey (Grabenhorst et al., 2019). Overall, there is thus evidence that some amygdala neurons reflect reward value, yet do not reverse their value-related responses rapidly (in the one trial shown by orbitofrontal cortex neurons), and the evidence from the effects of selective amygdala lesions (Murray and Izquierdo, 2007) is consistent with this.

11.4.8 Neuronal responses in the amygdala to faces

Another interesting group of neurons in the amygdala has been discovered that respond primarily to faces (Rolls, 1981c; Leonard, Rolls, Wilson and Baylis, 1985). Each of these neurons responds to some but not all of a set of faces, and thus across an ensemble could convey information about the identity of the face (see Fig. 11.31). These neurons are found especially in the basal accessory nucleus of the amygdala (Leonard, Rolls, Wilson and Baylis, 1985), a part of the amygdala that develops markedly in primates (Amaral et al., 1992). Similar neurons have been further analyzed (Gothard et al., 2007, 2018), and, as with face-selective neurons in the orbitofrontal cortex (Rolls, Critchley, Browning and Inoue, 2006a), some neurons respond to face identity, some to face expression, and some to combinations of identity and expression. In addition, some neurons in the primate amygdala respond during social interactions, some may respond preferentially to eyes (as do some neurons in the temporal lobe visual cortex (Perrett, Rolls and Caan, 1982)), and their output may influence face expression (Brothers and Ring, 1993; Gothard et al., 2018). Face-selective neurons have also been found now in the human amygdala (Rutishauser et al., 2011, 2015), and some are tuned to fear face expressions, and others to happy face expressions (Wang, Yu, Tyszka, Zhen, Kovach, Sun, Huang, Hurlmann, Ross, Chung, Mamelak, Adolphs and Rutishauser, 2017). In an fMRI investigation, activation of the amygdala predicted rejection of artificial social partners (Rosenthal-von der Putten, Kramer, Maderwald, Brand and Grabenhorst, 2019).

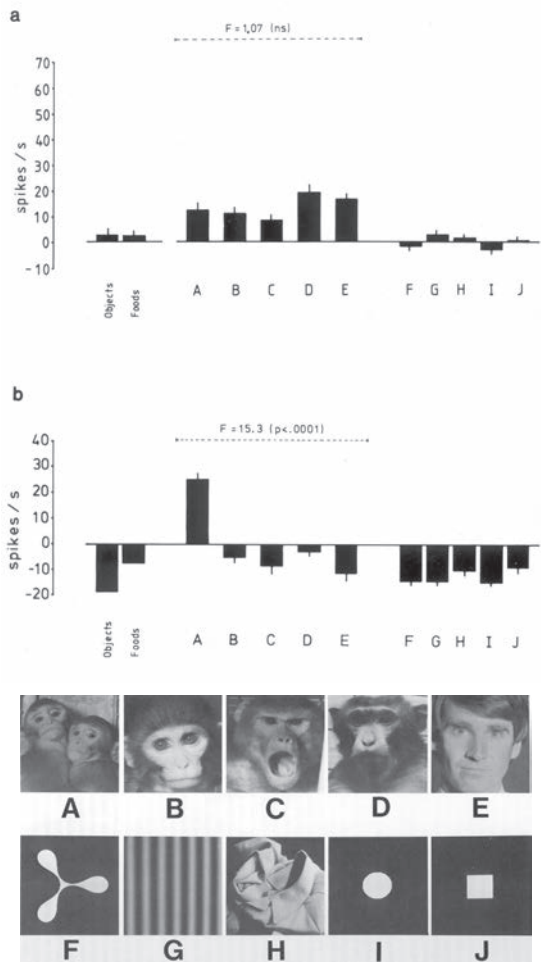

Fig. 11.31 Some amygdala neurons respond to the sight of faces. The responses of two neurons (a,b) in the amygdala to a variety of monkey and human face stimuli (A–E), and to non-face stimuli (F–J, objects, and foods). Each bar represents the mean response above baseline with the standard error calculated over 4 to 10 presentations. The F ratio for an analysis of variance calculated over the face sets indicates that the neurons shown range from very selective between faces (neuron b, Y0809) to relatively non-selective (neuron A, Z0264). Some stimuli produced inhibition below the spontaneous firing rate. (Reprinted from C.M.Leonard, E. T. Rolls, F.A.W.Wilson, and G.C.Baylis (1985) Neurons in the amygdala of the monkey with responses selective for faces. Behavioral Brain Research 15: 159–176. Copyright © Elsevier B.V.)

Neurons that are sensitive to the rank of the individual being viewed in the social hierarchy are found in the macaque amygdala (and also in the closely connected orbitofrontal cortex, and anterior cingulate cortex (Munuera et al., 2018)). In addition, it has been shown in the macaque that amygdala neurons are involved in social, observational learning in a reversal learning task, and that some neurons even predicted the choices of the partner monkey (Grabenhorst et al., 2019). These processes – assessing the social rank of individuals, learning from social partners, anticipating their behavior – are critical for social life. However, the balance may shift from the amygdala towards the orbitofrontal cortex in humans, as described next.

11.4.9 Evidence from humans

In relation to neurons in the macaque amygdala with responses selective for faces and social interactions (Leonard, Rolls, Wilson and Baylis, 1985; Gothard, Mosher, Zimmerman, Putnam, Morrow and Fuglevand, 2018), a patient (DR) has been described who has bilateral damage to or disconnection of the amygdala, and has an impairment of face-expression matching and identification, but not of matching face identity or in discrimination (Young et al., 1995, 1996). This patient is also impaired at detecting whether someone is gazing at the patient, another important social signal (Perrett et al., 1985b). The same patient is also impaired at the auditory recognition of fear and anger (Scott et al., 1997).

Adolphs et al. (1994) also found face expression but not face identity impairments in a patient (SM) with bilateral damage to the amygdala, and extended this to other patients (Adolphs et al., 2002b). The bilateral amygdala patient SM was especially impaired at recognizing the face expression of fear, and also rated expressions of fear, anger, and surprise as less intense than control subjects. It has been shown that SM's impairment stems from an inability to make normal use of information from the eye region of faces when judging emotions, which in turn is related to a lack of spontaneous fixations on the eyes during free viewing of faces (Adolphs et al., 2005), though this is mainly evident just for the first fixation (Kennedy and Adolphs, 2011). Although SM fails to look normally at the eye region in all facial expressions, her selective impairment in recognizing fear is explained by the fact that the eyes are the most important feature for identifying this emotion. Indeed, SM's recognition of fearful faces became entirely normal when she was instructed explicitly to look at the eyes. This finding provides a mechanism to explain the amygdala's role in fear recognition, and points to new approaches for the possible rehabilitation of patients with defective emotion perception.

The changes in emotion in patients with amygdala lesions are much less marked than those in patients with orbitofrontal cortex damage, and special tests, analogous in some cases to those developed in rodent studies, are necessary to reveal deficits (Phelps and LeDoux, 2005). For example, patients with amygdala lesions are impaired at learning conditioned skin conductance responses when a blue square is associated with a shock, and are also impaired in acquiring the same autonomic response to fear by verbally instructed learning or by observational learning (Phelps, 2004; Phelps et al., 2001; Phelps, 2006; Whalen and Phelps, 2009). The human amygdala has been described as being important mainly for some fear responses to some stimuli, such as whether an individual backs off in a social encounter (Adolphs, 2003; Adolphs et al., 2005; Phelps, 2004; Schiller et al., 2010; Feinstein et al., 2011). Interestingly, the amygdala was involved during aversive conditioning with primary reinforcers (electric shock) and less so with a secondary reinforcer (money), as suggested by both an fMRI analysis and a follow-up case study with a patient with bilateral amygdala damage (Delgado et al., 2011).

The important point has been made that the amygdala may be involved in some of the behavioral responses in humans related to emotion, but that the subjective emotional feeling conscious state may be unaltered by treatments that reverse some of these behavioral measures (LeDoux and Pine, 2016; LeDoux et al., 2018). One implication is that the amygdala, at least in humans, may have quite restricted roles in emotional feelings (LeDoux, 2020). In contrast, damage to the orbitofrontal cortex has major effects not only on emotional behavior, but also on subjective, conscious, feelings of emotion in humans as described above (Hornak et al., 2003). Two conclusions follow. First, the orbitofrontal cortex, due to its great development and evolution in primates including humans, may be much more important in emotion than the amygdala (Rolls, 2017b). Second, subjective emotional states are not necessarily closely related to at least some behavioral measures of emotion, consistent with the multiple

routes to action concepts developed in Section 11.3.9 and more fully elsewhere (Rolls, 2014a, 2018a). To emphasise what is an important point with many implications: some behavioral measures related to emotion in humans may not reflect or be closely related to subjective emotional state; and vice versa (Rolls et al., 2023b).

An interesting advance conceptually is provided by the finding that personality interacts with whether particular stimuli activate the human amygdala. For example, happy face expressions are more likely to activate the human amygdala in extraverts than in introverts (Canli et al., 2002). In addition, positively affective pictures interact with extraversion to produce activation of the amygdala (Canli et al., 2001). This supports the conceptually important point that part of the basis of personality may be differential sensitivity to different rewards and punishers, and omission and termination of rewards and punishers (Rolls, 2014a). It has additionally been found that negative pictures interact with neuroticism in producing differential activation of the human amygdala (Canli et al., 2001). Further, FFFS and BIS-related personality traits related to an anxiety-related ‘Behavioral Inhibition System’, and to a fear-related ‘Fight, Flight, Freeze System’, are positively correlated to activity in the amygdala in response to negative stimuli (Kennis et al., 2013). However, a meta-analysis found that there is over many studies little relation between amygdala structure and function, and psychopathy (Deming et al., 2022).

11.4.10 Connectivity of the human amygdala

To understand better what is computed by the human amygdala, important evidence comes from understanding the inputs to the amygdala, and what it connects to, and the discoveries made in such a study are now described (Rolls et al., 2023b).

The cortical connectivity of the amygdala in humans is shown in Fig. 11.32 (Rolls et al., 2023b). The amygdala’s effective connectivity with the cortex is much less than that of the orbitofrontal cortex (cf. Figs. 11.24, 11.25, and 11.27) (Rolls et al., 2023b). The implications of this, and of the connectivities that the amygdala does have with the cortex, and with subcortical structures, are now considered (Rolls et al., 2023b).

The effective connectivity to the human amygdala from the superior anterior parts of the temporal lobe (STSda, STG, TGD and extending back as far as A5) provides a route for auditory and visual information to reach the amygdala (Rolls et al., 2023b) (Fig. 11.32)¹⁸. The cortex in the macaque superior temporal sulcus (STS) includes neurons that we discovered respond to face expression and to socially relevant head motion such as turning the head or opening or closing the eyes to make or break social contact (Hasselmo, Rolls, Baylis and Nalwa, 1989b; Hasselmo, Rolls and Baylis, 1989a), and there is complementary evidence for humans (Critchley et al., 2000; Yokoyama et al., 2021; Freiwald, 2020) in what has become accepted as a third visual pathway for socially relevant stimuli (Pitcher and Ungerleider, 2021). Consistent with this, neurons in the primate amygdala respond to socially relevant stimuli such as face expression (Leonard, Rolls, Wilson and Baylis, 1985; Rolls, 1984) and the social stimuli produced by others (Grabenhorst and Schultz, 2021; Grabenhorst et al., 2019; Zangemeister et al., 2016; Grabenhorst et al., 2016; Hernadi et al., 2015). Those anterior superior temporal cortical regions receive connectivity from the inferior temporal cortex part of the ventral visual stream so are likely to include representations of objects as well as faces (Rolls et al., 2023e, 2022b). We discovered that these anterior superior temporal cortex regions also contain auditory neurons (Baylis, Rolls and Leonard, 1987), and some

¹⁸The functional connectivity of the amygdala with this set of cortical regions but relatively few others (Rolls et al., 2023b) is supported by another investigation (Klein-Flugge et al., 2022b), though that did not measure effective connectivity nor utilize the helpful categorisation of cortical areas provided by the HCP-MMP atlas (Glasser et al., 2016a; Huang et al., 2022).

Fig. 11.32 Effective connectivity of the human amygdala: schematic diagram. The width of the arrows reflects the effective connectivity with the size of the arrowheads reflecting the connectivity in each direction. The connectivity from most cortical areas (STGa and TGd, STSda and A5, and pyriform olfactory cortex) is only towards the amygdala. The connectivity with the hippocampal system (Hipp, entorhinal cortex EC, and perirhinal cortex PeEc) is in both directions. The abbreviations are listed in Section 1.12. (From Rolls, E.T., Deco, G., Huang, C.-C. and Feng, J. (2023) Human amygdala compared to orbitofrontal cortex connectivity, and emotion. *Progress in Neurobiology* 220: 102385.)

neurons respond to combinations of auditory and visual stimuli (Khandhadia et al., 2021) which are likely to be important in decoding the meaning of social and related stimuli. Given that there is also connectivity in humans from somatosensory and olfactory cortical regions to the amygdala (Rolls et al., 2023b), these form the inputs needed to associate visual and auditory stimuli with their consequences in the form of primary rewards and punishers such as pleasant or aversive touch and perhaps odor. This system could then be the primate including human equivalent of the auditory to electric shock associative learning investigated in the rodent amygdala (Johansen et al., 2010; LeDoux, 2000; Rogan et al., 1997; Quirk et al., 1996; LeDoux, 1996, 1995, 1994; Killcross et al., 1997).

But the question then arises of what the outputs are of this stimulus-reward or stimulus-punishment associative system in the amygdala. The paucity of the output connectivity of the amygdala directed to the neocortex in humans (Fig. 11.32), with most of the neocortical connectivity being only towards the amygdala without strong backprojections (Rolls et al.,

2023b), and different from the orbitofrontal cortex as illustrated in Figs. 11.24, 11.25, and 11.27, suggests that the amygdala does not have major cortical outputs to lead to actions performed to obtain goals in instrumental learning, which the evidence suggests is implemented by the orbitofrontal cortex outputs to the anterior cingulate cortex (Rushworth et al., 2012, 2011; Rolls et al., 2023c). An alternative, given the paucity of amygdalo-neocortical connectivity for amygdala output, is that much of the amygdala output is directed to brainstem regions in humans as well as rodents (Rolls et al., 2023b; Klein-Flugge et al., 2022b) to elicit responses such as autonomic responses, freezing, conditioned cortical arousal elicited via the cholinergic basal nucleus of Meynert, and incentive effects. That would in fact be consistent with the amygdala outputs identified for the rodent auditory-aversive shock system (Quirk, Armony, Repp, Li and LeDoux, 1996). These effects are conditioned responses, and not instrumental goal-directed actions to obtain reinforcers, and the difference is important for understanding emotional behavior (Cardinal et al., 2002; Rolls, 2014a, 2023b), especially as emotions can be defined as states elicited by instrumental reinforcers (Rolls, 2014a).

In non-human primates, connections are found between the amygdala and the medial orbitofrontal cortex (including pOFC), both directly and via the mediodorsal nucleus of the thalamus pars magnocellularis (Timbie, Garcia-Cabezas, Zikopoulos and Barbas, 2020; Price and Drevets, 2010; Freese and Amaral, 2009). Consistently, in humans anatomical connections were demonstrated with diffusion tractography between the amygdala and medial orbitofrontal cortex region pOFC, and also between the amygdala and pregenual / subgenual anterior cingulate cortex (Rolls et al., 2023b). This is interesting in two ways. First, the amygdala, which is evolutionarily old, has anatomical connections with the human posterior orbitofrontal cortex (region pOFC) which is likely to be the evolutionarily oldest part of the human orbitofrontal cortex (Passingham, 2021). Second, the lack of effective connectivity, and low functional connectivity, provides new evidence that these amygdalo-orbitofrontal connections have relatively low functional effects in humans, and are indeed much lower than the effective connectivity of the orbitofrontal cortex with cortical regions and of the amygdala with subcortical regions including the septum and basal nucleus of Meynert (Rolls et al., 2023b).

The paucity of outputs of the amygdala to the neocortex including language regions in humans (Fig. 11.32) also implies that the human amygdala may not be closely involved in reported human subjective emotions and feelings. That evidence is in fact consistent with what is now believed by those who have worked on the rodent amygdala and auditory to electric shock conditioning, in that interventions such as the use of pharmacological agents that influence amygdala function have little effect on reported human emotions, though they do influence in humans the conditioned responses referred to above that are found in rodents (Taschereau-Dumouchel et al., 2022; Mobbs et al., 2019; LeDoux and Daw, 2018; LeDoux et al., 2018; LeDoux, 2017; LeDoux and Pine, 2016; LeDoux, 2012a, 2020). In addition, damage to the human amygdala may influence some responses, such as which parts of a face are fixated (Adolphs et al., 2005), or learning autonomic responses to a visual stimulus associated an electric shock (Whalen and Phelps, 2009; Phelps, 2006; Delgado et al., 2006; Phelps and LeDoux, 2005; Phelps, 2004; Schiller et al., 2010), but does not lead to severe changes in emotional behavior and reported emotional feelings (Feinstein et al., 2011; Whalen and Phelps, 2009; Young et al., 1995; Aggleton, 1992; Spezio et al., 2007; Adolphs et al., 2005; Young et al., 1996; Calder et al., 1996; Scott et al., 1997; Adolphs et al., 1994, 2002a; Kennedy and Adolphs, 2011; Damasio et al., 2013; LeDoux, 2020) that are comparable to those produced by damage to the orbitofrontal cortex (as described above). Indeed, when patient SM with amygdala damage did fixate faces including the eyes, the reported emotion was not impaired (Adolphs et al., 2005; Kennedy and Adolphs, 2011). That left LeDoux (and colleagues) (LeDoux, 2020; Taschereau-Dumouchel et al., 2022; Mobbs et al.,

2019; LeDoux et al., 2018; LeDoux, 2017; LeDoux and Pine, 2016; LeDoux, 2012a) with the conundrum: if the amygdala is not involved in reported human emotion, what brain systems are?

The answer to that question, of what brain systems are involved in human emotion, is that the orbitofrontal cortex, together with the regions to which its outputs are directed, the ventromedial prefrontal cortex, and anterior cingulate cortex (Rolls et al., 2023c)), are the key brain regions involved in reported (declarative) human emotion (Rolls et al., 2023c; Rolls, 2023b, 2014a, 2019e). For example, damage to the human orbitofrontal cortex impairs not only reward-related reversal learning, and relates to disinhibited emotional behavior (Hornak et al., 2004; Rolls et al., 1994a; Berlin et al., 2005, 2004; Fellows, 2011), and the identification of face and vocal emotional expression (Hornak et al., 2003, 1996; Tsuchida and Fellows, 2012), but also impairs the reported subjective experience of emotion (Hornak et al., 2003; Rolls, 2021h). In addition, activations of the human orbitofrontal cortex occur to many emotion / reward-related and punishment-related stimuli (O'Doherty, Kringelbach, Rolls, Hornak and Andrews, 2001a; O'Doherty, Winston, Critchley, Perrett, Burt and Dolan, 2003b; Grabenhorst and Rolls, 2011; Rolls, O'Doherty, Kringelbach, Francis, Bowtell and McGlone, 2003d; Rolls, 2014a, 2019e), and also linearly track the reported subjective pleasure produced by stimuli (Kringelbach, O'Doherty, Rolls and Andrews, 2003; Grabenhorst, Rolls and Bilderbeck, 2008a; Grabenhorst and Rolls, 2008).

Based on evidence of this type, the human orbitofrontal cortex is the key brain region involved in emotion (including reported, subjectively experienced, emotion) in humans, rather than the amygdala (Rolls, 2014a, 2019e, 2021b), and the evidence on the connectivity of the human amygdala and orbitofrontal cortex described here helps to provide a connectional foundation for this understanding. Further, a new concept proposed (Rolls et al., 2023b) is that given the connectivity of some human lateral orbitofrontal cortex regions (e.g. 47l and 47s) with language regions (Rolls et al., 2022b), some of the impulsiveness of humans with orbitofrontal cortex damage and their focus on immediate rewards rather than long-term planning (Rolls et al., 1994a) may be related to interruption of language-based planning influences of the reasoning system on the orbitofrontal cortex. At the same time, these connectivities from the lateral orbitofrontal cortex to language regions provide a direct route for the orbitofrontal cortex emotion system to gain access to the language systems to make declarations about emotional feelings.

The amygdala is evolutionarily old, and its role may continue to be largely in linking stimuli to responses such as autonomic responses, freezing, cortical arousal, and effects of incentive stimuli. In contrast, the orbitofrontal cortex develops greatly in non-human primates and even further in humans (Rolls, 2019e; Passingham, 2021; Passingham and Wise, 2012), with the extensive cortical connectivity with neocortex described here, and related to this great development and neocortical connectivity, may play a key role in human emotion including reported emotional feelings. Further, it is notable that the amygdala has no effective connectivity directed towards dorsolateral and inferior frontal regions of the prefrontal cortex that are implicated in short-term memory functions (Goldman-Rakic, 1996; Miller et al., 2018) that are even related to language (Rolls et al., 2023f, 2022b); and that prefrontal route (Rolls et al., 2023b) (Fig. 11.32) may be an important route for activity in the human orbitofrontal cortex to become incorporated into experienced and reported emotional feelings (Rolls, 2020a, 2008a; Lau, 2022). The orbitofrontal cortex on the other hand has increasing and strong effective connectivity to these lateral prefrontal cortex regions as one moves forward from pOFC to 13l and to 11l (Rolls et al., 2023b).

A cautionary note is in order here. Sometimes behavioral and autonomic responses such as changes in heart rate and skin conductance, and freezing or other responses, are used as measures of 'emotion'. Given the points just made, we need to be aware that such responses

are not closely related to reported human emotion and are mediated by a different brain system, so may not be fully appropriate measures that relate to human subjectively felt and reported emotions. The instrumental choice of stimuli based on reward value may be a better measure of the value of a good to an animal or human (Rolls, 2023b), but even here we cannot be sure that this always reflects reported consciously felt emotions in humans (Rolls, 2021e.g, 2020a). Further, although associations of amygdala functional connectivity with mental disorders have been described (Klein-Flugge et al., 2022b), these are associations, and do not show whether the amygdala functional connectivities are caused by or cause the different mental disorders.

The connectivity of the human amygdala to the basal nucleus of Meynert (Rolls et al., 2023b) which contains cholinergic neurons that provide the cholinergic input to the neocortex (Huang et al., 2022; Zaborszky et al., 2018, 2008) is of considerable interest. Medial orbitofrontal cortex region pOFC is the only cortical area found to have effective connectivity to the nucleus basalis of Meynert (Rolls et al., 2023c). Different magnocellular neurons in the macaque basal nucleus of Meynert which are probably cholinergic respond to reinforcing (reward or punishing), or novel, stimuli (Wilson and Rolls, 1990a,b,c), both represented in the orbitofrontal cortex (Rolls et al., 2005a; Rolls, 2019f,e). It is now proposed that the amygdala, as well as the more recently evolved human orbitofrontal cortex, may both contribute to cortical arousal, attention, and consolidation of memory in the neocortex given that acetylcholine is involved in long-term synaptic potentiation (Zaborszky et al., 2018; Newman et al., 2012; Hasselmo and Sarter, 2011) when aversive or rewarding stimuli are encountered, in ways that are described more fully elsewhere (Rolls, 2022b; Rolls et al., 2023c) (Section 9.2.8.5).

The strong effective connectivity of the human amygdala with the hippocampus, entorhinal, and perirhinal cortex, which is a little stronger towards the hippocampal system (Rolls et al., 2023b), is also of great interest. This connectivity is consistent with what has been described in macaques (Stefanacci et al., 1996). There is corresponding connectivity of the orbitofrontal cortex with the hippocampus (Rolls et al., 2023c,b). It is now proposed here that the amygdala connectivity to the hippocampus implements similar functions to those proposed for the orbitofrontal cortex inputs to the hippocampus, including enabling reward/punishment information to be incorporated into episodic memory, and also enabling any information recalled from episodic memory about rewards and punishers to influence whether that episodic memory is consolidated into neocortical long-term semantic memory, as described in detail elsewhere (Rolls, 2022b) (Section 9.2.8.5). When memories are recalled from the hippocampus to the amygdala, this may enable autonomic and related responses to be produced when memories are retrieved.

In addition to the differences in the connectivity of the human amygdala and orbitofrontal cortex described here, internal differences in their connectivity are likely to contribute to their different computational functions related to emotion. The amygdala has relatively little recurrent collateral excitatory connectivity between its neurons (Millhouse and DeOlmos, 1983)¹⁹, whereas the orbitofrontal cortex, like all neocortex, has highly developed local excitatory recurrent collateral connectivity between its pyramidal cells (Rolls, 2021b, 2016b). These recurrent collaterals are implicated in short-term memory functions, enabling representations to remain active by maintaining the activity of an interconnected set of neurons to continue firing because of the strength of the recurrent collateral synapses of the neurons in each set (Rolls, 2021b, 2016b). An implication is that memory states related to emotion-provoking

¹⁹Nuclei in the brain may in general have much less excitatory recurrent collateral connectivity between their neurons than the neocortex, and this is proposed to be fundamental to understanding computation by the cortex (Rolls, 2021b).

stimuli can be maintained using the orbitofrontal cortex but much less by the amygdala. This orbitofrontal cortex recurrent collateral connectivity not only may enable the memory of rewards and punishers received recently to influence future behavior, but also may enable a mood state to be maintained (e.g. happiness or sadness) that can adaptively influence future behavior (Rolls, 2014a, 2018a). This functionality may become even more developed especially in humans because the orbitofrontal cortex has reciprocal connectivity with areas such as the angular gyrus involved in language that may implement ‘long loop’ attractors because of the reciprocal connectivity between these two cortical regions, and thereby contribute to the sad ruminating thoughts that can be a feature of human depression (Rolls, 2016e; Cheng, Rolls, Qiu, Liu, Tang, Huang, Wang, Zhang, Lin, Zheng, Pu, Tsai, Yang, Lin, Wang, Xie and Feng, 2016a; Rolls, Cheng and Feng, 2020a; Rolls, 2018a; Zhang, Rolls, Wang, Xie, Cheng and Feng, 2023a).

11.5 How the computations are performed in the orbitofrontal cortex

This section describes current approaches to *how* the orbitofrontal cortex performs some of its key computations.

One of the key computations is decision-making. This is addressed in Sections 11.5.1 and 11.5.2. The context of the description is orbitofrontal cortex computations, but this class of neuronal decision-making network is proposed to apply to decision-making in many cortical areas, each specialized for a different type of decision, so this type of network should be thought of as generic (Rolls and Deco, 2010). Indeed, the application to decision-making in other brain regions is described in Rolls and Deco (2010) and Deco, Rolls, Albantakis and Romo (2013). The description provided in Section 11.5.1 is supplemented by a formal description of the equations in the integrate-and-fire model of decision-making in Sections B.6.2, B.6.3, B.8.2, and B.8.3. Other approaches to decision-making, some much less biologically plausible than the approach described here, such as the drift-diffusion and race models, are described by Deco, Rolls, Albantakis and Romo (2013).

Another key computation performed in the orbitofrontal cortex is association learning between stimuli (such as a visual stimulus) and a reward (such as a taste), and this is probably implemented by pattern association learning of the type described in Section B.2. More generally, this can be described as learning between secondary reinforcers (such as the sight of a food), and primary, unlearned reinforcers, such as the taste of a food (Rolls, 2014a). This is described further in Section 11.5.3

However, when the stimulus-reward association needs to be reversed very rapidly, in one trial, a rule-based system is required that holds in a short-term memory the current rule, which then controls how incoming stimuli are treated, and a model that implements this is described in Section 11.5.3.

Further, when an error is made, and the visual stimulus is no longer associated with the primary reward (in reversal or extinction), then error neurons fire in the orbitofrontal cortex, and a network that can implement this is described in Section 11.5.4.

11.5.1 Decision-making in attractor networks in the brain

11.5.1.1 An attractor decision-making network

Consider the attractor network architecture shown in Fig. 11.33a (with more details in Section B.3). A set of cortical neurons has recurrent collateral excitatory synaptic connections w_{ij} from the other neurons. The evidence for decision 1 is applied via the λ_1 inputs, and for

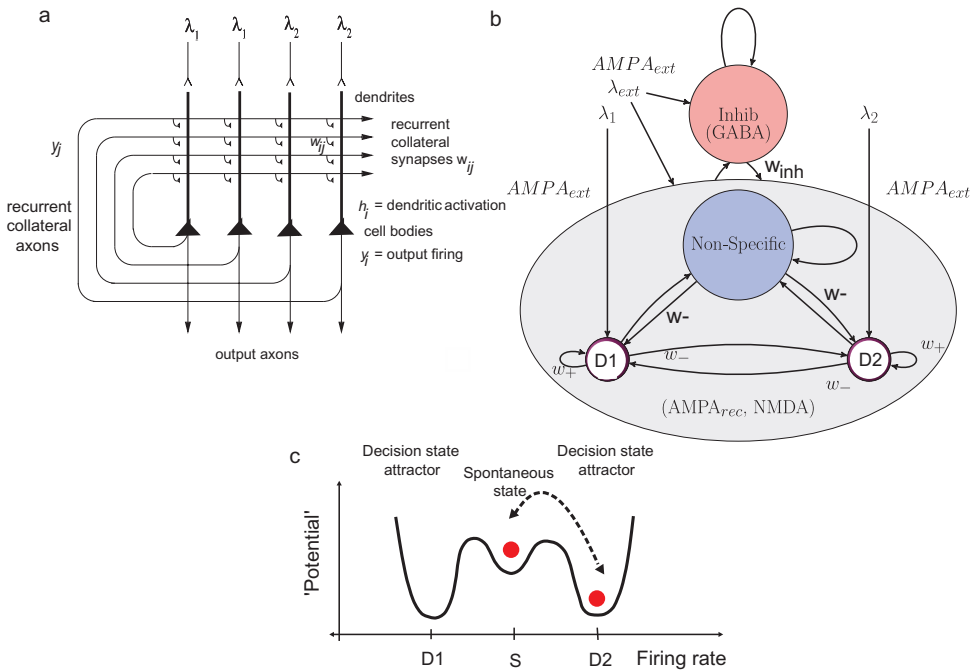

Fig. 11.33 (a) Attractor or autoassociation single network architecture for decision-making. The cell body of each neuron is shown as a triangle (like a cortical pyramidal cell), the dendrite is vertical, and receives recurrent collateral synaptic connections w_{ij} from the other neurons. The evidence for decision 1 is applied via the λ_1 inputs, and for decision 2 via the λ_2 inputs. The synaptic weights w_{ij} have been associatively modified during training in the presence of λ_1 and at a different time of λ_2 . When λ_1 and λ_2 are applied, each attractor competes through the inhibitory interneurons (not shown), until one wins the competition, and the network falls into one of the high firing rate attractors that represents the decision. The noise in the network caused by the random spiking times of the neurons (for a given mean rate) means that on some trials, for given inputs, the neurons in the decision 1 (D1) attractor are more likely to win, and on other trials the neurons in the decision 2 (D2) attractor are more likely to win. This makes the decision-making probabilistic, for, as shown in (c), the noise influences when the system will jump out of the spontaneous firing stable (low energy) state S, and whether it jumps into the high firing state for decision 1 (D1) or decision 2 (D2). (b) The architecture of the integrate-and-fire network used to model decision-making (see text). The synaptic weights between the neural populations (decision pools D1 and D2, the non-specific pool, and the inhibitory pool) are 1 except where indicated. In particular, the recurrent weights, indicated by a recurrent arrow, between the neurons within an attractor decision-making pool have strong weights w_+ , and between the different pools have the weak strength w_- . (c) A multistable 'effective energy landscape' for decision-making with stable states shown as low 'potential' basins. Even when the inputs are being applied to the network, the spontaneous firing rate state is stable, and noise provokes transitions from the low firing rate spontaneous state S into the high firing rate decision attractor state D1 or D2. If the noise is greater, the escaping time to a decision state, and thus the decision or reaction time, will be shorter. (After Rolls, E. T. and Deco, G. (2010) *The Noisy Brain: Stochastic Dynamics as a Principle of Brain Function*. Oxford University Press: Oxford; and Rolls, E. T. (2016) *Cerebral Cortex: Principles of Operation*. Oxford University Press: Oxford.)

decision 2 via the λ_2 inputs. The synaptic weights w_{ij} have been associatively modified during training in the presence of λ_1 and at a different time of λ_2 . The Hebbian or associative synaptic modification is such that if the presynaptic terminal and the postsynaptic neuron are simultaneously active, the synaptic connections become stronger. There are inhibitory neurons (not shown in Fig. 11.33a) that keep the total firing in the network within bounds, and in fact implement competition between the neuronal populations. As a result of the associative synaptic modification (specified in Equation B.9), there are strong connections within the set of neurons activated by λ_1 , and strong connections within the set of neurons activated by λ_2 . These strengthened synapses provide positive feedback, so that if the whole or part of λ_1 is applied, that set of neurons becomes active, and maintains its activity for a long period even when the input λ_1 is removed. The neurons activated by λ_1 if firing inhibit the neurons activated by λ_2 through the inhibitory interneurons, so that just one population wins the

competition and maintains its activity. This thus provides a model of memory, and its retrieval. This is called an attractor network, because a subset of the neurons within either population is sufficient to attract the system into a state in which all the neurons in that population are active, by using the strengthened recurrent collateral connections. The properties of attractor or autoassociation networks are described in Section B.3 and elsewhere (Rolls, 2016b; Hertz et al., 1991; Hopfield, 1982).

For decision-making, when λ_1 and λ_2 are applied simultaneously, each attractor competes through the inhibitory interneurons (not shown), until one wins the competition, and the network falls into one of the high firing rate attractors that represents the decision. When the network starts from a state of spontaneous firing, the biasing inputs encourage one of the attractors to gradually win the competition, but this process is influenced by the Poisson-like firing (spiking) of the neurons, so that which attractor wins is probabilistic. (Poisson-like indicates that the firing times are random for a given mean firing rate.) If the evidence in favour of the two decisions is equal, the network chooses each decision probabilistically on 50% of the trials. The model shows how probabilistic decision-making could be implemented in the brain. The model also shows how the evidence can be accumulated over long periods of time because of the integrating action of the attractor short-term memory network, with the recurrent collaterals feeding back information to be combined with the continuing inputs λ_1 and λ_2 . The model produces shorter reaction or decision times as a function of the magnitude of the difference between the evidence for the two decisions: difficult decisions take longer, partly because the firing rates take longer to reach a decision threshold if the difference between the inputs is small.

11.5.1.2 An integrate-and-fire implementation of the attractor network for probabilistic decision-making

Because cortical neurons have almost random firing times for a given mean firing rate, i.e. the firing times follow approximately a Poisson distribution (Rolls and Treves, 2011), the mean firing rates over short periods (e.g. 20–100 ms) of all the neurons in one of the decision-making populations may be higher than in the other population. These are referred to as statistical fluctuations. These fluctuations can result in the mean rate of one decision population increasing more than the other on a single trial, and influencing which decision is taken on that trial. To model these neuronal spiking time related fluctuations, we need an implementation of the decision-making network that incorporates spiking times. A simple such model is an integrate-and-fire model, which models the synapses and the membrane potentials as dynamical variables, and then produces a spike (not itself modelled to keep the implementation simple) which is then transmitted to the other neurons.

A leaky integrate-and-fire neuron along the lines just introduced can be modelled as shown schematically in Fig. 11.34. The model describes the depolarization of the membrane potential V (which typically is dynamically changing as a result of the synaptic effects described below between approximately -70 and -50 mV) until threshold V_{thr} (typically -50 mV) is reached when a spike is emitted and the potential is reset to V_{reset} (typically -55 mV). The membrane time constant τ_m is set by the membrane capacitance C_m and the membrane leakage conductance g_m where $\tau_m = C_m/g_m$. Changes in the membrane potential V (see right of Fig. 11.34) are produced by the input spikes operating through the dynamically modelled synapses (left of Fig. 11.34). There are very many such synapses, and the input currents produced from all these synapses result in excitatory postsynaptic potentials (EPSPs) and inhibitory postsynaptic potentials (IPSPs) that are summed by the integrate-and-fire neuron. When the threshold for firing is reached by the membrane potential V , a spike is emitted. The equations for the implementation are given in Section B.6.3.

An attractor network model of decision-making using integrate-and-fire neurons was

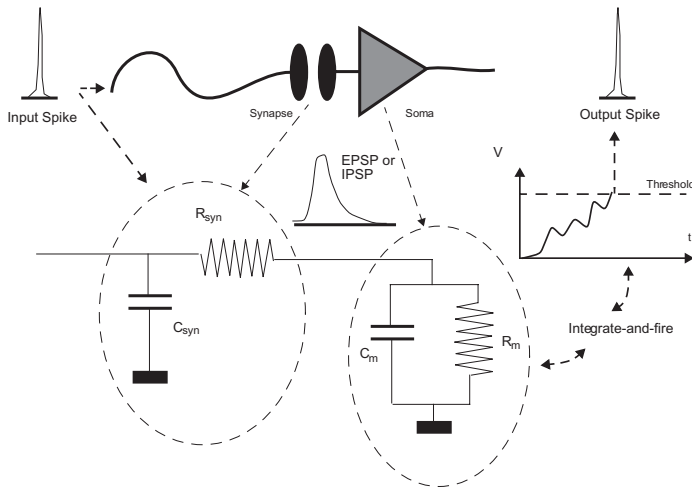

Fig. 11.34 Integrate-and-fire neuron. The basic circuit of an integrate-and-fire model consists of the neuron's membrane capacitance C_m in parallel with the membrane's resistance R_m (the reciprocal of the membrane conductance g_m) driven by a synaptic current with a conductance and time constant determined by the synaptic resistance R_{syn} (the reciprocal of the synaptic conductance g_j) and capacitance C_{syn} shown in the figure. These effects produce excitatory or inhibitory postsynaptic potentials, EPSPs or IPSPs. These potentials are integrated by the cell, and if a threshold V_{thr} is reached a δ -pulse (spike) is fired and transmitted to other neurons, and the membrane potential is reset. developed by Wang (2002), based on a neurodynamical model introduced by Brunel and Wang (2001). The model has been extended and successfully applied to several experimental paradigms including attention and short-term memory as well as decision-making (Rolls and Deco, 2002; Deco and Rolls, 2002, 2003, 2004; Deco, Rolls and Horwitz, 2004; Szabo, Almeida, Deco and Stetter, 2004; Deco and Rolls, 2005b, 2006; Wang, 2008; Rolls, Grabenhorst and Deco, 2010b,c; Rolls and Deco, 2010; Smerieri, Rolls and Feng, 2010; Deco, Rolls and Romo, 2010; Rolls and Deco, 2011b; Rolls, 2012c; Martinez-Garcia, Rolls, Deco and Romo, 2011; Rolls, Dempere-Marco and Deco, 2013; Deco, Rolls, Albantakis and Romo, 2013; Rolls and Deco, 2015a,b, 2016; Rolls and Mills, 2019).

In this framework, probabilistic decision-making is modelled by an attractor single network organized into a discrete set of neuronal populations or pools, as illustrated in Fig. 11.33b. The network contains N_E (excitatory) pyramidal cells and N_I inhibitory interneurons. In the simulations, we often use $N_E = 800$ and $N_I = 200$, consistent with the neurophysiologically observed proportion of 80% pyramidal cells versus 20% interneurons (Abeles, 1991; Rolls, 2016b) for a network with 1000 neurons, but effects of the number of neurons N in the network can be investigated. The neurons are fully connected (with synaptic strengths that are 1.0 unless specified otherwise). In the network illustrated in Fig. 11.33b, there are two decision-making populations, D1 and D2, each with 10% of the excitatory neurons, but the number of decision populations can be altered as needed. The recurrent synaptic connections within a decision population (indicated by the recurrent arrows in Fig. 11.33b) have a high strength of w_+ (typically 2.1), so that the population is self-sustaining in its activity, once started, and is at a biologically realistic firing rate. The remainder of the excitatory neurons are in a non-specific pool (NS), which represent other neurons in the cortex that are not involved in the particular task but fire spontaneously and contribute to the background noise (randomness) caused by the Poisson-like firing of the integrate-and-fire neurons. Their connections to the decision-making pools and the connections between the different decision-making pools are set to a value w_- which is calculated as a fraction of w_+ to make the total excitation in the

network constant so that it balances the inhibition and produces a mean spontaneous firing rate for all the excitatory neurons of 3 spikes/s when no inputs λ_1 etc. have been applied (Brunel and Wang, 2001; Wang, 2002; Deco and Rolls, 2006). A typical value for w_- is 0.86. These synaptic connection strengths are prescribed, but are generally consistent with a Hebbian associative learning process, in which synapses are strengthened when there is both presynaptic and postsynaptic activity (Equation B.9). In this way, the synapses between neurons within a decision-making pool, which tend to be firing at the same time due to the λ inputs, are strong, and the synapses between neurons in different pools, which tend to be active at different times, are weaker.
